## 1. INTRODUCTION

Since the discovery of carbon nanotubes a lot of experimental and theoretical work has appeared investigating and analyzing their structural and electronic properties [1–3]. Especially single walled carbon nanotubes (SWNTs) were proposed both as microcavities for storage [4–9] and as ideal molecular wires for microelectronic applications [10]. Furthermore the functionalization of the SWNT surface was found to affect both their storage capacity [9] and their electronic properties [10–12].

Hydrogen has been recognized as an ideal energy carrier but has not been used yet to a large extent. One of the major problems is the difficulty of efficient storage. In the beginning metal alloys were tested for storage tanks but even though they have sufficient storage capacity, they are expensive and heavy for commercial production focused on mobile applications. In the recent years, carbon based materials attracted attention due to the discovery of novel carbon nanomaterials like fullerenes, nanofibers, and nanotubes [1–3]. Especially SWNTs, which have diameters of typically a few nanometers, have been suggested as suitable materials for gas storage [4]. Since pores of molecular dimensions can adsorb large quantities of gases, hydrogen can condense to high density inside narrow SWNTs even at room temperature [5]. The high hydrogen uptake of these

materials suggests that they can be used as hydrogen-storage materials for fuel-cell electric vehicles [6–8].

Recently it was experimentally proved that the electronic and transport properties of SWNTs are extremely sensitive to their exposure to gas molecules [10–12]. Especially oxygen attracted a lot of interest due to the importance of its interaction with SWNTs both in their synthesis by purification and their functionalization for controlling their electronic properties. Considering that all previous experimental studies of SWNTs have used samples exposed to air, the results of these measurements must be carefully reevaluated.

## 2. A BRIEF EXPERIMENTAL OVERVIEW

A lot of recent experiments are trying to investigate the hydrogen storage in SWNTs. First, in 1997, Dillon et al. reported that SWNTs could store hydrogen [4]. Using temperature-programmed desorption spectroscopy they showed that hydrogen would condense inside SWNTs under conditions that do not induce adsorption within a standard mesoporous activated carbon.

Two years later Liu et al. found out that this storage can take place in room temperature [5]. They used SWNTs of 1.85 nm diameter, synthesized by a semicontinuous hydrogen arc discharge method, and found a storage capacity of 4.2 wt% at room temperature and under modestly high pressure; 78.3% of the adsorbed hydrogen can be released under ambient pressure and room temperature.

The same year Chen et al. reported that alkali-doped carbon nanotubes possess high hydrogen uptake [9]. They investigated lithium and potassium doped carbon nanotubes and found hydrogen absorption of 14 to 20 wt% between 400 °C and room temperature. These values are higher than those of metal hydride and cryoadsorption systems. The stored hydrogen could be released at higher temperatures and the sorption–adsorption cycle can be repeated with minor loss of the storage capacity.

After that a lot of experimental work has been performed trying to investigate the hydrogen adsorption in SWNTs and to improve the storage capacity of the tubes by doping them

[13–20]. Nevertheless the experiments on hydrogen storage in nanotube samples have been controversial as reported by the recent review of Ding et al. [8].

Concerning the electronic properties of the nanotubes, Collins et al. reported that they are extremely sensitive to the chemical environment [10]. The exposure to atmospheric air or oxygen dramatically influences the nanotubes' electrical resistance, thermoelectric power, and density of states, as determined by transport measurements and scanning tunneling microscopy [10]. The most interesting observation of Collins et al. is that these electronic parameters can be reversibly tuned by a surprisingly small concentration of adsorbed gases.

### 3. THE NEED FOR THEORETICAL MODELING

On the other hand, until recently, there was no sufficient theoretical explanation of gas adsorption in SWNTs but only guesses about this procedure. This affected badly both the understanding of the nature of these materials and the improvement of their storage capacity that ended up in a random procedure. The need for theoretical modeling was crucial because even though the experiments can inform us *what* is happening, only theory allows us to find out *why* it is happening and what will happen in similar conditions.

Concerning the gas adsorption in carbon nanotubes, the theoretical calculations can be extremely useful for understanding the elementary steps of the adsorption procedure and give an insight into the phenomenon.

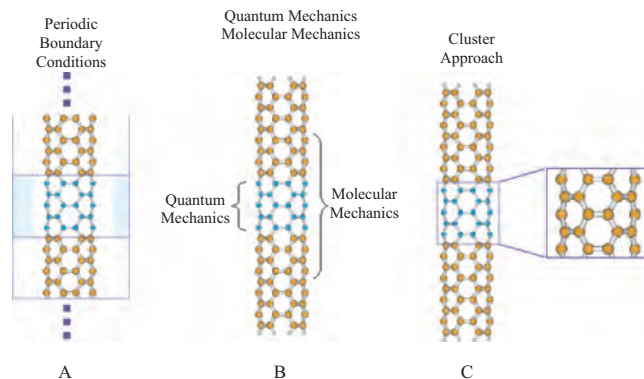

### 4. AB INITIO APPROACHES IN LARGE SYSTEMS

One of the major headaches in computational material science is how accurate theoretical techniques can be applied in large systems. By “accurate theoretical techniques” we mean quantum chemistry methods, called *ab initio*, due to the fact that they do not enforce any parameters to the system but solve the Schrödinger equations from first principles. The greater advantage of the *ab initio* methods is that they can provide structural, electronic, and dynamic properties of the calculating system in high accuracy. On the other hand the computational cost increases dramatically with the number of the electrons in the system.

The problem that arises in polyatomic systems is how to compromise the relatively large size of the system and an accurate *ab initio* method without ending up with a prohibitively large calculation. There are three possible solutions to this dilemma of treating large systems with *ab initio* methods: (a) the periodic density functional theory model, (b) the mixed quantum mechanics/molecular mechanics model, and (c) the cluster model.

#### 4.1. Periodic Density Functional Theory Model

The periodic density functional theory (DFT) model is schematically presented in Figure 1a for a (4,4) SWNT. A part of the system (central part of the tube presented

**Figure 1.** Three possible models for treating large systems with *ab initio* methods. (A) Periodic DFT model simulating a (4,4) SWNT. A part of the system (blue colored carbon atoms) is separated and treated as unit cell for a periodic building of the system. (B) The QM/MM model simulating a (4,4) SWNT. The total 200-atom tube was separated in three cylindrical parts. The inner one was treated with DFT (40 blue color carbon atoms) while the two outer parts with molecular mechanics (brown color carbon atoms). The dangling bonds at the ends of the tube were saturated with hydrogen atoms. (C) The *cluster* model. A part of the system is separated and treated as individual cluster.

with blue color carbon atoms) is separated and treated as a unit cell. This unit cell is periodically repeated in the space (for the tube in one dimension only) building an infinite system. Implementation of periodic boundaries conditions to the equations solves the mathematical part of the problem. The advantage of this approach is that the total system is treated with *ab initio* techniques. The disadvantage is that local interactions and defects studied in the unit cell are automatically repeated periodically. In this way local properties become periodic. An example of the use of this approach is presented in Section 5.3.1.

#### 4.2. Quantum Mechanics/Molecular Mechanics Mixed Model

The mixed quantum mechanics/molecular mechanics (QM/MM) model is schematically presented in Figure 1b. The basic idea of this method is that the system is divided in two parts: one is treated by *ab initio* methods and the other by molecular mechanics. The bordering of the two parts is arranged by introducing link atoms. More details for this model can be found in [21].

For the (4,4) SWNT presented in Figure 1b, the total 200-atom tube was separated in three cylindrical parts. The inner one was treated with DFT (40 blue color carbon atoms) and the two outer parts with molecular mechanics (brown color carbon atoms). The dangling bonds at the ends of the tube were saturated with hydrogen atoms.

The advantage of the QM/MM model is that no periodic constraints are introduced to the systems. The disadvantage is that only a relatively small part of the system is treated quantum mechanically while the rest is used for constraining the boundaries. This method is suitable for studying local properties. An example of the implementation of the QM/MM approach in SWNTs is presented in Section 5.3.2.

### 4.3. The Cluster Model

In the *cluster* model (Fig. 1c) a part of the system is separated and treated as an individual cluster. Extra attention has to be given to the dangling bonds that are generated at the braking areas. These dangling bonds have to be saturated properly with the addition of extra atoms (for example hydrogens). In this way the boundary instabilities that arise from QM/MM and the periodicity problems introduced by periodic DFT can be eliminated. The drawback of this method is that only a relatively small part of the system can be used. An example using the cluster model approximation is presented in Section 6.1.

It is clearly shown that no one of all these three techniques gives a perfect and unique solution to the problem. All show advantages and disadvantages and the decision as to which one we should choose have to be made according to the problem we face each time.

## 5. HYDROGEN INTERACTION WITH CARBON NANOTUBES

The theoretical simulations in this field can be generally classified in two categories according to the theoretical approximation that they are based on. The first group employs Monte Carlo and molecular mechanics *classical* algorithms in order to investigate the physisorption of hydrogen in SWNTs while the second uses *ab initio* or semiempirical *quantum* techniques for studying mainly the chemisorption of atomic hydrogen in SWNTs. A review of theoretical calculation of hydrogen storage in carbon-based materials can be found in [22].

### 5.1. Hydrogen Physisorption in Carbon Nanotubes

First Darkrim and Levesque in late 1998 using a Lennard-Jones potential performed a grand canonical Monte Carlo simulation of hydrogen storage in a cell of SWNTs and investigated the influence of the tube diameter on the storage capacity [23]. They found that adsorption decreased as the SWNT diameter increased due to the fact that a large part of the volume inside or outside the tube is out of the attractive force range of the solid-gas interaction. They also note the dependence of their results on the intermolecular potential used for the hydrogen-carbon interaction. This is the major disadvantage of classical simulations and points to the need for *ab initio* calculations in the field.

In 1999 Johnson and co-workers using the Silvera-Goldman potential for the H<sub>2</sub>-H<sub>2</sub> interaction and the Crowell-Brown potential the H<sub>2</sub>-tube interaction studied hydrogen adsorption in neutral [24] and positively and negatively charged [25] SWNTs. Their results show that idealized graphitic nanofibers (slit pores) give significantly better performance for hydrogen storage than SWNT arrays. They also underline the importance of the packing geometry of the SWNTs in the storage capacity. In addition, a 0.1 e/C charging of the nanotubes increased the adsorption up to 30%.

In the year 2000 Williams and Eklund simulated H<sub>2</sub> physisorption in finite-diameter carbon nanotube ropes

using grand canonical Monte Carlo [26]. Their simulation clearly shows that small diameter ropes are preferable for hydrogen storage. They also point out an essential difference between models and experiments that has to do with the ideal and “atomically clean” surface of the tubes in the simulation.

The great advantage of these classical approaches, except for the luxury to take into account large systems, is the temperature dependence of the simulations. On the other hand they are parameter dependent and cannot provide an insight into the chemical bond as the *ab initio* methods do.

### 5.2. Quantum Approaches

In 2001 the *quantum picture* was introduced to the molecular dynamic study of hydrogen in SWNTs either by quantum molecular dynamics algorithms [27] or by minimal *ab initio* calculations in parts of classical-optimized tube geometries [28]. In the first case, Cheng et al. using the Vienna *ab initio* simulation package performed a quantum mechanical molecular dynamics simulation of H<sub>2</sub> absorption in a trigonal two-dimensional lattice of armchair (9,9) SWNTs [27]. The potential energy surface near the equilibrium point was found to be relatively flat and significant changes of the lattice constants (>0.5 Å) resulted in only small changes in the lattice energy (<1 kcal/mol). Cheng et al. also investigated the site selectivity during the adsorption, since arrays of SWNTs with open ends may accommodate hydrogen inside the tube (endohedral adsorption) or inside the pores formed by different tubes (exohedral adsorption). According to their thermodynamical studies, the exohedral adsorption was found to be energetically more favorable [27].

On the other hand Ma et al. first used a many body Tersoff-Brenner potential to simulate low energy collision of atomic H on the sidewall of an armchair (5,5) SWNT [28]. On top of this they performed minimal HF/STO-3G *ab initio* calculations to some selected snapshots of the molecular dynamics simulations. The interesting part of their work is the sorting of the collision results with respect to the hydrogen energy. Their results indicate that if the hydrogen energy is in the range of 1–3 eV the H will be adsorbed in the tube sidewall while with a energy between 4 and 14 eV the H has large possibility to rebound off the wall. With energy in the interval of 16–25 eV the H has a high probability of penetrating into the tube and being trapped inside forming hydrogen molecules and gradually condensing to become liquid hydrogen inside the tube. Finally with an energy range from 20 to 30 eV the H atom can enter the tube from one side and escape from the other or break a C–C bond [28].

Since only quantum chemistry calculations can give insight into the hydrogen interaction with SWNTs, Dubot and Cenedese used semiempirical AM1 simulations to give binding sites, energetics, and orbital pictures of lithium and molecular hydrogen adsorption in SWNTs [29]. They found that Li can adsorb inside and outside a zigzag tube and the most stable site is above the center of a tube hexagon. After the Li adsorption, molecular hydrogen can be bound to the Li atom with a binding energy of 0.5 eV. Their AM1 calculation showed also that molecular hydrogen is repelled from the tube wall if the tube is not doped [29].

In 1999 Jeloica and Sidis used DFT to investigate hydrogen adsorption on a graphitic cluster model [30], but only in 2000 did first principle calculations of the hydrogen adsorption in SWNTs appear in the literature [31–35].

The main reason that *ab initio* calculations in SWNTs appear lately is the system size. In order to take into account a large enough model of SWNT you need approximately 200 atoms. The problem that arises in such an attempt is how to compromise the large size of the system and an accurate *ab initio* method without ending up in a prohibitively large calculation.

As analyzed in Section 4, there are three different ways to overcome this dilemma. Two of them were used in this specific problem. The first uses the periodicity of the SWNTs and combines an *ab initio* method with periodic boundary conditions [31, 32]. The second uses a two level quantum mechanics/molecular mechanics (QM/MM) approach [21, 33–35]. In the latter the tube is divided into two different parts treated with different methods. The advantage of the first is that the total system is treated with *ab initio* techniques while the obvious disadvantage is that an external periodicity is forced to the system. For the QM/MM model there is no periodic constrain. The disadvantage is that only a relatively small part of the system is treated quantum mechanically while the rest is used for constraining the boundaries. In addition, both approaches have the disadvantage of excluding temperature from the calculations.

### 5.3. Atomic Hydrogen Interaction with Carbon Nanotubes

#### 5.3.1. Application of Periodic DFT Model

The hydrogen chemisorption in SWNTs was studied with both quantum chemistry models that we described earlier. Lee and Lee first employed the periodic DFT approach for studying chemisorption site of atomic hydrogen outside and inside of a (5,5) and a (10,10) SWNT [31]. They used supercells of eight layers along the tube axis and their results are presented in Figure 2. Their periodic-DFT calculations showed two hydrogen chemisorption sites in SWNTs. Both are *top* positions, inside (Fig. 2b) and outside (Fig. 2d) the tube walls. They predict also that hydrogen molecules can exist in the empty space inside the nanotube. The maximum storage capacity is mainly determined by the steric interaction between the H<sub>2</sub> molecules and between the H<sub>2</sub> and the tube wall. As a result the capacity increases linearly with the tube diameter. Excessive hydrogen storage will result in large repulsion energies and eventually break down the tube wall [31].

#### 5.3.2. Application of QM/MM Mixed Model

The QM/MM mixed model has been employed for studying the hydrogen interaction with SWNTs by Bauschlicher [33, 34] and Froudakis [35]. In this approach the total system is divided in two different sections: the inner part that is treated with an accurate quantum chemistry method and the outer part where a molecular mechanics force field is employed (Fig. 1b). This two-level approach combines the high accuracy of the *ab initio* treatment of the inner part of the tube in which the interaction with hydrogens will take

**Figure 2.** The calculations of Lee and Lee [31] for the chemical adsorption of H in SWNTs: (a) (5,5) SWNT before storage; (b) hydrogens adsorbed at the exterior of the tube wall; (c) adsorption of a single hydrogen atom at the interior of the wall; (d) initial and (e) fully relaxed geometry of (d); (f) molecular hydrogen inside the (5,5) SWNT; (g) H<sub>2</sub> inside (10,0) SWNT with an analogy of two H per one C atom and with 2.4 H/C (f). Bond lengths are in Å.

place, with the relaxation accuracy that the large size of the tube guarantees.

Bauschlicher used an (10,0) carbon nanotube for studying the hydrogen and fluorine binding to its wall [33] and for examining the maximum coverage of the tube wall [34]. The entire model used 200 carbon atoms while the *ab initio* section includes 24 carbon atoms. The ONIOM two level method of Dapprich and co-workers [21] was used for this purpose as it is implemented in the Gaussian 98 program package [36]. The higher level was treated with DFT and the lower level with MM. More specifically the B3LYP hybrid functional together with the 4-31G basis set was employed for the QM part and the universal force field (UFF) for the MM part. The preferable sites for the chemisorption of one, two, and four hydrogen atoms in the tube walls are reported together with the binding energies [33].

In [35] we applied the QM/MM approach in a 200-atom (4,4) SWNT, treating up to 64 carbons and 32 hydrogens with the higher level of theory (Fig. 1b). The small diameter of the tube together with the large number of atoms considered allow the higher level model to include a cylindrical part of the tube. This is very critical for investigating changes of the shape of the tube during the adsorption procedure.

In Figure 1b, we can see the two-level ONIOM [21] model that was used in [35]. The B3LYP functional was employed for inner part of the tube, as in [33, 34]. Nevertheless a larger set of double- $\zeta$  basis was employed (6-31G\*) that includes polarization functions. The two outer cylindrical parts were treated with the UFF while the dangling bonds at the ends of the tube were saturated with hydrogen atoms.

All the computations were performed with the Gaussian 98 program package [36].

These studies [33–35] mainly try to answer two questions: The first concerns the coverage of SWNTs by hydrogen atoms and the second deals with the difficulty of putting hydrogen atoms inside the tube. From the work of Bauschlicher [33] and Froudakis [35] it is clear that the hydrogen atoms that approach the SWNT will be bound to the tube walls in neighboring C atoms for minimizing the loss of C–C  $\pi$  bonds. But there are many different ways of doing this: One is to follow a zigzag line parallel to the tube axis while another is to follow an armchair ring vertical to the tube axis. First principle calculations [35] showed that the second procedure is energetically more favorable as has also been found experimentally for similar systems [13].

Furthermore it is interesting to see the effect of the two different hydrogen chemisorption patterns mentioned before on the shape of the tube walls. In Figure 3 we can see the optimized structures with 64 C and 16 H atoms in the QM region from [35]. The C atoms that hydrogens are bonded to pass from the  $sp^2$  to  $sp^3$  hybridization. This affects drastically the bond lengths and the size of the tube hexagons. The C–C bond length increases from 1.43 to 1.59 Å while the diameter of the hexagons goes from 2.84 to 3.15 Å if four hydrogen atoms are attached to this hexagon (Fig. 3b). These cause a strain that leads to tube deformation.

In the case of the line orientation of the hydrogens the shape of the tube changes from cyclic to elliptic (Fig. 3a). The 5.4 Å diameter of the tube without hydrogen split to

**Figure 3.** Optimized geometries from [35] showing 16 hydrogen atoms bonded in the tube in the two different ways: (A) following two zigzag lines parallel to the tube axis and (B) following an “armchair” ring vertical to the tube axis. In the lower part of the figure we see the tube toward its axis and we report the changing of its diameter in angstroms. Modified from [35], G. E. Froudakis, *Nano Lett.* 1, 179 (2001). © 2001, American Chemical Society.

a small 4.1 Å and large 7.2 Å diameter of an ellipsis. In the case of the ring orientation we see an enlargement of the tube diameter from 5.4 to 6.2 Å but keeping the cyclic shape (Fig. 3b). The second orientation is more favorable because the strain can be relaxed with the enlargement of one ring that does not affect the whole tube, while in the first case, an axial enlargement of the tube cannot take place only in one zigzag C line. This effect results in an energy difference of 2.6 eV between these two orientations. It is worth mentioning that in the line format we have no change in the volume of the tube while in the ring one, we have a 30% enlargement of the volume.

Since the hydrogens “prefer” to form rings around the tube the next question that arise is how close can those rings be? For answering this question in [35] we performed calculations with two different zigzag ring orientations (48 carbons and 32 hydrogens in the QM region). In the first, the rings were separated and in the second they were close together as can be seen in Figure 4a (middle and right upper part, respectively). After optimizing the geometries the separated configuration showed a repeated increasing and decreasing of the tube diameter of almost 1 Å. On the other hand, when the rings were closed together, the tube diameter was increased in the first ring by 1 Å and decreased to the normal value at the last ring. The total energy of the “ring by ring” configuration was favored energetically from the “all rings together” configuration by 17 eV.

This energy difference can be explained from the nature of the hybridization of the carbon atoms. During hydrogen addition the carbon atoms pass from  $sp^2$  to  $sp^3$  hybridization and a three-dimensional (3D) bond orientation is preferable. This 3D orientation can be obtained by the continued changing of the tube diameter in the “ring by ring”

**Figure 4.** (A) Optimized geometries [35] of 32 hydrogen atoms bonded in the tube in the two different ways: “ring by ring” configuration (in the middle) and “all rings together” configuration (at the right part) as analyzed in the text. The geometry of the tube without hydrogens is also plotted for comparison (left part). (B) Potential curves during the hydrogen approach to the three different carbon nanotubes shown in (A) (SWNT with no hydrogen atoms to its walls: blue line; SWNT with walls half filled with hydrogens: red line; and SWNT with walls full with hydrogen: green line). Modified from [35], G. E. Froudakis, *Nano Lett.* 1, 531 (2001). © 2001, American Chemical Society.

configuration. In this case the tube wall is not flat toward the tube axis but shows a zigzag shape (Fig. 4a, middle). In the case of the “all rings together” configuration the tube wall is changing shape only in the beginning and at the end, while in between it stays flat (Fig. 4a, right). The flat wall shape that was favorable when carbon atoms had  $sp^2$  hybridization is not favored after the hydrogen adsorption because carbon atoms changed hybridization to  $sp^3$ . Extending this configuration to an infinite atom tube will end up to 50% coverage since one C-zigzag ring has hydrogens and the next does not, periodically. This procedure will cause a 15% enlargement of the tube volume (half of the rings gain 30% in volume).

Bauschlicher in [34] reported also 50% hydrogen coverage in a (10,0) SWNT. He tested with the ONIOM approach a lot of random and prefixed bonding configurations of hydrogen in the tube walls. The “pairs of lines” configuration is presented in Figure 5 and found to be energetically more favorable. This result is not in disagreement with that previously mentioned for a (4,4) SWNT by Froudakis [35] since the (10,0) tube is significantly larger than the (4,4), and the curvature was found to play an important role in the adsorption procedure to SWNTs [37–39]. Furthermore Froudakis has not calculated a “pair of lines” configuration in the (4,4) SWNT.

The second question we tried to answer in [35] is what happens after the adsorption of hydrogens to the tube walls. Is it easier to fill up the tube with hydrogens? In

**Figure 5.** The most stable configuration of 50% hydrogen coverage in a (10,0) SWNT calculated by Bauschlicher. Modified from [34], C. W. Bauschlicher, Jr., *Nano Lett.* 1, 223 (2001). © 2001, American Chemical Society.

Figure 4b we report the potential curves when atomic hydrogen approaches the center of three tube-wall hexagons which differ only in the adsorption rate. The first has no hydrogen, the second is half filled with hydrogen, and the third is full of hydrogen. Analyzing these potential curves we see two competing forces in the approaching procedure. In one hand it is clear that the more hydrogen we have in the C hexagon, the larger the hexagon is and the easier the outgoing H passes. This can be easily observed by lowering the barrier at the tube wall as the number of hydrogens in the hexagon increases. On the other hand, the hydrogen in the hexagon is screening the attraction of the carbon atom to the external hydrogen. This screening, in the case of a fully hydrogenated hexagon, inserts a barrier in the outgoing hydrogen at a distance of 1 Å from the tube wall (where the bonded hydrogens are actually located). As a result, the energetically favorable H approach is when the tube wall is half filled with hydrogens. This happens because in the first part of the approach there is no barrier caused by steric repulsion of the bonded hydrogens, while in the entrance of the tube wall the barrier is smaller by almost 0.3 eV than the case of the bare tube.

Comparing the QM/MM results of Froudakis [35] with those of Seifert et al. [32] and Kudin et al. [40] obtained with periodic boundary condition models, we find an agreement concerning the stoichiometry (C: 2 ligand: 1) and the deformation of the tube that take place during the adsorption. Nevertheless there is a disagreement about the ligand orientation around the tube wall that could be a consequence of the different approach used (QM/MM versus periodic box) and/or from the different ligand (H versus F) and/or from the different tube examined (4,4 versus 10,10 that have almost double diameter).

#### 5.4. Molecular Hydrogen Interaction with Doped Carbon Nanotubes

After 1999 when Chen et al. [9] reported that alkali-doped carbon nanotubes possess high hydrogen uptake a lot of experimental work has been performed trying to investigate the hydrogen adsorption in SWNTs and to improve the storage capacity of the tubes by doping them [15]. On the other hand, there was no sufficient theoretical explanation of this phenomenon.

All the theoretical calculations reported so far can be divided in two categories. Either they are empirical [23–29] or they are based on first principle methods but deal only with atomic hydrogen [30–35]. The first category cannot give an understanding of the elementary steps in the adsorption process. Since these methods are not *ab initio* but based on parameters, they cannot provide insight into the chemical bond. The first principle methods can, but they deal only with atomic hydrogen while the most important interaction for the storage, which is the molecular hydrogen interaction with SWNTs, remains untouched. The reason *ab initio* studies of the  $H_2$  interaction with SWNTs do not exist is obvious. The interaction is weak and the system is large.

In [41] we tried to investigate the nature of the  $H_2$  adsorption in alkali-doped SWNTs and to compare it with the adsorption in pure SWNTs. Only in this way it is possible to answer why alkali doped carbon nanotubes have high  $H_2$

uptake. In order to compromise the large size of the system together with an accurate *ab initio* method without ending up in a prohibitively large calculation we applied the QM/MM mixed model as described earlier (Section 4.2) in a closed (5,5) SWNT with 150 carbon atoms. K atoms dope the tube in a  $2 \times 2$  pattern as suggested by Gao et al. [42]. In this pattern the K atoms were placed on “hollow” positions above the center of the C hexagons of the tube in such a way that if one hexagon has potassium, all the neighboring ones do not (Fig. 6). A geometry optimization confirmed that these positions were optimum for our model, too. Twenty-four carbon atoms together with two potassium atoms and all the  $H_2$  molecules that were interacting with these two K atoms were kept in the QM region, while the rest of the atoms were treated by MM.

The first case considered (Fig. 6, left) was a doped tube where a single  $H_2$  molecule was interacting with each K atom. After the geometry was optimized, the binding energy of the  $H_2$  to the K was 3.4 Kcal/mol/ $H_2$ . The distance of the K atom from the center of the  $C_6$  hexagon of the tube was 3.0 Å while the distance of the closer H of the  $H_2$  molecule from the K was 3.0 Å, too. In the next case (Fig. 6, middle) two hydrogen molecules were interacting with each K and finally three (Fig. 6, right). The binding energies were 2.5 and 1.8 kcal/mol/ $H_2$  respectively. The  $H_2$  distance from the K was found to be 3.3 and 3.5 Å while the K–tube distance remained the same (3.0 Å).

From these results is clearly showed that at least three hydrogen molecules can bound each K atom of a doped tube even though the binding energy is consistently decreasing with the number of ligands. The two questions that immediately arise are: How many  $H_2$  can be accommodated to each alkali of the doped tube? And why do the doped tubes have larger hydrogen uptake that the pure carbon nanotubes?

For answering the first question we also calculated in [41] the case where five  $H_2$  molecules were attached at each K of the doped tube. The binding energy was 1.1 kcal/mol/ $H_2$ . Then the binding energy per hydrogen molecule was plotted with respect to the number of the  $H_2$  molecules. As can be seen from Figure 7 the binding energy decays exponentially. This result has to be considered together with the

**Figure 6.** Three of the alkali metal doped (5,5) SWNTs used by Froudakis [41] to study the interaction with molecular hydrogen. The first has one  $H_2$  per K, the second two, and the third three. A magnified part of all pictures is also presented.

**Figure 7.** Binding energy per hydrogen molecule with respect to the number of the  $H_2$  molecules. The hexagons represent the calculated values where the line was fitted. Modified from [41], G. E. Froudakis, *Nano Lett.* 1, 531 (2001). © 2001, American Chemical Society.

geometrical constrains (i.e., the space around the K atoms has a maximum number of  $H_2$  molecules that can be introduced without having steric interactions). From this graph we can estimate the amount of  $H_2$  molecules that can be attached to a doped tube according to the temperature that plays the role of the energetic cutoff.

For the second question (why the doped tubes have a larger hydrogen uptake) we have to understand the nature of the  $H_2$  interaction with the pure carbon and the alkali-doped nanotubes. In the case of the doped tube there is a charge transfer from the alkali metal to the tube. This charge was calculated by Mulliken population analysis to be 0.6  $|e|$  for the K doped tube [41]. The positively charged K atoms polarize the  $H_2$  molecules. Even though there is no charge transfer from the  $H_2$  to the K the charge induced dipole interaction gives the character of the bonding (Fig. 8). In the case of the pure tube, where the  $H_2$  interaction was calculated for comparison, there is neither charge transfer nor polarization of the  $H_2$  molecule and this results in an extremely weak interaction, under the accuracy of our theoretical level.

Comparing these results [41] with previous work for atomic hydrogen we can see *physisorption* of the molecular hydrogen to doped or undoped SWNTs while for the atomic hydrogen we have *chemisorption*. There is in agreement of our QM/MM results [41] and the semiempirical results of Dubot and Cenedese [29] indicating that the alkali metal is responsible for the adsorption of molecular hydrogen to doped tubes. Nevertheless they predict an adsorption energy of 11.5 kcal/mol [29], while we found 3.4 kcal/mol [41]. The fact that we use K while they use Li for doping the tube does not explain this large difference, which is probably due to the empirical nature of their calculations [29]. In addition, the explanation that the alkali metal act as a catalytic active center for the  $H_2$  dissociative adsorption proposed by Chen et al. [9] does not seem very possible since the alkali metal– $H_2$  interaction is too weak to cause a  $H_2$  dissociation.

**Figure 8.** Constant amplitude contours presenting the highest occupied molecular orbital of the (5,5) K-doped SWNT with one H<sub>2</sub> per K atom. The plotted area is also marked on the entire tube. Modified from [41], G. E. Froudakis, *Nano Lett.* 1, 531 (2001). © 2001, American Chemical Society.

## 6. OXYGEN INTERACTION WITH CARBON NANOTUBES

Despite the importance of oxygen adsorption on SWNTs the theoretical work existing in the literature about this interaction is controversial and can be briefly summarized in the next few paragraphs.

Jhi et al. combining pseudopotentials together with local density approximation (LDA) and local spin density approximation studied the oxygenation of an (8,0) SWNT [43]. They found that O<sub>2</sub> binds to a bridge position between to carbon atoms of the tube with adsorption energy of 0.25 eV and a distance of 2.7 Å. Nevertheless the O–O distance was kept frozen.

Zhu et al. performed tight binding (TB) DFT calculations to study the adsorption and desorption of an oxygen molecule to the edges of a (5,5) and a (9,0) SWNT [44]. They found that an O<sub>2</sub> molecule arriving at the tube wall edges will not adsorb on the wall but instead will glide into the edges with a binding energy of 4.61 eV [44, 45].

Sorescu et al. using pseudopotential DFT studied the adsorption of oxygen atom and molecules on an (8,0) SWNT [46]. The atomic O performed epoxide-like structures with adsorption energy up to 44 kcal/mol, while the molecular O<sub>2</sub>

is predicted to weakly physisorb (0.9 kcal/mol) to the SWNT surface. It is also found to perform unstable chemisorbed species 10.2 kcal/mol above the reactants [46].

Park et al. using the pseudopotential LDA method investigated atomic and molecular oxygen adsorption in the fullerene type caps of a (5,5) SWNT [47]. They observed epoxide-type bridge positions for the atomic oxygen with binding energies of 6.6 to 6.7 eV and square-type four-center geometries for the binding of the O<sub>2</sub> molecule with binding energies of 1.66 to 3.02 eV [47].

Even though all the references presented [43–47] use methods based on similar approaches like pseudopotential or TB, a big *variety* of binding energies is reported, as is also pointed out by Park et al. [47]. On top of this the question whether the molecular oxygen reacts exothermically with carbon nanotubes remains unanswered.

### 6.1. Application of the Cluster Model

In order to answer this question we performed a fully *ab initio* study of the atomic and the molecular oxygen adsorption to a carbon nanotube [48]. We use the DFT method in the *cluster* approximation. A large enough part of an armchair (4,4) SWNT containing 56 carbon atoms is separated and treated as an individual system. The dangling bonds at the end of the tube are saturated by hydrogen atoms (Fig. 1c).

The RI-DFT as implemented in the TURBOMOLE program package in combination with an auxiliary basis set was used for studying the atomic and molecular hydrogen interaction with the 56-atom SWNT [49]. The efficiency and the computational speed of the methodology we use made the geometry optimization of a C<sub>56</sub>H<sub>16</sub>O<sub>2</sub> system possible in a Linux personal computer.

### 6.2. Atomic Oxygen Interaction with Carbon Nanotubes

In the beginning we investigated the atomic oxygen adsorption on SWNTs [48]. As can be seen in Figure 9 there are only two stable positions. These positions are epoxide-like with the oxygen bridging two neighboring carbon atoms of the tube. All other possibilities of the O sitting on top of a single carbon atom or in the center of a C hexagon are unstable and relax to the bridge positions after geometry optimization. The binding energy for the 9a isomer is

**Figure 9.** The two stable isomers of the atomic oxygen chemisorption in a (4,4) SWNT forming epoxides. In the first (A) the C–C bond opens.

94.6 kcal/mol while that for the 9b is 62.6 kcal/mol. From the binding energies it is clearly shown that both additions are exothermic and the high energy gain indicates a chemisorption procedure.

Comparing these two different bridge positions of the atomic oxygen on carbon nanotubes we observe an energy difference of 33.8 kcal/mol. In order to explain the stabilization of bridge 9a over bridge 9b we have to look closer at the geometric features of the two isomers. In the 9a isomer the oxygen atom is actually breaking the C–C bond (2.062 Å) while the O–C bond is 1.397 Å. In the 9b case the C–C bond opens slightly, 1.522 from 1.415 Å of a bare tube, and the O–C bond is 1.450 Å. In both cases in the chemisorption procedure we have the addition of one C–O bond to each of two neighboring  $sp^2$ -hybridized carbon atoms of the tube. This leads to overcoordinated C atoms that either have to pass to  $sp^3$  hybridization or to break one bond. In the 9a isomer the breaking of the C–C bond is geometrically possible and energetically favorable. The cyclical shaped tube turned locally to an oval-shaped distorted one, and this allowed the C atoms that are connected to the O to keep the  $sp^2$  hybridization (Fig. 9a). The O is coming to the same plane with both the hexagonal rings that it is connected and the angle of these two hexagonal rings with respect to the oxygen is  $95^\circ$ .

In the bridge 9b isomer distortion of the tube parallel to the tube axis is not possible and that is why the C atoms change to unfavorable  $sp^3$  hybridization with weaker bonds (Fig. 9b). Thus the isomer 9b is energetically higher from the 9a by 33.8 kcal/mol. The same interesting phenomenon was observed also in the case of H adsorption in SWNTs (Section 5.3.2).

### 6.3. Molecular Oxygen Interaction with Carbon Nanotubes

Since the oxygen in the atmosphere appears in molecular form, it is of great importance to examine the molecular oxygen adsorption to carbon nanotubes and to analyze the nature of this procedure [48]. Using our *ab initio* method we perform geometry optimization of all the possible adducts of  $O_2$  molecules and (4,4) SWNTs. We tried both parallel and vertical orientations of the  $O_2$  molecule to the tube axis. Two different pathways of oxygen approach were tested (one oxygen atom attaching the tube walls; both oxygen atoms attaching the tube walls). Finally all these were combined with binding positions on *top* of a carbon atom, in the *hollow* position of C hexagons, and *bridging* C–C bonds.

After the geometries were optimized we found two stable adducts presented in Figure 10. In both of these local minima the oxygen molecule is *bridging* C–C bonds—the two different kinds of bonds that exist in the tube—making square rings. In the first case the bridged C–C bond is vertical to the tube axis (Fig. 10a) and in the second it is semiparallel (Fig. 10b). All other possibilities of  $O_2$  approaching the tube walls were either unstable or after the geometry optimization end up in the bridge positions (Fig. 10a or b).

In the first bridge isomer the C–C bond opens from 1.40 to 1.68 Å, the O–O is 1.51 Å, and the two C–O are 1.45 Å while in the second case the C–C bond opens from 1.41 to 1.55 Å, the O–O is 1.51 Å, and the two C–O are 1.48 Å.

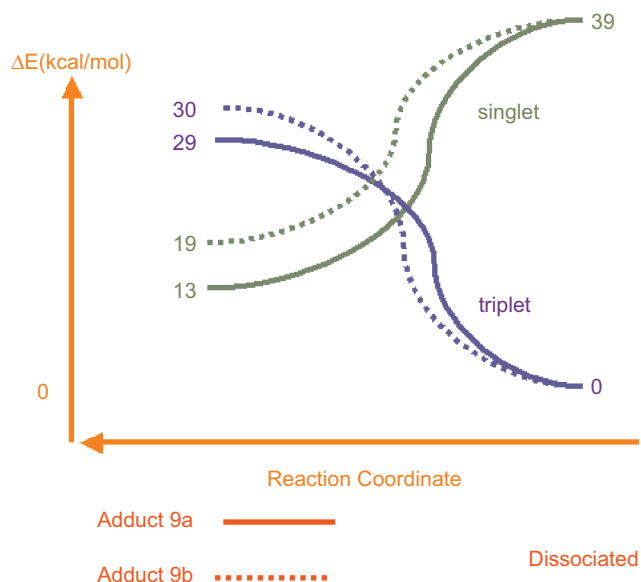

In the second isomer the formed square ring is not totally planar but slightly twisted (dihedral angle  $19^\circ$ ). The binding energies of these two species are +13 and +18 kcal/mol respectively and the addition is endothermic in both cases. The electron density of the bonding area of isomer 10a is presented in Figure 10c.

From our fully optimized calculations, without any symmetry constraints, it is clear that both bridge adducts are local minima. Nevertheless for the discussion of the binding energy we have to take into account the electronic configuration of the reactants together with the one of the product cluster (SWNT +  $O_2$ ). Since for both adducts (bridge 1 & 2) the ground state configuration is singlet, we consider first the singlet reaction.

For bridge 1 (9a) the addition  $^1\text{SWNT} + ^1O_2 \rightarrow ^1(\text{SWNT} + O_2)$  is exothermic by 25 kcal/mol. Despite this the ground state of the  $O_2$  is triplet. The analogous triplet addition  $^1\text{SWNT} + ^3O_2 \rightarrow ^3(\text{SWNT} + O_2)$  is endothermic by 29 kcal/mol. These two energy curves are separated from the complicated multidimensional energy hypersurface of the system and presented in Figure 11 (solid lines). Since they are of different symmetry they can cross each other (diabatic curves) and some more reaction possibilities arise. This also explains the controversial results existing in the literature.

**Figure 10.** The two stable isomers of the molecular oxygen adsorption in a (4,4) SWNT forming orthogonal rings. The electron density of the bonding area of isomer 10a is presented in (C).

**Figure 11.** Four energy curves separated from the complicated multidimensional energy hypersurface of the (4,4) SWNT when  $O_2$  is approaching from the left side of the diagram. Solid lines end up in the adduct 9a with dashed lines for 9b. Blue lines represent triplet states and green lines singlet states.

The curve connecting the two ground states starts from the separate  $^1SWNT$  and  $^3O_2$ , presents a barrier where the total symmetry changes to singlet (crossing point), and falls down to the adduct  $^1(SWNT + O_2)$ . This barrier is approximately 15 kcal/mol.

According to this figure there are two different possibilities for  $O_2$  adsorption to the SWNT: In the first the  $O_2$  is excited to its singlet electronic configuration and then it automatically reacts exothermically with the tube. In the second case we start with  $O_2$  in its triplet ground state and energy of  $\sim 15$  kcal/mol has to be offered to the system in order to overpass the energy barrier and react with the tube.

For the bridge 2 (9b) adsorption a picture completely analogous to bridge 1 (9a) exists and is presented in Figure 11 (dashed lines). The only difference is the relative energy values. Finally, since all these cases (singlet and triplet, bridge 1 and 2) are coexisting, a combination of all these four energy curves is needed in order to have the complete adsorption picture (Fig. 11).

In real—and not ideal—systems, when the tubes possess defects and the temperature is not absolute zero—as in quantum mechanical calculations—the triplet  $O_2$  adsorption is possible. The barrier is relatively small and the defects of the tube can lower it even more. Also the temperature “movements” can help the procedure.

## 7. CONCLUSIONS

In this chapter we review the existing theoretical literature of hydrogen and oxygen interaction to single walled carbon nanotubes. The importance of theoretical simulations for understanding the adsorption procedure and for improving the storage capacity of these nanomaterials is underlined. We report three different approaches to treating large

systems with *ab initio* methods the periodic DFT, the mixed QM/MM model, and the *cluster* model. For all advantages and disadvantages are presented.

Specifically for the hydrogen adsorption, it is showed that both periodic DFT and mixed QM/MM models can successfully be employed in the SWNT and provide a solution to the problem of making accurate calculations in large systems like nanotubes. The results of Bauschlicher [34] and Froudakis [35] demonstrate that atomic hydrogen will bind to the tube walls and not enter in the tube interior. This binding can take place either in pairs of lines toward the tube axis, as the first suggests, or in zigzag rings around the tube walls, supported by the second. This will result in a change of the tube shape during the hydrogen adsorption and an enlargement of the tube volume [35]. Both found 50% to be the maximum coverage of the tube walls. After the tube walls are half filled with hydrogen, the energetically more favorable procedure of hydrogen insertion in the tube is obtained [35].

Since the storage capacity is mostly obtained by molecular hydrogen, Froudakis [41] tried to answer why alkali-doped carbon nanotubes possess high hydrogen uptake as put forward by Chen et al. in 1999 [9]. His results demonstrate a charge transfer from the alkali metal to the tube that polarizes the  $H_2$  molecule. This charge induced dipole interaction characterizes the  $H_2$  physisorption on alkali metal doped tubes and is responsible for the higher hydrogen uptake of the doped tubes.

As a general remark for hydrogen we can report that in the last couple of years the theoretical modeling of the hydrogen storage in carbon nanotubes has obtained only its first goal (i.e., to give an understanding of what it is going on in the laboratory experiments by explaining the elementary parts of the adsorption procedure). The second and most important goal, which is still to come, is to predict how the storage capacity of carbon nanotubes can be improved and reach a sufficient level for commercial use in fuel-cell electric vehicles.

As far the oxygen adsorption in carbon nanotubes is concerned we showed that atomic oxygen exothermically reacts with the tube walls performing epoxides. For molecular oxygen the picture is not so clear. Both singlet and triplet states have to be taken into account. These configuration states have to be combined with the two different isomers found, resulting a complicated potential energy hypersurface (PES). This complicated PES characterizes the oxygen adsorption to carbon nanotubes and is also responsible for the controversy existing in the literature.

According to our results there are two different possibilities for the atmospheric oxygen adsorption to carbon nanotubes: In the first the  $O_2$  is excited to its singlet electronic configuration and then it automatically reacts exothermically with the tube. In the second case we start with  $O_2$  in its triplet ground state and an energy of  $\sim 15$  kcal/mol has to be offered to the system in order to overpass the energy barrier and react with the tube. The latter pathway can be supported by the existence of defects in the tube and temperature in the environment.

Considering this theoretical result together with the experimental observation that the electronic and transport properties of carbon nanotubes are extremely sensitive to

their exposure to gas molecules [10–12], we can draw the conclusion that the results of all previous experimental studies of SWNTs must be carefully reevaluated, since all measurements have used samples exposed to air.

## GLOSSARY

**Ab initio methods** Theoretical quantum chemistry techniques that solve the Schrödinger equation for the electrons of a molecular system. They are very accurate since they do not enforce any parameters to the system but on the other hand they are computationally very heavy.

**Atomic cluster** A collection of atoms that form a unique system stabilized by interatomic forces.

**Carbon nanotubes** Rolls of graphitic sheets that come in a variety of forms and shapes. They can be zigzag, armchair, or chiral because of the different ways that the graphitic sheet can be rolled. They are valuable for nanoelectronics and as storage devices.

**Chemisorption** An adsorption in which the adsorbed system is stabilized by strong chemical bonds.

**Monte Carlo method** A statistical mechanics empirical method for obtaining optimal conformations of molecular systems. The trial movements of the atoms are performed randomly and for this reason the method took its name from the famous casino.

**Physisorption** An adsorption in which the adsorbed system is stabilized by weak interactions.

**Single walled carbon nanotube** A carbon nanotube that consists of only one graphitic sheet. If the tube has more than one cylindrical shell it is called a multi walled nanotube.

## 1. INTRODUCTION

There has been an ever-increasing interest in sustainable and renewable energy technology due to environmental and climate change pressures. The search for such technologies

has intensified in the last decade, mainly due to the debate of climate change and the Kyoto protocol. The public and legislative demand for more renewable or sustainable energy supplies has been driving the push for the so-called "hydrogen economy." Such an economy is one where hydrogen is used for energy storage, distribution, and utilization. Fuel cell technology has emerged as a forerunner of the clean energy race. The promises of fuel cells utilizing hydrogen as the fuel are tantalizing; they have the potential to simultaneously double the energy efficiency of cars while significantly reducing air pollution and greenhouse gas emissions. If the predictions are true, over the next few decades, we will see a shift away from the current fossil-fuel-based economy toward a cleaner hydrogen future.

Hydrogen's physical and chemical properties make it a good low-polluting energy carrier. However, several technological problems must be overcome before we can realize the full hydrogen economy. These relate to how hydrogen will be generated in an efficient and low-polluting manner, and how it will be transported, distributed, and stored. Once

both of these questions are answered in an economical way, the hydrogen economy will be in place. Here, we look at recent work on the use of carbon nanotubes for the storage of hydrogen.

### 1.1. Hydrogen Storage Technologies

Although many advances in hydrogen production and utilization technologies have been made, hydrogen storage technologies must be significantly advanced if a hydrogen-based energy system, particularly in the transportation sector, is to be established [1]. Hydrogen can be made available on board vehicles in several ways: compression, as a liquid, metal hydrides, chemical storage, or gas-on-solid adsorption. Although each method possesses desirable characteristics, currently no approach satisfies all of the efficiency, size, weight, cost, and safety requirements for transportation or utility use.

Liquid hydrogen storage systems lose up to 1% a day by boiling and up to 30% during filling, as well as requiring good (bulky) insulation to keep the hydrogen at 20 K.

Daimler Chrysler's Nectar II utilizes compressed hydrogen gas, and suffers from permeability of the tank housing and high energy input to achieve pressurization. The associated safety risks from hydrogen continually being released currently make both of these approaches impractical. Storage in a solid-state matrix, as a metal hydride for instance, has a safety advantage, and is the current method for storage above room temperatures and below 2–4 MPa. The disadvantages of a metal hydride system are a hydrogen storage capacity of at most 7 wt% (the ratio of stored hydrogen weight to the system weight) and typically 2 wt% [2] and a large desorption energy, making it less than ideal for automotive applications [3].

Physical adsorption of hydrogen onto an adsorbent has the advantage of a low desorption energy, but currently very low storage capacities. In contrast to the chemisorption in metal hydrides, the adsorbent adsorbs hydrogen molecules by physical, van der Waals type forces. This generally requires cryoadsorption, where the adsorbent is cooled to very low temperatures, to store large amounts of hydrogen. Hydrogen adsorption studies on highly porous amorphous carbon at 123 K showed that they had a capacity of 0.05 wt% of carbon at 2 MPa [4]. Recent parametric modeling of adsorption storage on activated carbons has shown that a passive adsorbent system could approach the U.S. Department of Energy (DOE) goals at low temperatures ( $\sim 77$  K) by improving the bulk density and specific surface area of the adsorbent [5]. Although not as severe as liquid hydrogen, cryoadsorption suffers as an economic proposition because of the need to maintain such a low temperature [6, 7].

### 1.2. Novel Carbon Adsorbents

The discovery of the third carbon allotrope Buckminsterfullerene ( $C_{60}$ ) in 1985 by Kroto et al. initiated a novel, round, and curved carbon nanocosmos [8]. Subsequently,

the mass production of  $C_{60}$  and the family of fullerenes became available [9]. It was in this light that the discovery of carbon nanotubes received instant recognition. Carbon nanotubes (CNTs) were discovered accidentally in 1991 by Iijima [10], while looking for new carbon structures in the deposit formed on graphite cathode surfaces during the electric arc discharge that is commonly employed to produce fullerene soot. They were identified as fullerene tubes consisting of multiple shells in which many tubes were in a coaxial, concentric arrangement. The scanning electron microscopy (SEM) and transmission electron microscopy (TEM) images of multiwalled carbon nanotubes (MWNTs) synthesized by the catalytic chemical vapor deposition method are shown in Figure 1. Each layer is composed of a cylindrical graphene sheet, with an interlayer spacing of 0.34 nm, which is slightly larger than the 0.336 nm spacing found between sheets of graphite [11]. In retrospect, hollow carbon tubules were observed in the 1970s as forming the core of carbon fibers in a certain process, although the broad implications were not clearly realized at the time.

In 1993, Iijima's group and Bethune and his colleagues independently found that the use of transition-metal

**Figure 1.** SEM image (A) and TEM image (B) images of MWNTs obtained by the catalytic pyrolysis of  $C_2H_2$  at 700 °C in a flow of  $H_2$ . Images are from [57], R. G. Ding et al., unpublished work (2003).

catalysts led to nanotubes with only one single shell [12, 13]. Due to their simple and well-defined structure, such single-wall nanotubes (SWNTs) serve as model systems, both for theoretical calculations and for key experiments. Carbon nanotubes are cylindrical molecules with a diameter as little as 1 nm and a length up to many micrometers. The high-resolution TEM images of typical SWNTs and MWNTs are shown in Figure 2. They have unique structural, mechanical, and electrical properties that make them attractive systems for fundamental scientific studies, as well as for a broad range of applications.

The unique properties of carbon nanotubes hold the promise for applications such as catalysis and energy storage. The theoretical description of capillarity in carbon nanotubes by Pederson and Broughton [14] suggested that gaseous species such as hydrogen might be drawn into the capillaries of carbon nanotubes.

There have been some reviews of experimental and theoretical investigations of hydrogen storage in carbonaceous materials available in the literature [1, 3, 15–18]. The field of hydrogen storage on CNTs is undergoing rapid progress. Here, we attempt to provide a comprehensive and critical review of this topic at the time of writing. Both experimental and theoretical calculation studies are included, along with an outline of current challenges in the field.

**Figure 2.** High-resolution transmission electron microscopy images of typical SWNT (A), (B), MWNT (C), and a carbon nanofiber (CNF) of the herringbone-type morphology (D) and corresponding schematic structures. Two individual SWNT tubes with a diameter of  $\sim 1$  nm are shown in (A), and an SWNT bundle consisting of two tubes with an outer diameter of  $\sim 2$  nm is shown in (B). Open MWNT tip is shown in panel (C). The separation between the closely spaced fringes in the MWNT is 0.34 nm, close to the spacing between graphite planes. Every layer in the image correspond to the edges of each cylinder in the nanotube assembly. Images are from [57], R. G. Ding et al., unpublished work (2003).

## 2. EXPERIMENTAL STUDIES OF HYDROGEN STORAGE BY CARBON NANOTUBES (CNTs)

Of the problems to be solved for the utilization of hydrogen energy, how to store hydrogen easily and inexpensively, has been given high priority. A vehicle powered by a fuel cell would currently require  $\sim 3.1$  kg of hydrogen for a 500 km range. This amount of hydrogen stored in the weight and volume of a typical petrol tank (50 L) requires system densities approaching 6.5 wt% or  $63 \text{ kg H}_2/\text{m}^3$  [19]. Therefore, the U.S. Department of Energy Hydrogen Plan has set this as the standard for providing a commercially significant reversible hydrogen storage technology [7]. No storage technology is currently capable of meeting these goals [17]. Meeting this target requires major advances in storage density, and the energy required for storage without compromising safety and cost. Most of these issues would be resolved by a lightweight material capable of reversibly storing and releasing hydrogen in a modest range of near-ambient temperatures and pressures. Novel lightweight carbon nanotubes were seen to be an ideal candidate as it was assumed that hydrogen molecules could be physisorbed both inside the tubes and in the interstitial pore spaces between the tubes.

A large number of hydrogen adsorption experiments have been conducted to measure the storage capacity of carbon nanotubes. At the same time, many researchers have calculated the adsorption performance of the carbon nanotubes by means of various models and theories. Here, we first summarize the recent experimental and theoretical results, then briefly discuss the interaction between hydrogen and carbon nanotubes for elucidating the hydrogen adsorption nature within carbon nanotubes. Currently, there are two major methods of hydrogen storage in carbon nanotubes being studied: gaseous storage and electrochemical storage.

The three main methods for the preparation of carbon nanotubes are electric arc discharge, chemical vapor deposition, and laser ablation. All of these methods rely on creating highly energetic carbon clusters that condense to form carbon materials such as fullerenes and nanotubes. Recent advances have been to use metals as condensation catalysts that template and promote certain types of materials. The prepared nanotubes can then be purified and/or treated in some manner to open the nanotube ends. It is interesting to note that high-capacity room-temperature adsorption was first demonstrated for arc-generated SWNTs, and not laser-produced nanotubes. This may be attributed to a much smaller number of ends or defects in the laser produced tubes and/or an enhancement in their stability toward opening procedures or cutting [1]. Significant research has been undertaken to improve synthesis methods, and to more accurately characterize the unique mechanical and chemical properties of carbon nanotubes. A discussion of these topics is outside the scope of this chapter, but the reader can be directed to a wealth of related literature [20–25].

## 2.1. Hydrogen Storage Measurement Techniques

The main methods used for determining the hydrogen storage capacity are temperature-programmed desorption (TPD), volumetric analysis, thermogravimetric analysis (TGA), and the electrochemical method.

The temperature-programmed desorption method consists of using a mass spectrometer to measure the hydrogen desorbed from a carbon sample during controlled heating [26]. Thermal desorption spectroscopy is highly sensitive, allowing the study of samples with masses below 1 mg. The sensitivity can be even improved by using deuterium-loaded samples, and avoiding any disturbing background from water or other hydrogen-containing adsorbates [27]. For calibration, the hydrogen desorption of a well-known metal hydride or an alloy of known hydrogen content has to be measured [28]. The activation energy of desorption can be directly measured from the temperature at which hydrogen appears in the spectrometer. As different adsorption mechanisms and sites will have different activation energies, each peak in the thermogram will indicate a different site or mechanism. It will be shown that carbon adsorbents have a desorption peak around 130 K, and nanotubes can have one (at  $\sim 300$  K) or more additional peaks. The amount of hydrogen desorbed requires integration of the signal, and may have significant errors [26]. In volumetric analysis, the adsorption of hydrogen is measured by a pressure change in a fixed volume, with pressure variations attributed to adsorption or desorption. A complication with this technique is the presence of thermal effects during the filling of the sample cell. Hydrogen has an appreciable temperature-dependent compressibility that needs to be taken into account as the temperature changes due to compressing the gas during filling and the exothermic adsorption. Unless this problem is specifically addressed, the change in pressure caused by temperature fluctuations will cause overestimation of the amount of hydrogen adsorbed [18]. The calibration should be done by measuring a well-known metal hydride.

The thermogravimetric analysis method consists of measuring the weight of a sample as the temperature is varied under constant pressure. The technique is well known, with the difficulty being the sensitivity of the instrumentation on the relatively small sample sizes used in these studies. The gravimetric analysis is capable of measuring very low sample masses of about 10 mg in specially designed devices, but it is a nonselective analysis. The high specific surface area of carbon nanotubes increases the possibility of the adsorption of residual gases. Therefore, the apparatus has to be extremely clean, and high-purity hydrogen has to be used.

Hydrogen can be incorporated into the sample due to the electrochemical technique. To prepare the carbon-containing working electrode, the carbon material has to be mixed with conductive powder, for example, nickel or gold and compacted [29–31]. The counterelectrode is, for example, metallic nickel. Both electrodes are placed in a KOH solution which provides the hydrogen atoms, and they are separated by a polymer separator. During the charging process, water dissociates at the negative working electrode, and atomic hydrogen may intercalate into the carbon material. The following discharge process results in the recombining of water. By maintaining a constant current, the voltage

is measured across the two electrodes during the charging and discharging. The amount of desorbed hydrogen is determined by measuring the electric charge in a galvanostatic setup.

A comprehensive study which involved a broad range of carbon materials was conducted recently by Tibbetts et al. [32], whose experimental results cast serious doubts on many claims so far for room-temperature hydrogen sorption in carbon materials larger than 1 wt%. The authors analyzed the possible pitfalls in the gaseous hydrogen adsorption process using volumetric techniques [32], and proposed techniques to handle all of those problems [33]. The chief areas where hydrogen adsorption experiments may be in error are as follows.

The first is that leaks can be difficult to distinguish from hydrogen storage. Hydrogen molecules disappear from a pressurized reservoir. If hydrogen molecules leak from a system of volume  $V$  at a nearly constant rate  $L = dP/dt$  over the period of the experiment  $t$ , an observer could incorrectly attribute the pressure decrease to a wt% hydrogen stored in a sample of mass  $m$  proportional to  $VL/m$ . For small sample masses, the consequences of this can be particularly treacherous.

A second source of error is that, in a high-pressure experiment, pressure changes arising from ambient temperature variations can be mistakenly interpreted as substantial sorption. At 10 MPa and 300 K, the pressure change with temperature is 33.3 kPa/K. If this were interpreted as sorption by a 1 g sample in a 1 L volume, the result would be 2.6 wt% per degree temperature drop. Most reports in the literature have samples smaller than 1 g.

A more significant, but less obvious source of temperature variation stems from the thermodynamic principle that a chamber being pressurized experiences a temperature rise. The enthalpy of high-pressure gas is higher than that of low-pressure gas, and so the flux of high-enthalpy molecules from a high-pressure chamber to a low-pressure chamber raises the temperature of the gas in the low-pressure chamber. This temperature is not easily measured if the temperature sensor is not in good thermal contact to the gas or if the walls of the chamber have a large heat capacity. For an ideal gas adiabatic ally bled into an evacuated chamber, the temperature rise is  $(C_p/C_v - 1)I_{\text{initial}}$ , corresponding to a 41% increase in absolute temperature for hydrogen [34]. The authors believed that many high-pressure adsorption experimental results should be carefully corrected to exclude the pressure drop brought by return to thermal equilibrium after pressurization. Figure 3 shows the effect of thermal equilibrium after pressurization on the pressure change in the sample chamber [32].

It is worth noting that the metal hydride research community has devised experimental techniques to handle all of these problems [33]. First, to avoid spurious readings from gas cooling to ambient, use two calibrated volumes connected by a valve, one an initially pressurized reservoir and the other containing the sample. Then determine the precise equilibrium temperatures and pressures of both volumes before and after opening the connecting valve. Second, to unambiguously establish that there are no leaks, measure not only the gas adsorbed, but also the gas desorbed from

**Figure 3.** Hydrogen pressure versus time for a 307 mL chamber containing no sample. This shows pressurization to 11.97 MPa from vacuum at 25.3 h and the subsequent pressure decrease. Reprinted with permission from [32], G. G. Tibbetts et al., *Carbon* 39, 2291 (2001). © 2001, Elsevier Science.

the sample. Third, present a complete pressure composition isotherm that precisely defines the pressure and composition at which the hydrogen-adsorbent bond is formed and decomposes. A complete pressure composition isotherm would show an interesting change in curvature with pressure that would be very useful in classifying the sorption, and lending credibility to the research [32].

## 2.2. Gaseous Hydrogen Storage in CNTs

A summary of gaseous hydrogen storage in undoped and doped carbon nanotubes from the literature is given in Table 1.

Dillon et al. [26] were the first to publish experimental data on hydrogen adsorption in nanotubes, and measured exactly the desorption of hydrogen of nonpurified SWNT samples (containing additional cobalt catalyst and amorphous carbon). Using TPD, the authors found that the hydrogen desorbed from both the nanotubes and activated carbon samples at about the same temperature ( $\sim 133$  K). However, a second peak appeared at higher temperature for SWNTs ( $\sim 290$  K), indicating that there were additional adsorption sites in SWNTs. They proposed that these sites were when hydrogen molecules had access to the nanotube cores. The authors did not see this high-temperature site in either activated carbon or in arc-generated soot produced without a catalyst. The SWNT constituent of the sample appeared to be especially effective for hydrogen adsorption, and an activation energy for hydrogen desorption was found to be  $19.6 \text{ kJ} \cdot \text{mol}^{-1}$  (approximately five times that of planar graphite). In 2000, Heben's group performed inelastic neutron scattering on this material, and showed that hydrogen is physisorbed [35], but the authors made no statement about the total amount.

The hydrogen storage capacity was estimated to range between 5 and 10 wt% [26]. This figure was derived from the measured hydrogen desorption of 0.01 wt% and an SWNT content estimated at 0.2 wt%. Furthermore, it was assumed

that only the SWNTs in the sample contributed to the hydrogen adsorption, so the analysis required a large correction for 99.8 wt% of material that was assumed inert. However, hydrogen adsorption in high-porosity carbon (AX-21 carbon) is as high as 5.3 wt% at a temperature of 77 K and a hydrogen pressure of 1 MPa [36].

In a more recent paper, Dillon et al. [37] presented an oxidative technique to open the nanotubes: the degassing of the samples in vacuum to 970 K, and an oxidizing in water in the 325–975 K temperature range. They measured the adsorption of hydrogen in such treated samples by their TPD method, and found a noticeable enhancement (up to a factor of 3 in the most favorable case) of the characteristic desorption peak between 250 and 300 K. They attributed this improvement of the adsorption capacity to the opening and filling of the nanotubes. Taking into account that their carbon soot samples containing only 0.05% of nanotubes can adsorb  $\sim 0.005\%$  weight of hydrogen, Dillon and his colleagues believed that the pure adsorbed hydrogen was therefore  $\sim 10$  wt%. These authors have further developed a cutting method to produce samples with a high concentration of short SWNTs with open ends that are accessible to the entry of hydrogen molecules. With these better characterized nanotube samples, they were able to achieve a more accurate determination of hydrogen adsorption, which they estimated to be at  $\sim 3.5$ – $4.5$  wt% hydrogen at room temperature and 0.07 MPa hydrogen pressure [38]. By opening and recapping the nanotubes, they concluded that most of the hydrogen is stored within the capillary, rather than in the interstitial spaces between the SWNT.

Ye et al. [39] were motivated to perform measurements on SWNT material of high purity because the previous measurements were made on dilute SWNTs which required a large correction for material that was assumed inert. Ye et al. were the first to report hydrogen-adsorption investigations on purified [40] laser-generated [41] SWNTs. They undertook their experimental measurements of hydrogen adsorption on high-purity “cut SWNTs.” To cut the SWNT material and disrupt the tightly packed rope structure found in highly crystalline pristine SWNTs, a small quantity of material was sonicated in dimethylformamide, and then extracted from the solvent by vacuum filtration. TEM revealed that this treatment broadens the diameter distribution of the SWNT ropes, and also increases the number of SWNT terminations within ropes (hence the SWNTs are said to be “cut”). These differences were not evident in the X-ray diffraction patterns of the material before and after the treatment, perhaps indicating that the average rope diameter was largely unchanged.

The adsorption of hydrogen was measured by the volumetric method without correction for thermal effects. The highest gravimetric hydrogen storage capacity achieved in SWNT material treated in this manner was 8.25 wt% (an H/C atomic ratio of 1.0), at a temperature of 80 K and pressure of  $\sim 7$  MPa. At a pressure of  $\sim 4$  MPa, a sudden increase in the adsorption capacities of the SWNT samples was reported; the authors suspected that a structural phase transition was responsible for this effect. In their method, the ropes were split into individual tubes, thereby increasing the surface area available for physisorption. In their conclusion, the authors [39] advanced that the ability of SWNT

**Table 1.** Summary of the reported gaseous hydrogen storage capacity in carbon nanotubes and carbon nanofibers.

Sample	Purity (%)	$T$ (K)	$P$ (MPa)	wt% $H_2$	Ref.

material to adsorb and desorb hydrogen over a narrower range of pressure may be used in storage systems without wide pressure excursions.

High hydrogen-storage capacities on a total sample weight basis were subsequently demonstrated on SWNTs with a large mean diameter of about 1.8 nm produced at high yield by a semicontinuous arc-discharge method [42]. In this study, a sulfur promoter (FeS) was added, and H<sub>2</sub> rather than He was used as the buffer gas, and the electrodes made an oblique angle in the synthesis process which were a little different from the traditional arc method [43]. They treated their samples (containing ~50% SWNTs) by soaking in hydrochloric acid and heating to high temperature (770 K) under vacuum. Their adsorption measurement technique consisted of monitoring the pressure change of hydrogen versus time in a constant-volume cell containing the nanotubes sample; when equilibrium is achieved, the pressure decrease corresponds to the amount of hydrogen adsorbed. The results at room temperature and 10.1 MPa were 2, 2.5, and 4.2 wt% for nontreated, partially treated, and entirely treated samples, respectively (Fig. 4). The relatively high hydrogen storage capacity was attributed to the large mean tube diameter of about 1.85 nm, which they ascribed to the addition of a sulfur-containing growth promoter [44, 45]. About 78.3% of the adsorbed hydrogen (3.3 wt%) could be released under ambient pressure at room temperature, while the release of the residual stored hydrogen (0.9 wt%) required heating of the sample.

The same group examined the storage capacity of single-walled carbon nanotubes pressed into tablets and heat treated under argon flow at 1473 K for 2 h. They obtained a storage capacity of 4 wt% at room temperature and 11 MPa [46]. About 70% of the adsorbed hydrogen was released under ambient pressure. However, these high storage capacities could not be confirmed by other groups using the same measuring method. Tibbetts et al. [32] found storage capacities of below 0.05 wt% for different nanotubes at

**Figure 4.** Amount of H<sub>2</sub> in wt% for SWNT samples, and the pressure change versus the adsorption time. Sample 1 was used as synthesized. Sample 2 was soaked in 37% HCl acid for 48 h, rinsed with deionized water, and dried at 423 K. Sample 3 was pretreated in the same way as sample 2, then vacuum heat treated for 2 h. 11 MPa and room temperature. Chen et al. examined different purified and nonpurified SWNTs with the volumetric method at 77 K and room temperature, applying hydrogen pressures up to 8 MPa. The measurements gave no indication that carbon nanotubes exceed the storage capacity of activated carbon. At room temperature, the hydrogen uptake was below 1 wt%, and at 77 K about 1.5 wt% [47].

Wu et al. [48] probed the hydrogen-adsorption properties of multiwall nanotubes synthesized by the catalytic decomposition of CO and CH<sub>4</sub> on powdered La<sub>2</sub>O<sub>3</sub> catalysts. The CO-generated tubes consisted of concentric cylinders, while the CH<sub>4</sub>-produced tubes contained graphite layers that were tilted with respect to the tube axis, forming cones. In both cases, the catalyst was removed by stirring in dilute nitric acid. The purified nanotubes were then annealed to 1370 K in vacuum in order to increase crystallinity. The TGA analysis in flowing hydrogen showed that CO-generated CNTs adsorbed a small quantity of hydrogen (0.25 wt%) when the sample was cooled from 470 K to room temperature.

With a tapered element oscillating mass analyzer, Smith et al. [49] measured SWNTs from Tubes@Rice at room temperature and pressures up to 4.8 MPa. The highest storage capacity of 1.2 wt% at 4.8 MPa was obtained for purified SWNTs after an oxidation under a stream of CO<sub>2</sub> at about 900 K. The activation of the SWNT samples by mild oxidation in CO<sub>2</sub>, followed by heat treatment in an inert atmosphere, increases the hydrogen adsorption capacity of the SWNT samples by about a factor of 3 at 4.8 MPa.

A newly developed high-energy ultrasonic cutting procedure which incorporates a TiAl<sub>0.1</sub>V<sub>0.04</sub> alloy has been applied to purified, laser-generated SWNT materials, allowing high-capacity hydrogen adsorption at ambient conditions [50]. The degassed samples underwent a brief room-temperature H<sub>2</sub> exposure at 0.07 MPa, and the H<sub>2</sub> TPD spectrum is characterized by two separate desorption signals peaked at ~375 and 600 K, indicating at least two different types of sites for hydrogen adsorption. The hydrogen adsorption capacity, as measured by calibrated TPD, was ~6.5 wt% on a total sample weight basis after sonication in 4 M HNO<sub>3</sub> for 16 h at 50 W · cm<sup>-2</sup> and degassing to 825 K. This sample was found to contain ~15 wt% alloy of composition TiAl<sub>0.1</sub>V<sub>0.04</sub> due to decomposition of the ultrasonic probe. The pure TiAl<sub>0.1</sub>V<sub>0.04</sub> samples generated using the same method exhibited X-ray patterns consistent with the alloy found in the SWNT samples and only ~2.5 wt% hydrogen adsorption. Assuming that the alloy in the SWNT sample behaves like the pure alloy sample, the hydrogen uptake on the SWNT fraction is ~7.2 wt%. Samples with higher alloy contents had reduced overall hydrogen capacities, but the value of ~7 wt% on the SWNT fraction was relatively constant. The presence of the alloy might, in fact, stimulate hydrogen adsorption and desorption. Several control experiments have shown that the observed uptake is not solely due to the presence of the alloy, and there are some experimental indications of partial electron transfer being responsible for the stability of the hydrogen [50]. Unfortunately, the high storage capacity of about 6.5 wt% could not be confirmed by volumetric measurements performed by the same group, which give a value of 2.3–2.8 wt% [51]. In the DOE report of year 2001, Heben's group declared that, unfortunately, they cannot reproduce the high hydrogen storage capacities using

SWNTs generated with a new laser [52]. The hydrogen storage capacities of these new SWNTs range from 2 to 4 wt%.

Recently, Hirscher et al. [53] investigated the influence of sonication on the hydrogen storage capacity of SWNTs. The samples were sonicated in 5 M  $\text{HNO}_3$  for various periods of time using an ultrasonic probe of the alloy Ti-6Al-4V or stainless steel. The sonication treatment introduces particles of the Ti alloy or Fe into the samples, and the hydrogen storage capacity increases with the sonication time. After heating in high vacuum up to 900 K, the maximum value of overall hydrogen storage at room temperature was found to be 1.47 wt% in an SWNT-alloy composite, with a sharp comparison to the value below 0.005 wt% in the SWNT-Fe composite. Directly after the sonication treatment, the samples show no hydrogen uptake at room temperature, whereas after heating in high vacuum up to 900 K, hydrogen storage at room temperature is observed. This is the well-known activation procedure of titanium removing the natural oxide layer under vacuum and in the temperature range from 700 to 900 K [54]. Afterwards, titanium readily takes up hydrogen at room temperature. With increasing sonication time, the hydrogen storage capacity increases, as well as the titanium content in the carbon samples. After hydrogen loading, X-ray diffraction measurements yield clear evidence of the formation of titanium hydride (see Fig. 5). If the total amount of hydrogen is ascribed to the fraction of Ti-alloy particles in the SWNTs, the maximum content in the alloy will be 3.3 wt%, which is below the maximum storage capacity of this Ti alloy and titanium itself. Encouraged by these findings, the authors concluded that all of the hydrogen uptake could be ascribed to the Ti-alloy particles [53].

Heben suggests that nanotubes in some of the samples are being “activated” in some way by the alloy particles so that they adsorb more hydrogen than they would in the absence of the metal [55]. The alloy, he believes, may assist hydrogen uptake by a catalytic effect in which the titanium dissociates the  $\text{H}_2$  or via thermal effects, where the exothermic reaction of hydrogen with the titanium could locally create

**Figure 5.** X-ray diffraction spectra (Cu  $K_\alpha$  radiation) of SWNTs sonicated in 5 M  $\text{HNO}_3$  for 16 h using a Ti-alloy horn. The as-sonicated material shows the diffraction peaks of titanium. After deuterium loading (0.08 MPa  $\text{D}_2$  at room temperature for 15 min) these maxima vanish, and the diffraction peaks of titanium deuteride appear. Reprinted with permission from [53], M. Hirscher et al., *Appl. Phys. A* 72, 129 (2001). © 2001, Springer-Verlag.

thermal disturbances to the tube that might aid in the addition of the hydrogen. A mechanism that is midway between physisorption and chemisorption is favored because much of the stored hydrogen desorbs at higher temperatures than is typically found for physisorption. The mechanism could involve fractional electron charge transfer between hydrogen molecules and the nanotube, with the hydrogen molecule remaining intact [55].

Another strategy that might help crack the hydrogen-storage mystery is to “decouple” the nanotube-cutting process from the alloy-introduction step. With this in mind, Heben’s group found ways to cut nanotubes without sonication using a controlled dry cutting method that nondestructively cuts the SWNTs without incorporating a metal alloy in the latest DOE report of 2002 [56]. It is regrettable that the details of this process have not been revealed yet. In order to establish the degree of control achieved, they used Raman spectroscopy to monitor the degree of cutting caused by the new method. They found that, when identical conditions are employed to presumably achieve similar degrees of cutting, the ratio of the Raman  $D$  band, which is correlated to the number of defects (i.e., ends), to the  $G$  band of the nanotubes increases by a fixed amount.

The hydrogen storage capacities of samples obtained by this cutting method were evaluated with temperature-programmed desorption. Hydrogen exposures were at room temperature and 0.07 MPa for several minutes, and the samples were then cooled in the presence of the gas. The TPD spectra of both uncut and cut samples contain a hydrogen desorption peak at  $\sim 138$  K, which can be attributed to the normal physisorbed hydrogen which is seen for activated carbons. The spectrum of the cut sample additionally shows a hydrogen desorption peak at  $\sim 338$  K, revealing the presence of hydrogen that is stabilized at ambient temperatures. The hydrogen desorption peaks occur at the different temperature ranges for the sonicated samples which incorporate metal hydride alloy and “dry-cut samples” without metal species. Obviously, the hydrogen adsorption mechanism is strongly influenced by the incorporation of the metal hydride species. Unfortunately, the hydrogen storage capacity was not clearly provided, although the “dry-cut” samples were evaluated with temperature-programmed desorption and volumetric techniques. It was estimated that this new cutting process avoided metal impurities, and resulted in storage capacities below 1 wt% [56]. However, they claimed that the values scattered, and were hard to reproduce. Optimization of the process and the subsequent incorporation of catalytic metallic species will be explored in the future to determine if high-temperature, high-storage capacity materials may be prepared in a reproducible manner [56].

Ding et al. [57] tested CVD-grown MWNTs using the volumetric measurement method with corrections for thermal effects. The MWNTs were prepared by acetylene decomposition, and pressed into pellets without further treatment. These pellets were degassed at 673 K for 6 h to remove the moisture and other absorbed contaminants. The ambient temperature was carefully monitored to correct the pressure changes arising from the temperature variation. At the same time, the sample chamber temperature was also recorded. The gravimetric hydrogen storage capacity

found was 2.0 wt% at room temperature and a pressure of  $\sim 6.5$  MPa.

Hirscher et al. [58] also conducted the hydrogen storage on ball-milled graphite, graphite nanofibers, and SWNTs which were ball milled under Ar or D<sub>2</sub> atmosphere in order to modify the microstructure. A very low reversible hydrogen uptake for the SWNTs milled under argon was observed. However, they found 0.3, 0.5, and 1.0 wt% hydrogen uptake on graphite, graphite nanofibers, and SWNTs, respectively, and reversible hydrogen storage only for SWNTs. During high-energy ball milling under hydrogen pressure, the microstructure of carbon nanotubes is severely damaged by mechanical impact, and furthermore, dangling carbon bonds may be formed which can react with the surrounding hydrogen atmosphere. It is suggested that opening or cutting of the tubes and ropes is essential.

The hydrogen uptake of carbon nanotubes in the low-pressure range up to ambient pressure was measured by Adu et al. [59] with a thermogravimetric analyzer. The storage capacity at ambient temperature is nearly constant, and about 0.5 wt%. However, Pradhan et al. [60] obtained a hydrogen storage capacity of up to 6 wt% at 0.2 MPa with processed bundles of SWNTs utilizing the same measuring method.

Zhu et al. [61] tested the bundles of well-aligned multiwalled carbon nanotubes, and found that the hydrogen storage capacity is over 3 wt% under 290 K and  $\sim 10$  MPa pressure. However, they obtained a value of 0.68 wt% for the random material at the same pressure. The same group obtained a similar value of 2.4 wt% under similar conditions for the aligned MWNT samples [62]. Unfortunately, the masses used for the volumetric measurement have been far below 1 g (about 100 mg). Even more startling were the claims of Chen and his co-workers [63], who reported that certain aligned carbon nanotubes can store hydrogen at levels exceeding 5–7 wt% at room temperature under a pressure of 1 MPa. Aligned carbon nanotubes with diameters of 50–100 nm were grown on a stainless-steel wafer by plasma-assisted hot-filament chemical vapor deposition. The mass of the examined carbon material was less than 1 mg, and the weight of the substrate about 60–70 mg. They measured the mass decrease of loaded nanotubes together with the substrate by heating up to 600 K. In this study, quadruple mass spectroscopy and thermogravimetric analysis were employed to probe the hydrogen storage capacity. However, a reference measurement of the substrate is missing. After the pretreatments of heating the samples to 570 K and removing the catalyst tips, the hydrogen storage capacity can be increased up to 13.8 wt% and the pressure required for storage decreased. However, the community still awaits confirmation of these experimental results by workers in other research groups.

### 2.3. Gaseous Hydrogen Storage in Doped CNTs

All the above H<sub>2</sub>-uptake systems require high pressure or subambient temperatures, or both. Recently, Chen and co-workers [64] reported high hydrogen adsorption in alkali-metal-doped carbon nanotubes at ambient pressure and slightly elevated temperatures. The carbon nanotubes used

in this work were synthesized by catalytic decomposition of methane. Doping of the carbon nanotubes was carried out by means of solid-state reactions with Li- or K-containing compounds such as carbonates and nitrates. The extent of hydrogen uptake was determined by TGA and confirmed by TPD. The authors reported dramatic enhancement of hydrogen storage in the alkali-doped systems, with the best results found in the case of Li-CNTs (20 wt% gravimetric storage). The remarkable storage improvement in Li-CNTs (Fig. 6) relative to the virtually negligible (0.4 wt%) storage in undoped nanotubes was attributed by them to adsorption by means of metal hydride interaction.

Using *in-situ* FTIR spectroscopy, the authors correlated an increase in intensity of the characteristic lithium hydride vibration at  $\sim 1420$  cm<sup>-1</sup> with increased hydrogen adsorption in the temperature range of 473–673 K. A new infrared band, which the authors attributed to C–H stretching vibration, appeared in the spectral region of  $\sim 2600$ – $3400$  cm<sup>-1</sup>. This feature was observed to disappear upon thorough desorption of hydrogen. The authors suggested that an explanation for the remarkable boost in storage capacity may require dissociation of H<sub>2</sub>, catalyzed by the intercalated alkali metal in the carbon nanotubes. The special open-ended, layered structure of the nanotubes are also helpful to improve the adsorption performance of hydrogen.

However, Yang [65] thought that the above measurement results for the hydrogen adsorption should be corrected. The grade of hydrogen used in the work of Chen et al. was not reported, but a purity 99.99% was noted [64]. Therefore, special care should be taken to eliminate possible moisture contamination. In addition, special caution needs to be taken in using TGA for measuring adsorption or reaction kinetics. Upon a change in temperature or gas composition/flow rate, the accompanying change caused by changes in buoyancy and friction forces from the gas flow is usually of the same order of magnitude as the signal that is being measured (i.e., the actual weight change). Hence, rigorous calibration must be done for all changes.

**Figure 6.** TGA profile of reversible H<sub>2</sub> sorption-desorption cycle on Li-doped CNT. The sample was cooled to 300 K, and then heated again to 873 K. Yang prepared alkali-doped carbon nanotubes according to the method prescribed in the work of Chen et al. [64]. Nevertheless, ultrahigh-purity hydrogen (99.999%, with moisture trap) was used to conduct the adsorption measurements on Li-doped SWNT (Fig. 7). The results of hydrogen adsorption with added water (2.3 vol%) was also obtained to compare with the results of dry hydrogen adsorption (Fig. 8). Furthermore, calibration runs were made under the same conditions to calibrate the weight gains/losses [65]. The similar qualitative features of the result of Chen et al. [64] were reproduced over Li/nanotubes; however, the total weight differential was only 2.5%, rather than 20% reported by Chen et al. The essential qualitative feature of the TGA profile was still maintained with moisture addition, and the total weight differential in wet  $H_2$  was substantially greater, at 12%, compared to 2.5% in dry  $H_2$ . The weight gains reached 1.8 and 21% over K/nanotubes in dry or wet  $H_2$ , respectively, compared to 14% reported by Chen et al.

Yang also reported the IR spectrum of LiOH (with one hydrate), and a striking similarity existed between this spectrum and that of Chen et al. This shows that the alkali hydroxide and additional hydrates may form. The weight gains by forming hydroxides (plus hydrates) agreed well with the total weight gains reported by Chen et al. Although Chen et al. did not find the emergence of water in the desorption product using TPD, the work of Yang showed that the TGA measurements strongly depended on the concentration and rate of supply of moisture.

Pinkerton et al. [66] made further investigations on doped CNTs. The results indicate that, on Li-doped CNTs, neither hydrogen nor carbon is required to generate the qualified

TGA cycling features, which are strikingly similar to those reported by Chen [64] and Yang [65]. This result is obtained for Li-containing samples measured in Ar without  $H_2$  and in LiOH samples measured in either  $H_2$  or Ar. To elucidate the species responsible for weight cycling, additional gases ( $N_2$ ,  $O_2$ ,  $H_2O$ , or air) are deliberately introduced into the TGA furnace (Fig. 9). Adding 0.5 sccm of dry air to the TGA gas stream has spectacular effects on the cycling features, and the magnitude grows as the  $O_2$  concentration increases with continued exposure. The amplification derives from the catalytic reaction between  $H_2$  and  $O_2$  under the specific conditions with the Pt pan as a catalyst. Therefore, these cycling features arise from atmospheric impurities in the TGA which finally react with Li or K to form LiOH or KOH. The authors conclude that the cycling species responsible for the weight changes is, in fact,  $H_2O$ , in agreement with Yang [65]. The  $H_2$  storage results vary from 0.72 to 4.2 wt%, depending on the initial weight and scan rate under 46%  $H_2$  in Ar on Li-doped CNTs.

Zidan and Rao [67] believed that the introduction of nanoparticles (dopants) to the nanotubes can enhance hydrogen bonding at the edge and inside the tubes, allowing for hydrogen storage to occur. The success of making doped carbon nanotubes with transition metals and alloys can allow for a weak covalent bond similar to cases of a dihydrogen bond that is not restricted to a pure physisorption or chemisorption bond [68, 69]. Controlling the type and size of tubes and dopant is expected to tune the product for hydrogen sorption to occur at a desired temperature and pressure. Preliminary results showed an indication of 0.5–1% by weight hydrogen uptake and release from samples. A thermogravimetric system capable of operating at a wide

**Figure 9.** Temperature cycling characteristics of Li-doped multiwall nanotubes in an  $H_2/Ar$  gas mixture with dry air added to the input gas stream. The solid curve shows the cycling behavior in  $H_2/Ar$  with additional  $N_2$ ; the  $N_2$  by itself has essentially no effect on the cycling characteristic compared with that in  $H_2/Ar$  alone. The first cycle (dash-dot curve) and second cycle (dashed curve) after introducing 0.5 sccm of dry air to the input gas trace the evolution of greatly enhanced cycling magnitude. range of temperatures was used to measure the hydrogen uptake and release. Unfortunately, no samples and experimental details were revealed in this study [67].

#### 2.4. Electrochemical Hydrogen Storage

Table 2 summarizes reported experimental results thus far achieved for electrochemical hydrogen storage in carbon nanotubes. The electrochemical hydrogen storage capacity

**Table 2.** Summary of the reported electrochemical  $H_2$  storage capacity in carbon nanotubes.

Sample	Purity (%)	Charge capacity (mA · h/g)	Max. wt% $H_2$	Ref.
SWNT	unpurified	110	0.40	[30]
MWNT	(10–40%)	100	0.37	[30]
SWNT	unpurified	550	2.0	[31]
SWNT	—	160	0.57	[29]
MWNT	—	200	0.74	[73]
SWNT	80	800	2.9	[74]
SWNT	—	360	0.9	[75]
SWNT	90	440	1.6	[76]
Li-CNT	—	160	0.59	[76]
Li-SWNT	—	640	2.4	[76]
SWNT rope	—	503	1.84	[78]
SWNT	95	316	1.2	[77]
MWNT	95	1157	4.1	[79]
SWNT	purified	1200	4.35	[80]
Li-SWNT	—	1080	3.9	[81]

Note: — represents data unavailable.

of SWNTs was measured by Nutzenadel et al. [30] using carbon nanotube samples from worldwide research groups or companies. In each case, 20 mg of SWNTs were finely ground, mixed with 80 mg of Au powder (which serves as a compacting additive, and does not participate in the electrochemical reaction), and pressed at a pressure of 500 MPa to form a pellet. The SWNT/Au pellet served as the negative electrode, and an Ni plate was used to form the counterelectrode. Experiments were conducted in a half cell, using a solution of 6 M KOH as the electrolyte; potentials were referred to an  $Hg/HgO/OH^-$  reference electrode. The hydrogen weight density was deduced from the amount of discharged current. The obtained hydrogen storage capacity was  $\sim 0.40$  wt%. Nevertheless, the effect of chemical posttreatment and/or metallic impurities on the absorptive capacity of the SWNT samples was not quantified in this work. MWNT samples exhibited a similar hydrogen storage capacity of 0.37 wt%. The same group presented further investigations on a variety of carbon nanotubes [31, 70]. The storage densities range from 0.04 up to 2 wt%, and correlate with the specific surface area of the sample [71]. Nijkamp et al. [72] also observed a similar correlation in low-temperature volumetric measurements on high-surface-area carbon materials.

Lee et al. [29] conducted electrochemical charge-discharge cycling experiments recently. CNT-based composite electrodes were fabricated by mixing and grinding first with conductive Ni powders (99.8%) for 50 min, and later with the organic binder of polytetrafluoroethylene (PTFE) for 20 min with a mixing composition ratio of CNT:Ni:PTFE = 40:50:10. The pellet was made by pressing the mixture into a mold of 10 mm diameter at 200 MPa. This pellet was inserted into Ni metal mesh, and used for a working electrode. The counterelectrode Ni was separated by a polymer separator. The charge-discharge cycles were carried out in a solution of 6 M KOH solution. An  $Ag/AgCl$  standard electrode was used as a reference electrode in this measurement. A charge/discharge capacity of 160 mA · h/g was demonstrated, which corresponds to a gravimetric capacity of  $\sim 0.57$  wt%.

Qin et al. [73] investigated the electrochemical properties of an MWNT-Ni electrode. The MWNT-Ni electrode was found to have a high discharge capacity of 200 mA · h/g ( $\sim 0.7$  wt%) and a long charge/discharge cycle life. Recently, electrodes made of purified and open SWNTs behaved like metal hydride electrodes in Ni-MH batteries, showing high electrochemical reversible charging capacity up to 800 mA · h/g corresponding to a hydrogen storage capacity of 2.9 wt% [74]. Most recently, Züttel et al. [75] studied the electrochemical hydrogen storage capacity of a series of CNTs, and found the highest value of capacity up to 0.9 wt%.

Kibria et al. [76] investigated the electrochemical hydrogen storage behaviors of undoped and alkaline-metal-doped CNTs produced by various preparation techniques. Laser-ablation-grown CNTs produce the highest hydrogen storage capacity of 1.6 wt%. The alkali metal-doped CNTs showed higher hydrogen storage capacities than undoped CNTs. Although the hydrogen storage capacities of Li-doped CVD and AD (arc discharge)-grown CNTs were six times higher than that of undoped CNTs, it is only 0.6 wt%.

For Li-doped LA grown CNTs, the hydrogen storage capacity reached 2.4 wt%. The high hydrogen storage capacity of alkali metal-doped CNTs seems to originate from increasing the hydrogen adsorption sites of CNTs due to introducing the doped metals in nanotube bundles, and separating the tubes, but not from their chemical effects. Purified SWNTs with a large mean diameter of approximately 1.85 nm, which were synthesized by a semicontinuous hydrogen arc-discharge method [42], were also used for electrochemical hydrogen adsorption experiments [77]. After high-temperature treatment, a reproducible maximum discharge capacity of 316 mA · h/g, corresponding to 1.2 wt% hydrogen storage, was achieved at 298 K under normal pressure. After 100 charge/discharge cycles, >81% of the maximal capacity was maintained.

Dai et al. [78] further measured the electrochemical charge/discharge hydrogen capacity of macroscopically long ropes (up to 100 mm in length) of well-aligned SWNTs (60–70 wt% purity) with a larger mean diameter of about 1.72 nm. A discharge capacity of 503 mA · h/g, corresponding to 1.84 wt% hydrogen, was achieved reproducibly at ambient temperature under normal atmosphere. A much higher charge capacity of 1157 mA · h/g, corresponding to 4.1 wt% hydrogen, was obtained using electrodes made up of MWNTs [79].

Reversible insertion of lithium into purified single-wall carbon nanotubes was achieved electrochemically [80]. Carbon nanotubes exhibited reversible capacities of approximately 460 mA · h/g and very high irreversible capacities of 1200 mA · h/g, corresponding to 4.35 wt% hydrogen, which the authors ascribe to the large specific surface area (350 m<sup>2</sup>/g). *In-situ* X-ray diffraction revealed an irreversible loss of crystallinity, suggesting that doping disrupts the intertube binding, analogous to exfoliation in layer hosts. In another study, lithium-inserted carbon nanotubes exhibited reversible capacities approximately 780 mA · h/g and very high irreversible capacities of 1080 mA · h/g, corresponding to 3.9 wt% hydrogen [81].

Pekker et al. [82] performed the hydrogen storage experiments with carbon nanotubes and graphite via a dissolved metal reduction method in liquid ammonia. Dried ammonia was condensed to the carbon material which had been mixed with lithium under an inert atmosphere. The suspension was stirred for 1 h at about 220 K, and then ammonia was evaporated by heating to room temperature. After a second condensation, methanol was added to the sample. The sample was heated again to room temperature to evaporate NH<sub>3</sub>, and then it was washed and dried. With thermoanalytical and electron-microscopic studies, the authors could show that the applied hydrogenation method gives rise to the formation of strongly bound derivatives. Desorption of hydrogen takes place at around 770 K, and the content was 1.7 and 0.7 wt% for graphite and carbon nanotubes, respectively.

Generally speaking, the electrochemical loading of carbon nanostructures shows no spectacular high storage capacity. Furthermore, the uptake seems to be proportional to the specific surface area of the carbon material, and therefore comparable to activated carbon [28].

## 2.5. Hydrogen Storage in Carbon Nanofibers

Carbon nanotubes are not the only carbon structures which are able to retain hydrogen in their framework; graphite nanofibers also exhibit hydrogen adsorption potential. The hydrogen storage experimental results for graphite nanofibers are also listed in Table 1. Rodriguez's group prepared various graphite nanofibers, and conducted hydrogen adsorption experiments using the produced nanofibers [83]. These graphite nanofibers consist of catalytically produced graphene sheets that are oriented to form various fibrous structures. The orientation of the sheets in the fibers can be controlled by the choice of catalyst. Hydrogen gas applied at 11.35 MPa was absorbed at room temperature (298 K). The hydrogen storage capacity was found to be, for CNTs, 11.26 wt%, for herringbone carbon fibers 67.55 wt%, for platelet fibers 53.68 wt%, and finally, for graphite 4.52 wt%. Unfortunately, this surprising hydrogen adsorption capacity has not been confirmed to date, neither experimentally nor theoretically [18]. Attempts by other researchers to reproduce these high-hydrogen storage densities have failed, and typically, results of only 0.08 wt% have been achieved [84]. The extraordinarily high results were later suggested to be influenced by the presence of water vapor, which expanded the spacing between the graphite layers (typically ~3.4 Å) to accept multiple layers of hydrogen [85]. Browning et al. [86] synthesized carbon nanofibers at 870 K by passing ethylene over a series of Fe–N–Cu catalysts. They obtained a hydrogen storage capacity in their sample at room temperature and 12 MPa of 4.18 and 6.54 wt% with a postproduction treatment. Poirier et al. [87] tested the hydrogen storage performance of carbon nanofibers, as well as intercalated and exfoliated carbon materials. At room temperature, carbon nanofibers adsorb 0.7 wt% at a hydrogen pressure of 10.5 MPa, which is comparable to activated carbon. However, the hydrogen coverage per unit surface area is found to be substantially larger on carbon nanostructures than on activated carbon. de la Casa-Lillo et al. [88] found that the highest values of hydrogen adsorption in activated carbons or activated carbon fibers was close to 1 wt% at 10 MPa and room temperature. Hwang et al. [89] reported that the carbon nanofibers from methane decomposition using an Ni–MgO catalyst exhibited a hydrogen adsorption capacity up to 1.4 wt% after heat treatment at 1470 K in N<sub>2</sub> atmosphere. Hirscher et al. [28] also performed volumetric measurements at 11 MPa and 300 K using GNFs prepared by catalytic vapor deposition, and observed a hydrogen uptake lower than 0.1 wt%. Nevertheless, the ball-milled graphite fiber reached up to 0.5 wt% hydrogen adsorption capacity at 0.9 MPa and room temperature using the TDS technique [58]. Tibbetts et al. [32] studied the sorption of hydrogen very carefully by nine different carbon materials at pressures up to 11 MPa and temperatures from 193 to 773 K. The largest sorption observed is less than 0.1 wt% hydrogen at room temperature and 3.5 MPa. Ritschel et al. [90] observed a storage capacity of 1273 K Ar-treated GNF less than 0.2 wt% at room temperature and 4.5 MPa.

Using the thermogravimetric analysis, Ströbel et al. [91] measured the hydrogen adsorption of carbon nanofibers and activated carbon at high pressure. At a pressure of 12.5 MPa

and room temperature, they observed a maximum weight increase corresponding to a hydrogen uptake of 1.6 wt% in activated carbon and of 1.2 wt% for the fibrous material. Harutyunyan et al. [92] obtained consistent results on purified tubular-formed and herringbone-type GNFs. They found 1.8 wt% at 77 K and about 1 wt% at room temperature under 1.5 MPa hydrogen pressure.

However, encouraging results have been reported by Gupta and Srivastava [93, 94], who achieved hydrogen adsorption capacities of  $\sim 10$  and  $\sim 15$  wt% for graphite nanofibers grown by thermal cracking. The GNFs were activated by heating 1 h at 420 K under  $10^{-7}$  MPa in a steel reactor. After 15–16 h, hydrogen absorption started, and the hydrogen uptake saturated at pressures higher than 9 MPa. More recently, Fan et al. reported a 10–13 wt % hydrogen adsorption capacity using vapor-grown carbon fibers [95]. In a further research paper [45], the same group reduced the storage capacity of carbon fibers by a factor of 2. As with carbon nanotubes, a large degree of variation in the results exists, and further verification is required.

The rather scattered experimental results published on hydrogen storage measurements of carbon nanofibers also listed in Table 1. The figures in the table show that the large discrepancies between claims of high hydrogen storage capacities and almost no storage at all exist up to the present day. The experimental data range from 67.55 down to 0.08 wt%.

### 3. THEORETICAL CALCULATIONS OF HYDROGEN STORAGE BY CARBON NANOTUBES

Theoretical models allow the study of ideal systems, and are useful tools for investigating complex systems. Models have been made of the physical adsorption of molecular hydrogen on carbon nanotubes, as well as chemical adsorption of both atomic and molecular hydrogen. These studies have investigated hydrogen binding sites on the carbon framework and adsorption isotherms and density profiles. Theoretical investigations can be extremely useful in developing an understanding of the elementary steps in the adsorption process, as well as in predicting an upper limit on the hydrogen storage capacity.

The theoretical calculations are generally classified into two groups according to how they treat time within their theoretical model. Statistical mechanics and molecular dynamics include time, and are used for looking at molecules in motion. Quantum mechanics (electronic structure methods) and molecular mechanics are time independent, and can perform accurate energy calculations on snapshots of the molecular system.

#### 3.1. Statistical Mechanics (Monte Carlo) Methods

Most grand canonical Monte Carlo (GCMC) studies on hydrogen adsorption in carbon nanotubes have used a 12:6 Lennard–Jones [96–98] potential to model the classical molecular interactions. The study of hydrogen adsorption

is complicated by a significant contribution from quantum effects [99, 100]. Darkrim and co-workers [99, 101] state that Chakravarty et al. [102] found that, for molecular hydrogen clusters at temperatures above 20 K, a full path-integral formalism was unnecessary, and the less computation-intensive Feynman–Hibbs [103] perturbative approach to modeling quantum effects seemed sufficient. Darkrim found that, for simulations of hydrogen adsorption on nanotubes, the Feynman–Hibbs-based corrections accounted for a 5% difference at room temperature and about 15–25% at 77 K. This clearly demonstrates that, while an uncorrected Lennard–Jones potential can be used successfully for qualitative work at room temperature and above, quantitative work requires treatment of the quantum effects. Another complicating factor now often included is a treatment of the quadrupole and dipole interactions [104, 105], and which were mandatory for the studies of charged systems [106]. A summary of the methods and some parameters can be found in Table 3.

All of the simulations reported so far have made two assumptions. First, they base their calculations on semiempirical potentials taken from work on planar graphite systems. Second, they assume that the same potentials can be used for both endohedral and exohedral adsorption. It is therefore reasonable to be skeptical of the quantitative accuracy of these studies until these two assumptions are shown to be reasonable enough to give good quantitative results.

#### 3.2. Electronic Structure Method Studies

One approach to eliminate the two assumptions made for the statistical mechanic studies (*vide supra*) is to use electronic structure methods. These methods may also treat quantum effects and electron correlation directly or indirectly, and can lead to highly accurate results ( $\pm 4$  kJ  $\cdot$  mol $^{-1}$ ) [107]. The major difficulty of these methods is the computational effort required, with the more accurate methods scaling catastrophically with model size [e.g.,  $O(N^{5-7})$ ]. Additionally, processes involving hydrogen particularly require the more accurate methods to be used, due to the problem of basis-set incompleteness [108]. However, these methods are ideal for studies of process mechanisms and thermodynamics. This makes these studies complementary to the statistical mechanics studies, as they can be used to refine the statistical mechanic models and parameters.

Recent advances in electronic structure methods have allowed larger systems to be studied more accurately than before. The development of several methods that use periodic boundary conditions has been very advantageous for indefinite systems such as graphite, crystals, and nanotubes. The pseudopotential plane-wave method [109] or the self-consistent charge-density-functional-based tight-binding method (SCC–DFTB) [110] are the main methods used to study nanotubes. These methods use either a local density approximation (LDA) [111] or a generalized gradient approximation (GGA) [112]. The GGA is generally more accurate than the LDA, but it has been criticized for overestimating repulsive interactions in systems characterized by weak bonding forces. Another new development

is the ONIOM [113] method that allows simple molecular mechanics methods to be combined with more accurate quantum mechanics. These new methods are allowing ever more accurate studies to be performed on carbon nanotube systems.

### 3.3. Binding Sites for Molecular Hydrogen Physisorption on Graphitic Materials

Molecular hydrogen physisorption can occur at a number of sites on graphitic systems. These include on top of atoms, bonds, and the center of the carbon hexagons. One density functional theory study [114] used a local density approximation (LDA), and they found that the most stable configuration for hydrogen molecules was above the center of a hexagon, although the preference for this position was small, indicating that the barriers for classical diffusion would be small. Dubot and Cenedese [115] used semiempirical AM1 simulations to model Li-doped SWNTs, and found that Li adsorbed inside and outside the tube, with the most stable site also being the center of a hexagon. More recently, both static and dynamic calculations were conducted by Arelano et al. [116] to investigate the interaction of molecular and atomic hydrogen with single-wall carbon nanotubes. An *ab initio* FGI96MD code [117] was selected, in which the DFT was used to compute the electron density and the total energy of the system, and LDA to account for exchange and correlation effects. Molecular physisorption inside and outside the nanotube walls was predicted to be the more stable state of those systems, with the binding energies for physisorption of the hydrogen molecule outside the nanotube in the range 4–7 kJ · mol<sup>–1</sup>. From their GCMC study of nanotube bundles, Williams and Eklund [118] showed that the geometry of the site affected the average adsorption potential experienced by the hydrogen molecule. They found that the three endohedral sites they studied had a larger potential than sites inside the nanotube. The largest

potential was for endohedral sites in the internal channels (11 kJ · mol<sup>–1</sup>), followed by the grooves (9 kJ · mol<sup>–1</sup>) and surfaces (6 kJ · mol<sup>–1</sup>) on the outer surface of the bundle, with the sites inside the tube being only (5 kJ · mol<sup>–1</sup>). This means that physical adsorption and desorption of molecular hydrogen from nanotubes are low-energy processes, as many experimental studies have shown. A recent study of the interaction of molecular hydrogen with planar graphite clusters by Okamoto and Miyamoto [119] confirmed that the LDA interaction energy curve was in very good agreement with the results of *ab initio* second-order Møller–Plesset (MP2) calculations.

### 3.4. Hydrogen Density Profile

Lee et al. [29, 120] used SCC–DFTB calculations, and found that hydrogen molecules existed in a number of concentric layers inside the nanotubes. At room temperature, statistical mechanics studies that reported the density profile about the carbon nanotube exhibited a single dense monolayer of hydrogen molecules close to the nanotube wall [100, 101, 106, 121, 122]. This monolayer was present both inside and outside the tube. After this monolayer the density rapidly reduced to the equivalent of a bulk phase at the same compression, indicating that the thermal vibration energy overcomes the ordering enthalpy for the second and subsequent monolayers. Statistical mechanics studies show that at 77 K, the lower thermal vibration energy of the hydrogen molecules did allow a second [99] dense monolayer shell to form, with a density intermediate between the first monolayer and the bulk phase.

Adding charge to the carbon nanotube increased the interaction with hydrogen molecules, and also induced a second monolayer shell at room temperature [106]. The authors of this study suggest that such a charged system could be created by either metal intercalation or by electrostatic charging. Dubot and Cenedese [115] used semiempirical

AM1 simulations to study molecular hydrogen adsorption in Li-doped SWNTs. The molecular hydrogen bound to the Li atom with a binding energy of  $43 \text{ kJ} \cdot \text{mol}^{-1}$ , and was repelled from the tube wall if the tube was not doped. Froudakis [123] used the ONIOM method to investigate the nature of the hydrogen adsorption in K-doped SWNTs, and to compare it with the adsorption in pure SWNTs. The calculations showed that the charge transfer from the alkali metal to the tube polarizes the hydrogen molecule, and this charge-induced dipole interaction is responsible for higher hydrogen uptake in the doped tubes. This may explain why the hydrogen uptake is improved by the doping of catalysts used in making the carbon nanotube.

All of these monolayers appear to have an average thickness of  $\sim 3.5 \text{ \AA}$ . This agrees nicely with the SCC-DFTB calculations of Tada et al. [124], who found that there was an energy threshold to entering the nanotube that was dependent on the tube diameter, with the barrier reducing to ambient energy levels only when the diameter was above  $6 \text{ \AA}$ . The density of the external monolayer is higher than for the same monolayer on an ideal graphite sheet, and the density of the internal monolayer is higher again [121].

### 3.4.1. Implications of the Density Profile

The increased adsorption of ideal carbon nanotubes appears to be based on the presence of the dense monolayer. These monolayers are dependent on the surface area, which scales with the number of carbons. Alternately, the bulk phase is dependent on the interstitial spaces and nanotube internal volume. These areas are dependent on the square of the number of atoms. This means that a graph of either nanotube size or nanotube packing separation against system density over bulk density will have a maximum. Therefore, when compared with a simple nonadsorbent system, the carbon nanotubes will have configurations of maximum benefit. For systems for which a single monolayer is predicted, this maximum occurs when one monolayer is adsorbed on the nanotube surfaces (radius  $\sim 1.2 \text{ nm}$ , tube separation  $\sim 0.7 \text{ nm}$ ) [101]. No one has quantified the maximum for charged or low-temperature systems where two monolayers may exist, but intuitively, it would be expected to be at an additional multiple of  $3.5 \text{ \AA}$ , a radius of  $\sim 1.55$  or  $\sim 1.9 \text{ nm}$  and a separation of  $\sim 1.05$  or  $\sim 1.4 \text{ nm}$ . Countering any "ideal" configuration is the random distribution of diameter and nanotube arrangement in experimental systems. A recent theoretical study [125] on randomly generated bundles predicted adsorption isotherms that appeared insensitive to the details of the geometry.

### 3.5. Isotope Separation Using Carbon Nanotubes

The separation of atomic isotopes is an energy-intensive and time-consuming process. A recent paper by Challa et al. [126] modeled that separation of the isotopes of hydrogen using a GCMC method including quantum treatment via a path-integral method. They calculated selectivities of 10,000 for  $\text{T}_2/\text{H}_2$  and 1000 for  $\text{D}_2/\text{H}_2$  at low temperature and pressure ( $20 \text{ K}; 10^{-4} \text{ Pa}$ ), which reduced to, respectively, 6 and 5 at  $77 \text{ K}$  and  $1300 \text{ Pa}$ . These results indicate that

carbon nanotubes have great potential for use in isotope separation.

### 3.6. Nanotube Properties

The chemical reactivity of nanotubes has been analyzed by comparing unstrained and strained systems. One group [127] used first principle calculations to look at atomic hydrogen adsorption on a tube that had been elastically squashed to form an elliptic tube. They found a large ( $\sim 100 \text{ kJ} \cdot \text{mol}^{-1}$ ) difference in the binding energy between the regions of high and low curvature in the ellipse. Another group [128] analyzed, using an empirical method, the reactivity at areas of high curvature caused by twisting or bending the nanotubes. They also found that sites of higher curvature have higher binding energies ( $\sim 155 \text{ kJ} \cdot \text{mol}^{-1}$ ) for atomic hydrogen. They also presented some preliminary experimental evidence that nanotubes can preferentially react at strained sites. The finding that the reactivity of carbon nanotubes is modifiable by physical distortion of the tube structure makes carbon nanotubes quite different from planar graphitic materials where increased reactivity occurs only at defect sites.

### 3.7. Chemical Adsorption on Carbon Nanotubes

No chemical adsorption was observed in studies using statistical mechanic methods on systems with molecular hydrogen at ambient energy levels. Only the studies with atomic hydrogen discussed below had reactions leading to chemisorption of the hydrogen. None of those systems modeled carbon nanotubes at conditions proposed for hydrogen storage nor proposed a mechanism for release of the chemisorbed hydrogen. However, it is well known that certain metal catalysts promote the formation of atomic hydrogen, and some of these metals are being combined with carbon nanotubes.

Using density functional theory, Jeloica and Sidis [129] calculated the interaction between atomic hydrogen and a graphite surface. A coronene-like model of the (0001) graphite surface is considered. Two adsorption regions separated by a barrier were found: a physisorption region around  $3 \text{ \AA}$  from the surface, and a chemisorption region around  $1.5 \text{ \AA}$ . The former is site independent, and compatible with a high mobility of the hydrogen atoms parallel to the surface. The latter is located exclusively on top of a carbon atom, which was consistent again with earlier studies using the semiempirical method [130–133], and more details can be found from our recent review [134]. Yang and Yang [135] focused on the adsorption of H atoms on three faces of graphite: (0001) basal plane, (1010) zigzag edge, and (1121) armchair edge. The relative energies of adsorption (or C–H bond energies) follow the order zigzag edge > armchair edge > basal-plane edge. They also found that adsorption on the basal plane sites is exothermic and stable. On the edge sites, the C–H bond energy decreases by nearly  $125 \text{ kJ} \cdot \text{mol}^{-1}$  when two H atoms are adsorbed on the same site. On the basal plane, the C–H bond energy decreases from  $190 \text{ kJ} \cdot \text{mol}^{-1}$  when two H are adsorbed on alternating sites to  $110 \text{ kJ} \cdot \text{mol}^{-1}$  when they are adsorbed on two adjacent sites.

Lee et al. [29, 120] used an SCC–DFTB method, and identified two chemisorption sites for atomic hydrogen on SWNTs: similarly to graphite, the carbon atom top sites at the exterior and the interior of the tube wall. Gülseren and co-workers [127, 136] and Tada et al. [124] found that the binding energy depends sensitively on the curvature of the nanotubes, either zigzag or armchair, and was proportional to the inverse of the radius. They found that the  $sp^3$  rehybridization of a single carbon atom from  $sp^2$  was always exothermic, provided the new bonding orbital was exohedral, and predicted that no chemisorption could occur inside the nanotube. However, Tada et al. reported repulsive interactions between hydrogen and a planar graphite layer that are not in agreement with the results of Arellano et al. [114]; the discrepancy between the results of the two calculations may be due to the different treatments (GGA by Tada et al. and LDA by Arellano et al.), with GGA known to overestimate repulsive interactions. Gülseren and co-workers [127, 136] also found that the  $C_nH_n$  nanotubes formed were direct band insulators with a gap of 1.5–2.0 eV at the G point of the electronic band structure, in contrast to pure nanotubes which are metallic or semiconductors.

Bauschlicher [137] used a (10,0) carbon nanotube for studying the hydrogen and fluorine binding using the ONIOM method (B3LYP/4-31G:UFF). The addition of two or four hydrogen atoms (from molecular hydrogen) to a (10,0) tube is computed to be endothermic. As a comparison, fluorine atoms appear to favor bonding next to existing fluorine atoms, and the adsorption is quite exothermic. The reason may be that the  $H_2$  bonding energy (460  $\text{kJ} \cdot \text{mol}^{-1}$  at B3LYP level) is larger than  $F_2$  bonding energy (140  $\text{kJ} \cdot \text{mol}^{-1}$ ). In another study, Bauschlicher [138] examined the maximum coverage of the tube wall, finding that the average C–H bond energy for the more stable 50% coverage is 240  $\text{kJ} \cdot \text{mol}^{-1}$ , which is higher than that of 100% coverage (160  $\text{kJ} \cdot \text{mol}^{-1}$ ). This indicates that it is very difficult to achieve 100% coverage on a (10,0) tube. The favorable 50% coverage corresponds to about 4% by weight storage of hydrogen.

Froudakis [139] applied the ONIOM approach to a 200-atom (4,4) SWNT, treating up to 64 carbons and 32 hydrogens with the higher level of theory. The small diameter of the tube together with the large number of atoms considered allow the higher level model to include a cylindrical part of the tube. The calculations showed that hydrogen atoms bond to the tube walls, and do not enter the tube interior. This binding takes places in zigzag rings around the tube walls, and not in lines toward the tube axis, changing the tube shape and causing an enlargement of the tube volume by 15%. After the tube walls are half filled with hydrogens, the energetically more favorable procedure of hydrogen insertion in the tube is obtained.

These results for hydrogen chemisorption on the exterior wall of SWNT are in fair agreement with that on the basal plane of graphite. The values of 110  $\text{kJ} \cdot \text{mol}^{-1}$  from Yang and Yang [135] and 160–240  $\text{kJ} \cdot \text{mol}^{-1}$  from Bauschlicher [138] agree well with 96  $\text{kJ} \cdot \text{mol}^{-1}$  from experimental desorption of hydrogen from MWNT. However, more studies, both experimental and theoretical, need to be made to eliminate the remaining differences. Furthermore, these large energy barriers somewhat preclude hydrogen

chemisorption as a useful storage method at ambient temperatures.

### 3.8. Hydrogen Storage Inside Closed SWNT

In another series of studies [140, 141], hydrogen atoms were used to bombard the wall of a model nanotube in a molecular dynamics study. They found that atoms with kinetic energy in the range 90–360  $\text{kJ} \cdot \text{mol}^{-1}$  were chemically adsorbed on the surface. Atoms with energy higher than this but lower than 1.3  $\text{MJ} \cdot \text{mol}^{-1}$  bounced off the tube. Atoms with energy higher than 1.3  $\text{MJ} \cdot \text{mol}^{-1}$  began to pass through the tube wall; some did this without damaging the wall, some would remain in the tube while others passed out the other side, and some entered and damaged the wall. The study also showed that any damage was “healed” within a short time (1–3 ps). The studies proposed that carbon nanotubes could be used as molecular-sized containers for hydrogen, or deuterium and tritium, particularly where very high densities are required.

Lee et al. [142] addressed the issue of a possible mechanism for the insertion of hydrogen molecules into the nanotubes using an SCC–DFTB method. According to their hypothesis, a hydrogen atom bonded to a carbon atom in an arch-type geometry could push the carbon atoms down, and then flip into the C–C midbond. The C–C bond recovers after the H atom flips into the internal space. Once the first atoms has flipped in, the nearest neighbor top site atoms can flip more easily because of the lower activation barrier, leading to a continuous flip-in process. Then the zigzag flip-in process, that is, the continuous flip-in process in the second nearest neighbor top site, ultimately results in the formation of zigzag geometry. A kick-in mechanism was proposed to explain hydrogen insertion in the nanotubes. Repeating the kick-in process eventually leads to the formation of molecular hydrogen inside the tubes. The storage mechanism is completed by a similar hydrogen extraction mechanism with a low energy barrier. Similarly to Gülseren and co-workers [127, 136] mentioned earlier, the calculations revealed that C–H bond formation changes the electronic structures of metallic carbon nanotubes to semiconductors during the electronic chemical storage process. This suggests that doping or adding conductive materials to the nanotube electrode was required in the electrochemical storage experiments.

## 4. INTERACTION BETWEEN HYDROGEN AND CNTS

Current theoretical studies of simple physical adsorption on pure carbon nanotubes predict a maximum of 14 wt% under low temperature and ideal conditions. The real adsorption process is likely to be more complicated, and the theoretical simulations have the potential for further refinement. In particular, as more quantitative and microscopically in-depth experimental results become available, the model parameters and assumptions will become more realistic.

Only some of the experimental results agree well with the theoretical calculations. It is not difficult to understand this because experiments are performed on real-world

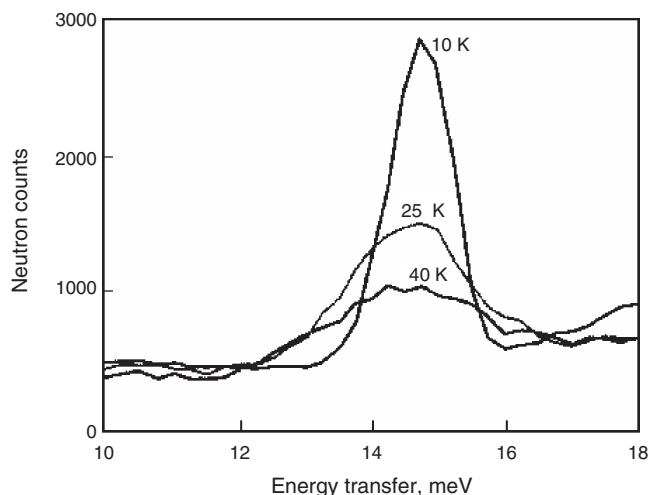

materials, whereas calculations are based on idealized models. The carbon nanotubes made from various preparation methods under varied conditions will have different structural features. It is also probable that the carbon nanotubes are synthesized with defects or damaged, disordered, and functionalized during purification and cutting treatments. Molecular simulations which consider the effects of packing disorder, diameter polydispersity, functionalization, and nanotube wall effects are currently underway [143].

Little is known of the effects of nanotube stereochemistry on hydrogen uptake. SWNTs may, in the future, be prepared in bulk quantities with a variety of diameters and stereochemistries, depending on the nature of the rolling process of the graphitic sheet. Zigzag, armchair, and chiral nanotubes have been identified by Raman spectroscopy [144], but methods of forming them in pure high yield have not been discovered. The structure of the nanotube affects its properties, including conductance, density, and lattice structure, and possibly hydrogen adsorption. For example, an SWNT is metallic if the value ( $m - n$ ) is divisible by 3. Consequently, when tubes are formed with random values of  $m$  and  $n$ , we would expect that two-thirds of nanotubes would be semiconducting, and the other third metallic. Raman studies at multiple wavelengths which enable the differentiation between semiconducting and metallic nanotubes may enable an answer which is better suited for hydrogen adsorption [145]. If a preference is determined, the aim of current preparative carbon nanotube research should be directed to producing specific metallic or semiconducting nanotubes. Recently, diameter tuning of SWNTs has been reported through variation in laser pulse power [146]. This advance is important in furthering progress toward the DOE goals since there is theoretical and experimental evidence that the diameter of SWNTs can affect the capacity, thermodynamics, and kinetics of hydrogen storage. In addition to controlling nanotube size distributions, Heben's group also learned how to detangle and order nanotubes on a large scale [147]. This capability may eventually be important for achieving high packing densities, and therefore high volumetric hydrogen storage densities.

There is considerable debate over the issue of how SWNTs interact with hydrogen in the scientific community [50]. Is it a purely physical or chemical interaction or is it perhaps somewhere in between? It is important to obtain a deeper understanding of this process so that accurate theoretical models and predictions may be developed. Factors such as tube diameter and chirality may need to be targeted for synthesis, and so that their interaction with storage capacity and performance characteristics can be understood and optimized. In a previous study, Dillon et al. [26] showed that hydrogen is not dissociated when adsorbed on arc-generated SWNTs, even though the binding energy is  $19.62 \text{ kJ} \cdot \text{mol}^{-1}$ . Recently, they used TPD and FTIR techniques to show that hydrogen is nondissociatively adsorbed on laser-generated nanotubes [50]. They found that the interaction between hydrogen and SWNTs was midway between conventional van der Waals adsorption and chemical bond formation. Both infrared and Raman investigations on hydrogen-charged high-capacity purified samples of SWNTs are presently underway in an effort to better understand the nature of the carbon-hydrogen interaction.

None of the experiments has so far addressed the local structure of the binding sites, further complicating comparisons with theoretical predictions. Binding energies of physisorbed hydrogen can be obtained by thermal analysis, but these do not provide atomic-scale geometric information about the binding sites. Furthermore, experimental binding energies are generally much larger than values calculated for the idealized structure. Inelastic scattering of thermal neutrons, a spectroscopic technique that is sensitive to the local environment in which the hydrogen molecules are trapped, is now being used to probe the nature of the hydrogen adsorption site in carbon nanotubes [148]. A proof-of-principle experiment was recently published, and Figure 10 shows the temperature dependence of the neutron energy-loss spectra from this work. In principle, one should be able to determine how much hydrogen is trapped in multiple sites of different symmetry. Furthermore, the temperature dependence of the energy-loss peaks associated with different sites is a direct measure of the binding energy, a quantity that can be directly compared with theory. The shift in peak position and the decrease in intensity with temperature signify physisorption on a tube surface, with a binding energy slightly larger than would be obtained on a flat graphite surface. This experiment demonstrates that rotational spectroscopy using thermal neutrons provides important microscopic information about hydrogen-binding sites in nanotubes, although the experimental conditions are of no practical interest (0.6 g as-grown SWNTs, 25 K, 11 MPa).

As shown in Table 1, there is a large range of published values for reversible hydrogen storage in carbon nanotubes. One reason for this range may be insufficient characterization of the carbon nanotubes as mixtures of opened and unopened, single-walled and multiwalled, various diameter and helicities have been tested together with other unknown carbonaceous species. Another reason may be insufficient rigor in making hydrogen adsorption measurements on samples on the order of several milligrams where minute parasitic effects can easily and erroneously be attributed to

**Figure 10.** Neutron energy-loss spectra of raw SWNT material loaded with hydrogen at low temperature and high pressure show a peak resulting from excitation of quantized molecular rotation levels of physisorbed hydrogen. hydrogen uptake. This means that we should be interpreting currently described experiments with care. Nevertheless, these results do give some indications that reaching the DOE target for hydrogen storage may be achievable, and they must be regarded as an intermediate step within an advanced learning process.

## 5. FUTURE PERSPECTIVES

Research reports aimed at optimizing the carbon nanotubes for hydrogen storage appear frequently in the literature. The current reliable values for hydrogen uptake in carbon nanostructures [3, 32] need to be greatly increased to meet the DOE target. The feasibility of a viable carbon-nanostructure-based storage medium for hydrogen remains undetermined from the results reviewed here, with the current state of the art not providing a solution. This field of study is complicated by the publication of inaccurate storage capacities. It has been shown that it is easy to make large errors in determining hydrogen storage capacities. In this quickly moving field, it becomes critical for every experimental result to be confirmed and corroborated by other groups, to avoid the continued dissemination of unreliable results. In this regard, we would like to advocate that systematic studies of the complementary measurement methods should be carried out, and standard procedures for measuring the  $H_2$  uptake within the limitations of each method should be established. International conferences and workshops on gas adsorption measurement in carbon nanotubes should be called to discuss this challenging topic.

The computational chemistry studies provide a useful model of hydrogen physisorption on carbon nanotubes. At room temperature, a single dense monolayer of molecular hydrogen forms on the inside and outside of the tube. Due to the geometry of the system, this implies that a limiting arrangement for maximum storage exists. A second monolayer, less dense than the first, can form at low temperature and when the nanotubes are charged. This will further increase the storage capacity, but will also have a limiting geometric arrangement. This second charge-induced monolayer may be one explanation for the enhanced storage in nanotubes with intercalated metals. Alternately, a mechanism that involves the hydrogen molecule dissociating on a metal catalyst followed by atomic hydrogen moving across the tube surface before adsorption is proposed. However, it remains to be shown experimentally or theoretically that these metals can directly promote hydrogen chemisorption and, more importantly for hydrogen storage, whether such a process is reversible.

The temperature and pressure requirements for molecular hydrogen adsorption and desorption, and the kinetics for charging and discharging are also expected to be a function of nanotube diameter and aspect ratio, and still need to be addressed. More work needs to be done to refine these theoretical models, and to develop a model compatible with the requirements of the DOE Hydrogen Plan. Highly accurate experimental results could provide more realistic modeling parameters for the theoretical simulations of hydrogen storage.

It may be a combination of experimental and theoretical efforts that will lead to a full understanding of the adsorption process, so that the uptake can be rationally optimized to commercially attractive levels. It is scientifically interesting and challenging to continue research on the sophisticated experimental techniques and interactions of hydrogen with different and well-characterized carbon nanostructures. On the basis of a thorough understanding of the hydrogen adsorption in carbon nanotubes, fine adjustments and optimization of the production conditions can be conducted to obtain carbon nanotubes with specific structures which facilitate the hydrogen storage in carbon nanotubes. After optimization is complete, it will be necessary to scale up the synthetic and purification techniques that generate the ideal adsorbent nanotubes. These issues represent significant technological and theoretical challenges in the years to come.

## GLOSSARY

***Ab initio* method** Method solely based on the laws of quantum mechanics—the first principles referred to the name *ab initio*—and on the values of a small number of physical constants.

**AM1 simulations** Semiempirical electronic structure method. The full name is Austin Model 1, similar to MNDO (modified intermediate neglect of differential overlap), based upon NDDO (neglect of diatomic differential overlap).

**Buckminsterfullerene** Broad term covering the variety of buckyballs and carbon nanotube structures. Named after the architect Buckminster Fuller, who is famous for the geodesic dome, which buckyballs resemble.

**Capillarity** General term for phenomena observed in liquids due to intermolecular attraction at the liquid boundary, for example, the rise or depression of liquids in narrow tubes, the formation of films, drops, bubbles, and so on.

**Compressed hydrogen storage** Hydrogen storage pressure (typically some 20 MPa).

**Density functional theory** In parallel to the development of *ab initio* theory, it was theorized that all molecular properties could be described as a function of the electron density (Hohenberg and Kohn, 1964). Density function theory is a theoretical approach to describe the electron density by using mathematical functions, called functionals.

**Electronic structure method** Uses the laws of quantum mechanics rather than classical physics as the basis for their computation. Quantum mechanics states that the energy and other related properties of a molecule may be obtained by solving the Schrödinger equation ( $H\psi = E\psi$ , where  $H$  is the Hamiltonian operator,  $E$  is the energy of the particle, and  $\psi$  is the wavefunction). There are now three major classes of electronic structure methods: semiempirical method, *ab initio* method, and density functional method.

**Fuel cell** Electrochemical device that continuously converts the chemical energy of a fuel to electrical energy.

**Hydrogen economy** Such an economy is one where hydrogen is used for energy storage, distribution, and utilization.

**Inelastic neutron scattering (INS)** Process of scattering neutrons from a specimen, accompanied by a change in energy of the neutron. Neutron beams for INS may be produced by nuclear reactors or by spallation reactions induced by accelerating charged particles into an appropriate target. After moderation, a monochromatic neutron beam can be extracted either using crystal monochromators or via time-of-flight methods.

**Lennard–Jones potential** Mathematical form of the potential-energy curve that describes the interaction of molecules, which stems from the work of the English chemist J.E. Lennard–Jones.

**Metal hydride storage** Storage of hydrogen by use of a metal alloy. The hydrogen is soaked into the alloy like into a sponge, and fills the spaces in the crystal lattice of the alloy. The storage is filled, applying a modest overpressure, and is usually operated in the temperature range of 20–80 °C.

**Molecular dynamics** Simulation of the time-dependent behavior of a molecular system, such as vibrational motion or Brownian motion. It requires a way to compute the energy of the system, most often using a molecular mechanics calculation. This energy expression is used to compute the forces on the atom for any given geometry.

**Molecular mechanics method** Uses the laws of classical physics to predict the structures and properties of molecules.

**Møller–Plesset (MP) calculation** This was theorized that the electron correlation was a perturbation of the wavefunction, and so the MP perturbation theory could be applied to the HF (Hartree–Fock) wavefunction to include the electron correlation. As more perturbations are made to the system, more electron correlation is included; these methods are denoted as MP2, MP3, and MP4.

**Monte Carlo methods** There are many types of calculations that are referred to as Monte Carlo calculations. All Monte Carlo methods are built around some sort of a random sampling, which is simulated with a random-number-generating algorithm. In computational chemistry, a Monte Carlo simulation is usually one in which the location, orientation, and perhaps geometry of a molecule or collection of molecules are chosen according to a statistical distribution.

**MWNT** Multiwalled carbon nanotube.

**ONIOM approach** The full name is “our own *n*-layered integrated molecule orbital and molecular mechanics” developed by Svensson et al. at Emory University, USA, in 1996. This method allows the accuracy of quantum mechanics and the large molecule capability of molecular mechanics methods to be combined. The method works by dividing a molecular system into successively smaller domains that can each be treated at increasingly sophisticated theory levels.

**Semiempirical method** Uses parameters derived from experimental data to simplify the computation. It solves an approximate form of the Schrödinger equation that depends on having appropriate parameters available for the type of chemical system under investigation.

**Statistical mechanics methods** Statistical mechanics is the mathematical means to calculate the thermodynamic properties of bulk materials from a molecular description of the materials. Statistical mechanics computations are often

tacked onto the end of *ab initio* vibrational frequency calculations for gas-phase properties at low pressure. For condensed-phase properties, often molecular dynamics or Monte Carlo calculations are necessary in order to obtain statistical data.

**SWNT** Single-walled carbon nanotube.

## 1. INTRODUCTION

Hydrogenated nanocrystalline silicon (nc-Si:H) or microcrystalline Si ( $\mu$ c-Si:H) films appear as a promising material for thin-film devices such as solar cells, thin-film transistors, and sensors, since the electron mobility of nc-Si:H is much improved compared to that of hydrogenated amorphous silicon films (a-Si:H). Understanding the electronic transport and optical properties of nc-Si:H is very important for improving such device properties. As schematically shown in Figure 1, structure of nc-Si:H is very complex and is characterized by “crystalline grain clusters” (region A) which consist of crystalline grains from nano-size to  $\sim 20$  nm, and it is surrounded by “disorder zones” (region B) [1, 2]. Region A forms columnar clusters of much larger dimensions extending perpendicular to the substrate. Although the influences of the grain size and crystalline volume fraction on the electronic transport have been discussed, the details of their quantitative natures are still not clear [1–8].

To understand the physical properties in such complex materials, a percolation approach may be useful. A percolation path for electronic transport in nc-Si:H films has been suggested [3]. In fact, three-dimensional conductance network calculations (computer simulations) for the conductivity,  $\sigma$ , and Hall mobility,  $\mu_H$ , show an existence of critical threshold of such percolation path [9]. It is suggested that an effective medium approximation (EMA) [10] is useful for explaining the quantitative transport and optical properties in inhomogeneous systems [11]. In the present chapter,

current understanding of electronic and optical properties of nc-Si:H films is briefly reviewed along the idea of EMA in which random mixture of particles (region A and B) is assumed for simplicity [11].

Nonactivated behavior of electronic transport (temperature-dependent dc conductivity), on the other hand, is one of the important and unsolved problems, which can be related to complicated structure of nc-Si:H films. In some cases, the dc conductivity seems to be proportional to  $\exp(-B/T^{1/2})$  [12, 13]. Reasons for these behaviors have been discussed in terms of hopping conductivity in a traditional manner [12, 13]. In this chapter, the non-activated behavior can be, alternatively, explained in terms of thermionic emissions of electrons over random barriers between crystalline clusters [14].

## 2. PREPARATION OF HYDROGENATED NANOCRYSTALLINE SILICON

Low-temperature fabrication process can be required for thin-film transistors and photovoltaic cells with inexpensive substrates. The following preparation techniques have been used to achieve it: (i) plasma-enhanced chemical vapor deposition (PECVD) of silane ( $\text{SiH}_4$ ) gas diluted in  $\text{H}_2$  gas, (ii) thermocatalytic or hot-wire assisted chemical vapor deposition (HWCVD) of  $\text{SiH}_4$  gas diluted in  $\text{H}_2$  gas, and (iii) pulsed laser crystallization (PLC) of amorphous silicon films. These techniques are summarized below.

### 2.1. Plasma-Enhanced CVD

This method has been well established in depositing hydrogenated amorphous silicon films (a-Si:H) and hence we only modify the deposition conditions to prepare nanocrystalline silicon (nc-Si:H) [1–5]. The structural compositions of nc-Si:H vary by changing the deposition conditions, that is, the silane to hydrogen ratio and the plasma excitation frequency. Unlike a-Si:H deposition, decrease of the silane to hydrogen gas ratio (less than 2% in gas ratio) is required to increase volume fraction of crystalline. It should be noted that the material prepared by PECVD is a phase mixture of amorphous and crystalline regions. The substrate

**Figure 1.** Schematic illustration of a structure of  $\mu\text{c-Si:H}$ . Region A is a crystalline grain cluster and region B is a disordered zone which surrounds region A.

temperature is taken to be around  $200\text{ }^\circ\text{C}$ . Higher plasma excitation frequency up to  $100\text{ MHz}$  leads to a simultaneous increase of the deposition rate (commercially very important and is  $\sim 0.1\text{ nm/s}$ ) [15, 16], the crystalline volume fraction ( $\sim 80\%$ ), and the average grain size ( $\sim 30\text{ nm}$ ) [15]. It is known that atomic hydrogen (H) plays an important role for nucleation of crystallization, although the reason for this is not clear.

## 2.2. Hot-Wire Assisted CVD

Hot filament, such as tungsten (W) or tantalum (Ta) filament, assists catalytic decomposition of a silane and hydrogen gas mixture in this technique [17–19]. A wide range of deposition parameters is adjustable for the deposition. The most important parameter for this technique to produce nc-Si:H is the silane to hydrogen gas ratio (less than  $\sim 3\%$  in gas ratio). A filament diameter, for example, is  $250\text{ }\mu\text{m}$  and substrates are placed in the cm range from the filament whose temperature is kept around  $1600\text{ }^\circ\text{C}$ . Substrate temperature is around  $200\text{ }^\circ\text{C}$ . Much higher deposition rate in this technique than PECVD has been reported and it approaches  $\sim 3\text{ nm/s}$  depending on deposition conditions. Although overall qualitative electronic properties of HWCVD nc-Si:H are similar to those of PECVD nc-Si:H, the mobility-lifetime product, for example, is smaller in HWCVD samples than PECVD ones. This can be attributed to larger number of defects in HWCVD nc-Si:H films.

## 2.3. Pulsed Laser Crystallization

Crystallization of amorphous silicon films occurs at a liquid-solid phase induced by pulsed excimer laser heating (see, e.g., [20]). To reach the melting threshold, the laser energy,  $160\text{ mJ/cm}^2$  for example, is required for the pulse width around  $30\text{ ns}$ . This required energy is very small, since the region heated by irradiation is limited to near surface. A rapid crystallization with low processing temperature is achieved by this method and the grain size around  $100\text{ nm}$  is obtained. Uniformity and reproducibility in crystallization may still be a problem.

## 3. SPECTROSCOPIC CHARACTERIZATION

As the optical transmission properties (optical absorption below and above bandgap) will be discussed in the next section, we concentrate here on only the structure-related spectroscopies. As already stated, nanocrystallines prepared by PECVD and HWCVD have complex structures. Combined data of X-ray diffraction (XRD), Raman spectroscopy (RS), and transmission electron microscopy (TEM) can be useful to analyze the structure of nanosilicon [4]. Raman spectroscopy and XRD are used to estimate crystalline volume fraction, in which the intensity ratio of the different signal contributions is calculated from a deconvolution of the spectra. A popular method to estimate the grain size is the application of the Scherrer formula on XRD peaks.

It is noted that RS and XRD are not sensitive for low crystalline volume fraction  $X_c$  ( $10\text{--}20\%$ ) and are not sensitive to the spatial distribution of crystallites (or amorphous phase), although TEM imaging still reveals isolated grains in amorphous tissue for low  $X_c$ . TEM imaging in cross section is important to know the spatial inhomogeneity. It is noted also that the crystalline volume fraction  $X_c$  estimated from Raman spectroscopy is always smaller than that estimated from XRD [4]. In spite of this difficulty of exact determination of  $X_c$ , RS or XRD is an easy technique and hence these techniques are often used as a measure of crystalline volume fraction.

The other spectroscopic methods, such as electron spin resonance (ESR) study, produce information on defect structure [7, 8, 21]. The ESR signals at  $g$ -values,  $2.0052 \pm 0.004$ ,  $2.0043 \pm 0.002$ ,  $1.996 < g < 1.998$  (depending on doping and temperature), and  $2.1$ , have been found in nanocrystalline silicon films and each can be attributed to Si dangling bonds ( $2.0052$ ), dangling bonds in oxygen-rich regions ( $2.0043$ ), electrons in conduction band, conduction band tails or donor states ( $1.996\text{--}1.998$ ) which is called the conduction electron (CE) resonance, and acceptor states ( $2.1$ ). The spin densities of  $g = 2.0052$  and  $2.0043$  resonances remain around  $10^{16}\text{ cm}^{-3}$  for undoped and doped samples, while the spin density of  $g = 1.996\text{--}1.998$  increases with P-doping up to around  $10^{18}\text{ cm}^{-3}$ . The CE resonance increases with the dc conductivity, which will be discussed also in Section 4, and the density of CE is reported to be almost the same as that of the donor density.

The number of Si dangling bonds ( $g = 2.0052$ ) is smaller compared with polycrystalline Si, which may be due to an excellent hydrogen passivation during the PECVD process. The majority of Si dangling bonds are expected to locate at the boundaries between crystalline column and disordered (amorphous) region.

## 4. ELECTRONIC AND OPTICAL PROPERTIES

In this section, we concentrate on the electronic and optical properties of nanocrystalline Si prepared by the PECVD method. Since particular interest has been paid to the electronic and optical properties of these films, the thermal and mechanical properties have not been discussed so far. As the

deposition temperature is around 200 °C, the physical properties should be stable below this temperature. Si is classified into a “hard” material and thus nanocrystalline Si should also be expected as a mechanically tough material.

### 4.1. Effective Medium Approximation

We briefly introduce the effective medium approximation (EMA) before proceeding with the discussion. The EMA predicts the total network conductance  $\sigma_m$  for composite materials in  $D$  dimensions:

$$\left\langle \frac{\sigma - \sigma_m}{\sigma + (D - 1)\sigma_m} \right\rangle = 0 \tag{1}$$

where  $\sigma$  is a random variable of conductivity. Assuming that a random mixture of particles of *two* different conductivities, for example, a volume fraction,  $C$ , has conductivity of  $\sigma_0$ , and the remainder has conductivity of  $\sigma_1$ , substantially less than  $\sigma_0$ , simple analytical expressions of dc conductivity and Hall mobility as a function of  $C$  have been derived (see the pioneering works by Kirkpatrick [10] and Cohen and Jortner [22]). EMA has been also extended to calculate the ac conductivity in which case  $\sigma$  in Eq. (1) becomes a complex admittance ( $\sigma^* = \sigma_1 + i\sigma_2$ ) [23]. As the dielectric constant,  $\varepsilon^* = \varepsilon_1 - i\varepsilon_2 = \sigma_2/\omega - i\sigma_1/\omega$ , is closely related to  $\sigma^*$ , optical absorption coefficient  $\alpha(\omega)$  can be calculated using  $\alpha(\omega) = 4\pi\sigma(\omega)/cn$ , where  $c$  is the light speed and  $n$  the refractive index [11].

### 4.2. Application of EMA to the Experimental Data

Solid circles in Figure 2 show the dc conductivity at room temperature as a function of crystalline volume fraction,  $X_c$ , for a series of undoped  $\mu c$ -Si:H films [3]. Note that theoretical prediction of such a dependence for complicated systems is a very hard task. Shimakawa [11] has applied the

**Figure 2.** Room-temperature conductivity as a function of crystalline volume fraction for a series of undoped nc-Si:H. Reprinted with permission from [11], K. Shimakawa, *J. Non-Cryst. Solids* 266–269, 223 (2000). © 2000, Elsevier Science.

EMA to the experimental data and the result of the EMA is shown by the solid line, where  $\sigma_1 = 3 \times 10^{-9}$  ( $X_c = 0$ ) and  $\sigma_0 = 3 \times 10^{-2}$  S cm<sup>-1</sup> ( $X_c = 1$ ) were used in  $D = 3$ . The experimental data do not fit the solid line very closely, which may be attributed to the varying grain sizes. In other words, the system we treated cannot be an ideal case for EMA. Following the solid line, however, the percolation threshold appears at  $X_c = 0.33$ , which agrees very well with the computer simulation ( $X_c = 0.32$ ) [9].

Solid circles in Figure 3 show the room temperature Hall mobility in undoped  $\mu c$ -Si:H as a function of volume fraction of crystalline Si [24]. Shimakawa [11] has tried to apply the Cohen and Jortner approach (EMA) [22] and the solid line shows the calculated result with  $\mu_1 = 0.2$  ( $X_c = 0$ ) and  $\mu_0 = 2$  cm<sup>2</sup> V<sup>-1</sup> s<sup>-1</sup> ( $X_c = 1$ ). Note, however, that  $\mu_1 = 0.2$  cm<sup>2</sup> V<sup>-1</sup> s<sup>-1</sup> used here is not the true Hall mobility of the amorphous state ( $X_c = 0$ ), because the well-known anomaly of the Hall effect observed in hydrogenated amorphous silicon (a-Si:H) interferes with obtaining a proper value of Hall coefficient [25]. The fitting of the calculation to the experimental data is reasonably good and the percolation threshold is shown to exist at  $X_c = 0.33$  [11]. The small Hall mobility ( $\sim 2$  cm<sup>2</sup> V<sup>-1</sup> s<sup>-1</sup>) even at  $X_c = 1.0$  is about three orders of magnitude smaller than that for single-crystalline Si [26]. This can be attributed to the complicated structure of  $\mu c$ -Si:H. As already shown in Figure 1, the grain boundaries (between region A) dominate the transport properties and hence the mobility of  $\mu c$ -Si:H films is reduced significantly. This means that crystalline Si wears “grain boundary” and hence the mobility for a crystalline itself is still small.

Next, we argue the size effect of crystallite on the Hall mobility. In earlier works [3, 5, 26], the Hall mobility with the same  $X_c$  has been suggested to increase *linearly* with crystallite size  $\delta$  and has been explained by the *grain-boundary trapping* model (electronic transport is dominated by thermionic emission over a potential barrier). In commercial viewpoint, this may be very hopeful, since higher-mobility materials can be easily realized by bigger size of

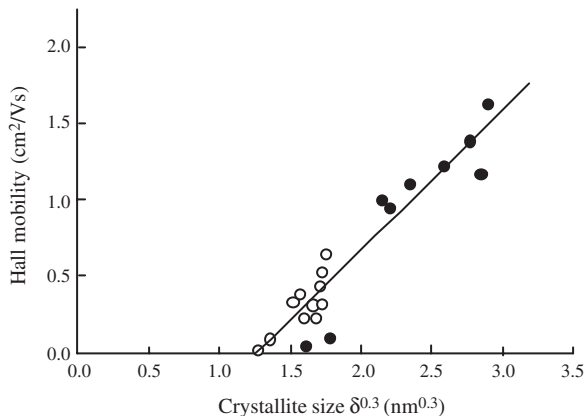

**Figure 3.** Room-temperature Hall mobility as a function of crystalline volume fraction in undoped nc-Si:H. Reprinted with permission from [11], K. Shimakawa, *J. Non-Cryst. Solids* 266–269, 223 (2000). © 2000, Elsevier Science.

crystallites. Unfortunately, however, as shown in Figure 4, a series of experimental data of the Hall mobility is shown to depend on the crystallite size as  $\delta^\gamma$  with  $\gamma \approx 0.3$  [11]. This *sublinear* dependence of  $\mu_H$  has been explained by the following way [11]: At the same  $X_c$ , the area of a disordered zone (DZ) (and hence the number of localized states in region B) can be regarded to be proportional to the surface to volume ratio  $R_{SV}$ . Since  $\mu_H$  is expected to be inversely proportional to the area of DZs, we get  $\mu_H \propto R_{SV}^{-1}$ . As  $R_{SV}$  is proportional to  $\delta^\alpha/\delta^\beta$ , where  $\alpha = 2.0$  and  $\beta = 3.0$  in Euclid space dimension and  $\alpha < 2$  and  $\beta < 3.0$  in fractal space, the relation of  $\mu_H \propto \delta^\gamma$  gives  $\gamma = \beta - \alpha$ .

In Euclid space dimension, we get  $\gamma = 1$ . This can be also easily understood by the following way. Imagine a cubic length  $\delta = L$  in Euclid space. The total surface area for this cubic is  $6L^2$ . When it is divided into eight parts, that is,  $\delta = L/2$ , the total surface area is  $12L^2$ . The total surface area (grain boundary) is thus expected to be inversely proportional to  $\delta$ , when the volume is kept the same  $L^3$ . However, if we consider  $\alpha$  and  $\beta$  in the fractal dimensions, one gets the sublinear dependence. In fact, the fractal dimensions of  $\beta \approx 1.9$  and  $\alpha \approx 1.6$  are predicted from a computer simulation for metallic clusters growing in thin films [27], which gives  $\mu_H \propto \delta^{0.3}$ .

Next, the *excess* optical absorption in fundamental absorption region is discussed. A larger optical absorption coefficient for nc-Si:H than for crystalline silicon (c-Si) from the infrared to the blue region has been reported [5, 28, 29]. This is an advantage for using solar cells, because many more photons can be absorbed in the films. An example of this difference is shown in Figure 5. Three solid lines are the experimental data for a-Si:H, nc-Si:H, and c-Si. Why such an excess optical absorption is observed in  $\mu c$ -Si:H is still a matter of debate. Although a scattering of light is suggested to be an origin of the enhanced optical absorption [29], Shimakawa [11] took the EMA, in an alternative way, to explain the excess absorption. The results obtained from EMA for  $X_c = 0.8$  and  $D = 3$  are shown by open circles. The frequency (energy)-independent refractive index,  $n_0 = 3.9$  for c-Si and  $n_1 = 3.2$  for a-Si:H which can be given as the root of real part of optical dielectric constant, are used in the

**Figure 4.** Hall mobility at room temperature as a function of grain size. Reprinted with permission from [11], K. Shimakawa, *J. Non-Cryst. Solids* 266–269, 223 (2000). © 2000, Elsevier Science.

**Figure 5.** Comparison of the optical absorption coefficient of a-Si:H, nc-Si:H, and c-Si. The EMA results are given by solid circles. Reprinted with permission from [11], K. Shimakawa, *J. Non-Cryst. Solids* 266–269, 223 (2000). © 2000, Elsevier Science.

calculation. The calculated results agree very well with the experimental data, except at energy of around 1.7 eV. This suggests that a mean field constructed by mixture of amorphous and crystalline states dominates the optical absorption in nc-Si:H. The multiple light scattering seems to be not so important in this energy range.

### 4.3. Transport Mechanism

We understand in the preceding section that the EMA is useful to understand the *macroscopic* electronic and optical properties of composite materials, in particular the dependence of crystalline volume fraction of physical properties of nc-Si:H. In this section, we discuss the *microscopic* electronic transport mechanisms of nc-Si:H. For example, the mechanism of dc conductivity is very unclear.

Data shown in Figure 6 exhibit the temperature dependence of dc conductivity for n-type nc-Si:H films [6]. These cannot be fitted to the conventional relation  $\sigma_{dc} = \sigma_0 \exp(-\Delta E/kT)$  with a single activation energy at higher

**Figure 6.** Band diagram near the conduction band. A percolation threshold for electronic transport by thermionic emission process is represented by the dashed line. The Fermi level is given by the dash-dotted line.

temperatures. Above 20 K, Finger and co-workers [6] have suggested that conduction occurs across potential barrier  $\phi$  ( $=\Delta E$ ) between different crystalline regions and a barrier energy distribution leads to a curvature of  $\ln \sigma_{dc}$  versus  $1/T$ . They further suggested that the transport takes place across higher barriers at higher temperatures and lower barriers at lower temperatures [8].

More quantitative discussion of the transport mechanism is given as follows by Shimakawa [14]. At relatively high temperatures, the dc conductivity due to thermionic emission of electrons over a potential barrier between crystalline grain clusters is expected to occur and can be given as

$$\sigma_{dc} = AT^2 eW \exp(-\phi/kT)/kT \quad (2)$$

where  $A$  is the Richardson constant,  $W$  the barrier width, and  $\phi$  the barrier height measured from the Fermi level [30]. Figure 7 shows the band diagram representing this situation. The barrier height may be randomly distributed and hence the electronic transport can be dominated by the percolation level  $E_{pc}$  (dashed line).  $\phi$  defined here should therefore correspond to  $E_{pc} - E_F$ . Note that Eq. (2) is based on one-dimensional array of potential barriers and therefore, strictly speaking, Eq. (2) cannot be applied to the present materials, since we should consider three-dimensionally distributed potential barriers. This point will be discussed in a future publication.

Here the nonactivated behavior suggests that  $\phi$  ( $=E_{pc} - E_F$ ) decreases with decreasing temperature, which can be attributed to the temperature-dependent ionization of donors (upward shift of the Fermi level). From this temperature-dependent conductivity, temperature variation of  $E_{pc} - E_F$  can be deduced. The temperature dependence of  $E_{pc} - E_F$  should include the temperature dependence of bandgap in the discussed temperature range, that is,  $\gamma T$ , where  $\gamma$  is the coefficient of temperature variation in bandgap and is taken to be  $4 \times 10^{-4}$  eV/K [31]. The net temperature variation of  $E_{pc} - E_F$  ( $=\phi(T) - \gamma T$ ) is given in Figure 8. From the pre-exponential term in Eq. (2), the barrier width  $W$  is also estimated. It is of interest that  $W = (2-4) \times 10^{-6}$  cm is estimated for *all* the samples. This value seems to be a reasonable value.

A linear temperature dependence of the value of  $E_{pc} - E_F$ , at relatively high temperatures, suggests that the donors are essentially all ionized (“exhaustion” or “saturation” regime) [31]. In this regime,  $E_{pc} - E_F$  is given as follows:

$$E_{pc} - E_F = kT \ln \frac{N_c}{N_d} \quad (3)$$

**Figure 7.** Temperature variation of  $\sigma_{dc}$  at relatively high temperatures as a function of doping levels.

**Figure 8.** Temperature variation of the magnitude of  $E_{pc} - E_F$ .

where  $N_c$  (effective density of conduction band) is taken to be  $5 \times 10^{19}$   $\text{cm}^{-3}$ , and  $N_d$  is the donor concentration. From Eq. (3), the estimated values of  $N_d$  are plotted as a function of doping gas ratio, which are shown in Figure 9.  $N_d$  is almost linearly dependent on the doping gas ratio and this relationship deduced here is nearly the same as those obtained from the SIMS and the other measurements such as ESR by Finger et al. [8].

**Figure 9.** Estimated correlation between the donor concentration and doping gas ratio.

Finally, we should discuss the other transport mechanisms which have been proposed so far. The temperature-dependent dc conductivity below room temperature, on one hand, has been represented by the following expression in undoped and doped  $\mu\text{c-Si:H}$  films:

$$\sigma_{\text{dc}} = \sigma_0 \exp\left[-\left(\frac{T_0}{T}\right)^x\right] \quad (4)$$

where  $T_0$  is a constant and  $x = \frac{1}{2}$  [12, 13]. This type behavior can be understood either by *variable-range* hopping in the Coulomb gap [32] or by *nearest-neighbor* hopping between granular (conducting) islands [33]. Ram et al. [13] suggest that the unrealistically large Coulomb gap is estimated from the parameter  $T_0$  and hopping of electrons between granular islands dominates the transport. It should be noted that the pre-factor  $\sigma_0$  in Eq. (4) has a serious problem: It is well known that there is the discrepancy, by many orders of magnitude, between experimental and theoretical values of the constant  $\sigma_0$  [34]. This means that the experimentally observed conductivity cannot be replicated by Eq. (4) quantitatively. To the present author's view, therefore, a careful treatment using the concept of variable-range hopping may be required for reaching proper conclusion.

The model of thermionic emission over potential barriers cannot be applied to the carrier transport at lower temperatures below 20 K. Instead, nearest-neighbor hopping of electrons between donor sites has been suggested, in which carriers move *through* potential barriers (hopping sites also exist in barrier regions). Hopping of carriers is a special issue and hence the details of hopping conductivity at lower temperatures are discussed elsewhere [14].

There are also many interesting features of these inhomogeneous materials, for example, the growth mechanisms and related ac transport [2] and the photoconductivity [19]. A general behavior of photoconductivity in nc-Si:H is very similar to that found in a-Si:H [19]. A recent work of ac and dc photoconductivities in a-Si:H [35, 36], in which "inhomogeneity" is taken into consideration, may be useful to understand the photoconductivity in the present materials as well. These were not discussed in the present brief review.

## 5. APPLICATIONS

Nanocrystalline Si (nc-Si:H) thin films prepared by PECVD or HWCVD are a candidate for electronic and photovoltaic applications such as thin-film transistors (TFTs) (see, e.g., [37]) and solar cells. Nanocrystalline Si solar cells are more stable than a-Si:H-based solar cells [38, 39], since nc-Si:H is relatively free from light-induced degradation. Taking p-i-n structure, the open circuit voltage  $V_{\text{oc}}$  is achieved to be 600 meV and the efficiency is approaching 10% [40, 41].

The applications of TFTs in large-area flat panel displays are very attractive using Si thin films. TFTs based on hydrogenated amorphous silicon films (a-Si:H) have been used in massive produced displays and sensor arrays. Although the mobility (TFT mobility) of a-Si:H TFTs is low ( $\sim 1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ), they are suitable as the pixel switches in active matrix liquid crystal displays. This is due to a capability of

fabrication with low cost and large area ( $> 15 \text{ in}$ ), with high yield and very uniform performance. To get high-resolution displays, larger electron mobility should be required in the pixel TFTs. The major drawbacks for a-Si:H-based TFTs are (i) low electron mobility and (ii) low stability: the threshold voltage  $V_{\text{th}}$  shifts with successive switching. The TFT mobility using nc-Si:H is reaching  $\sim 20 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  and higher stability is reported. Note that the TFT mobility in polycrystalline Si by pulsed laser crystallization (PLC) is reported to be  $\sim 600 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  [20]. The challenge to get higher mobility and higher stability in nc-Si:H films is continuing.

## 6. CONCLUSIONS

The study of hydrogenated nanocrystalline Si (nc-Si:H) is advancing day by day, since nc-Si:H films are regarded as promising materials for commercially accepted large-area solar cells and thin-film transistors. The nc-Si:H films take very complex structures consisting of disordered (amorphous) and ordered (crystalline) forms. The quantitative explanation of the electronic and optical properties of nc-Si:H, therefore, is very hard.

A current understanding of nc-Si:H films has been briefly reviewed in the present chapter, including preparation methods and spectroscopic characterization. It was shown that an effective medium approximation was useful to explain the electronic transport and optical properties in nano- or microcrystalline Si films, which strongly depend on the volume fraction of crystallite. The present chapter also made clear the following unknown properties of these complicated materials: (i) The Hall mobility is sublinearly proportional to the crystallite size, which can be attributed to a fractal nature of the microcrystalline system. (ii) The nonactivated temperature variation of dc conductivity at relatively high temperatures is well explained in terms of the band transport across the potential barriers (percolation-limited thermionic emission process). Hopping transport may dominate only at lower temperatures.

All results predicted here may help further understanding and development of nano-, micro-, and polycrystalline materials.

## GLOSSARY

**EMA** Effective medium approximation, one of the percolation approximations which are useful to calculate the electrical and optical properties in condensed matters.

**Variable-range hopping** One of the hopping mode of electron hopping between localized states, which has been proposed by Mott.

## 1. INTRODUCTION

The real confined systems, also called low-dimensional systems or nanostructures, are any three-dimensional quantum systems in which the carriers are free to move in only two, one, or even zero dimensions.

In nanostructured semiconductors the concept of quasi-particles is related to electrons, holes, and excitons; the characteristic length that defines the confinement degree is the effective Bohr radius of excitons,  $a_B^*$ . This magnitude may be considerably larger than lattice constant,  $a_L$ . Therefore, it is possible to create a mesoscopic structure which is, in one, two, or three dimensions, comparable to or even lesser than  $a_B^*$  but still larger than  $a_L$ . In these structures the elementary excitations will experience quantum confinement, resulting in a finite motion along the confinement axis and an infinite motion in other directions. This way, one deals with the so-called nanostructured systems or, in a broad accepted classification, the quasi-two-dimensional systems (single heterostructures, quantum wells, multiple quantum wells, and

superlattices), quasi-one-dimensional systems (quantum well wires), and quasi-zero-dimensional systems (quantum dots, crystallites, and quantum boxes).

The confinement degree of quasi-particles is related to the magnitudes  $a_B^*$  and the quantum confinement size  $d$  (or  $r_0$ ); two regimes can be readily distinguished: the weak confinement regime and the strong confinement regime. The weak confinement regime corresponds to the case when the nanostructure confinement size [ $d$  (or  $r_0$ )] is smaller but still a few times larger than  $a_B^*$ . The mathematical condition is  $a_B^* \ll d$  (or  $r_0$ ). In this case, the electron and hole are correlated; the exciton can be envisioned as a quasi-particle moving around inside the nanostructure with only little energy increment due to confinement. In this case, the infinite potential well model (within the single band effective mass approximation) gives a reasonable description of the experimentally observed shift in the exciton ground state energy.

The strong confinement regime corresponds to the condition  $a_B^* \gg d$  (or  $r_0$ ). In this case the confinement effect dominates over the Coulomb potential, and the electron and hole should be viewed as individual particles predominantly in their respective single particle ground states with only little spatial correlation between them. In this regime the exciton in the nanostructure “feels” the boundary effects strongly, and the inclusion of a finite height for the confining potential barrier has become an important requirement in order to account for recent experiments on the optical properties of small nanostructures.

In general the nanostructures are fabricated using two different materials A and B, considering that A and B are semiconductors with bandgaps  $\varepsilon_g^A$  and  $\varepsilon_g^B$ , respectively. In the nanostructure growth process, one of the materials is deposited over the other one and a potential barrier is formed in the interface due to the difference of bandgaps. According to the gap positions and values, three types of

nanostructures can be obtained which we will identify as type I, II, and III nanostructures (see Fig. 1).

In the type I nanostructures, B material is a barrier for both the valence and conduction electrons, which are localized within the same A material. Examples of type I nanostructures are GaAs–Ga(Al)As,  $\text{Ga}_{0.47}\text{Al}_{0.53}\text{As}$ –InP, GaSb–AlSb, etc.

In the type II nanostructures (also called staggered nanostructures) one material acts as a well for conduction electrons but as a barrier for valence electrons. Examples of the type II nanostructures are InP– $\text{Al}_{0.53}\text{In}_{0.48}\text{As}$  where the electrons are mostly in the InP material and the holes in  $\text{Al}_{0.53}\text{In}_{0.47}\text{As}$ , and InAs–GaSb where the electrons are mostly in the InAs semiconductor and the holes are mostly in the GaSb semiconductor. In type II nanostructures, we deal with interface excitons where the interacting particles are spatially separated, a situation which is reminiscent of that of the bound impurity states created by impurities placed in the barriers of the quantum structures.

The general importance of the confined systems and nanostructured materials has been widely suggested to be a key process in the future of nanotechnology and of interest in diverse fields including magnetics, pharmaceuticals, aerospace, nanoelectronics, optoelectronics, etc.

Several methods for obtaining the confined systems exist, namely, the reduction of some spatial directions to quantum scale, by the application of any kind of fields or by limiting the borders in the synthesis of the materials.

Several forms of classifying the confined systems exist; the most universal considers the number of directions where the particle could move freely. For example, quasi-two-dimensional systems (Q2D) have two directions for the free movement of the carriers and one confined spatial direction (see Fig. 2). The Q1D system has only one direction for free movement and two directions of confined movement where the carriers are compelled to move in a reduced space of quantum scale (see Fig. 3). The Q0D systems have no directions for free movement; the three spatial directions are confined (see Fig. 4). The energy spectrum in the spatial direction of confinement is always discrete if the particle remains totally confined and discrete and continuous if the particle remains partially confined.

Recently, a great number of experimental type articles have been published which are related to the impurity states and atomic systems confined in different types of nanostructures; we will mention some of them. Cheong and Jeong [1] studied the GaAs/AlGaAs quantum wells

using reflectance-based optically detected resonance spectroscopy. This technique consists of monitoring changes in the strength of the  $e_1h_1$  excitonic reflectance feature induced by the far-infrared laser beam. A reflectance signal is modulated when the far-infrared photon energy matches the energy difference between two electronic states of the system under study. The more conventional optically detected resonance spectroscopy with which the interband photoluminescence intensity is monitored will be referred to as photoluminescence based optically detected resonance [2–6]. By comparing photoluminescence optically detected resonance and reflectance-based optically detected resonance results from the same samples it was established that reflectance-based optically detected resonance was sensitive to both neutral and negatively charged donors. In this work they proved the utility of this new technique, reflectance-based optically detected resonance, for investigating the electronic states of neutral and negatively charged donors in several GaAs/AlGaAs multiple-quantum-well samples. The high sensitivity of reflectance-based optically detected resonance reveals new internal donor transitions of negatively charged donors. These results were agreed with theoretical calculations [6, 7].

Zhu and Xu [8] presented advances in nanoscopic probing techniques that have led to the development of direct spatial and spectroscopic methodologies, which have revealed a wealth of information about single quantum dots. These techniques, combined with the favorable properties of naturally formed quantum dots, have allowed one to

treat a single exciton confined to a quantum dot as a single solid state quantum absorber in analogy to atomic and molecular systems. Direct measurements on these systems, including absorption and coherent nonlinear spectroscopy, have revealed dipole moments and dynamic time scales of the individual excitations. Combined with microscopy, these probes have revealed global properties of the quantum dot system.

Zhao et al. [9] experimentally and theoretically studied the electronic structures of acceptors confined at the center of  $\text{In}_x\text{Ga}_{1-x}\text{As}/\text{Al}_{0.3}\text{Ga}_{0.7}\text{As}$  quantum wells. The aim of this investigation was to explore the effects of biaxial deformation potential on acceptors confined in quantum well structures. Satellite peaks related to  $2S$  and  $2P$  of the confined acceptors were observed in selective photoluminescence spectra. The deduced energy separations between the acceptor heavy-hole-like ground state and different excited states were compared with the theoretical calculated results. The impurity states were calculated using a four-band effective mass theory, in which the valence band mixing as well as the mismatch of the band parameters and the dielectric constants between well and barrier materials were taken into account. An excellent agreement between experimental and theoretical data was found.

In [10] coherent transport in Si metal–oxide–semiconductor field-effect transistors with nominal gate lengths 50–100 nm and various widths at very low temperature were investigated. Independent of the geometry, localized states appear when  $G \cong e^2/h$  and transport is dominated by resonant tunneling through a single quantum dot formed by an impurity potential. They found that the typical size of the relevant impurity quantum dot is comparable to the channel length and that the periodicity of the observed Coulomb blockade oscillations is roughly inversely proportional to the channel length. The spectrum of resonance and the nonlinear  $I$ – $V$  curves allowed them to measure the charging energy and the mean level energy spacing for electrons in the localized state. Furthermore, they found that in the dielectric regime the variance  $\text{var}(\ln g)$  of the logarithmic conductance  $\ln g$  is proportional to its average value  $\langle \ln g \rangle$ , consistent with one-electron scaling models.

On the other hand, there are many theoretical works carried out on the impurity states and atomic systems confined in the nanostructures. We will mention some of them. Thus, in [11] the effect of a spatially dependent effective mass in a finite  $\text{GaAs}/\text{Al}_x\text{Ga}_{1-x}\text{As}$  parabolic quantum well with a magnetic field on hydrogenic impurity ground state ( $1S$ ) binding energies and lowly excited state ( $2p_{\pm}$ -like) was calculated, respectively, as a function of well width and magnetic field and impurity position by using the one-dimensional method. They compared their results with square quantum wells and without the effect of spatially dependent effective mass result. The physical meaning of the square wavefunction was discussed.

Hsieh and Chuu [12] studied the binding energy of the ground state of a hydrogenic impurity located at the center of a multilayered quantum wire within of the effective mass approximation. The multilayered quantum wire consisted of a core wire (GaAs) coated by cylindrical shell ( $\text{Ga}_{1-x}\text{Al}_x\text{As}$ ) and then embedded in the bulk ( $\text{Ga}_{1-x}\text{Al}_x\text{As}$ ). The calculation was performed, by using a trial wavefunction. To make a comparison, the ground and excited state ( $1s$ ,  $2p$ , and  $3d$  states) binding energies of a hydrogenic impurity located at the center of a single-layered quantum wire were also calculated. It was found for small wire radius that the ground state binding energy of the hydrogenic impurity located at the center of a multilayered quantum wire behaves very differently from that of a single-layered quantum wire.

Hsieh [13] calculated the ground state binding energy of the hydrogenic impurity located at the center and off center of a multilayered quantum wire in a constant magnetic field applied parallel to the wire axis by using the effective mass approximation. His system was constructed as a core wire made of GaAs surrounded by a cylindrical shell of  $\text{Al}_x\text{Ga}_{1-x}\text{As}$  and then embedded in the bulk of  $\text{Al}_y\text{Ga}_{1-y}\text{As}$ . A variational trial wavefunction was proposed. It was found for a small wire radius that the ground state binding energy of a hydrogenic impurity located at the center of a multilayered quantum wire behaves very differently from that of a single-layered quantum wire. The calculation showed that the binding energy depends on the potential profiles, potential barrier height, impurity position, shell thickness, magnetic field, and the difference between the Al concentration contained in the shell and bulk regions. His trial function was also able to reproduce the binding energies of a hydrogenic impurity located at the center of a single-layered quantum wire; a good agreement with the previous results was obtained.

In [14] the ground state energies of several interacting electrons confined in a parabolic dot in two dimensions were obtained by using hyperspherical coordinates and high order perturbation theory. The effect of a perpendicular magnetic field is to change the ground state discontinuously in orbital angular momentum  $L$ . The preferred values of  $L$  for the ground state and the associated electronic structures were studied in detail. It was found that the effective interaction between two electrons moving in different cyclic orbits is a short-range attraction matched a long-range repulsive tail. Because of this, electrons tend to fill adjacent cyclic orbits and form bunches in the ground states. The effects of an impurity ion were also considered.

Chen et al. [15] employed a simple approximation treatment, which combines the spirit of the variational principle and the perturbation approach to study the confined phonon effect on the binding energy of a hydrogenic impurity located inside a quantum well. The electron bulk longitudinal optical phonon and the electron surface phonon interactions were both taken into account in their calculation. The image charge effects may be significant if there is a large dielectric discontinuity between the well and the surrounding medium. However, since the purpose of this work is to concentrate on the confined phonon effects on the impurity binding energies, the image effects were not taken into account in their calculation.

Sali et al. [16] reported a calculation of the photoionization cross-section describing the excitation of a shallow bound electron from the hydrogenic donor impurity ground state to three of the conduction subbands  $n_x$ ,  $n_y$ , and  $n_z$  corresponding, respectively, to the  $x$ ,  $y$ , and  $z$  directions of the dot in the case of an infinite well model. The photoionization cross-section associated with a hydrogenic shallow donor impurity was calculated as a function of the excitation energy  $\hbar\omega$  in a GaAs quantum dot for several values of the dimensions of the dot and for an on-center donor impurity and off-center donor impurities.

Reyes-Gómez et al. [17] extended the fractional-dimensional space approach to study exciton and shallow-donor states in symmetric-coupled GaAs/Ga<sub>1-x</sub>Al<sub>x</sub>As multiple quantum wells. In this scheme, the real anisotropic “exciton (or shallow donor) plus multiple quantum well” semiconductor system is mapped, for each exciton (or donor) state, into an effective fractional-dimensional isotropic environment, and the fractional dimension is essentially related to the anisotropy of the actual semiconductor system. Moreover, the fractional-dimensional space approach was extended to include magnetic-field effects in the study of shallow-impurity states in GaAs/Ga<sub>1-x</sub>Al<sub>x</sub>As quantum wells and superlattices. In their study, the magnetic field was applied along the growth direction of the semiconductor heterostructure and introduced an additional degree of confinement and anisotropy besides the one imposed by the heterostructure barrier potential. The fractional dimension was then related to the anisotropy introduced both by the heterostructure barrier potential and magnetic field. Calculations within the fractional-dimensional space scheme were performed for the binding energies of 1s-like heavy-hole direct exciton and shallow-donor states in symmetric-coupled semiconductor quantum wells, and for shallow-impurity states in semiconductor quantum wells and superlattices under growth-direction applied magnetic fields. Fractional-dimensional theoretical results were shown to be in good agreement with previous variational theoretical calculations and available experimental measurements.

Reference [18] presented that interelectron interactions and correlations in quantum dots can lead to spontaneous symmetry breaking of the self-consistent mean field, resulting in the formation of Wigner molecules. With the use of spin-and-space unrestricted Hartree–Fock calculations, such symmetry breaking was discussed for field-free conditions, as well as under the influence of an external magnetic field. Using as paradigms impurity-doped (as well as the limiting case of clean) two-electron quantum dots (which are

analogous to heliumlike atoms), it was shown that the interplay between the interelectron repulsion and the electronic zero-point kinetic energy leads, for a broad range of impurity parameters, to the formation of a singlet ground state electron molecule, reminiscent of the molecular picture of doubly excited helium. A comparative analysis of the conditional probability distributions for the spin-and-space unrestricted Hartree–Fock and exact solutions for the ground state of two interacting electrons in a clean parabolic quantum dot revealed that both of them describe the formation of an electron molecule with similar characteristics. The self-consistent field associated with the triplet excited state of the two-electron quantum dot (clean as well as impurity doped) exhibits a symmetry breaking of Jahn–Teller type, similar to that underlying formation of nonspherical open-shell nuclei and metal clusters. Furthermore, they showed that impurity and/or magnetic field effects can be used to achieve controlled manipulation of the formation and pinning of the discrete orientations of the Wigner molecules. Impurity effects were further illustrated for the case of a quantum dot with more than two electrons.

In [19] Buonocore et al. presented the results of their theoretical studies on the influence of hydrogenic impurities on the electron localization in a deformed quantum wire. Although their primary interest was on porous silicon, it must be said that the calculation methods they illustrated are very general and can be applied to all those situations where the effects of the nanostructure geometry cannot be neglected.

Kayanuma [20] showed that the eigenvalue problem for bound states of hydrogenic donors located at the edge of a semiconductor surface could also be solved exactly for arbitrary values of the edge angle. Considering a neutral donor located at the edge of a crystal surface, which is formed by an intersection of two flat surfaces, he chose the edge line as the  $z$  axis. The two surfaces were assumed to be given by  $y = \pm \tan(\phi_0/2)x$ , with  $\phi_0$  the angle between edges. For  $0 < \phi_0 < \pi$ , the crystal surface has a wedgelike shape, but for  $\pi < \phi_0 < 2\pi$ , it has a notch. The polar coordinates  $(r, \theta, \varphi)$  of the electron were defined in the usual way. It was assumed that the electron is completely confined in the region  $-\phi_0/2 \leq \phi \leq \phi_0/2$ . Throughout his work, he adopted the effective mass approximation. The attractive potential due to the positive ion core was given by  $V(r) = -e^2/\kappa r$ , in which  $\kappa$  is the dielectric constant of the crystal. The penetration of the wavefunction outside the crystal and the effect of the image potential were both neglected. All these effects should be taken into account as a refinement of the model in actual analyses of experimental data [21]. Levine’s model of the surface donor [22] was included in his model as a special case.

Kandemir and Cetin [23] studied the dependence of low-lying energy levels of impurity magnetopolaron subjected to a 3D parabolic potential on both magnetic field and spatial confinement length. To achieve this, they restricted to the case of bulk longitudinal optical (LO) phonons and introduced a trial wavefunction taken to be the direct product of an electronic part and a part of coherent phonons. They were also concerned with the study of the effects due to the electron–LO–phonon interaction, quantum confinement, and magnetic field on the cyclotron masses associated with

the transitions between the ground and first-excited states of an electron bound to a hydrogenic impurity in a 3D parabolic potential. They found an analytical expression for the impurity magnetopolaron energy that allows them to perform a systematical analysis of the effects of both magnetic field and spatial confinement on the binding energies of impurity magnetopolaron in quantum dots, quantum well wires, and quantum wells. They established a unified treatment that allows them to make comparisons between the results of binding energies of impurity magnetopolarons in these three systems.

Schlottmann [24] studied an Anderson impurity placed at the center of a nanosized metallic sphere. The main difference with the standard mixed-valence problem is that the energy spectrum of the host is now discrete. Similar to the Kondo impurity [25], the problem could be mapped onto the Bethe ansatz solution of the Anderson model [26, 27]. The model and the Bethe ansatz equations diagonalizing were solve numerically for the ground state and the lowest energy charge and spin excitations. The energies of the states increase monotonically with the  $f$ -level energy. For an even number of electrons in the system (in  $s$  states and localized at the impurity), the impurity in the ground state is spin compensated into a spin singlet via the Kondo effect. The specific heat and the susceptibility are exponentially activated at low  $T$  due to the discreteness of the energy spectrum, with the gaps given by the lowest energy charge and spin excitations. The model also represented a quantum dot as a side branch to a short quantum wire.

Yen [28] theoretically studied resonant states of shallow donor arbitrarily lying in a two-dimensional quantum well structure based on the multisubband model. The density-of-states spectra of the resonant states were obtained using the resolvent operator technique. For illustration, he calculated the binding energy, the density of state spectrum width, and the resonance energy shift of the  $2p_0$  state in a quantum well as a function of the impurity position. Considerable coupling was found. It caused a capture or escape time as short as  $\approx 0.1$  ps.

Apalkov and Chakraborty [29] considered a system of an incompressible quantum Hall liquid in close proximity to a parabolic quantum dot containing a few electrons. They observed a significant influence of the interacting electrons in the dot on the excitation spectrum of the incompressible state in the electron plane. Their calculated charge density indicates that, unlike the case of an impurity, interacting electrons in the dot seem to confine the fractionally charge excitations in the incompressible liquid.

Yang and Hsu [30] calculated the binding energy of the ground state of hydrogenic impurity seated at the center of quantum well GaAs/Ga<sub>1-x</sub>Al<sub>x</sub>As with the inclusion of the effect due to the image charges (excluding the self-energy image potential). For a given depth of the quantum well, they found that the absolute value of the image potential energy without the metallic mirror is equal to that with a fixed metallic mirror while a certain width of the quantum well is met. Hence, it was proposed that the binding energy of the shallow impurity ground state in the quantum well with and without the metallic mirror could be separately measured by the variation of the width of quantum well. The contribution of the image potential energy to the binding

energy of the shallow impurity ground state could then be deduced.

Essaoudi et al. [31] discussed the stability of an exciton bound to an ionized donor impurity in a GaAs/Ga<sub>1-x</sub>Al<sub>x</sub>As semiconductor quantum well subjected to an external magnetic field for different values of the impurity location. The binding energy was calculated in the effective mass approximation by means of variational method. At zero magnetic field, the complex becomes unstable when the impurity is far away from the center of the well. When the magnetic field increases, the stability holds in all cases for an impurity located at the center of the well.

Brandi et al. [32] treated the interaction of light with a spherical GaAs/AlGaAs quantum dot within a dressed-band approach. The Kane band structure scheme was used to model the GaAs bulk semiconductor and the interaction with the laser field is treated through the renormalization of the semiconductor energy gap and conduction/valence effective masses. This approach, valid far from resonances, was used to investigate the light shifts induced in the electronic and shallow on-center donor states in semiconductor quantum dots, which were shown to be quite considerable. This model calculation could be extended to include magnetic-field effects, and it was suggested that the strong localization of the electronic and impurity states due to the quantum dot and enhanced by laser confinement could prove useful for manipulation of electronic and donor states in some proposed solid-state-based quantum computers.

Stébé et al. [33] concentrated their study on the  $(D^+, X)$  complex resulting from the binding of an exciton  $X$  to an ionized hydrogenic donor impurity  $D^+$ . Its possible existence was predicted in 1958 by Lampert [34]. Its stability and binding in 3D semiconductors was the subject of several theoretical studies within the effective-mass approximation as a function of the electron to hole effective mass ratio  $\sigma = m_e/m_h$ . As a result, it appeared [35] that the  $(D^+, X)$  complex is stable if  $\sigma \leq \sigma_c = 0.454$ . It was expected that due to the quantum confinement, the  $(D^+, X)$  complex will be more stable in quantum wells than in 3D semiconductors. There are few measurements available [36–40] on an exciton bound to ionized donors in quantum wells. From the theoretical point of view, variational determinations of the ground state energies [41, 42] have first proven that the  $(D^+, X)$  complex with the impurity located at the center of the well is stable in GaAs/Ga<sub>1-x</sub>Al<sub>x</sub>As quantum wells with  $x = 0.15$  and  $x = 0.30$ .

## 2. METHODS OF SYNTHESIS AND FABRICATION OF NANOSTRUCTURED MATERIALS

There is increasing interest in producing structures of nanometer size for use in device fabrication and proof of physics laws in nanometer sized structures. This is a growing field and nowadays is very important for investigating new techniques for nanometer device fabrication.

The most used materials for production of nanostructured materials are, in first place, semiconductors and metals and, in second place, dielectrics, magnetic, and superconductor compounds. They are also manufactured using organic materials, polymers, biomaterials, etc.

Nowadays there are so many methods of synthesis and production of nanostructured materials, in a laboratory scale, but the most important are those where high quality quantum nanostructures are achieved. These methods produce materials that have one atomic layer precision, with abrupt grown interfaces with one monolayer roughness and with great control for purity and doped impurities.

In addition to this technology, in order to guarantee the high quality of the nanostructured materials, the investigation laboratories need to count on several characterization techniques *in-situ*. Independently of the dimensionality of the grown nanostructures, the most used and known techniques for the production or fabrication of the different kinds of nanostructured materials are molecular beam epitaxy (MBE), metal organic chemical vapor deposition (MOCVD), and lithography, also known as nanolithography.

## 2.1. Molecular Beam Epitaxy

MBE is a method by means of which a semiconductor, such as GaAs, is grown in an ultrahigh vacuum environment by supplying molecular and/or atomic beams of Ga, As, and other constituents onto a cleaned crystalline substrate [43–51]. Because one can prepare semiconductor films of high quality by MBE with a precision in thickness of one atomic layer or better, it is now widely used in all nanostructured materials. MBE is one of the best methods for the preparation of a very flat surface of one semiconductor on which another semiconductor of an arbitrary thickness can be deposited. This feature allows one to control the composition profile and thereby to implement an artificial potential  $V(z)$  as a function of position  $z$  along the direction of stacking. A number of studies have shown, however, that interfaces of GaAs–AlAs (or AlGaAs) grown by MBE are generally abrupt but have a roughness  $\Delta$  of one monolayer,  $a = 2.83 \text{ \AA}$ . Hence it is very important to clarify the origin and nature of such roughness and to establish a method for controlling the atomic structure of interfaces. In addition, one should note that the atomic structure of an interface is usually a frozen image of the freshly grown surface and therefore provides valuable information on the microscopic process of epitaxial growth. On the other hand, the high purity of the low-dimensional system obtained by MBE indicates that the mobility is dominated mainly by scattering by phonons. The advantages of epitaxial growth by MBE, with respect to other methods or technologies, are multiple techniques *in-situ* that permit an absolute control of the ground parameters of the grown structure, such as size, high purity, abruptness and flatness of interface and impurities in doped heterostructures, and the ultrahigh vacuum environment that it possesses.

## 2.2. Metal Organic Chemical Vapor Deposition

The MOCVD method is the most useful and conventional process for fabricating thin layer semiconductor heterostructures. In general MOCVD has a reaction chamber that is basically dependent upon the heating system, which fits for long growth run. It is possible to use a radio frequency

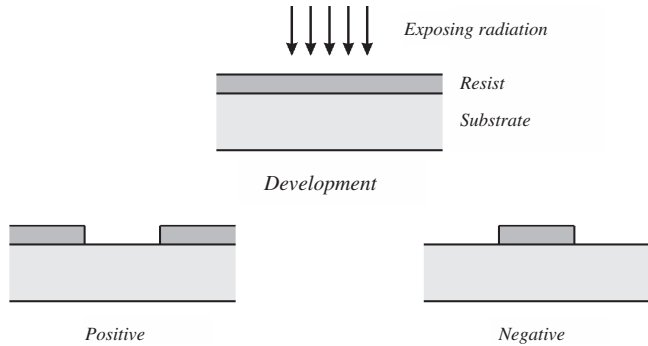

induction coil as an alternative heater; there is a possibility of dissociation of gases, which produces radicals due to a plasma discharge in reduced pressures, and then it is necessary to employ a large-scaled electric power supply in connection with a precise electric circuit. However, in the case of synthesis of the II–VI compound semiconductors, it should be pointed out that there are several problems concerning the difficulty in precisely controlling the II/VI mole ratio because of the high dissociation pressure of VI elements and also the premature reaction taking place in the vapor phase prior to epitaxial deposition on a substrate. In order to avoid such problems, Yamada [52] has used new metal organic sources diluted in a He gas, namely, dimethylzinc (DMZn) with a concentration of 1.06% in a He gas, for the growth of cubic-structured  $\text{Cd}_x\text{Zn}_{1-x}\text{S}$ –ZnS strained-layer multiple quantum wells [53–55]. A mixture of 10%  $\text{H}_2\text{S}$  in a  $\text{H}_2$  gas was used as the sulfur source. Its MOCVD apparatus consists of a main reaction chamber and a sample exchange supplemental chamber with a transfer tube. A special feature is that they employ a halogen lamp capable of heating substrates up to 600 °C by infrared radiation. Two chambers are constructed for all VI materials and each inner wall is coated with TiN films, to avoid accidental impurity contamination. In order to control the gas flow ratio of II/VI, a personal computer connected to a relay box linked to an interface which was capable of switching both the piezovalves of the MFC (mass flow controller) and air valves on or off is used. Then, all of gas sources flowed directly into the MFCs, so that the bubbling system by a carrier gas was unnecessary for the metal organic (DMZn and DMCD) gas flow as well as the  $\text{H}_2\text{S}$  gas flow [56, 57]. Therefore, the process using the low-pressure MOCVD system with all gaseous sources has proven to be advantageous for precise control of II/VI mole ratio as well as lower temperature growth (350 °C) of the II–VI compound heterostructures.

## 2.3. Lithography

It is instructive to consider the conventional but advanced forms of lithography as practiced today. As it has developed for the semiconductor industry, lithography is the creation of a pattern in a resist layer, usually an organic polymer film, on a substrate material. A latent image, consisting of a chemical change in the resist, is created, by exposing the desired area with some form of radiation. The pattern is developed by selectively removing either the exposed areas of resist (for a positive resist) or the unexposed areas (for a negative resist). These processes are shown schematically in Figure 5. The development of a polymeric resist is usually done with a solvent that brings out the pattern based on the solubility difference created by exposure.

### 2.3.1. Overview of Lithography

Electrons, ions, and photons can all be used for exposure in the lithography process. Because of intrinsic scattering mechanisms, in no case can the energy provided by the exposing radiation be confined to arbitrarily small volumes. First, the radiation or particle beam cannot be confined arbitrarily because of diffraction, Coulomb repulsion

**Figure 5.** Schematic diagram of the basic lithographic steps of resist exposure and development.

among particles, optical limitations, or other effects. Second, the energy incident on a resist layer spreads in the film, because of intrinsic scattering mechanisms in the solid.

The figures of merit for a resist/developer system include: the sensitivity to the exposure dose dependence of the resist response, the resolution dictating the minimum feature size, and the suitability of the resist for pattern transfer. While the sensitivity and contrast of a system are vital in determining the speed and process latitude, it is the resolution and pattern transfer utility that are most important to research level nanostructure fabrication.

Inorganic resist materials exist and have been applied in the high resolution of the field. Related processes include vapor or plasma developments that operate on difference in gas phase or plasma reactivity rather than liquid development based on solubility differences. Self-developing resists are of some importance in the high resolution of the area. For these materials the exposing radiation volatilizes the resist, creating a pattern in the resist without a development step. By this method, structures on the order of unit cell dimensions were made some years ago [58].

### 2.3.2. Photon Lithography

The use of photons for high resolution of the lithographic exposure is a broad field that includes most of the lithography in use today. This is the technique most widely used by the semiconductor industry and illustrates the general technique of lithography. It can be taken to include X-ray lithography and deep and near-ultraviolet photolithography. Only the shortest wavelengths are directly relevant to high resolution of the fabrication. The projection and proximity printing processes to be described are analogous to processes that could be used at nanometer dimensions for parallel printing with electrons or ions.

In projection lithography a mask containing the desired pattern is demagnified by an optical system and projected on the resist layer. This is desirable since there is no damaging contact between the mask and wafer, and the fabrication of the mask is not so critical since it is demagnified. The resolution is limited, however, by diffraction and the quality of the optics. The diffraction limit for the minimum resolvable grating period is usually taken as the Rayleigh criterion for the overlap of the diffraction peaks, which is approximately

$$\text{minimum line resolvable spacing} \approx \frac{\lambda}{\text{NA}} \quad (1)$$

where  $\lambda$  is the wavelength and NA is the numerical aperture of the optical system, which is of the order of one. The shortest wavelength to be used with conventional optics is about 193 nm from an excimer laser source. The use of wavelengths much shorter than this is limited by absorption in optical materials. While the technology constantly improves, with better optics, improved contrast enhanced resists, and sources of shorter wavelength, the limit of far-field diffraction is a fundamental one that prevents its use for feature sizes smaller than the wavelength of light. Photolithography is essentially ruled out for fabrication at dimensions below 100 nm.

Projection systems employing X-rays would reduce diffraction effects, but the problem of fabricating optics to use in the X-ray region remains. Work in this area is advancing, with the development of multilayer mirrors and X-ray mask technology.

Proximity printing allows the 1:1 replication of a mask pattern. The effects of near field diffraction can be arbitrarily reduced by decreasing the distance between mask and substrate. Qualitatively, the minimum linewidth is

$$d \approx \sqrt{\lambda s} \quad (2)$$

where  $s$  is the separation between mask and substrate.

Proximity printing can be done effectively by X-ray exposure where the shorter wavelengths, of the order of 1 nm, allow much greater mask-substrate separation. With short wavelength X-rays, diffraction can effectively be ignored for attainable gaps of the order of a few micrometers. However, the exposure of polymeric resist by X-rays takes place primarily through the generation of photoelectrons, which then expose the resist by the same mechanisms as an electron beam. The range of the photoelectrons in the resist will limit the resolution. Since the photoelectrons can have energies up to that of the X-rays, their range can be greater than 100 nm for the shorter wavelength X-rays. We can see qualitatively that there is a trade-off between diffraction and the range of photoelectrons in limiting the resolution. Perhaps the most significant problem with X-ray printing is the creation of a durable and stable mask of high contrast. All materials absorb X-rays, so the transparent area of the mask must be very thin or nonexistent. An absorbing metal, such as gold supported on a thin film such as  $\text{SiN}_4$ , is one type of mask. Some of the smallest features replicated by X-rays were 17.5 nm in extent, fabricated by using edge-evaporated metal as a mask. Some other high-resolution process is necessary to generate the mask features; in most cases this means electron beam lithography.

### 2.3.3. Electron Beam Lithography

This technique has now developed substantially and has been used extensively for the generation of photolithographic masks. Schemes for electron beam 1:1 printing similar to those using X-rays or ions have been explored but generally not for the creation of nanostructures. Because of the ready availability of small electron sources and the high

quality of electron optics, electron beams can be focused to dimensions less than 1 nm and scanned with great accuracy.

In scanned electron beam lithography, a small electron source is imaged on the substrate through a series of electromagnetic lenses in an electron-optic column. The beam can be rapidly scanned over the sample to trace out any desired pattern. In the normal exposure of organic polymer resist, the electron beam causes the breaking of bonds or induces additional chemical bonds to be formed. This results in different molecular sizes in the exposed versus the unexposed areas, and this can be translated into differences in solubility in an appropriate developer.

The problem with electron beams is to confine the deposition of energy to a small area in the resist. There are several scattering processes in the material that lead to the deposition of energy at distances remote from the initial impact point of the electron. This leads to the well-known proximity and resolution limiting affects.

The scattering effect of longest range is the backscattering of electrons, resulting in large-angle scattering with energies near that of the incident electron. The range of these backscattering electrons can be many micrometers for typical electron beam energies. This range has been determined to have a dependence power law, proportional to (Energy)<sup>1.7</sup>, over a wide electron energy range. This presents the greatest problems for energies where the electron range is comparable to the feature spacing [59].

Because of small-angle scattering events, forward scattering tends to spread the incident beam passing through the resist. The scattering angles decrease with electron energy, and the spread of the beam is obviously more important for thicker resist layers.

With electron beams it is possible to expose such small areas that the molecular size of the resist can become significant. This can be of the order of 10 nm for large organic molecules. The grain size of a polycrystalline layer to be patterned can also become larger than the size of the desired features. Clearly there are many new materials considerations to be addressed at nanometer dimensions. Another consideration important for the ultrasmall size range is the time it takes to write a pattern by a scanning serial process. This time is inversely related to the size of the pixel. The smaller the electron beam size, the lower the current available for exposure and the longer the exposure time. The resists of highest resolution also require higher exposures. Fortunately the areas involved in exposures for devices are small. The time for writing is insignificant for experimental devices where only a few objects are being written, and the benefits and success of scanned electron beam lithography have been great.

A recently studied alternative approach to scanned electron beam lithography is to use technology related to the scanning tunneling microscope to scan a low energy electron beam in close proximity to the surface. The use of low energy beams allows only thin conducting layers to be modified by the electron beam. There are exciting possibilities for manipulating individual atoms, as demonstrated by IBM researchers. For dimensions larger than this, the flexibility and capabilities of scanned beams as opposed to scanned sources are, as yet, more significant for fabricating devices for research.

### 2.3.4. Ion Beam Lithography

The use of ion beams is diverse, with a great range of ion species and energies. Both collimated beams of large area and scanned focused beams have been applied. The interaction of the ion beam with a solid can be to expose resist, which is most appropriate for high energy and low mass ions. It is also possible to etch away material, to change the chemistry by implantation, to deposit films selectively, or to induce structural changes within a selected area [60].

For ion lithographic printing, the effects of diffraction are negligible, because of the extremely small de Broglie wavelengths. Masks of high contrast are a challenge to fabricate, since the ions are absorbed in all solids. The use of ion channeling masks consisting of absorbers on oriented single crystals and of shadow masks supported by grids has been demonstrated. These masks are usually defined by electron beam lithography. Considerations of ion scattering in solids are similar to those for electrons but are less severe.

Scanned focused beams can be used to draw patterns of any desired shape. The limits of the size of the ion source and the quality of focusing optics have been the factors limiting focused beam resolution. The quality of ion optics is poor compared to light optics and aberrations have limited the size of the spot. Advances with liquid metal field emitters have been significant in producing bright ion sources. Scanned focused systems with liquid metal sources have been demonstrated with beam diameters as small as about 20 nm.

In the exposure of resist by scanned ion beams there is no proximity effect of the type seen for electron beams, and energy is transferred very efficiently to the resist. By appropriate choices of resist processes, it is possible to expose thin imaging layers very efficiently without ion damage to the substrate. Resist features as small as 20 nm have been demonstrated by exposure using focused systems with liquid metal ion sources. Direct ion milling with scanned focused beam or chemically assisted ion milling processes can be used to etch materials directly with impressive resolution approaching the size of the beam. However, the rates achieved limit this approach to removal of small volumes of material.

By implantation-enhanced disordering within selected areas, lateral quantum structures have been created in GaAs–AlGaAs heterostructures. These techniques allow for lateral modulation of the composition and the bandgap, without exposing surfaces.

## 2.4. Envelope Function Approximation

In this section we shall deal with the determination of eigenstates in the low-dimensional systems. The emphasis will be focused on a simple description of these eigenstates.

First, we shall present the assumptions used to derive the envelope function scheme. The reader will perceive that when the  $\vec{k}$  wavevector of carrier is zero, the algebra is relatively easy. Let see, in general way, what the method fundamentals are. The description is based on the dispersion relations of the host materials.

Remember that the electronic state in the periodic field is described by a Bloch function,

$$\phi_{\vec{k}n}(\vec{r}) = \exp(i\vec{k} \cdot \vec{r})u_{\vec{k}n}(\vec{r}) \quad (3)$$

which is periodic in the “ $\vec{k}$ ” space,

$$\phi_{\vec{k}n}(\vec{r}) = \phi_{\vec{k}+\vec{g},n}(\vec{r}) \quad (4)$$

where  $\vec{g}$  is a reciprocal lattice vector and  $n$  is the band number. Therefore, this function can be expressed as in a Fourier series in the reciprocal space,

$$\phi_{\vec{k}n}(\vec{r}) = \frac{1}{\sqrt{N}} \sum_{\vec{l}} a_n(\vec{r}, \vec{l}) \exp(i\vec{k} \cdot \vec{l}) \quad (5)$$

where  $\vec{l}$  is a direct lattice vector. The coefficients of this expansion,

$$a_n(\vec{r}, \vec{l}) = \frac{1}{\sqrt{N}} \sum_{\vec{k}} \phi_{\vec{k}n}(\vec{r}) \exp(-i\vec{k} \cdot \vec{l}) \quad (6)$$

are denominated the Wannier functions, They can also be written as

$$a_n(\vec{r}, \vec{l}) = \frac{1}{\sqrt{N}} \sum_{\vec{k}} u_{\vec{k}n}(\vec{r}) \exp[i\vec{k} \cdot (\vec{r} - \vec{l})] \quad (7)$$

Remember that  $N$  is the number of possible values of  $\vec{k}$  for the  $n$ th band in the first Brillouin zone.

One can appreciate that the Wannier functions do not depend on the  $\vec{k}$  wavevector, possessing also the following properties:

1. There are as many Wannier functions as points in the direct lattice and therefore as values of  $\vec{k}$  in the first Brillouin zone.  
Indeed, in Eq. (5) there are as many terms [and consequently many values of  $a_n(\vec{r}, \vec{l})$ ] as different values of  $\vec{l}$  (actually  $N$ ).
2. The Wannier functions are located at the proximity of each  $\vec{l}$  node of the direct lattice.
3. The Wannier functions obey also that

$$a_n(\vec{r}, \vec{l}) = a_n(\vec{r} - \vec{l}) \quad (8)$$

which is almost evident if we take into account the periodicity of  $u_{\vec{k}n}(\vec{r})$  in Eq. (7).

4. The Wannier functions satisfy the relation

$$a_n(\vec{r} - \vec{s}, \vec{l}) = a_n(\vec{r}, \vec{l} + \vec{s}) \quad (9)$$

which is obtained immediately from Eq. (8).

5. The Wannier functions are orthonormalized:

$$\int a_n^*(\vec{r}, \vec{l}') a_n(\vec{r}, \vec{l}) d\vec{r} = \delta_{nn'} \delta_{\vec{l}'\vec{l}} \quad (10)$$

That is,

$$\begin{aligned} \int a_n^*(\vec{r}, \vec{l}') a_n(\vec{r}, \vec{l}) d\vec{r} &= \frac{1}{N} \sum_{\vec{k}'} \sum_{\vec{k}} \exp[-i(\vec{k} \cdot \vec{l} - \vec{k}' \cdot \vec{l}')] \\ &\quad \times \int \phi_{\vec{k}',n'}^*(\vec{r}) \phi_{\vec{k}n}(\vec{r}) d\vec{r} \\ &= \frac{1}{N} \delta_{nn'} \sum_{\vec{k}} \exp[-i\vec{k} \cdot (\vec{l} - \vec{l}')] \\ &= \delta_{nn'} \delta_{\vec{l}'\vec{l}} \end{aligned} \quad (11)$$

### 2.4.1. Effective Hamiltonian

We will now look for the solution of the nonstationary Schrödinger equation for one electron in the crystal, under an external potential; that is,

$$\{\widehat{H} + \widehat{U}\} \psi(\vec{r}, t) = i\hbar \frac{\partial \psi(\vec{r}, t)}{\partial t} \quad (12)$$

where  $\widehat{H}$  is the Hamiltonian of the electron in the periodic field of crystal and  $\widehat{U}$  is the perturbation potential associated with the external field.

Let us look for a solution of the form

$$\psi(\vec{r}, t) = \sum_n \sum_{\vec{l}} f_n(\vec{l}, t) a_n(\vec{r}, \vec{l}) \quad (13)$$

where  $f_n(\vec{l}, t)$  is denominated envelope function of the  $n$ th band. Notice that the solution involves all the bands.

Substituting the Eq. (13) in (12), after multiplying by  $a_n^*(\vec{r} - \vec{l}')$  and integrating, we get

$$\begin{aligned} \sum_n \sum_{\vec{l}} \int a_n^*(\vec{r} - \vec{l}') [\widehat{H} + \widehat{U}] a_n(\vec{r} - \vec{l}) f_n(\vec{l}, t) d\vec{r} \\ = i\hbar \sum_n \sum_{\vec{l}} \frac{\partial f_n(\vec{l}, t)}{\partial t} \int a_n^*(\vec{r} - \vec{l}') a_n(\vec{r} - \vec{l}) d\vec{r} \end{aligned} \quad (14)$$

Considering the normalization condition of the Wannier functions and making the sum in the right side of the equation we get

$$\sum_n \sum_{\vec{l}} f_n(\vec{l}, t) \int a_n^*(\vec{r} - \vec{l}') [\widehat{H} + \widehat{U}] a_n(\vec{r} - \vec{l}) d\vec{r} = i\hbar \frac{\partial f_n(\vec{l}', t)}{\partial t} \quad (15)$$

Remembering that for the nonperturbed electron

$$\widehat{H} \phi_{\vec{k}n}(\vec{r}) = \varepsilon_n(\vec{k}) \phi_{\vec{k}n}(\vec{r}) \quad (16)$$

we apply the  $\widehat{H}$  operator to the Wannier functions [Eq. (6)] and taking into account Eq. (5) we get

$$\begin{aligned} \widehat{H} a_n(\vec{r} - \vec{l}) &= \frac{1}{\sqrt{N}} \sum_{\vec{k}} \varepsilon_n(\vec{k}) \phi_{\vec{k}n}(\vec{r}) \exp(-i\vec{k} \cdot \vec{l}) \\ &= \frac{1}{N} \sum_{\vec{k}} \varepsilon_n(\vec{k}) \exp(-i\vec{k} \cdot \vec{l}) \\ &\quad \times \sum_{\vec{l}'} a_n(\vec{r} - \vec{l}') \exp(i\vec{k} \cdot \vec{l}') \end{aligned}$$

$$\begin{aligned}
&= \frac{1}{N} \sum_{\vec{l}} a_n(\vec{r} - \vec{l}) \sum_{\vec{k}} \varepsilon_n(\vec{k}) \exp[i\vec{k} \cdot (\vec{l} - \vec{l}')] \\
&= \sum_{\vec{l}} \varepsilon_{n, \vec{l} - \vec{l}'} a_n(\vec{r} - \vec{l}') \quad (17)
\end{aligned}$$

where we have introduced

$$\varepsilon_{n, \vec{l} - \vec{l}'} = \frac{1}{N} \sum_{\vec{k}} \varepsilon_n(\vec{k}) \exp[-\vec{k} \cdot (\vec{l} - \vec{l}')] \quad (18)$$

that is, the Fourier transform of the energy in the  $\vec{k}$  space that shows the overlap integral of  $\hat{H}$  between two Wannier functions in  $\vec{l}$  and  $\vec{l}'$  for the same band. That is,

$$\begin{aligned}
\int a_n^*(\vec{r} - \vec{l}') \hat{H} a_n(\vec{r} - \vec{l}) d\vec{r} &= \sum_{\vec{l}} \varepsilon_{n, \vec{l} - \vec{l}'} \int a_n^*(\vec{r} - \vec{l}') a_n(\vec{r} - \vec{l}) d\vec{r} \\
&= \sum_{\vec{l}} \varepsilon_{n, \vec{l} - \vec{l}'} \delta_{nn'} \delta_{\vec{l}\vec{l}'} = \varepsilon_{n, \vec{l} - \vec{l}'} \delta_{nn'} \quad (19)
\end{aligned}$$

Substituting (19) in (15), we obtain

$$\sum_n \sum_{\vec{l}} \{ \delta_{nn'} \varepsilon_{n, \vec{l} - \vec{l}'} + U_{nn'}(\vec{l}, \vec{l}') \} f_n(\vec{l}, t) = i\hbar \frac{\partial f_{n'}(\vec{l}', t)}{\partial t} \quad (20)$$

where

$$U_{nn'}(\vec{l}, \vec{l}') = \int a_n^*(\vec{r} - \vec{l}') \hat{U} a_n(\vec{r} - \vec{l}) d\vec{r} \quad (21)$$

is the matrix element of the perturbation potential.

Considering that the Fourier series for energy, in the  $\vec{k}$  space, is

$$\varepsilon_n(\vec{k}) = \sum_{\vec{l}} \varepsilon_{n\vec{l}} \exp(i\vec{k} \cdot \vec{l}) \quad (22)$$

where the  $\varepsilon_{n\vec{l}}$  coefficients are given by Eq. (18), and considering that

$$\vec{k} \rightarrow -i\nabla \quad (23)$$

we can get the following product:

$$\varepsilon_n(\vec{k}) f(\vec{r}) = \sum_{\vec{l}} \varepsilon_{n\vec{l}} \exp[i(-i\nabla) \cdot \vec{l}] f(\vec{r}) = \sum_{\vec{l}} \varepsilon_{n\vec{l}} \exp(\vec{l} \cdot \nabla) f(\vec{r}) \quad (24)$$

But

$$\exp(\vec{l} \cdot \nabla) = 1 + \vec{l} \cdot \nabla + \frac{1}{2} (\vec{l} \cdot \nabla)^2 \quad (25)$$

Then

$$\begin{aligned}
\varepsilon_n(-i\nabla) f(\vec{r}) &= \sum_{\vec{l}} \varepsilon_{n\vec{l}} \left\{ f(\vec{r}) + \vec{l} \cdot \nabla f(\vec{r}) + \frac{1}{2} \vec{l}^2 \nabla^2 f(\vec{r}) + \dots \right\} \\
&= \sum_{\vec{l}} \varepsilon_{n\vec{l}} f(\vec{r} + \vec{l}) \quad (26)
\end{aligned}$$

where we have taken into account that the term in curls is the Taylor series for the function  $f(\vec{r} + \vec{l})$ .

Using Eq. (26), we can get

$$\begin{aligned}
\sum_{\vec{l}} \varepsilon_{n', \vec{l} - \vec{l}'} f_{n'}(\vec{l}, t) &= \sum_{\vec{l}} \varepsilon_{n', \vec{l} - \vec{l}'} f_{n'}(\vec{l}' + \vec{l} - \vec{l}', t) \\
&= \varepsilon_{n'}(-i\nabla) f_{n'}(\vec{r}, t) |_{\vec{r}=\vec{l}'} \quad (27)
\end{aligned}$$

Then, we can write Eq. (20) as follows:

$$\begin{aligned}
&\left[ \varepsilon_{n'}(-i\nabla) f_{n'}(\vec{r}, t) - i\hbar \frac{\partial f_{n'}(\vec{r}, t)}{\partial t} \right]_{\vec{r}=\vec{l}'} \\
&+ \sum_{n'} \sum_{\vec{l}} U_{nn'}(\vec{l}, \vec{l}') f_n(\vec{l}, t) = 0 \quad (28)
\end{aligned}$$

This is the expression for the envelope function, also called the Schrödinger equation in the Wannier representation.

Suppose that the electron moves in only one band. This means that the external potential is weak enough in order to not induce interband transitions; therefore

$$U_{nn'}(\vec{l}, \vec{l}') = \delta_{nn'} U_{nn}(\vec{l}, \vec{l}') \quad (29)$$

We will also consider that the potential varies slowly with the position; that is,

$$a_L \frac{\Delta U}{U} \ll 1 \quad (30)$$

$a_L$  being the lattice constant. Then,

$$U_{nn}(\vec{l}, \vec{l}') = U(\vec{r}, t) \delta_{\vec{l}\vec{l}'} \quad (31)$$

where we have taken into account Eqs. (10) and (21).

Introducing

$$U_{nn}(\vec{l}, \vec{l}') = U(\vec{r}, t) |_{\vec{r}=\vec{l}'} \quad (32)$$

and substituting Eqs. (29) and (31) in Eq. (28) we obtain

$$\left[ \varepsilon_n(-i\nabla) + U(\vec{r}, t) - i\hbar \frac{\partial}{\partial t} \right] f_n(\vec{r}, t) = 0 \quad (33)$$

where it is clear that  $\vec{r} = \vec{l}'$ .  $f_n(\vec{r}, t)$  is formally tried as a continuous function that varies slowly with the position around  $\vec{l}'$  [according to Eq. (30)].

Indeed, let us compare Eq. (13) with Eq. (5) [considering Eq. (8)].

If a weak external field, which varies slowly in distances of the order of lattice constant, is applied, the electron wavefunction in a determined band is expressed as [according to Eq. (13)]

$$\phi_{\vec{k}n}(\vec{r}, t) = \sum_{\vec{l}} a_n(\vec{r} - \vec{l}) f_n(\vec{l}, t) \quad (34)$$

where  $f_n(\vec{l}, t)$  is defined from (33). We have considered that the following relation must be satisfied:

$$f_n(\vec{r}, t) |_{\vec{r}=\vec{l}} = f(\vec{l}, t) \quad (35)$$

and where we formally have passed from the discrete variable  $l$  to the continuous one  $\vec{r}$ , which is acceptable if  $f_n(\vec{l}, t)$  varies slowly in distances of the order of the lattice constant, around the  $\vec{l}$  node.

In absence of external field [ $U(\vec{r}, t) = 0$ ], we simply obtain

$$f_n^0(\vec{l}, t) = \exp\left[i\left(\vec{k} \cdot \vec{l} - \frac{\varepsilon(\vec{k})}{\hbar} t\right)\right] \quad (36)$$

which, if is substituted in Eq. (34), leads to the equation of the stationary states.

Notice that instead of the original Eq. (12), now we have a Schrödinger equation for the envelope function, in which the  $\widehat{H} + \widehat{U}$  Hamiltonian has been substituted by the effective Hamiltonian

$$\widehat{H}_{ef} = \varepsilon_n(-i\nabla) + \widehat{U} \quad (37)$$

that, as one can appreciate, depends on the dispersion relation  $\varepsilon_n(\vec{k})$ .

Thus, the envelope function can be understood like the effective wavefunction for the electron in the crystal.

Fortunately, in most of physical phenomena occurring in semiconductors and metals, the participating electrons are those situated in the bottom or the top of the bands (this is, in their extremes). For these electrons it is convenient to introduce the effective mass and the effective Hamiltonian, which can be written as follows:

$$\widehat{H}_{ef} = -\left[\frac{\hbar^2}{m_{nx}^*} \frac{\partial^2}{\partial x^2} + \frac{\hbar^2}{m_{ny}^*} \frac{\partial^2}{\partial y^2} + \frac{\hbar^2}{m_{nz}^*} \frac{\partial^2}{\partial z^2}\right] + \widehat{U} \quad (38)$$

In the isotropic crystal case, the effective masses are equal in any direction and Eq. (38) is rewritten as

$$\widehat{H}_{ef} = -\frac{\hbar^2 \nabla^2}{2m_n^*} + \widehat{U} \quad (39)$$

where  $m_n^*$  is the effective mass of the  $n$  band.

In this case we say that the band is parabolic since the dispersion relation is given by

$$\varepsilon_n(\vec{k}) = \frac{\hbar^2 k^2}{2m_n^*} \quad (40)$$

which is, besides, isotropic.

So for a constant potential (in the time) one can write the effective Schrödinger equation for a stationary state as

$$\left\{ -\frac{\hbar^2}{2} \left[ \frac{1}{m_{nx}^*} \frac{\partial^2}{\partial x^2} + \frac{1}{m_{ny}^*} \frac{\partial^2}{\partial y^2} + \frac{1}{m_{nz}^*} \frac{\partial^2}{\partial z^2} \right] + \widehat{U}(\vec{r}) \right\} f_n(\vec{r}) = \varepsilon f_n(\vec{r}) \quad (41)$$

which is widely used.

This method is known as the effective mass approximation.

## 2.5. Envelope Function Description of Quasi-Particle States for Nanostructured Systems

The envelope function model is particularly adequate to study quasi-particle properties of low-dimensional semiconductor structures. This is a dynamic method for the determination of energy bands of particles in solid state physics, and the nanostructures are considered dynamic systems since they are always under the action of either a barrier potential or interface potential. The envelope function scheme and the effective mass approximation were clearly discussed, for first time, by Bastard [61, 62].

In order to obtain the nanostructure energy states, in the envelope function scheme, our problem will be to find the boundary conditions which the slowly varying part of the nanostructure wavefunctions must fulfill at the heterointerfaces.

Other approaches to the nanostructure eigenenergies have been proposed which are more microscopic in essence than the envelope function description. The tight-binding model is nowadays successfully used for nanostructures of any size, although it may have difficulties in handling self-consistent calculations, which arise when charges are present in the nanostructures. Another microscopic approach is the pseudo-potential formalism, which is very successful for the bulk materials. The advantage of these microscopic approaches is their capacity to handle any nanostructure energy levels (i.e. those close to or far from the  $\Gamma$  edge). This occurs because these models reproduce the whole bulk dispersion relations. The envelope function approximation has no such generality. Basically, it is restricted to the vicinity of the high-symmetry points in the host's Brillouin zone ( $\Gamma, X, L$ ). However, we feel that it is invaluable due to its simplicity and versatility. It often leads to analytical results and leaves the user with the feeling that he can trace back, in a relatively transparent way, the physical origin of the numerical results. Besides, most of the nanostructures energy levels relevant to actual devices are relatively close to a high symmetry point in the host's Brillouin zone.

In the following we shall assume that A and B materials constituting the nanostructure are perfectly lattice matched and they crystallize with the same crystallographic structure. In order to apply the envelope function model two key assumptions are made:

- (1) Inside each material the wavefunction is expanded on the Wannier functions (with  $\vec{l} = 0$ ) of the edges under consideration

$$\psi(\vec{r}) = \sum_n f_n^A(\vec{r}) u_{n, \vec{k}_0}^A(\vec{r}) \quad (42)$$

if  $\vec{r}$  corresponds to an A material, and

$$\psi(\vec{r}) = \sum_n f_n^B(\vec{r}) u_{n, \vec{k}_0}^B(\vec{r}) \quad (43)$$

if  $\vec{r}$  corresponds to a B material, where  $\vec{k}_0$  is the point in the Brillouin zone around which the nanostructure states are built. The summation over  $n$  runs over as many edges as are included in the analysis.

- (2) The periodic parts of the Bloch functions are assumed to be the same in each kind of material, which constitutes the nanostructure

$$u_{n,\vec{k}_0}^A(\vec{r}) \equiv u_{n,\vec{k}_0}^B(\vec{r}) \quad (44)$$

Thus our nanostructure wavefunction will be written as

$$\psi(\vec{r}) = \sum_n f_n^{A,B}(\vec{r}) u_{n,\vec{k}_0}(r) \quad (45)$$

and our objective will be to determine  $f_n^{A,B}(\vec{r})$ . The envelope function  $f_n^{A,B}(\vec{r})$  depends of the kind of low-dimensional system.

### 2.5.1. Quasi-Two-Dimensional System

The quasi-two-dimensional systems are formed by multiple heterostructures such as quantum wells, multiple quantum wells, and superlattices. The envelope function in this case is

$$f_n^{A,B}(\vec{r}_\perp, z) = \frac{1}{\sqrt{S}} \exp(i\vec{k}_\perp \cdot \vec{r}_\perp) \chi_n^{A,B}(z) \quad (46)$$

where  $S$  is the sample area and  $\vec{k}_\perp = (k_x, k_y)$  is a two-dimensional wavevector which is the same in the A and B layers in order to preserve translational invariance in plane  $(x, y)$ .

Although  $\vec{k}_\perp$  could theoretically span the whole in-plane section of the host's Brillouin zone, it is in practice seldom larger than  $\approx 1/10$  of its size.

We shall also assume that for all  $n$ ,  $\chi_n^{A,B}(z)$  varies slowly at the scale of the host's unit cell. Thus the heterostructure wavefunction  $\psi(\vec{r})$  is a sum of the products of rapidly varying functions.

The heterostructure Hamiltonian can be written in the form

$$\hat{H} = \frac{\hat{p}_x^2}{2m_x^*} + \frac{\hat{p}_y^2}{2m_y^*} + \frac{\hat{p}_z^2}{2m_z^*} + V_A(\vec{r})Y_A + V_B(\vec{r})Y_B \quad (47)$$

where  $Y_A(Y_B)$  are step functions which are unity if  $\vec{r}$  corresponds to an A layer (to a B layer) and  $V_A(V_B)$  is the potential in the A(B) layer.

The envelope function in the  $z$  direction,  $\chi_n(z)$ , of an A/B layer is the solution of the Schrödinger equation

$$\left\{ -\frac{\hbar^2}{2m_{nz}^*} \frac{d^2}{dz^2} + V_n(z) \right\} \chi_n(z) = \varepsilon_n \chi_n(z) \quad (48)$$

where  $V_n(z)$  is the heterostructure potential determined by the band discontinuity:  $m_{nz}^* \equiv m_n^*(z) = m_{n,A}^*(m_{n,B}^*)$  and  $V_n(z) = 0$  in the A(B) layer.

Let us see the general case of a superlattice. In a given A/B superlattice there is a new periodicity along the growth direction  $z$ . The SL period  $d$  (sum of the layer thickness of the A and B layers,  $d_A + d_B$ ) is longer than the lattice constants of the constituents, so that a new mini-Brillouin zone is formed in the wavevector range of  $-\pi/d \leq k_z \leq \pi/d$ . The mini-Brillouin zone formation results in generation of miniband structures in the conduction and valence bands.

We consider the miniband structures of the  $\Gamma_6$  conduction band and the  $\Gamma_8$  valence band (heavy hole,  $|J, M_J\rangle = |3/2, \pm 3/2\rangle$  and light hole,  $|3/2, \pm 1/2\rangle$ ). The total wavefunction in each layer can be written in the form

$$\psi_{\vec{k}}^{A,B}(r) = \sum_n f_{n,\vec{k}}^{A,B}(\vec{r}) u_{n,\vec{k}=0}(\vec{r}) \quad (49)$$

where we can use the following form of the envelope function:

$$F_{n,\vec{k}}^{A,B}(\vec{r}) = \exp(ik_{n,x}^{A,B}x) \exp(ik_{n,y}^{A,B}y) f_{n,\vec{q}}^{A,B}(z) \quad (50)$$

Then  $f_{n,\vec{q}}^{A,B}(z)$  is the envelope function determined by the SL potential and the effective masses, and  $\vec{q}$  is the SL wavevector parallel to  $z$ . The periodicity of the SL results in the Bloch theorem for the envelope function:

$$f_{n,\vec{q}}^{A,B}(z + md) = \exp(imqd) f_{n,\vec{q}}^{A,B}(z) \quad (51)$$

where  $m$  is integer.

The envelope function of an A/B SL is the solution of the Schrödinger equation

$$\left\{ -\frac{\hbar^2}{2m_n^*(z)} \frac{d^2}{dz^2} + V_n(z) \right\} f_{n,\vec{q}}(z) = \varepsilon_n f_{n,\vec{q}}(z) \quad (52)$$

where  $V_n(z) = 0(\Delta\varepsilon_n)$  in the A(B) layer. For convenience we will omit the band index  $n$  in the following treatment. The form of the envelope function can be written as

$$f_{\vec{q}}(z) = \begin{cases} f_{\vec{q}}^A(z) = \alpha_{\vec{q}}^A \exp(ik_A z) + \beta_{\vec{q}}^A \\ \quad \times \exp(-ik_A z) & \text{in the A layer} \\ f_{\vec{q}}^B(z) = \alpha_{\vec{q}}^B \exp(ik_B z) + \beta_{\vec{q}}^B \\ \quad \times \exp(-ik_B z) & \text{in the B layer} \end{cases} \quad (53)$$

$$k_A = \sqrt{2m_A^* \varepsilon / \hbar} \quad k_B = \sqrt{2m_B^* (\varepsilon - \Delta\varepsilon) / \hbar} \quad (54)$$

Considering the continuity of the probability density,  $|f_{\vec{q}}(z)|^2$ , for a stationary state, we obtain the following boundary condition of the envelope function at the A/B interface for  $(z_A - z_B) \rightarrow 0$ :

$$\begin{aligned} f_{\vec{q}}^A(z_A) &= f_{\vec{q}}^B(z_B) \quad \text{and} \\ \frac{1}{m_A^*} \frac{df_{\vec{q}}^A(z_A)}{dz} &= \frac{1}{m_B^*} \frac{df_{\vec{q}}^B(z_B)}{dz} \end{aligned} \quad (55)$$

Finally, the miniband dispersion relation, which is similar to the well known Kronig-Penney relation, is given by

$$\begin{aligned} \cos(qd) &= \cos(k_A d_A) \cos(k_B d_B) \\ &- \frac{1}{2} \left( \frac{k_A m_B^*}{k_B m_A^*} + \frac{k_B m_A^*}{k_A m_B^*} \right) \sin(k_A d_A) \sin(k_B d_B) \end{aligned} \quad (56)$$

This equation has been widely used to calculate the miniband energies.

Figure 6 shows (a) the potential structure and the envelope function profiles of the electron and heavy hole in a

**Figure 6.** Potential structure and the envelope function profiles in superlattice. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

GaAs(3.2 nm)/AlAs(0.9 nm) SL and (b) the dispersion relations of the electron and heavy hole minibands, calculated using Eq. (56). In Figure 6a, the solid and dashed lines indicate the envelope functions at the mini-Brillouin-zone center ( $q = 0$ ,  $\Gamma$  point) and the mini-Brillouin-zone edge ( $q = \pi/d$ ,  $\pi$  point), respectively. In this calculation, the following effective-mass parameters are used [63]:  $m_e^* = 0.0665m_0$ ,  $m_{hh}^* = 0.34m_0$ , and  $m_{lh}^* = 0.117m_0$  for the electron, heavy hole, and light hole GaAs, and  $m_e^* = 0.15m_0$ ,  $m_{hh}^* = 0.4m_0$ , and  $m_{lh}^* = 0.18m_0$  for AlAs, where  $m_0$  is the free-electron mass. The miniband dispersions are tailored by changing the layer thickness, potential height, and effective masses, which are structural parameters in crystal growth. Figure 7 shows the  $n = 1$  and  $n = 2$  electron miniband of the energies at  $\Gamma$  and  $\pi$  points in a GaAs(3.2 nm)/AlAs( $d_B$  nm) SL as a function of the AlAs layer thickness. This figure exhibits a typical example of the miniband tailoring. The miniband width increases with the decrease of the AlAs (barrier) thickness, which results from the increase of the coupling strength of wavefunctions because of the increase of the tunneling probability. In the case of the disappearance of the miniband width, the electronic state corresponds to a quasi-two-dimensional state in an isolated quantum well (QW).

The  $z$  dependence of the effective mass means, in principle, that it is different in different layers but in general may vary even in a given medium if no abrupt interfaces are considered. Then, the kinetic energy term in Eq. (52) should be substituted by the more general Ben Daniel and Duke [64] hermitian form

$$-\frac{\hbar^2}{2} \frac{\partial}{\partial z} \frac{1}{m^*(z)} \frac{\partial}{\partial z} \quad (57)$$

**Figure 7.** Electron miniband energies at  $\Gamma$  and  $\pi$  points in a superlattice. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

Finally, Eq. (52) for the envelope function can be generalized as

$$\left\{ -\frac{\hbar^2}{2} \frac{\partial}{\partial z} \frac{1}{m^*(z)} \frac{\partial}{\partial z} + V(z) \right\} \chi(z) = \varepsilon \chi(z) \quad (58)$$

### 2.5.2. Quasi-One-Dimensional System

Let us consider a quasi-one-dimensional system with finite length and width formed by A and B materials; in general, the wavefunction can be written as

$$\psi(\vec{r}) = \sum_n f_n^{A,B}(\vec{r}) u_{n,\vec{k}_0}(r) \quad (59)$$

We will also consider that the quasi-one-dimensional system is a quantum well wire of rectangular or circular cross-section, where the  $z$  direction coincides with the free direction of the carrier motion; that is, the confinement direction is in the cross section.

The envelope function for both cases can be written as

$$f_n^{A,B}(\vec{r}) = \exp(ik_z z) \chi_n^{A,B}(\vec{r}_\perp) \quad (60)$$

where  $\chi_n^{A,B}(\vec{r}_\perp)$  depends on the cross section symmetry,

$$\chi_n^{A,B}(\vec{r}_\perp) = \begin{cases} X_{n,l}^{A,B}(x) Y_{n,m}^{A,B}(y) & \text{rectangular quantum} \\ & \text{well wire} \\ \exp(il\theta) R_{n,l}^{A,B}(r) & \text{circular quantum} \\ & \text{well wire} \end{cases} \quad (61)$$

where  $l, m$  are integer numbers and  $(r, \theta, z)$  are the cylindrical coordinates. For convenience we will omit the band index  $n$  in the following treatment.

The differential equations for the envelope functions are now

$$\begin{cases} -\frac{\hbar^2}{2m^*(x)} \frac{d^2}{dx^2} + V_b^{A,B}(x) \} X_l^{A,B}(x) = \varepsilon_l X_l^{A,B}(x) \\ -\frac{\hbar^2}{2m^*(y)} \frac{d^2}{dy^2} + V_b^{A,B}(y) \} Y_m^{A,B}(y) = \varepsilon_m Y_m^{A,B}(y) \end{cases} \quad (62)$$

for rectangular symmetry. In this case the barrier potential is

$$V_b^{A,B}(\vec{r}) = \begin{cases} V_b^{A,B}(x) = \begin{cases} 0 & \text{for } 0 < x < a \\ \infty & \text{for } a < x \end{cases} \\ V_b^{A,B}(y) = \begin{cases} 0 & \text{for } 0 < y < b \\ \infty & \text{for } b < y \end{cases} \\ V_b^{A,B}(z) = 0 & \text{for } -L < z < L \end{cases} \quad (63)$$

The rectangular quantum well wire behavior is, according to the  $x$ ,  $y$  directions, as two isolated single quantum wells under the action of an infinite barrier potential, where the boundary conditions are simply  $X_l^{A,B}(a) = 0$  and  $Y_m^{A,B}(b) = 0$ . With this requirement the eigenfunctions are

$$\begin{aligned} X_l^{A,B}(x) &= \sqrt{\frac{2}{a}} \sin \frac{l\pi}{a} x \\ Y_m^{A,B}(y) &= \sqrt{\frac{2}{b}} \sin \frac{m\pi}{b} y \quad l, m = 1, 2, 3, \dots \end{aligned} \quad (64)$$

The energy levels for the  $n$ th band are

$$\varepsilon_{l,m} = \frac{\pi^2 \hbar^2}{2m_A^* a^2} l^2 + \frac{\pi^2 \hbar^2}{2m_B^* b^2} m^2 \quad (65)$$

For circular symmetry the differential equation for the envelope function is

$$\frac{d^2 R_l^{A,B}}{d\rho^2} + \frac{1}{\rho} \frac{dR_l^{A,B}}{d\rho} \pm \left(1 \mp \frac{l^2}{\rho^2}\right) R_l^{A,B} = 0 \quad (66)$$

where

$$\rho = \alpha^{A,B} r \quad \alpha^A = \sqrt{\frac{2m_A^*(r)\varepsilon_l}{\hbar^2}} \quad \alpha^B = \sqrt{\frac{2m_B^*(V_0 - \varepsilon_l)}{\hbar^2}} \quad (67)$$

The upper signs in Eq. (66) correspond to material A (we are considering that the potential  $V_b^A$  is zero) and the lower signs correspond to material B, where the interface potential is  $V_b^B = V_0$ . Equation (66) is the Bessel differential equation (+, -) and modified Bessel differential equation (-, +) respectively.

Integrating Eq. (66) for each material we obtain the Bessel function of the first kind,  $J_l(\alpha^A r)$ , and the modified Bessel function,  $K_l(\alpha^B r)$ , respectively; these functions and their derivatives must satisfy the continuity requirement for  $R_l$  in the  $r = r_0$  interface, where  $r_0$  is confinement circular section radius. That is,

$$\begin{aligned} aJ_l(\alpha^A r_0) &= bK_l(\alpha^B r_0) \quad \text{and} \\ \frac{a}{m_A^*} J_l'(\alpha^A r_0) &= \frac{b}{m_B^*} K_l'(\alpha^B r_0) \end{aligned} \quad (68)$$

where  $a$ ,  $b$  are constants which are determined using the normalization condition for the wavefunction  $\psi(\vec{r})$ . Then we can calculate the energy levels for each  $n$  band solving the following transcendental equation;

$$\frac{J_l'(\alpha^A r_0)}{m_A^* J_l(\alpha^A r_0)} = \frac{K_l'(\alpha^B r_0)}{m_B^* K_l(\alpha^B r_0)} \quad (69)$$

### 2.5.3. Quasi-Zero-Dimensional System

In this case the electron is totally or partially confined in the three spatial directions and since there is no direction for the free movement, the total energy does not depend on any of reciprocal space  $\vec{k}$  wavevector components. Nor can we define, in a mathematical sense, the effective mass as a function of  $\vec{k}$ . However, since the electron still is under the action of the crystalline field, we can use the concept of effective mass as the change of its properties, as well as the effective mass scheme.

Therefore, if we continue with the final result obtained from the envelope function method or the effective mass approximation, the wavefunction can be written as

$$\psi(\vec{r}) = \sum_n f_n^{A,B}(\vec{r}) u_{n,\vec{k}_0}(\vec{r}) \quad (70)$$

where we are assuming that the quasi-zero-dimensional system is a spherical quantum dot formed by two materials A and B, where the potential  $V_0$  is given by

$$V_b^{A,B}(r) = \begin{cases} 0 & 0 \leq r \leq r_0 \quad (\text{A material}) \\ V_0 & r > r_0 \quad (\text{B material}) \end{cases} \quad (71)$$

Taking into account the problem symmetry, it is reasonable to consider the spherical coordinates ( $r$ ,  $\theta$ ,  $\varphi$ ). In these coordinates the Hamiltonian can be written as

$$\hat{H} = -\frac{\hbar^2}{2m_{A,B}^*} \left\{ \frac{\partial^2}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} - \frac{\hat{L}^2}{r^2 \hbar^2} \right\} + V_b^{A,B}(r) \quad (72)$$

where the  $\hat{L}^2$  operator is

$$\hat{L}^2 = \frac{1}{\sin \theta} \left[ \frac{\partial}{\partial \theta} \left( \sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2}{\partial \varphi^2} \right] \quad (73)$$

In this case, the envelope function  $f_n^{A,B}(\vec{r})$  is expressed as a product of functions of  $r$ ,  $\theta$ , and  $\varphi$ ,

$$f_n^{A,B}(\vec{r}) = f_n^{A,B}(r) Y_{l,m}(\theta, \varphi) \quad (74)$$

where  $Y_{l,m}(\theta, \varphi)$  are the spherical harmonics, and  $f_n^{A,B}(r)$  are the new envelope functions that fulfill with the equations

$$\frac{d^2 f_{n,l}^{A,B}}{d\rho^2} + \frac{1}{\rho} \frac{df_{n,l}^{A,B}}{d\rho} \pm \left(1 \mp \frac{l(l+1)}{\rho^2}\right) f_{n,l}^{A,B} = 0 \quad (75)$$

where the new variable  $\rho$  is defined as

$$\begin{aligned} \rho &= \alpha^{A,B} r \quad \alpha^A = \sqrt{\frac{2m_A^*(r)\varepsilon_{n,l}}{\hbar^2}} \\ \alpha^B &= \sqrt{\frac{2m_B^*(V_0 - \varepsilon_{n,l})}{\hbar^2}} \end{aligned} \quad (76)$$

For convenience we will omit the band index  $n$  in the following treatment.

The upper signs correspond to the interior region of quantum dot and lower signs correspond to the exterior. The solutions of these equations are the envelope functions in A and B materials and can be written as

$$f^{A,B}(\vec{r}) = \begin{cases} f_l^A(\rho)Y_{l,m}(\theta, \varphi) = aj_l(\alpha^A r)Y_{l,m}(\theta, \varphi) \\ f_l^B(\rho)Y_{l,m}(\theta, \varphi) = bk_l(\alpha^B r)Y_{l,m}(\theta, \varphi) \end{cases} \quad (77)$$

where  $j_l(\alpha^A r)$  is the spherical Bessel function of the first kind,  $k_l(\alpha^B r)$  is the modified spherical Bessel function of the third kind, and  $a, b$  are constants which are determined with the normalization condition of the wavefunction. The new boundary condition in the  $r = r_0$  interface of quantum dot can be expressed as

$$\begin{aligned} aj_l(\alpha^A r_0) &= bk_l(\alpha^B r_0) \quad \text{and} \\ \frac{a}{m_A^*} j_l'(\alpha^A r_0) &= \frac{b}{m_B^*} k_l'(\alpha^B r_0) \end{aligned} \quad (78)$$

Then, the eigenstates are determined solving the following transcendental equation:

$$\frac{j_l'(\alpha^A r_0)}{m_A^* j_l(\alpha^A r_0)} = \frac{k_l'(\alpha^B r_0)}{m_B^* k_l(\alpha^B r_0)} \quad (79)$$

The energy states  $\varepsilon_{n,l,m}$  of the system are characterized by three quantum numbers, namely, the principal number  $n$ , the orbital number  $l$ , and the magnetic number  $m$ . The orbital quantum number determines the angular momentum value  $\hat{L}$ :

$$\hat{L}^2 = \hbar^2 l(l+1) \quad l = 0, 1, 2, 3 \dots \quad (80)$$

The magnetic quantum number determines the  $\hat{L}_z$  component parallel to the  $z$  axis:

$$\hat{L}_z = \hbar m \quad m = 0, \pm 1, \pm 2, \dots, \pm l \quad (81)$$

Every state with a certain  $l$  value is  $(2l+1)$  degenerate according to  $2l+1$  values of  $m$ . The states corresponding to different  $l$  values are usually denoted as  $s, d, f,$  and  $g$  states and so forth in alphabetical order. For example, states with zero angular momentum ( $l=0$ ) are referred to as  $s$  states, those with  $l=1$  are denoted as  $p$  states, and so on. The parity of states corresponds to the parity of the  $l$  value, because the radial function is not sensitive to inversion ( $r$  remains the same after inversion) and spherical function after inversion transforms as follows:

$$Y_{l,m}(\theta, \varphi) \rightarrow (-1)^l Y_{l,m}(\theta, \varphi) \quad (82)$$

The specific values of energy are determined by the  $V_b^{A,B}(\vec{r})$  function. Consider a simple case corresponding to one spherically symmetric potential well with an infinite barrier; that is,

$$V_b^{A,B}(\vec{r}) = \begin{cases} 0 & \text{for } 0 \leq r \leq r_0 \\ \infty & \text{for } r > r_0 \end{cases} \quad (83)$$

In this case energy values are expressed as

$$\varepsilon_{n,l} = \frac{\hbar^2 X_{n,l}^2}{2m_A^* r_0^2} \quad (84)$$

where  $X_{n,l}$  are roots of the spherical Bessel functions with  $n$  being the number of the root and  $l$  being the order of the function.

This formulation can be adapted to the case of a rectangular quantum box where the envelope function can be written as

$$f_{n,x}^{A,B}(\vec{r}) = X_n^{A,B}(x)Y_n^{A,B}(y)Z_n^{A,B}(z) \quad (85)$$

and thus we obtain three equations in order to calculate the  $X, Y,$  and  $Z$  new envelope functions for each direction,

$$\begin{aligned} \left\{ -\frac{\hbar^2}{2m_{A,B}^*(x)} \frac{d^2 X_n^{A,B}(x)}{dx^2} + V_b^{A,B}(x) \right\} X_n^{A,B}(x) \\ = \varepsilon_{n,x} X_n^{A,B}(x) \end{aligned} \quad (86)$$

$$\begin{aligned} \left\{ -\frac{\hbar^2}{2m_{A,B}^*(y)} \frac{d^2 Y_n^{A,B}(y)}{dy^2} + V_b^{A,B}(y) \right\} Y_n^{A,B}(y) \\ = \varepsilon_{n,y} Y_n^{A,B}(y) \end{aligned} \quad (87)$$

$$\begin{aligned} \left\{ -\frac{\hbar^2}{2m_{A,B}^*(z)} \frac{d^2 Z_n^{A,B}(z)}{dz^2} + V_b^{A,B}(z) \right\} Z_n^{A,B}(z) \\ = \varepsilon_{n,z} Z_n^{A,B}(z) \end{aligned} \quad (88)$$

which represent three uncoupled equations corresponding to three isolated single quantum wells. If we consider that the dimensions of the rectangular quantum box are  $a, b,$  and  $c,$  according to  $x, y,$  and  $z$  directions, respectively, then, taking into account the infinite barrier potential between A and B materials, we obtain the solutions

$$\begin{aligned} X_l^A(x) &= \sqrt{\frac{2}{a}} \sin \frac{l\pi}{a} x & Y_m^A(y) &= \sqrt{\frac{2}{b}} \sin \frac{m\pi}{b} y \\ Z_p^A(z) &= \sqrt{\frac{2}{c}} \sin \frac{p\pi}{c} z \end{aligned} \quad (89)$$

where  $l, m,$  and  $p$  are quantum numbers taking positive nonzero integers.

In this case energy values are expressed as follows:

$$\varepsilon_{l,m,p} = \frac{\pi^2 \hbar^2}{2m_A^*(x)a^2} l^2 + \frac{\pi^2 \hbar^2}{2m_A^*(y)b^2} m^2 + \frac{\pi^2 \hbar^2}{2m_A^*(z)c^2} p^2 \quad (90)$$

The theory of the quasi-particle states used previously to study the nanostructures is suitable for quasi-particles like electrons and holes; however, in order to be used for the excitons we need to make some modifications.

## 2.6. Idealized Confined Systems when Symmetry of the Confinement Region Does Not Have Regular Form and the Schrödinger Equation is Nonseparable

When the Schrödinger equation for a given quantum system is nonseparable in nature, then some approximation techniques must be used to study its solution. In a similar situation for a confined quantum system, the variational method might constitute an economical and physically appealing approach. It has been shown that the variational method is useful for studying this class of systems when their symmetries are compatible with those of the confining boundaries.

We will only consider the application of the variational method in the case of a symmetric quantum system confined by impenetrable potentials, as a simple example of a more general situation.

### 2.6.1. General Description of the Method

For the moment, let us assume that, for a given system, the time-independent Schrödinger equation can be written as

$$\hat{H}\psi_n = E_n\psi_n \quad (91)$$

where  $\hat{H} = -(1/2)\nabla^2 + V(q)$  is the associated Hamiltonian for this system,  $\{q\}$  is the set of coordinates on which  $V$  depends, and  $\hbar = m = 1$ .

An approximate solution of Eq. (91) may be obtained by replacing  $\psi_n$  by a trial wavefunction  $\chi_n$ , which possesses a similar behavior at the “origin” as well as asymptotically at infinity. An estimate of the energy of the system is then obtained by minimizing the functional

$$\int \chi_n^* \hat{H} \chi_n d\tau \quad (92)$$

with the additional restriction that

$$\varepsilon_n = \min \int \chi_n^* \hat{H} \chi_n d\tau = \delta_{n,n'} \quad (93)$$

As is shown in any quantum mechanics textbook, one can find that

$$\varepsilon_n = \min \int \chi_n^* \hat{H} \chi_n d\tau \geq E_n \quad (94)$$

That is, a poor guess of  $\chi_n$  leads to a poor estimate of  $\varepsilon_n$ , which means that we have not properly included our qualitative knowledge of the system under study.

In practical calculations, the functions  $\chi_n$  depend upon the coordinates, say  $\{q_1, q_2, \dots, q_s\}$ , and on a set of unknown parameters  $\{\alpha_1, \alpha_2, \dots, \alpha_k\}$  such that  $\varepsilon_n = \varepsilon_n\{\alpha_1, \alpha_2, \dots, \alpha_k\}$ . In order to determine the set  $\{\alpha_k\}$  one must solve the system of equations

$$\frac{\partial \varepsilon_n}{\partial \alpha_i} = 0 \quad i = 1, 2, \dots, k \quad (95)$$

from which  $\varepsilon_n$  can be readily obtained. In doing this we have  $\varepsilon_n$  and  $\chi_n$  as an approximate energy and wavefunction for the state  $n$ , respectively.

Let us assume a quantum system confined within a domain  $D$ , for which the Hamiltonian can be written as

$$\hat{H} = \hat{H}_0 + V(q) \quad (96)$$

where  $\hat{H}_0$  is the Hamiltonian for the free system, and

$$V(q) = \begin{cases} +\infty & q \notin D \\ 0 & q \in D \end{cases} \quad (97)$$

is the confining potential.

The solution of Eq. (96) must satisfy

$$\psi(q) = 0 \quad q \in \partial D \quad (98)$$

where  $\partial D$  is the boundary of  $D$ .

In order to use the variational method, we must construct a trial wavefunction that satisfies the boundary condition imposed by Eq. (98). This function can be defined as

$$\chi(q) = g(q)\psi_0(q, \alpha) \quad (99)$$

where  $\psi_0(q, \alpha)$  has a structure similar to the solution of the Schrödinger equation for  $\hat{H}_0$ , but the good quantum number(s) that define the energy of the free system is (are) replaced by a parameter (or a set of parameters)  $\alpha$ , because the confining conditions impose new quantization rules.

The function  $g(q)$  must satisfy the boundary condition given by Eq. (98). This technique can be used when the symmetry of the confining potential is compatible with the symmetry of the system under study.

When the latter is not the case, the form of the trial wavefunction given by Eq. (99) must be slightly changed since the symmetry is broken by the confinement potential. However, in spite of the lack of compatibility between both symmetries, the system and confinement domain often are related through a coordinate transformation of the form

$$q = q(q') \quad (100)$$

where  $q'$  are the coordinates of the center of symmetry of  $D$  and  $q$  are the coordinates of the center of symmetry of the system.

Even in the aforementioned case, it is still possible to construct the trial wavefunction as in Eq. (99), except that the coordinates  $q$  of the system under study must be written in terms of the coordinates  $q'$  of  $D$  using the rule given in Eq. (100). Under such conditions the trial wavefunction for this asymmetry situation can be written as

$$\chi(q(q')) = g(q(q'))\psi_0(q(q'), \alpha) \quad (101)$$

Once the latter has been done, the energy functional can be constructed and minimized with respect to  $\alpha$ , as usual.

### 3. PHYSICAL EFFECTS OF IMPURITY STATES AND ATOMIC SYSTEMS CONFINED IN SEMICONDUCTOR NANOSTRUCTURES

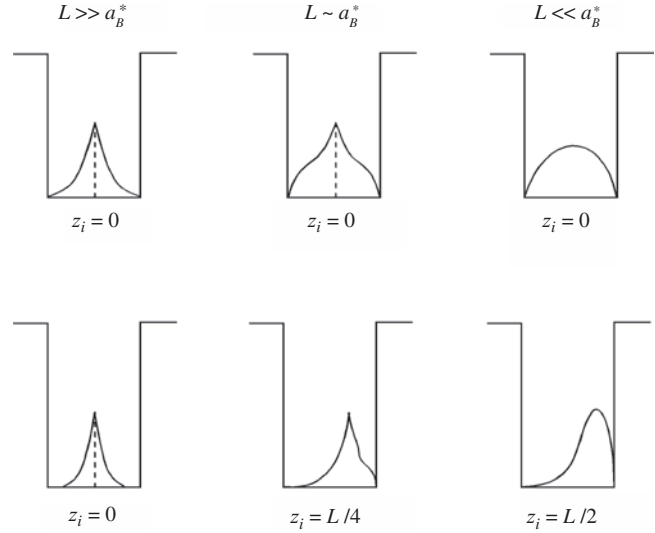

In contrast to bulk materials, the nanostructures are characterized by a lack of translational invariance along the confinement direction. Thus, the impurity binding energy explicitly depends on the precise location of the impurity. It is important to know where the impurity atom is placed in the nanostructure, and the binding energy of the donor state associated with impurity atom will depend on whether the impurity atom sits at the center or the axis of the nanostructure.

The second important feature of Coulombic problems in nanostructures is the variation of the impurity binding energy with the characteristic dimension of the well. When the nanostructure confinement dimension (confinement size) decreases, the impurity binding energy increases, as long as the penetration of the unperturbed nanostructure wavefunction in the barrier remains small. This may seem surprising at first sight since we intuitively associate extra kinetic energy with the localization of a particle in a finite region of space. Moreover, it is actually true that the energy of the ground bound state of the impurity increases as the confinement size decreases, when it is measured from some fixed reference. However, the onset of the impurity continuum, which (for donors) coincides with the energy of the nanostructure bound state, also moves up with decreasing confinement size. The binding energy finally increases since, in the bound impurity states, the carrier is kept near the attractive center by nanostructure walls and thus experiences a larger potential energy than in the absence of a nanostructure. On the other hand the onset of the impurity continuum does not benefit from any extra potential energy gain, as the continuum states are hardly affected by the Coulombic potential.

When the Schrödinger equation for a given quantum system is nonseparable in nature, then some approximation techniques must be used to study its solution. In a similar situation for a confined quantum system, the variational method might constitute an economical and physically appealing approach [65]. It has been shown [66] that the variational method is useful for studying this class of systems when their symmetries are compatible with that of the confining boundaries. In general, in the problems related to impurity and atoms confined in the different nanostructures, these considerations are fulfilled.

#### 3.1. Hydrogenic Impurity in Quasi-Two-Dimensional Systems

In Figure 8, we sketched the shape of the impurity wavefunction, keeping the in-plane distance between the carrier and the attractive center  $\rho$  ( $\rho = \sqrt{x^2 + y^2}$ ) equal to zero. Several quantum well thicknesses (upper part of Fig. 8) and several impurity positions in a thick well (lower part of Fig. 8) have been considered. For thick wells ( $L \gg a_B^*$ ) the on-center impurity wavefunction resembles that of the bulk 1s states. On the other hand, the on-edge impurity

**Figure 8.** Evolution of the shape of the impurity wave function in a quantum well of decreasing well thickness for an on-center impurity (upper part) and with the impurity position in a thick well (lower part).

wavefunction approaches the shape of a  $2p_z$  wavefunction if  $(L/a_B^*) \gg 1$ . This is because the barrier potential forces the impurity wavefunction to almost vanish at  $z = \pm L/2$ . If  $L/a_B^* \ll 1$  and if the barrier height is very large, the electron  $z$  motion becomes forced by the quantum well potential. Thus, along the  $z$  axis the impurity wavefunction looks like the ground state wavefunction of the well  $\chi_1(z)$ .

#### 3.1.1. Approximate Solutions of the Hydrogenic Impurity Problem

In all that follows we will consider donorlike impurities unless otherwise specified. The conduction bands of both host materials of the quantum well are assumed to be isotropic and parabolic in  $k$ . We neglect the effective mass jumps at the interfaces as well as the differences in the relative dielectric constants of the two host materials. The impurity envelope functions are the solutions of the effective Hamiltonian

$$\hat{H} = \hat{H}_0 + V_I = \frac{\hat{p}_z^2}{2m_e^*} + \frac{\hat{p}_x^2 + \hat{p}_y^2}{2m_e^*} + V_0 Y\left(z^2 - \frac{L^2}{4}\right) - \frac{e^2}{\kappa \sqrt{\rho^2 + (z - z_i)^2}} \quad (102)$$

where  $V_0$  is the barrier height and  $Y(x)$  is the step function [ $Y(x) = 1$  if  $x > 0$ ;  $Y(x) = 0$  if  $x < 0$ ]. The impurity position along the growth axis is  $z_i$ . The  $(x, y)$  origin is at the impurity site because all the impurity positions are equivalent in the layer plane;  $\vec{\rho}$  is the projection of the electron position vector in the layer plane [ $\rho(x, y)$ ].

In the absence of the impurity the eigenstates of  $\hat{H}_0$  are separable in  $(x, y)$  and  $z$ ,

$$\hat{H}_0 |v, \vec{k}_\perp\rangle = \left( \varepsilon_v + \frac{\hbar^2 k_\perp^2}{2m_e^*} \right) |v, \vec{k}_\perp\rangle \quad (103)$$

where  $\nu$  labels the quantum well eigenstates (energy  $\varepsilon_\nu$ ), that is, the quantum well bound ( $\varepsilon_\nu < V_0$ ) and unbound states ( $\varepsilon_\nu > V_0$ ) and  $\vec{k}_\perp = (k_x, k_y)$ . Since the  $|\nu, \vec{k}_\perp\rangle$  basis is complete we may always expand the impurity wavefunction  $\psi_{\text{loc}}$  in the form

$$|\psi_{\text{loc}}\rangle = \sum_{\nu, \vec{k}_\perp} c(\nu, \vec{k}_\perp) |\nu, \vec{k}_\perp\rangle \quad (104)$$

The Coulombic potential couples a given subband  $\nu$ , as well as a given vector  $\vec{k}_\perp$  with all others. The intersubband coupling (especially the one with the subbands of the quantum well continuum) is difficult to handle. In a quasi-two-dimensional situation we would like to set  $c(\nu, \vec{k}_\perp) \equiv c_{\nu_0}(\vec{k}_\perp) \delta_{\nu, \nu_0}$ , that is, to neglect intersubband coupling [67, 68]. This procedure is convenient as the impurity wavefunction displays a separable form:

$$\langle \vec{r} | \psi_{\text{loc}} \rangle = \chi_{\nu_0}(z) \varphi(\vec{\rho}) \quad (105)$$

The wavefunction  $\varphi(\vec{\rho})$  is the solution of the two-dimensional Schrödinger equation

$$\left[ \frac{\hat{p}_x^2 + \hat{p}_y^2}{2m_e^*} + V_{\text{eff}}(\rho) \right] \varphi(\vec{\rho}) = (\varepsilon - \varepsilon_{\nu_0}) \varphi(\vec{\rho}) \quad (106)$$

where  $V_{\text{eff}}$  is the effective in-plane Coulombic potential,

$$V_{\text{eff}}(\rho) = \frac{-e^2}{\kappa} \int_{-\infty}^{+\infty} dz \chi_{\nu_0}^2(z) \frac{1}{\sqrt{\rho^2 + (z - z_i)^2}} \quad (107)$$

which is  $\nu_0$  and  $z_i$  dependent. A solution of Eq. (106) can be sought variationally, the simplest choice for the ground state being the nodeless one-parameter trial wavefunction

$$\varphi_0(\rho) = \frac{1}{\lambda} \sqrt{\frac{2}{\pi}} \exp(-\rho/\lambda) \quad (108)$$

where  $\lambda$  is the variational parameter. The bound state energy is obtained through the minimization of the function

$$\begin{aligned} \varepsilon_{\nu_0}(z_i, \lambda) &= \frac{\hbar^2}{2m_e^* \lambda^2} - \frac{2e^2}{\kappa \lambda} \int_0^\infty x e^{-x} \\ &\times \int_{-\infty}^{+\infty} \frac{dz \chi_{\nu_0}^2(z)}{\sqrt{x^2 + \frac{4}{\lambda^2} (z - z_i)^2}} dx + \varepsilon_{\nu_0} \end{aligned} \quad (109)$$

and the binding energy is

$$\varepsilon_{b\nu_0}(z_i) = \varepsilon_{\nu_0} - \text{Min}_\lambda \varepsilon_{\nu_0}(z_i, \lambda) \quad (110)$$

One should be aware that the decoupling procedure [Eqs. (105)–(110)] runs into difficulties in the limits  $L \rightarrow \infty$  and  $L \rightarrow 0$ . In the former case the energy difference  $\varepsilon_{\nu_0+1} - \varepsilon_{\nu_0}$  becomes very small and many subbands become admixed by the Coulombic potential. Clearly, for infinite  $L$  one cannot describe the bulk  $1s$  hydrogenic bound state by a separable wavefunction. In the latter case ( $L \rightarrow 0$ ) one finds similar problems due to the energy proximity between the ground quantum well subband  $\varepsilon_1$  and the top of the well  $V_0$ . Consequently  $\chi_1(z)$  leaks more and more heavily in the

barrier. At  $L = 0$  the only sensible result is to find a  $1s$  bulk hydrogenic wavefunction corresponding to the barrier-acting material (in this model the latter has a binding energy equal to  $R_y^*$ ). Once again this state cannot have a wavefunction like that of Eq. (105). If  $V_0$  is infinite the result at  $L = 0$  is qualitatively different. The quantum well only has bound levels whose energy separation increases like  $L^{-2}$  when  $L$  decreases. The smaller the well thickness, the better the separable wavefunction becomes. At  $L = 0$ , one obtains a true two-dimensional hydrogenic problem whose binding energy is  $4R_y^*$  whereas  $\lambda = a_B^*/2$ .

To circumvent the previous difficulties and obtain the exact limits at  $L = 0$  and  $L = \infty$  for any  $V_0$  one may use [69–71]

$$\psi_{\text{loc}}(\vec{r}) = N \chi_1(z) \exp\left[-\frac{1}{\lambda} \sqrt{\rho^2 + (z - z_i)^2}\right] \quad (111)$$

where  $N$  is a normalization constant,  $\lambda$  is the variational parameter, and attention is focused on the ground bound state attached to the ground quantum well subband  $\varepsilon_1$ . Calculations are less simple than with the separable wavefunction [Eq. (105)]. Comparing the binding energy deduced from Eqs. (105)–(111) one finds, for infinite  $V_0$ , that the separable wavefunction gives almost the same results as the nonseparable wavefunction if  $L/a_B^* \leq 3$ . This is the range where for most materials the quantum size effects are important.

Other variational calculations have been proposed [72, 73]. For example, instead of using a nonlinear variational parameter one uses a finite basis set of fixed wavefunctions (often Gaussian ones) in which  $\hat{H}$  is numerically diagonalized. The numerical results obtained by using a single nonlinear variational parameter compare favorably with these very accurate treatments.

### 3.1.2. Results for the Ground Impurity State Attached to the Ground Subband

Figures 9 to 11 give a sample of some calculated results for the ground impurity state attached to the ground subband. Two parameters control the binding energy:

- (i) Thickness dependence of the impurity binding energy: the dimensionless ratio  $L/a_B^*$  indicates the amount of two-dimensionality of the impurity state. If  $L/a_B^* \geq 3$  or  $L/a_B^* \leq 0.2$  and  $V_0 \approx 3$  eV in GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As the problem is almost three-dimensional. This is either because the subbands are too close ( $L/a_B^* \geq 3$ ) or because the quantum well continuum is too close ( $L/a_B^* \leq 0.2$ ). The on-center donor binding energy increases from  $R_y^*(L \rightarrow \infty)$  to reach a maximum ( $L/a_B^* \leq 1$ ) whose exact  $L$  location and amplitude depend on  $V_b$ . Finally it decreases to the value  $R_y^*$  at  $L = 0$  [72, 73]. If  $V_0$  is infinite, the maximum is only reached at  $L = 0$  and has a value of  $4R_y^*$  [69].
- (ii) Position dependence of the impurity binding energy: the impurity binding energy monotonically decreases when the impurity location  $z_i$  moves from the center to the edge of the well and finally deep into the

**Figure 9.** Calculated dependence of the on-edge (crosses) and on-center (circles) hydrogenic donor binding energy versus the well thickness  $L$  in a quantum well with an infinite barrier height. barrier. In Figure 12, it is shown that this decrease is rather slow for  $z_i > L/2$ ; for instance, a donor placed 150 Å away from a GaAs–Ga<sub>0.7As</sub>Al<sub>0.3</sub>As quantum well ( $L = 94.8$  Å) still binds a state by  $\approx 0.5R_y^*$  which is  $\approx 2.5$  meV [70].

### 3.1.3. Excited Subbands: Continuum

The procedure followed for the bound state attached to the  $\varepsilon_1$  subband can be generalized for excited subbands  $\varepsilon_2, \varepsilon_3, \dots$  as well as for the quantum well continuum.

However, it becomes rapidly cumbersome since a correct variational procedure for excited states requires the trial wavefunctions to be orthogonal to all the states of lower energies. For separable wavefunctions [Eq. (105)] this requirement is automatically fulfilled and one may safely minimize  $\varepsilon_{\nu_0}(z_i, \lambda)$  to obtain a lower bound of  $\varepsilon_{b\nu_0}(z_i)$ . The new feature associated with the bound states attached to excited subbands is their finite lifetime. This is due to their degeneracy with the two-dimensional continua of the lower lying subbands. This effect, however, is not very large [67, 68] since it arises from the intersubband coupling, which is induced by the Coulombic potential: if the decoupling procedure is valid the lifetime of the quasi-bound state calculated with Eq. (105) should be long.

For impurities located in the barriers (an important practical topic with regard to the modulation-doping technique), we have seen that they weakly bind a state below the  $\varepsilon_1$  edge. There exists (at least) a second quasi-discrete level attached to the barrier edge (i.e., with energy  $\approx V_0 - R_y^*$ ). This state is reminiscent of the hydrogenic ground state of the bulk barrier. Due to the presence of the quantum well slab it becomes a resonant state since it interferes with the two-dimensional continua of the quantum well subbands  $\nu(\varepsilon_\nu < V_0)$ . Its lifetime  $\tau$  can be calculated using the expression

$$\frac{\hbar}{2\tau} = \frac{2\pi}{\hbar} \sum_{\nu, \vec{k}_\perp} \left| \left\langle \tilde{\varphi}(\vec{r}, z_i) \left| \frac{-e^2}{\kappa\sqrt{\rho^2 + (z - z_i)^2}} \right| \nu \vec{k}_\perp \right\rangle \right|^2 \times \delta \left( V_0 - R_y^* - \varepsilon_\nu - \frac{\hbar^2 k_\perp^2}{2m_e^*} \right) \quad (112)$$

where  $\tilde{\varphi}$  is the  $1s$  bulk hydrogenic wavefunction of the barrier. If the distance  $d$  separating the impurity from the quantum well edge is much larger than  $a_B^*$ , Eq. (112) simplifies to

$$\frac{\hbar}{2\tau} \approx 16R_y^* \sum_\nu P_\nu \left( \frac{R_y^*}{V_0 - \varepsilon_\nu} \right)^{3/2} \exp \left( -\frac{2d}{a_B^*} \sqrt{\frac{V_0 - \varepsilon_\nu}{R_y^*}} \right) \quad (113)$$

where  $P_\nu$  is the total integrated probability of finding the carrier in the  $\nu$ th state (energy  $\varepsilon_\nu$ ) in any of the two barriers of the quantum well. One sees from Eq. (113) that the lifetime  $\tau$  is strongly dominated by the escape processes to the excited subband  $\varepsilon_\nu$  whose energy is nearest to  $V_0 - R_y^*$ . As an example let us take a GaAs–GaAlAs quantum well with thickness  $L = 50 \text{ \AA}$ ,  $V_0 = 0.2 \text{ eV}$  and assume that  $d = 3a_B^*$  (i.e.,  $d \approx 300 \text{ \AA}$ ). We then get  $\tau \approx 3 \times 10^{-6} \text{ s}$ . The quasi-bound state can thus be considered, to a reasonable approximation, as stationary ( $\hbar/\tau \approx 4 \times 10^{-8} R_y^*$ ).

### 3.1.4. Excited Impurity Levels Attached to the Subband

The Schrödinger equation [Eq. (102)] has several bound states below  $\varepsilon_1$ ; their binding energies have been calculated by several groups [72, 73]. The calculated energy

difference between the on-center donor ground state (quasi  $1s$ ) and the excited states (quasi  $2p_x, 2p_y$ ) agrees with the far-infrared absorption and magnetoabsorption data [74]. On-edge donor levels have also been investigated.

### 3.1.5. Acceptor Levels in a Quantum Well

The problem of acceptor levels in semiconductor quantum wells is much more intricate than the equivalent donor problem. This is due to the degenerate nature of the valence bands in cubic semiconductors. In quantum wells this degeneracy is lifted (light and heavy holes have different confinement energies).

However, the energy separation between the heavy and light hole subbands is seldom comparable to the bulk acceptor binding energies. Thus many subbands are coupled by the combined actions of the Coulombic potential and the quantum well confining barrier potential. No simple decoupling procedures appear manageable.

Masselink et al. [75] used variational calculations to estimate the binding energy of the acceptor level due to carbon (a well-known residual impurity in MBE grown GaAs layers). Their results, shown in Figure 13, agree remarkably with the experiments of Miller et al. [76]. One notices in Figure 13 the same trends versus quantum well thickness as displayed by Coulombic donors (Figs. 10 and 11). The binding energy first increases when  $L$  decreases (increasing

**Figure 13.** Dependence of the on-center carbon binding energy versus well width in GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As quantum wells.  $V_b(x) = 0.15 [\varepsilon_g(\text{Ga}_{1-x}\text{Al}_x\text{As}) - \varepsilon_g(\text{GaAs})]$  is the assumed hole confining barrier height. The open circles are the experimental values obtained by Miller et al. [76]. Reprinted with permission from [205], J. L. Marin et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

tendency to two-dimensional behavior), then saturates, and finally drops to the value of the acceptor binding energy of the bulk barrier. Finally, it should be noted that the relative increase in binding is smaller for acceptors than for donors. This is because the bulk acceptor Bohr radius is much smaller than that of the bulk donor.

### 3.2. Hydrogenic Impurities within Asymmetric and Symmetric Quantum Well Wires

In this section the energy of the ground and first excited states, the binding energy, and oscillator strengths for hydrogenic impurities confined within a cylindrical quantum well wire with a finite-height potential well are studied variationally as a function of the wire radius and of the relative position of the nucleus within the quantum well wire for different barrier-height potential [77]. The trial wavefunction is constructed as the product of the free wavefunction of hydrogen impurity and a simple auxiliary function that allows the appropriate boundary conditions to be satisfied.

In this context, the variational method here used constitutes a useful approach to study asymmetric and symmetric quantum systems confined by penetrable potentials.

#### 3.2.1. On-Axis Hydrogenic Impurity

If the nucleus of the hydrogen impurity is located on the symmetry axis of the cylindrical quantum well wire, the model Hamiltonian for the electron within the quantum well wire can be written in atomic units ( $\hbar = m_e^* = e = 1$ ) as

$$\hat{H} = -\frac{1}{2}\nabla^2 - \frac{1}{r} + V_b(\rho) \quad (114)$$

with

$$V_b(\rho) = \begin{cases} 0 & 0 \leq \rho \leq \rho_0 \\ V_0 & \rho_0 \leq \rho < \infty \end{cases} \quad (115)$$

where  $r = \sqrt{\rho^2 + z^2}$  is the electron–nucleus distance,  $\rho$  is the cylindrical coordinate parallel to  $xy$  plane,  $z$  is the coordinate along the wire axis,  $\rho_0$  is the wire radius, and  $V_0$  is the confining potential barrier.

The physical meaning of  $V_0$  in this context is to simulate, on the average, the effective potential step created by the composition difference between the quantum well wire and its surroundings.

It is well known that the Schrödinger equation for this Coulomb-type potential is not separable in cylindrical coordinates, the natural symmetry of the wire; thus we are forced to use an approximate method to calculate the ground state energy and first excited states for this system.

In order to use the variational method to solve approximately the Schrödinger equation with the Hamiltonian given by Eq. (114), we must construct a trial wavefunction  $\psi$  with the basic properties listed as follows:

$$\begin{aligned} \psi(0) & \text{ finite} \\ \psi(r) & \rightarrow 0 \text{ as } r \rightarrow \infty \\ \frac{1}{\psi(r)} \frac{\partial \psi(r)}{\partial \rho} & \text{ continua at } \rho = \rho_0 \end{aligned} \quad (116)$$

The function  $\psi$  will contain a parameter or a set of parameters that allows us to minimize the ground state energy by imposing that

$$\frac{\partial \varepsilon_0}{\partial \alpha_i} = 0 \quad (117)$$

where  $\{\alpha_i\}$  is the set of parameters mentioned earlier.

A possible ansatz wavefunction for this problem is of the form

$$\psi_{1s} = \begin{cases} \psi_i = A(\rho_0 - \alpha\rho) \exp(-\alpha r) & 0 \leq \rho \leq \rho_0 \\ \psi_o = B \exp(-\alpha r) \exp(-\beta\rho) & \rho_0 \leq \rho < \infty \end{cases} \quad (118)$$

where  $A$ ,  $B$  are normalization constants and  $\alpha$ ,  $\beta$  are the variational parameters involved in the calculation. These functions must satisfy

$$\psi_i|_{\rho=\rho_0} = \psi_o|_{\rho=\rho_0} \quad (119)$$

$$\left. \frac{\partial \psi_i}{\partial \rho} \right|_{\rho=\rho_0} = \left. \frac{\partial \psi_o}{\partial \rho} \right|_{\rho=\rho_0} \quad (120)$$

By imposing condition (120) to the function given by Eq. (118) we have that

$$\beta = \frac{\alpha}{(1 - \alpha)\rho_0} \quad (121)$$

That is, we need to find only one variational parameter to minimize the ground state energy. Furthermore, when  $V_0 \rightarrow \infty$ ,  $\alpha \rightarrow 1$ ,  $\beta \rightarrow \infty$ , and  $\psi_o \rightarrow 0$ , as expected.

The continuity condition on the boundary, Eq. (119), relates  $B$  and  $A$ :

$$B = A\rho_0(1 - \alpha) \exp\left(\frac{\alpha}{1 - \alpha}\right) \quad (122)$$

The suitable Hamiltonian for  $2p$ -type excited states is the same that given by Eq. (114), and the variational wavefunctions for  $2p_x$ ,  $2p_y$ , and  $2p_z$  states, when the nucleus of hydrogenic impurity is fixed on the symmetry axis of the wire, are of the form

$$\psi_{2p_x} = \begin{cases} \psi_i = C(\rho_0 - \gamma\rho) \\ \quad \times \exp(-\gamma r) \rho \cos \varphi & 0 \leq \rho \leq \rho_0 \\ \psi_o = D \exp(-\gamma r) \\ \quad \times \exp(-\xi\rho) \rho \cos \varphi & \rho_0 \leq \rho < \infty \end{cases} \quad (123)$$

$$\psi_{2p_y} = \begin{cases} \psi_i = C(\rho_0 - \gamma\rho) \\ \quad \times \exp(-\gamma r) \rho \sin \varphi & 0 \leq \rho \leq \rho_0 \\ \psi_o = D \exp(-\gamma r) \\ \quad \times \exp(-\xi\rho) \rho \sin \varphi & \rho_0 \leq \rho < \infty \end{cases} \quad (124)$$

$$\psi_{2p_z} = \begin{cases} \psi_i = C(\rho_0 - \gamma\rho) \\ \quad \times \exp(-\gamma r) z & 0 \leq \rho \leq \rho_0 \\ \psi_o = D \exp(-\gamma r) \\ \quad \times \exp(-\xi\rho) z & \rho_0 \leq \rho < \infty \end{cases} \quad (125)$$

where  $C$  and  $D$  are normalization constants and  $\gamma$ ,  $\xi$  are variational parameters to be determined and are related by

$$\xi = \frac{\gamma}{(1-\gamma)\rho_0} \quad (126)$$

and

$$D = C\rho_0(1-\gamma) \exp\left(\frac{\gamma}{1-\gamma}\right) \quad (127)$$

The results for the energy of the ground and  $2p_z$  states as a function of wire radius and different barrier heights are displayed in Figure 14. For a given value of the finite barrier potential the ground state (excited state) energy increases from  $-0.5$  ( $-0.125$ ) Hartrees as the wire radius is reduced. These values are characteristic of the “free” hydrogen atom.

The binding energy  $\varepsilon_b$  for the hydrogenic impurity is defined as the ground state energy of the system without Coulomb interaction  $\varepsilon_w$ , minus the ground state energy in the presence of electron–nucleus interaction  $\varepsilon_0$ ; that is,

$$\varepsilon_b = \varepsilon_w - \varepsilon_0 \quad (128)$$

The binding energy defined in this way is a positive quantity.

In Figure 15a, we display the variation of the hydrogenic impurity binding energy  $\varepsilon_b$  as a function of wire radius  $\rho_0$  for several values of finite potential barrier.

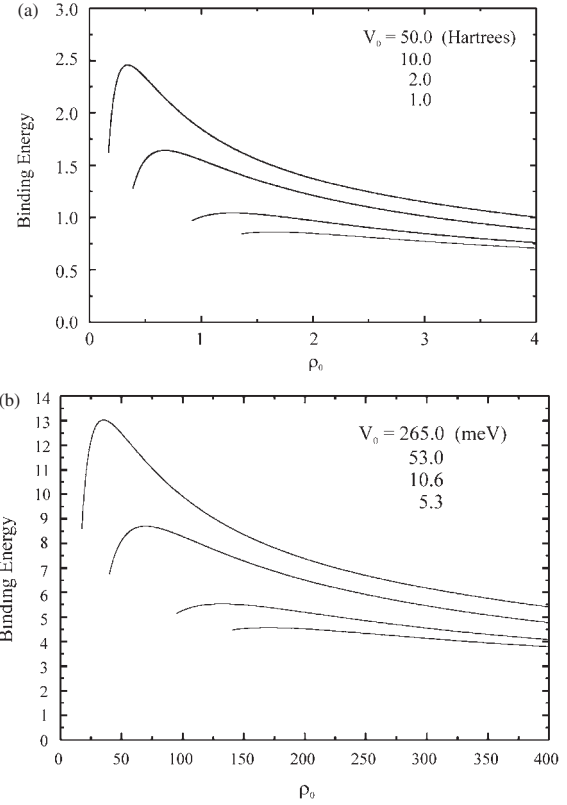

### 3.2.2. Off-Axis Hydrogenic Impurity

If the nucleus of the atom is located on the  $x$  axis, at a distance  $b$  from the axis of the wire, the electron–nucleus distance is

$$\begin{aligned} r' &= |\vec{r} - b\hat{e}_x| = \sqrt{(x-b)^2 + y^2 + z^2} \\ &= \sqrt{\rho^2 + b^2 + z^2 - 2\rho b \cos \varphi} \end{aligned} \quad (129)$$

**Figure 14.** Energy of the ground and  $2p_z$  states of the hydrogenic impurity confined in a penetrable quantum well wire with the nucleus on the axis as a function of wire radius and potential barrier heights. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Figure 15.** (a) Binding energy of the hydrogenic impurity confined in a penetrable quantum well wire with the nucleus on the axis as a function of the wire radius and potential barrier height. (b) Binding energy of the hydrogenic impurity confined in a penetrable GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As quantum well wire with the nucleus on the axis as a function of the wire radius and potential barrier height. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

with  $\vec{r}$  the position vector of the electron relative to the origin on the wire axis. Then the suitable Hamiltonian is

$$\hat{H} = -\frac{1}{2}\nabla^2 - \frac{1}{r'} + V_b(\rho) \quad (130)$$

where  $V_b(\rho)$  is the same as that given by Eq. (115).

The trial wavefunction for the ground state energy can then be written as

$$\psi_{1s} = \begin{cases} \psi_i = A(\rho_0 - \alpha\rho) \exp(-\alpha r') & 0 \leq \rho \leq \rho_0 \\ \psi_o = B \exp(-\alpha r') \exp(-\beta\rho) & \rho_0 \leq \rho < \infty \end{cases} \quad (131)$$

where, as before,  $A$  and  $B$  are normalization constants and  $\alpha$ ,  $\beta$  are the variational parameters involved in the calculation. Again,  $\alpha$ ,  $\beta$  and  $A$ ,  $B$  are, respectively, related by Eqs. (121) and (122).

When the nucleus of hydrogenic impurity is off the symmetry axis, it is not possible to find the wavefunctions, for the  $2p_x$  and  $2p_y$  states, that satisfy the orthonormality condition as is required by the method. Therefore we will restrict to the  $2p_z$  state only. The suitable Hamiltonian is the same

that given by Eq. (116), and the variational wavefunction is given by

$$\psi_{2p_z} = \begin{cases} \psi_i = C(\rho_0 - \gamma\rho)\exp(-\gamma r')z & 0 \leq \rho \leq \rho_0 \\ \psi_o = D\exp(-\gamma r')\exp(-\xi\rho)z & \rho_0 \leq \rho < \infty \end{cases} \quad (132)$$

where, as before,  $C$ ,  $D$  are normalization constants and  $\gamma$ ,  $\xi$  are the variational parameters involved in the calculation. Again,  $\gamma$ ,  $\xi$  and  $C$ ,  $D$  are, respectively, related by Eqs. (126) and (127).

In Figure 16, we show the energy of the ground and  $2p_z$  states as a function of  $(b/\rho_0)$  for  $\rho_0 = 1.0$  Bohr and several heights of potential barrier.

In Figure 17a, we display the variation of the hydrogenic impurity binding energy  $\varepsilon_b$  as a function of  $(b/\rho_0)$  for  $\rho_0 = 1.0$  Bohr and several heights of potential barrier.

### 3.2.3. Optical Properties

To predict the absorption peak due to  $1s-2p$  transitions as a function of the wire radius and confining degree, we have calculated the transition energy between these states as well as their oscillator strengths.

The  $f_0$  oscillator strength is defined as

$$f_0 = \frac{2}{3} |\langle 1s | \vec{r} \cdot \vec{e}_r | 2p \rangle|^2 \Delta\varepsilon \quad (133)$$

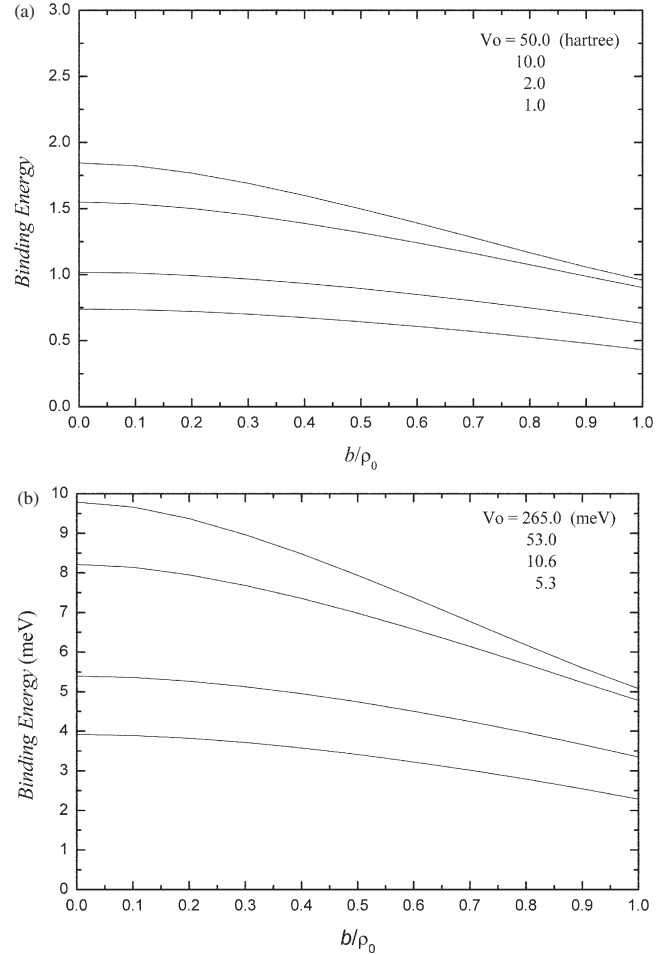

where  $\vec{e}_r$  is the incident light polarization vector and  $\Delta\varepsilon = \varepsilon_{2p} - \varepsilon_{1s}$  is the transition energy between  $2p$  and  $1s$  states.

The  $1s-2p_z$  oscillator strength  $f_0$  (for  $\vec{e}_r \parallel z$ ) is shown in Figure 18 as a function of wire radius for several heights of potential barrier, when the nucleus is fixed on the center of the wire. For a given value of the finite barrier potential the oscillator strength increases from 0.139, the characteristic value of the “free” hydrogen atom, as the wire radius is reduced.

Finally, in Figure 19, we show the oscillator strength  $f_0$  (for  $\vec{e}_r \parallel z$ ) as a function of relative nucleus position  $(b/\rho_0)$

**Figure 16.** Energy of the ground and  $2p_z$  states of an off-axis hydrogenic impurity enclosed within a penetrable quantum well wire of radius  $\rho_0 = 1.0$  Bohr as a function of the relative nucleus position and potential barrier height. for  $\rho_0 = 2.0, 3.0,$  and  $4.0$  Bohr and several potential barrier heights for the off-axis case.

In Figure 14, we show the ground and first excited states energies of the hydrogenic impurity confined within cylindrical quantum dot with the nucleus on the symmetry axis, as a function of  $\rho_0$  for several  $V_0$  values. The ground state energy has a similar behavior as in [65], as well as for the hydrogen atom and for electron systems (like  $H^-$ , He,  $Li^+$ , and  $Be^{2+}$ ) within a penetrable spherical box [78]; that is, the energy diminishes as the confinement box size increases (for a given value of  $V_0$ ), and for a given size of the box the energy increases as  $V_0$  increases. Similar behavior is found by Nag and Gangopadhyay [79] who show graphically qualitative results for heavy holes and electrons within a quantum well wire with cylindrical and elliptic cross-section. They have used the physical constants of the  $Ga_{0.47}In_{0.53}As/InP$  system.

**Figure 18.**  $1s-2p_z$  oscillator strength of the hydrogenic impurity confined in a penetrable quantum well wire with the nucleus on the axis as a function of the wire radius and potential height. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

This energy behavior can be understood on the basis of the uncertainty principle because when confinement dimensions are reduced the energy increases. If dimensions continue decreasing there will be a point at which the kinetic energy will be greater than the potential energy associated with internal interactions of the system. In an extreme situation of confinement the potential energy is only a perturbation of total energy for a free particle system. For attractive potentials, like Coulomb’s potential, there is a very clear competition between kinetic energy and potential energy. If  $\rho_0$  decreases, then potential energy decreases, but kinetic energy always increases because of the localization of wavefunction.

**Figure 19.**  $1s-2p_z$  oscillator strength of an off-axis hydrogenic impurity enclosed within a penetrable quantum well wire of radii  $\rho_0 = 2.0$ ,  $\rho_0 = 3.0$ , and  $\rho_0 = 4.0$  Bohr as a function of the relative nucleus position and potential height. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

In Figure 15a, we display the binding energy of a hydrogenic impurity in a quantum well wire with finite potential barrier, as a function of the width of the wire. The results show that, due to the finite confining capacity of the quantum well wire, there is a critical radius for which the electron is no longer confined. Indeed, as the confining barrier increases this critical radius become smaller, as expected from simple physical considerations. For a given value of the finite barrier potential the binding energy increases from its bulk value as the wire radius is reduced, reaches a maximum value, and then drops to the bulk value characteristic of the barrier material as the wire radius goes to zero. This is due to the fact that as the wire radius is decreased the electron wavefunction is compressed thus leading to an enhancement of the binding energy. However, below a certain value of  $\rho_0$  the leakage of the wavefunction into the barrier region becomes more important, and the binding energy begins to decrease until it reaches a value that is characteristic of the barrier material as  $\rho_0 \rightarrow 0$ . This effect has been studied for heavy and light excitons confined within quantum wires [80], for hydrogen impurities within quantum well wire of  $\text{GaAs}_{1-x}\text{Al}_x\text{As}$  [81, 82], and excitons within quantum well wire in the presence of a magnetic field [83]. In Figure 15b, we show the same results for the quantum well wire of  $\text{GaAs}_{1-x}\text{Al}_x\text{As}$  for the barrier potentials  $V_0 = 265.0$ , 53.0, 10.6, 5.3 meV that correspond to the  $x = 0.36$ , 0.08, 0.016, 0.008, Al concentrations, respectively. The quantitative comparison of the curves in Figure 15b with the results of [80, 82, 83] show that our variational calculations lead to the same results.

The peak in the binding energy occurs for the smallest value of  $\rho_0$  for which the probability of electrons to be found outside the well is not significant; that is, the enhancement in binding energy occurs because the confining potential is forcing the electrons to move only in a smaller space and to spend most of their time closer the nucleus. This strong enhancement of the binding energy has important consequences for optical and transport properties of quantum well wires.

In Figure 16, we show the ground and first excited state energies for the asymmetric case. The ground state energy approaches the value calculated in [65] for the infinite potential barrier case, as the potential barrier is increased, and when the size of the quantum well wire becomes infinite and the nuclei is close to the boundary. For a given value of the finite barrier potential the energy of the  $2p_z$  excited state is almost independent of the relative position of the nuclei within the quantum well wire, as compared with the variation of the ground state energy. This is due to the orientation of the orbital in which the electron moves; a similar effect has been studied for a hydrogen atom enclosed between two impenetrable parallel planes and for a heavy exciton in a CdS film in [84].

Also, we can note that for  $\rho_0 = 1$  Bohr, the ground state energies calculated for  $V_0 = 1, 2, 10, 50$  Hartrees are in exact agreement with the ground state energies when the atom nucleus is on the symmetry axis as we can see in Figure 14. The same is true for the first excited state energies (compare Fig. 16 with Fig. 14).

In Figure 17a, we can note that the value of the binding energy for the asymmetric case decreases as the nucleus

approaching the quantum well wire is increased. A similar behavior occurs for the binding and the ground state energy of a hydrogenic impurity placed in a rectangular cross-section quantum well wire of GaAs–Ga<sub>x</sub>Al<sub>1-x</sub>As [81].

In Figure 17b, we show the same results as in Figure 17a, for the case of a hydrogenic impurity within a cylindrical quantum well wire of GaAs–Ga<sub>x</sub>Al<sub>1-x</sub>As with  $\rho_0 = 103.4 \text{ \AA}$ . The calculations were carried out for barrier potentials  $V_0 = 265.0, 53.0, 10.6, 5.3 \text{ meV}$  that correspond to aluminum concentrations  $x = 0.36, 0.08, 0.016, 0.008$ . The quantitative comparison of Figure 16b with the results of [81] shows the effect of the geometry on the binding energy.

The binding energy for  $\rho_0 = 1 \text{ Bohr}$  is in agreement with the binding energy when the nucleus is on the axis of the wire (compare Fig. 17a with Fig. 15a).

In Figure 18, the  $1s-2p_z$  transitions of the studied states in the symmetric case are shown. We note a similar behavior to that found in other systems which are confined in regions with different symmetries, for example, the heavy exciton case confined in a KCl ionic sphere for several radii and penetrabilities, in which the excitonic transitions vanish for given sphere sizes, as a consequence of the finite confining potential value, and moreover in that case the absorption peak is shifted to high energies as the sphere radius decreases. This effect has been experimentally observed in SiO<sub>2</sub> spheres [84]. In addition, for  $V_0 = \infty$ , there is a critical radius of quantum well wire for which the absorption has a maximum and then returns to bulk value as the radius continues decreasing.

In Figure 19, we show the oscillator strength  $f_0$  (for  $\vec{e}_i \parallel z$ ) as a function of relative nucleus position ( $b/\rho_0$ ) for  $\rho_0 = 2.0, 3.0, \text{ and } 4.0 \text{ Bohrs}$ , with the following potential barrier values:  $V_0 = 0.1 \text{ and } 0.2 \text{ Hartrees}$  for the off-axis case. The maximum in the absorption peak allows us to predict the optimum site for the location of the hydrogenic impurity within the quantum well wire. We can note that, for the same parameter values as those mentioned earlier, the transition intensities are in agreement with the transition intensities of the studied states in the symmetric case (compare Fig. 19 with Fig. 18).

### 3.3. Asymmetric Confinement of Hydrogen by Hard Spherical and Cylindrical Surfaces

The variational method is used to calculate the ground state energy of the hydrogen atom confined within hard spherical and cylindrical surfaces, for an atomic nucleus, which is off the center of symmetry of the confining boundary. It is shown that the wavefunction for the free hydrogen atom in spherical coordinates (referred to the center of symmetry of the confining surface) can be used, without further assumptions, to construct the trial wavefunction systematically. The latter is assumed to be the product of the free wavefunction and a simple cutoff function that satisfies the appropriate boundary conditions.

In order to show the advantage of the method we present in detail two cases: the hydrogen atom confined within hard spherical and within cylindrical surfaces. The asymmetry of these systems is due to the nucleus of the atom being shifted off the center of symmetry of the confining surface (i.e.,

either off the center of the sphere or off the axis of the cylinder). Of course, in such cases the corresponding Schrödinger equation is no longer separable.

#### 3.3.1. Applications of the Method

In this section, two explicit examples using the variational method application will be described. Both involve the hydrogen atom confined within a domain with impenetrable boundaries. In the first example, we shall consider the atom within a spherical surface where the center of surface and the nucleus of the atom differ by a constant distance  $a$ . Referring to Figure 20, the coordinates of the electron of the hydrogen atom with respect to the nucleus ( $\vec{r}$ ) and with respect to the center of the confining sphere ( $\vec{r}'$ ) are related by

$$\vec{r}' = \vec{r} - \vec{a} \quad (134)$$

The corresponding Hamiltonian can now be written as

$$\hat{H} = -\frac{1}{2}\nabla^2 - \frac{1}{|\vec{r} - \vec{a}|} + V_b(r) \quad (135)$$

where  $V_b$  is a confining potential defined as

$$V_b(\rho) = \begin{cases} +\infty & r > r_0 \\ 0 & r < r_0 \end{cases} \quad (136)$$

The ground state wavefunction for the free hydrogen atom in spherical coordinates is given as

$$\psi_0 = A \exp(-r') \quad (137)$$

where  $r'$  is the electron–nucleus distance and  $A$  is a normalization constant.

**Figure 20.** Coordinates for the off-center hydrogen atom relative to the center of the confining sphere.

Without loss of generality, we can assume that the nucleus is located on the  $z$  axis. The trial wavefunction for the ground state can be written as

$$\chi(\vec{r}) = A(r - r_0) \exp(-\alpha|\vec{r} - \vec{a}|) \quad (138)$$

where  $r_0$  is the radius of the spherical confining domain,  $A$  is a normalization constant, and

$$|\vec{r} - \vec{a}| = [r^2 + a^2 - 2ar \cos \theta]^{1/2} \quad (139)$$

Here,  $\theta$  is the usual polar angle of the spherical coordinates.

The results of the variational calculations of the ground state energy with this trial wavefunction are displayed in Table 1. A comparison with the results obtained in [85, 86] is also shown. Figure 21 shows the ground state energy for different sizes of the confining sphere as a function of  $(a/r_0)$ .

In the case of cylindrical coordinates, it is obvious that the Schrödinger equation for the Coulomb potential is nonseparable; however, the application of the variational method is still possible in the same context as could be done for spherical coordinates, as we shall see.

If the nucleus of the atom is located at the  $x$ -axis, at a distance  $\vec{b}$  (as depicted in Fig. 22), the electron–nucleus distance  $r'$  and the position of the electron relative to the origin on the axis of the cylinder  $r$  are related by

$$r' = |\vec{r}'| = |\vec{r} - \vec{b}| \quad (140)$$

That is,

$$r' = [(x - b)^2 + y^2 + z^2]^{1/2} = [\rho^2 + b^2 - 2\rho b \cos \phi + z^2]^{1/2} \quad (141)$$

The trial wavefunction can be written as

$$\chi(r) = B(\rho - \rho_0) \exp(-\alpha|\vec{r} - \vec{b}|) \quad (142)$$

where  $\rho_0$  is the radius of the cylinder and  $|\vec{r} - \vec{b}|$  is given by Eq. (141). The ground state energies resulting from the

<sup>c</sup> Results of Brownstein [86] obtained by a variational method in which the trial wavefunction does not satisfy the boundary conditions.

**Figure 21.** Ground state energy for an off-center hydrogen atom enclosed within an impenetrable spherical box as a function of the position of the nucleus (relative to center of the sphere), for various radii of the confining box. Note that when  $a/r_0 \gg 1$  and  $r_0 \gg 1$ , the energy approaches  $-1/8$  Hartree which corresponds to the ground state of the hydrogen atom close to an infinite planar surface. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.), Academic Press, San Diego, 2001. © 2001, Academic Press.

variational calculations, using this trial wavefunction, are displayed in Table 2. A comparison with the results from [87] is also shown. In Figure 23, we show the ground state energy as a function of  $(b/\rho_0)$  for different values of  $\rho_0$ .

The trial wavefunction is accomplished by referring the electron–nucleus distance for the free atom to the origin placed at the center of symmetry of the confining surface, without further assumptions.

The results obtained by applying the direct variational method to compute the ground state energy of the hydrogen atom enclosed within spherical or cylindrical surfaces show good agreement with more elaborate calculations as can be seen from Tables 1 and 2. Furthermore, the trial wavefunctions are flexible enough to describe the case when the size of the confining surface becomes infinite and the nucleus is close to the boundary. The latter corresponds to the case when the hydrogen atom is close to a plane.

### 3.4. Confined Electron and Hydrogenic Donor States in a Spherical Quantum Dot

According to hydrogenic effective mass theory, exact solutions and quantum level structures are presented for confined electron and hydrogenic donor states in a spherical quantum dot of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As [88]. Calculated results reveal that the values of the quantum levels of a confined electron in a quantum dot can be quite different for cases with finite and infinite barrier heights. The quantum level sequence and degeneracy for an electron in a quantum dot are similar to those of a superatom of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As but different from those in a Coulombic field. There is stronger confinement and larger binding energy for a hydrogenic donor in a spherical quantum dot of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As than in the corresponding quantum well wires and two-dimensional quantum well structures. The binding energy and its maximum of the ground state of a donor at the center of a quantum well are found to be strongly dependent on the well dimensionality and barrier height.

Because the transverse and longitudinal variables do not separate, the impurity states in two-dimensional quantum wells and quantum well wires cannot be solved exactly. Therefore approximation methods should be used. A reasonable trial function is needed to obtain a correct variational state of an impurity in two-dimensional and one-dimensional confined systems, and calculated results are more accurate if the coupling effect between the impurity and well potentials is considered using a trial function which has (or a part of which has) correctly both donor and well potential effects [89]. However, for a hydrogenic donor at the center of spherical quantum dots the exact solutions [90] can be obtained. It is interesting not only from a physical point of view but also from a mathematical point of view to compare the solutions and binding energies with those of two-dimensional and one-dimensional systems. In this section the exact solutions and quantum level structures for confined electron and hydrogenic donor states in spherical quantum dots are reported. The dependence of the quantum levels and the binding energies on the dimensionality of quantum wells is also presented.

The calculation is based on the effective mass approximation. It has been known to give excellent results for the electronic structure of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As two-dimensional quantum wells and (AlAs)<sub>n</sub>/(GaAs)<sub>n</sub> superlattices if the well width or  $n$  is sufficiently large. The limit is estimated to be about 30 Å ( $n \approx 10$ ) [91]. Therefore it should also be valid for the GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As quantum dots, as the size (diameter for a ball) is sufficiently large. Based on the facts mentioned earlier, the limit for a ball diameter is also estimated to be the same value and equal to 30 Å. Here we treat the cases where the diameter is larger than the critical size. It is interesting to point out that the maximum quantum confinement of an electron in the GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As quantum ball is already obtained before the diameter approaches the critical value. In addition, polarization and image charge effects can be significant if there is a large dielectric discontinuity between the quantum ball and the surrounding medium [92]. However, this is not the case for the GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As quantum system; therefore we ignore such effects.

According to hydrogenic effective mass theory, the electron bound states and their binding energies have been found in two-dimensional quantum wells and quantum well wires. Normally, the effective mass equation is reliable for weakly bound states, and one might worry that the effective mass equation is inappropriate when the binding energy is greatly enhanced in spherical quantum dots of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As. However, the bandgap of GaAs is 1.4 eV, while  $R_y^* = 5.3$  meV. Thus roughly a 100-fold enhancement of the binding energy is necessary before the effective mass equation becomes inapplicable. This difference is much greater than the enhancement seen in the cases considered here, so that the theory is still reliable for the bound states in spherical quantum dots of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As.

Let us for definiteness consider a hydrogenic donor at the center of the quantum dot of radius  $r_0$ . The potential due to the discontinuity of the band edges at the GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As interface  $r = r_0$  is

$$V_b(r) = \begin{cases} V_0 & r \geq r_0 \\ 0 & r < r_0 \end{cases} \quad (143)$$

where  $r$  is the electron–donor distance. The barrier height  $V_0$  is obtained from a fixed ratio of the bandgap discontinuity. According to hydrogenic mass theory, the Hamiltonian for the donor is

$$\hat{H} = -\nabla^2 - \frac{2w}{r} + V_b(r) \quad (144)$$

It is written in a dimensionless form so that all energies are measured in units of the effective Rydberg  $R_y^*$  and all distances are measured in units of effective Bohr radius  $a_B^*$ .  $w$  is equal to 1.

In order to solve the Schrödinger-like equation

$$\hat{H}\psi(r, \theta, \varphi) = \varepsilon\psi(r, \theta, \varphi) \quad (145)$$

the wavefunctions of an electron with well-defined values of the orbital ( $l$ ) and magnetic ( $m$ ) quantum numbers in a spherical symmetric potential, which is the quantum well and Coulomb potential, are written in the form

$$\psi_{lm}(r, \theta, \varphi) = \psi^{(l)}(r)Y_{lm}(\theta, \varphi) \quad (146)$$

Substituting Eq. (146) in Eq. (145), we find an equation for the radial function:

$$r^2 \frac{d^2\psi^{(l)}(r)}{dr^2} + 2r \frac{d\psi^{(l)}(r)}{dr} + \{[\varepsilon(l) - V_b(r)]r^2 - l(l+1) + 2wr\}\psi^{(l)}(r) = 0 \quad (147)$$

Using the method of series expansion, we can solve Eq. (147) exactly. It should be noted that zero and infinity are a regular and an irregular singular point of Eq. (147), respectively. In the region  $0 < r$ , we have a series solution, which has a finite value at  $r = 0$  as

$$\psi^{(l)}(r) = Ar^l \sum_{n=0}^{\infty} a_n^{(l)} r^n \quad (148)$$

where  $A$  is a constant,

$$a_0^{(l)} = 1 \quad a_1^{(l)} = -\frac{1}{l+1} \quad (149)$$

and

$$a_n^{(l)} = -\left[2wa_{n-1}^{(l)} + \varepsilon(l)a_{n-2}^{(l)}\right] / n(n+2l+1) \quad n=2,3,4,\dots \quad (150)$$

In the region  $r_0 < r$ , we can obtain a normal solution [93]. It approaches zero at  $r = \infty$  and is found in the form

$$\psi^{(l)}(r) = B \exp(-K_l r) r^{\rho_l} \sum_{n=0}^N b_n^{(l)} r^{-n} \quad (151)$$

where

$$K_l = [V_0 - \varepsilon(l)]^{1/2} \quad \rho_l = -1 + \frac{w}{K_l} \quad (152)$$

and

$$b_0^{(l)} = 1 \quad b_{n+1}^{(l)} = -(\rho_l - n - 1)(\rho_l - n + l + 1)b_n^{(l)} / 2K_l(n+1) \quad n=0,1,2,\dots \quad (153)$$

$B$  is a constant. The series appears suitable for numerical computation for large  $r$  [93]. However, they are not suitable for  $r_0$  if it is small. In order to get exact value at small  $r_0$ , we find a solution of uniformly convergent Taylor series in the region  $r_0 < r \leq R_p$ , where  $R_p$  is a proper point (e.g.,  $R_p \geq 2a_B^*$ ) for using Eq. (151). For the sake of using the matching conditions at  $r = R_p$  to obtain the eigenenergy equation, it is written as

$$\psi^{(l)}(r) = C \sum_{n=0}^{\infty} c_n (r - R_p)^n + D \sum_{n=0}^{\infty} d_n (r - R_p)^n \quad (154)$$

where  $C$  and  $D$  are constants,  $c_0$  and  $d_1$  are equal to 1, and  $c_1$  and  $d_0$  are equal to 0, respectively. Noting that  $c_n$  and  $d_n$  are equal to 0 for negative  $n$ , the other  $c_n$  can be determined by the recurrence relation

$$c_n = \left\{ -2R_p(n-1)^2 c_{n-1} + [-(n-2)(n-1) + l(l+1) - 2wR_p + K_l^2 R_p^2] c_{n-2} + 2(K_l^2 R_p - w)c_{n-3} + K_l^2 c_{n-4} \right\} / [R_p^2 n(n-1)] \quad (155)$$

and the  $d_n$ 's obey a similar recurrence relation.

Using the matching conditions at the interface  $r = r_0$  and  $R_p$ , we can obtain the equation of the eigenenergies  $\varepsilon(l)$  as follows:

$$\begin{vmatrix} W_{11} & 0 & W_{13} & W_{14} \\ W_{21} & 0 & W_{23} & W_{24} \\ 0 & W_{32} & 1 & 0 \\ 0 & W_{42} & 0 & 1 \end{vmatrix} = 0 \quad (156)$$

That is,

$$W_{21}(W_{42}W_{14} + W_{32}W_{13}) - W_{11}(W_{42}W_{24} + W_{32}W_{23}) = 0 \quad (157)$$

where

$$\begin{aligned}
 W_{11} &= \sum_{n=0}^{\infty} a_n^{(l)} r_0^n & W_{13} &= \sum_{n=0}^{\infty} c_n (r_0 - R_p)^n \\
 W_{14} &= \sum_{n=1}^{\infty} d_n (r_0 - R_p)^n \\
 W_{21} &= \sum_{n=0}^{\infty} (l+n) a_n^{(l)} r_0^{n-1} & W_{23} &= \sum_{n=0}^{\infty} n c_n (r_0 - R_p)^{n-1} \\
 W_{32} &= \sum_{n=0}^N b_n^{(l)} R_p^{-n} \\
 W_{24} &= \sum_{n=1}^{\infty} n d_n (r_0 - R_p)^{n-1} \\
 W_{42} &= \sum_{n=0}^N (-n + \rho_l - K_l R_p) b_n^{(l)} R_p^{-n-1}
 \end{aligned} \tag{158}$$

can be solved numerically. Once the  $n$ th eigenenergy  $\varepsilon_n(l)$  is known, the  $A$ ,  $B$ ,  $C$ , and  $D$  [hence  $\psi_n^{(l)}(r)$ ] are known with the use of the normalized condition of  $\psi_n^{(l)}(r)$ . This  $\psi_n^{(l)}(r)$  depends on the value of  $l$ , the quantum well, Coulomb potential, and energy  $\varepsilon_n(l)$ . We should point that we have neglected the difference of the electron effective mass between GaAs and Ga<sub>1-x</sub>Al<sub>x</sub>As in the Hamiltonian and the matching conditions. If the effective mass difference is considered, similar formulas can be obtained.

If there is no Coulomb potential in the Hamiltonian of Eq. (144) (i.e.,  $w = 0$ ), using the same formulas, we can obtain wavefunction  $\psi_n^{(l)}(r, w = 0)$  and quantum levels  $\varepsilon_n(l, w = 0)$  of an electron in the quantum well. In fact, Eqs. (148) and (151) become the spherical Bessel function and Hankel function if  $w = 0$ . The equation of eigenenergies  $\varepsilon(l, w = 0)$  is

$$k_0 + K_0 \tan(k_0 r_0) = 0 \quad \text{if } l = 0 \tag{159}$$

$$\begin{aligned}
 i k_l h_l(i K_l r_0) j_{l-1}(k_l r_0) + K_l h_{l-1}(i K_l r_0) j_l(k_l r_0) &= 0 \\
 \text{if } l \geq 1 & \tag{160}
 \end{aligned}$$

and

$$k_l = [\varepsilon(l, w = 0)]^{1/2} \quad K_l = [V_0 - \varepsilon(l, w = 0)]^{1/2} \tag{161}$$

where  $j_l$  and  $h_l$  are the  $l$ th-order spherical Bessel function and Hankel functions of the first kind, respectively. Then, the same results are obtained if the wavefunctions and quantum levels are calculated with use of the Bessel and Hankel functions. Once  $\varepsilon_n(l, w = 1)$  and  $\varepsilon_n(l, w = 0)$  are obtained, the binding energy of the corresponding donor states in the spherical quantum dot is given by

$$\varepsilon_{nb}(l) = \varepsilon_n(l, w = 0) - \varepsilon_n(l, w = 1) \tag{162}$$

### 3.4.1. Quantum Levels and Binding Energies

A numerical calculation for GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As spherical quantum dots of the  $r_0$  between  $0.15a_B^*$  and  $7.0a_B^*$  with different  $V_0$  has been performed. In Table 3, the quantum levels of an electron in a spherical quantum dot with different  $r_0$  and  $V_0$  have been shown. The levels  $\varepsilon_n(l)$  are indicated by two symbols  $n$  and  $l$  as shown in Eq. (162).  $n$  is equal to the number of the root of Eqs. (158) or (159) and (160) in order of increasing magnitude (i.e.,  $n = 1, 2, 3, \dots$  and hence  $n - 1$  is the radial quantum number as usual).  $l$  is the usual notation (i.e.,  $s, p, d, \dots$ ). Thus we have  $1p, 1d, 2s, 1f$  levels (states) and so on if the  $n$  and  $l$  are used as the level notation, and we have  $1s, 2p, 3d, 2s, 4f$  levels, and so on, if the principal quantum number, which is equal to  $n + l$ , and  $l$  are used as the notation. It is interesting to point out that when  $V_0$  approaches infinity

$$\varepsilon_n(l) = (\mu_n^l / r_0)^2 \tag{163}$$

where  $\mu_n^l$  is the  $n$ th root of the  $l$ th-order spherical Bessel function. In Table 3, it is shown that the different values of  $\varepsilon_n(l)$  are obtained as  $r_0$  is equal to  $1a_B^*$  and  $2.5a_B^*$ , respectively. It is also shown that the values of quantum levels are different between infinite and finite barrier heights. The differences increase as the  $r_0$  and finite  $V_0$  decrease. There are an infinite number and a finite number of bound states for a spherical quantum dot with infinite and finite barrier heights, respectively. There is no bound state if  $r_0 < R_c = 0.5\pi/(V_0)^{1/2}$  [94]. However, the order of  $\varepsilon_n(l)$  is the same for both infinite and finite barriers [i.e., the unique level sequence  $1s, 1p(2p), 1s(3d), 2s, 1f(4f)$ , and so on]. We should note that the level order is different between both cases of a spherical quantum dot and Coulomb field, in which the level order of an electron is  $1s, 2s, 2p, 3s, 3p, 3d$ , and so on if the principal and orbital quantum numbers are used as the level notation. It is because of the lack of the deep attractive region in the vicinity of the center of a spherical quantum dot. For the motion of an electron in a Coulomb field, the quantum levels are only dependent on the principal quantum number  $n_p$  and degenerate with respect to both  $l$  (orbital quantum number) and  $m$  (magnetic quantum number). The total degree of degeneracy of a quantum level with  $n_p$  is equal to  $n_p^2$  (excluding spin degeneracy). For an electron in a spherical quantum dot, however,

**Table 3.** Quantum levels of an electron in a SQD of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As.

$\varepsilon(l)$	$nl$	1s (1s)	1p (2p)	1d (3d)	2s (2s)	1f (4f)	2p (3p)
$r_0 = 1$	$V_0 = \infty$	9.872	20.187	33.212	39.476	48.832	59.676
	80	7.957	16.225	26.593	31.425	38.919	47.016
	60	7.702	15.679	25.642	30.191	37.420	44.789
	40	7.292	14.786	24.045	28.004	34.777	
2.5	$\infty$	1.580	3.230	5.314	6.316	7.814	9.548
	80	1.446	2.958	4.866	5.781	7.151	8.735
	60	1.427	2.919	4.800	5.702	7.054	8.613
	40	1.396	2.854	4.692	5.572	6.892	8.409

*Note:* The notation with the principal quantum number is shown in parentheses. Effective atomic units are used.

the quantum levels are dependent on both  $n$  and  $l$  and only degenerate with respect to the  $m$ . The total degree of degeneracy of a quantum level with  $n$  and  $l$  is equal to  $2l + 1$  (excluding spin degeneracy). It is worthwhile to point out that the degeneracy can be lifted in the other kinds of quantum dots. In quantum boxes with circle cross-sections, for example, the degeneracy is lifted partly. Now, we can conclude that the quantum level sequence and degeneracy for an electron in a spherical quantum dot are quite different from those in a Coulomb field, and that this distinguishing feature of levels might cause new phenomena in this type of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As structure.

In Figure 24, the ground and first excited energy levels of an electron in a spherical quantum dot as a function of  $r_0$  for an infinite barrier height and two finite barrier heights  $V_0 = 40$  and  $80R_y^*$  were, respectively, plotted. It is shown that the differences of energy levels between different barrier heights increase as  $r_0$  is decreased and that the difference of the first excited state energy is larger than that of the ground state energy for a fixed value of  $r_0$ . It is also shown that there are no bound states for a spherical quantum dot with a finite  $V_0$  if  $r_0 < R_c$ , as mentioned earlier. In Figure 25, the binding energies of the ground and first excited states of a donor in a spherical quantum dot as a function of the  $r_0$  for three barrier heights  $V_0 = 80, 60,$  and  $40R_y^*$ , respectively, were shown. It is readily seen that as  $r_0$  decreases both the binding energies increase continuously until their maxima and then decrease fast. The values of the binding energies can be much larger than those of quantum well wire and a two-dimensional quantum well as  $r_0$  is smaller. It is interesting to point out the ratio  $\varepsilon_{1b}(0)/\varepsilon_{1b}(1)$  increases as  $r_0$  increases from some small value.  $\varepsilon_{1b}(0)$  and  $\varepsilon_{1b}(1)$  are almost independent of  $V_0$  and respectively equal to  $1.192$  and  $0.576R_y^*$  at  $r_0 = 7.0a_B^*$ . However, the ratio  $1.192/0.576$  is still much less than 4, which is the limit value of a three-dimensional hydrogenic donor as  $r_0$  (approaches infinity).

In Figures 24 and 25, it is easily seen that as the  $r_0$  decreases the binding energies with respect to different states of a donor in a spherical quantum dot increase until

**Figure 24.** Ground state energy ( $\varepsilon_{10}$ ) and first excited state ( $\varepsilon_{11}$ ) energy levels of an electron in a spherical quantum dot versus the dot radius  $r_0$ . The top and middle dashed curves represent the levels  $\varepsilon_{11}$  and  $\varepsilon_{10}$  of the dot of  $V_0 = \infty$ , respectively. The solid curves a, b, c, and d represent the levels  $\varepsilon_{11}$  and  $\varepsilon_{10}$  of the wells of  $V_0 = 80$  and  $40R_y^*$ , respectively. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Figure 25.** Binding energy of the ground state ( $\varepsilon_{0B}$ ) and the first excited ( $\varepsilon_{1B}$ ) states of a donor in a spherical quantum dot versus the dot radius  $r_0$ . The curves a, ab, and b represent  $\varepsilon_{0B}$  of the dot of  $V_0 = 80, 60,$  and  $40R_y^*$ , and the curves c, cd, and d represent  $\varepsilon_{1B}$  of  $V_0 = 80, 60,$  and  $40R_y^*$ , respectively. their maxima and that the increase of the binding energies is always much less than the increase of the energies of the corresponding states of an electron only confined by the spherical quantum dot, although the binding energies can be much larger than those in the corresponding two-dimensional quantum well and quantum well wire. It means that confinement effects [95, 96] are dominant in the range of  $r_0$ . Further, it is also true for the higher excited states. Therefore we can know what kind of quantum-level sequence we will have if the motion of an electron is confined by both a spherical quantum well and a Coulomb field with the same center. The level sequence is similar to that of a three-dimensional hydrogenic donor if  $r_0$  is much larger and quantum confinement due to the spherical quantum dot is very weak. However, it is similar to that of the electron in the spherical quantum dot if the quantum confinement of the spherical quantum dot is stronger than that of the Coulomb potential. Based on what we have mentioned, we can understand why the quantum level structure of GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As superatoms [93, 97] is similar to that of an electron in a spherical quantum dot and quite different from those of ordinary atoms and why the electronic structure of the superatoms is dominated by no-radial-node states of  $1s, 1p(2p), 1d(3d)$ , and so on.

In Figure 26, the maximum binding energies  $\varepsilon_{b\max}$  for the hydrogenic donor ground and first excited states in a spherical quantum dot as a function of the barrier height  $V_0$  were plotted. It is shown that the enhancement of the maximum is greater in a spherical quantum dot (quasi-zero-dimensional) than in the corresponding quantum well wire and two-dimensional quantum well as  $V_0$  is increased. This is because of the enhancement of the electron confinement in three dimensions in the spherical quantum dot. In Figure 27, it was shown that the maximum binding energy  $\varepsilon_{b\max}$  of ground states of a donor at the center of a different kind of quantum well depends on the well dimensionality and barrier height  $V_0$  and presents quasi-two-, one-, and zero-dimensional features of the hydrogenic donor, respectively. It is interesting to note that the mean values of

**Figure 26.** Maximum binding energies  $\varepsilon_{b\max}$  for the hydrogenic donor ground ( $l = 0$ ) and the first excited ( $l = 1$ ) states in a spherical quantum dot versus the barrier height  $V_0$ . Academic Press, San Diego, 2001. © 2001, Academic Press.

the maxima of the two-dimensional quantum well [89] and spherical quantum dot are very close to (slightly larger than) the maxima for the quantum well wire [82]. We should point out that the maximum binding energies of higher excited states can also be used to present the dimension features.

The radial Eq. (147) was solved and the exact solutions of confined electron and donor states in a spherical quantum dot were obtained. The quantum levels and binding

**Figure 27.** Maximum binding energies  $\varepsilon_{b\max}$  of a donor ground state in a quantum well versus the well dimensionality and the barrier height  $V_0$ . For the quasi-one-dimensional case, the dashed lines represent the maximum binding energies of quantum well wires and the solid lines represent the mean values of the maxima of the two-dimensional quantum wells and the spherical quantum dots. energies of a donor in the spherical quantum dot are calculated numerically. The numerical results reveal that the values of the quantum levels of a confined electron in a spherical quantum dot with a finite barrier height are different from those with an infinite barrier height. The differences increase as  $r_0$  decreases. However, the quantum level order is the same for both infinite and finite barrier heights. It is also shown that the quantum level sequence and degeneracy for an electron in a spherical quantum dot are similar to those of a superatom and different from those in a Coulomb field. The quantum level structure of a donor in a spherical quantum dot is similar to that of an electron only confined by the spherical quantum dot as the quantum confinement due to the well potential is stronger than that due to the donor potential. It is useful for understanding the shell model [97] in microclusters.

On the basis of the calculated results, the crossover from three-dimensional to zero-dimensional behavior of the donor states in a spherical quantum dot is shown when the radius becomes small. The binding energy of a hydrogenic donor state in the well of GaAs–Ga<sub>x</sub>Al<sub>1-x</sub>As and its maximum are strongly dependent on the well dimensionality and the barrier height and there is a larger confinement and binding energy of a donor state in a spherical quantum dot than in a quantum well wire and quantum well. Using calculated results of quantum well and quantum well wire, it has been shown that the maxima of the binding energies of hydrogenic donors in quantum wells, quantum well wire, and spherical quantum dots of GaAs–Ga<sub>x</sub>Al<sub>1-x</sub>As can be used to present, respectively, quasi-two-, one-, and zero-dimensional features of the hydrogenic donor states. Further, it has been found that the maximum of the binding energy of donor ground state in a GaAs–Ga<sub>x</sub>Al<sub>1-x</sub>As quantum well wire is about half of the summation of the maximum binding energies in the corresponding two-dimensional quantum well and spherical quantum dot.

It should be pointed out that impurities could be located anywhere in a spherical quantum dot and that the binding energies will decrease and the level ordering will change as the impurity location shifts to the edge or out of the spherical quantum dot. Based on the exact solutions obtained, the quantum levels and binding energies of a donor located out of the center of a spherical quantum dot can be obtained by use of a variation method. The exact solutions are also useful for the calculation of excited states in a spherical quantum dot, which is a kind of quantum dot. It will be interesting to compare the calculated results about quantum levels and binding energies of impurity and exciton states in a spherical quantum dot with those of other kinds of quantum dots.

### 3.5. Shallow Donors in a Quantum Well Wire: Electric Field and Geometrical Effects

In this section the effects of an external electric field on donor binding energies in quantum well wires with cylindrical and square cross-sections are investigated. A system with a GaAs quantum well surrounded by Al<sub>x</sub>Ga<sub>1-x</sub>As potential barriers in the  $x, y$  plane has been chosen. The electron is thus free to move in the  $z$  direction, in the absence of

a Coulomb center binding the electron. A realistic finite potential well model is considered [98].

The behavior of  $\varepsilon_b$  under an electric field is different for quantum well wires of rectangular and cylindrical cross-section. While the direction of the electric field is immaterial for cylindrical wires, it is very important for wires with rectangular cross-section.

It is found that the binding energy of the hydrogenic impurities is a rather sensitive function of the geometry of the wire especially under the influence of an electric field.

It is also found that the electric field effects on  $\varepsilon_b$  are extremely sensitive to the impurity position in or outside the wire.

### 3.5.1. Theory and Calculation

It is convenient to use the Cartesian coordinates for wires of rectangular cross-section and cylindrical coordinates for wires of circular cross-section. The Hamiltonian for the wire of rectangular cross-section, lying along the  $z$  direction, is

$$\hat{H}_0 = -\frac{\hbar^2}{2m_e^*} \left( \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) + V_b(x, y) \quad (164)$$

where

$$V_b(x, y) = \begin{cases} V_0 & x < -\frac{L_x}{2} & y < -\frac{L_y}{2} \\ 0 & -\frac{L_x}{2} \leq x \leq \frac{L_x}{2} & -\frac{L_y}{2} \leq y \leq \frac{L_y}{2} \\ V_0 & \frac{L_x}{2} < x & \frac{L_y}{2} < y \end{cases} \quad (165)$$

Thus, the electron is free to move along the  $z$  direction but is constrained along  $x$  and  $y$  directions. The wire subband structure is obtained by the variational method using the trial wavefunction

$$f_0(x, y) = N_0 \begin{cases} \exp[k_2(x+y)] & x < -\frac{L_x}{2} & y < -\frac{L_y}{2} \\ \cos(k_1 x) \cos(k_1 y) & -\frac{L_x}{2} \leq x \leq \frac{L_x}{2} & -\frac{L_y}{2} \leq y \leq \frac{L_y}{2} \\ \exp[-k_2(x+y)] & \frac{L_x}{2} < x & \frac{L_y}{2} < y \end{cases} \quad (166)$$

where  $N_0$  is the normalization coefficient, and

$$k_1 = \sqrt{2m_e^* \varepsilon_0 / \hbar^2} \quad k_2 = \sqrt{2m_e^* (V_0 - \varepsilon_0) / \hbar^2} \quad (167)$$

For the infinite potential barrier model  $V_0$  is taken to be infinite and the wavefunction outside the barrier is taken to be zero. Matching the wavefunction and its derivative at the boundaries yields

$$k_2^2 = \frac{k_1^2 (1 - \cos k_1 L)}{1 + \cos k_1 L} \quad (168)$$

where the cross-section has been taken to be a square with sides  $L_x = L_y = L$ .

Next, the effect of an electric field on the subband energies is calculated by using the Hamiltonian

$$\hat{H}_1 = \hat{H}_0 + \eta(x \cos \theta + y \sin \theta) \quad (169)$$

where  $\eta = |e|E$ .  $E$  is the electric field strength applied in the  $x, y$  plane and  $\theta$  is the angle between the electric field and the  $x$  axis. The trial function in this case is modified to be

$$\psi_1(x, y) = N_1 \psi_0(x, y) \exp[-\beta(x \cos \theta + y \sin \theta)/L] \quad (170)$$

where  $N_1$  is the normalization coefficient and  $\beta$  is the variational parameter.

With an impurity at  $(x_i, y_i, 0)$  the Hamiltonian becomes

$$\hat{H}_2 = \hat{H}_1 - \frac{\hbar^2}{2m_e^*} \frac{\partial^2}{\partial z^2} - \frac{e^2}{\kappa \sqrt{z^2 + (x - x_i)^2 + (y - y_i)^2}} \quad (171)$$

The trial function for this problem is taken to be

$$\psi_2(x, y, z) = N_2 \psi_1(x, y) \times \exp \left[ -\lambda \sqrt{z^2 + (x - x_i)^2 + (y - y_i)^2} \right] \quad (172)$$

where  $N_2$  is the normalization constant and  $\lambda$  is a variational parameter. The binding energy of the electron is written with respect to the subband energy calculated in the presence of an applied electric field. Numerical results are found for the GaAs/Ga<sub>1-x</sub>Al<sub>x</sub>As system where, within the finite barrier model that has been taken, it has been considered that the finite barrier potential and dielectric constant depend on the  $x$  concentration of Al as follows:

$$V_0 = 0.6(1.247x) \text{ eV} \quad \kappa = 12.5(1 - x) + 10.1x \quad (173)$$

For cylindrical quantum well wires, the Hamiltonian for the relative motion is given by

$$\hat{H}_0 = -\frac{\hbar^2}{2m_e^*} \left( \frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{1}{r^2} \frac{\partial^2}{\partial \varphi^2} \right) + V_b(r, \varphi) \quad (174)$$

where

$$V_b(r, \varphi) = \begin{cases} 0 & r \leq r_0 \\ V_0 & r \geq r_0 \end{cases} \quad (175)$$

The wavefunction for the ground state becomes

$$\psi_0(r, \varphi) = N_0 \begin{cases} J_0(k_{10} r) & r \leq r_0 \\ \frac{J_0(k_{10} r_0)}{K_0(k_{20} r_0)} K_0(k_{20} r) & r \geq r_0 \end{cases} \quad (176)$$

where

$$k_{10} = \sqrt{\frac{2m_e^*}{\hbar^2} \varepsilon_0} \quad k_{20} = \sqrt{\frac{2m_e^*}{\hbar^2} (V_0 - \varepsilon_0)} \quad (177)$$

With an applied electric field in the  $x, y$  plane, the Hamiltonian becomes

$$\hat{H}_1 = \hat{H}_0 + \eta r \cos(\varphi - \theta) \quad (178)$$

**Figure 28.** The binding energy as a function of (a) side length of the square wire and (b) radius of the cylindrical wire. For both cases  $E = 0, 10,$  and  $20$  kV/cm (from top to bottom). Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

The trial function in this case is taken to be

$$\psi_1(r, \varphi) = N_1 \psi_0(r, \varphi) \exp[-\beta r \cos(\varphi - \theta)/r_0] \quad (179)$$

where  $\beta$  is the variational parameter. The Hamiltonian becomes

$$\hat{H}_2 = \hat{H}_1 - \frac{\hbar^2}{2m_e^*} \left( \frac{\partial^2}{\partial z^2} \right) - \frac{e^2}{\kappa \sqrt{z^2 + (r - r_i)^2}} \quad (180)$$

The trial function for the bound electron is taken to be

$$\psi_2(r, \varphi, z) = N_2 \psi_1(r, \varphi) \exp \left[ -\lambda \sqrt{z^2 + (r - r_i)^2} \right] \quad (181)$$

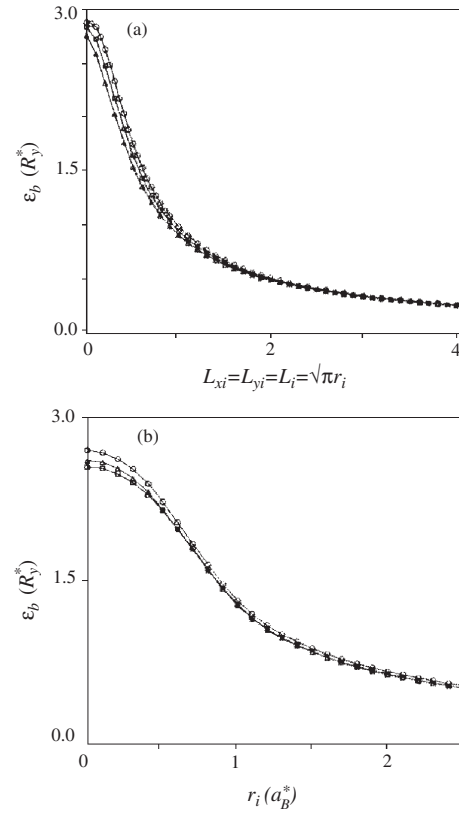

where  $\lambda$  is the variational parameter.

The calculations are carried out for the model system of GaAs/Al<sub>x</sub>Ga<sub>1-x</sub>As for which the effective Bohr radius is  $a_B^* = 98.7 \text{ \AA}$  and the effective Rydberg is  $R_y^* = 5.83 \text{ meV}$  for  $x = 0.3$ . The results are in perfect agreement with previous calculations without the electric field. For example, the binding energies are found to be almost identical for wires of circular and square cross-sections if wire dimensions are taken to be comparable. The binding energies are different for finite and infinite barrier potentials. For infinite barrier potentials, the binding energy  $\varepsilon_b$  tends to infinity as the diameter of the wire tends to zero. It tends to smaller finite values for finite barrier potentials.

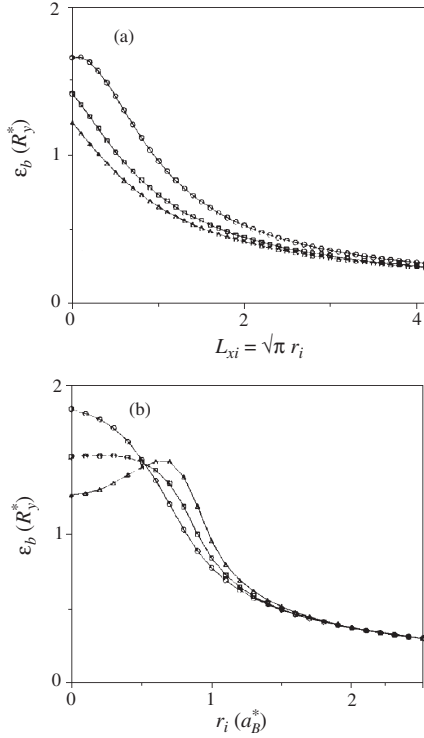

The behavior of the binding energy under a different electric field is shown in Figure 28a and b for wires of square and circular cross-sections, respectively. The electric field is taken to be applied along the positive axis direction with  $\theta = 0$ . Thus, the electron shifts toward the negative part of the axis. It is seen from these figures that the binding energy is a more sensitive function of the electric field for wires of cylindrical cross-section.

The impurity position dependence of the binding energy is shown in Figure 29a when the impurity position is changed along the diagonal of the square wire ( $L = \sqrt{\pi} a_B^*$ ) for different electric fields. The impurity position dependence of the binding energy is shown in Figure 29b when the impurity position is changed radially for a cylindrical wire ( $r_0 = a_B^*$ ) for different electric fields. As expected the binding energy becomes smaller for impurities located at the boundary of the wires since for this position the quantum well walls prevent the electron from feeling the full power of the Coulomb attraction.

The behavior of the binding energy is also checked as the wire dimension is increased. Figure 30a shows the binding energy as a function of impurity position along the  $x$ -axis of the square wire ( $L = \sqrt{\pi} 2a_B^*$ ) for different electric fields. Now, the binding energy is generally smaller since the walls are not pushing the electron closer to the Coulomb center.

**Figure 29.** The binding energy as a function of impurity position along the (a) diagonal of the square wire ( $L = \sqrt{\pi} a_B^*$ ) and (b) radius of the cylindrical wire ( $r_0 = a_B^*$ ). Figure 30b shows the binding energy as a function of impurity position along the radius of the cylindrical wire ( $r_0 = 2a_B^*$ ) for different electric fields. In this case also, the binding energy becomes generally smaller for the same reason.

The Al concentration ( $x$ ) dependence of the binding energy is shown in Figure 31. As expected, increasing the potential barrier increases the binding energy, because the electron is better pushed toward the Coulomb center when the walls are at a higher potential.

In conclusion, the variational method employed in this context is capable of giving all the correct trends for impurity binding energies as a function of the applied electric field, impurity position, and wire geometry.

### 3.6. Hydrogenic Impurities in a Spherical Quantum Dot in the Presence of a Magnetic Field

The ground state and binding energies for a hydrogenic impurity in a spherical quantum dot in the presence of a uniform magnetic field are calculated by a variational method within the effective mass approximation [99]. The simple hydrogenic trial wavefunctions used in this calculation are flexible enough to treat on-center, off-center, and edge states of impurities in a quantum dot. Overall results are in reasonable agreement when compared to other calculations. Interestingly enough, in the case of an off-center

**Figure 31.** The binding energy as a function of Al concentration for hydrogenic impurities in a cylindrical wire ( $r_0 = a_B^*$ ). Same electric field values as in Figure 28. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

impurity, a critical point from which bulk states change their nature (edge states) is also found.

Semiconductors composed of III–V materials usually have small effective masses, which means that the Bohr radius associated with the impurity is large compared with achievable quantum dot sizes. The binding energy of the impurity increases as the size of the confining region becomes of the order of Bohr radius, which makes possible, for instance, the fabrication of a low-threshold laser diode [100].

In this section a variational study about the effect of a magnetic field on the ground state and binding energies of a hydrogenic impurity within spherical quantum dot is made. The impurity can be located on (off) the center of symmetry to get a symmetric (asymmetric) situation, or near the boundary of quantum dot to get surfacelike states (edge states) of this system.

#### 3.6.1. Theory and Model

Within the framework of the effective mass approximation, the Hamiltonian of a hydrogenic impurity located at the center of symmetry of a spherical quantum dot of radius  $r_0$ , in the presence of magnetic field, can be written as

$$\hat{H} = \frac{1}{2m_e^*} \left( \hat{p} - \frac{e}{c} \vec{A} \right)^2 - \frac{e^2}{\kappa r} + V_b(\vec{r}) \quad (182)$$

where  $\kappa$  is the dielectric constant of material inside the quantum dot,  $m_e^*$  is the electron effective mass,  $\vec{A}$  is the vector potential, and  $V_b(\vec{r})$  is the confining potential defined by

$$V_b(\vec{r}) = \begin{cases} 0 & 0 \leq r \leq r_0 \\ \infty & r > r_0 \end{cases} \quad (183)$$

For a uniform magnetic field,  $\vec{A}(\vec{r}) = \vec{B} \times \vec{r}/2$  if the Coulomb gauge  $\nabla \cdot \vec{A} = 0$  is chosen. In spherical coordinates,

if the magnetic field is along the  $z$  direction,  $\vec{B} = B\hat{e}_z$ , the Hamiltonian can be expressed as

$$\hat{H} = -\frac{1}{2m_e^*}\nabla^2 - \frac{e^2}{\kappa r} - \frac{e}{2m_e^*c}B\hat{L}_z + \frac{e^2}{8m_e^*c^2}B^2r^2\sin^2\theta \quad (184)$$

Here,  $\hat{L}_z$  is the  $z$  component of the angular momentum operator, and  $\theta$  is the usual polar angle in these coordinates. The magnetic field preserves the azimuthal symmetry (i.e.,  $m$  is still a “good” quantum number). As only the ground state is studied, the value  $m = 0$  is required; thus the Hamiltonian [Eq. (184)] will retain the quadratic dependence on  $B$  only.

Because of confinement, the solution of the Schrödinger equation associated with Eq. (184) must satisfy

$$\psi(r = r_0, \theta, \varphi) = 0 \quad (185)$$

In order to use the variational method, the trial wavefunction for the calculation of the ground state energy is chosen as

$$\begin{aligned} \psi(r) &= N \exp(-\alpha r) \exp\left(-\frac{1}{8}Br^2\sin^2\theta\right)(r_0 - r) \\ &= N \exp(-\alpha r) \exp\left(-\frac{1}{12}Br^2\right)(r_0 - r) \end{aligned} \quad (186)$$

where  $N$  is the normalization constant and  $\alpha$  is a variational parameter to be determined. The last term has been obtained considering that in absence of  $\vec{A}$  the system holds spherical symmetry. A similar choice of the trial wavefunction to calculate the ground state energy has widely been used in the case of hydrogenic impurities within spherical quantum dots [65] and cylindrical quantum wires [77] without magnetic field.

In the case of a hydrogenic impurity displaced a constant distance  $a$  from the center of symmetry of a quantum dot, the Hamiltonian of Eq. (182) is modified as

$$\hat{H} = \frac{1}{2m_e^*}\left(\hat{p} - \frac{e}{c}\vec{A}\right)^2 - \frac{e^2}{\kappa|\vec{r} - a\hat{e}_z|} + V_b(\vec{r}) \quad (187)$$

where the confining potential,  $V_b(\vec{r})$ , is still given by Eq. (183), and  $\hat{e}_z$  is a unit vector on the  $z$ -axis. Hence, the corresponding Hamiltonian and trial wavefunction, Eqs. (184) and (186), are given by

$$\begin{aligned} \hat{H} &= -\frac{1}{2m_e^*}\nabla^2 - \frac{e^2}{\kappa|\vec{r} - a\hat{e}_z|} - \frac{e}{2m_e^*c}B\hat{L}_z \\ &\quad + \frac{e^2}{8m_e^*c^2}B^2r^2\sin^2\theta \end{aligned} \quad (188)$$

and

$$\psi(r) = N \exp(-\alpha|\vec{r} - a\hat{e}_z|) \exp\left(-\frac{1}{8}Br^2\sin^2\theta\right)(r_0 - r) \quad (189)$$

respectively.

Notice that the wavefunction [Eq. (189)] satisfies the boundary condition imposed by Eq. (185). Again, since

$m = 0$  is chosen, thus the Hamiltonian [Eq. (188)] will not have a linear dependence on magnetic field  $B$ , just like the symmetric case studied previously.

As we shall see, the trial wavefunction [Eq. (189)] is flexible enough to describe the case when the radius of the confining sphere becomes infinite and the hydrogenic impurity is close to its boundary. The latter would correspond to the case of a hydrogenic impurity close to a plane, which allows us to investigate the ground state edge level of the spherical quantum dot.

The binding energy ( $\varepsilon_b$ ) for the hydrogenic impurity is defined as the ground state energy of the system without Coulombic interaction ( $\varepsilon_w$ ) minus the ground state energy including the presence of the electron–nucleus interaction ( $\varepsilon_0$ ); that is,

$$\varepsilon_b = \varepsilon_w - \varepsilon_0 \quad (190)$$

The binding energy defined previously is a positive quantity. The  $\varepsilon_w$  term of Eq. (190) is the ground state energy of an electron confined inside a spherical quantum dot of radius  $r_0$ ; that is,

$$\varepsilon_w = \frac{\pi^2\hbar^2}{2m_e^*r_0^2} \quad (191)$$

The values of the physical parameters pertaining to a GaAs quantum dot used in these calculations, for the sake of comparison, are  $m_e^* = 0.067m_0$  and  $\kappa = 12.5$ ; thus  $a_B^* = 98.7 \text{ \AA}$  and  $R_y^* = 5.83 \text{ meV}$ . Moreover, the linear dependence term on  $B$ , in Eq. (184), can be scaled down to

$$\gamma m = \frac{e\hbar}{2m_e^*cR_y^*}Bm = \frac{m_0}{m_e^*R_y^*}\mu_0Bm \quad (192)$$

where  $\mu_0 = 5.78838263 \times 10^{-2} \text{ meV T}^{-1}$  is the Bohr magneton; then the value  $B = 6.75 \text{ T}$  corresponds to an effective Rydberg ( $\gamma = 1$ ).

The results for the symmetric case (on-center impurity) are displayed in Figure 32, in which the binding energy of the hydrogenic impurity is plotted as a function of the quantum dot radius for different magnetic field strengths. The qualitative and quantitative behaviors of the results are in good agreement with those of Xiao et al. [101] and Branis et al. [102], who studied the magnetic field dependence over the binding energies of hydrogenic impurities in quantum dots and quantum well wires, respectively. In the strong spatial confinement case, ( $r_0 < a_B^*$ ), the binding energy is relatively insensitive to the magnetic field and diverges as the dot radius  $r_0 \rightarrow 0$ , as in the case of zero magnetic field. The latter reflects that the main contribution to the binding energy is due to electron spatial confinement, which prevails over magnetic field confinement. The latter can be estimated through the magnetic length defined as

$$l_B = \sqrt{\frac{\hbar c}{eB}} = 484.82 \times B^{-1/2} \quad (193)$$

where  $l_B$  is expressed in effective Bohrs, and  $B$  is given in Teslas. For dot radius  $r_0 \cong a_B^*$ , the different magnetic field

**Figure 32.** The binding energy of an on-center hydrogenic impurity as a function of the quantum dot radius for different magnetic fields. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

curves deviate from each other reaching steady values as the dot radius increases. For weak spatial confinement ( $r_0 \gg a_B^*$ ), the binding energy converges asymptotically to the corresponding bulk values. In the limit of large dot radius, the binding energy for  $B = 0$  approaches its bulk value  $\varepsilon_b = 1R_y^*$ , as expected. An increase of the field strength decreases the magnetic length as compared with the dot radius; thus in this case the binding energy increases due to magnetic confinement that compels the electron to move “closer” to the on-center impurity.

Figure 33 shows the behavior of binding energy as a function of field strength for different dot radii of an on-center impurity. The variation of binding energy as the

**Figure 33.** The binding energy of an on-center hydrogenic impurity as a function of the magnetic field for different dot radii. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

field increases is less sensitive as dot radius decreases, thus enforcing the previous comment regarding Figure 32.

The results for the asymmetric case (off-center impurity) are plotted in Figures 34 and 35 with zero magnetic field. Figure 34 shows the ground state energy for different sizes of quantum dot versus the relative position of the off-center impurity ( $a/r_0$ ). The ground state energy increases from its on-center impurity value ( $a/r_0 = 0$ ) as the impurity is shifted off the center; this is a general behavior. For larger radii the ground state energy becomes lower, and then, for closer distances to the wall, evolves from the  $1s$  “free” hydrogen ground state ( $-1/2$  Hartree) to the  $2p_z$  “free” hydrogen first excited state ( $-1/8$  Hartree). These results are in good agreement with those of Brownstein [86], Gorecki and Byers Brown [85], and Marín et al. [65]. It is clear now that the trial wavefunction as chosen is flexible enough to describe the case when the size of the quantum dot becomes infinite and the nucleus is close to the surface. The latter corresponds to the case of a hydrogenic impurity close to a plane. This situation will be discussed later when the effect of a magnetic field on the ground state of a hydrogenic impurity near a semiconductor surface will be considered.

In Figure 35, the binding energy for different sizes of quantum dot versus the relative position of the off-center impurity ( $a/r_0$ ) was plotted. The binding energy decreases as the impurity approaches the boundary of a quantum dot. This behavior is due to the fact that wavefunctions vanish at the boundaries and thus their contributions to the binding energy of a quantum dot with an off-center impurity are smaller than a quantum dot with an on-center impurity. The results are similar to the case of a hydrogenic impurity placed in rectangular [81] or circular [77] cross-section quantum well wires, and in a spherical quantum dot [101].

The problem of a hydrogenic impurity near a crystal surface as a limit case of a hydrogenic impurity in a spherical quantum dot of very large radius will be considered next.

**Figure 34.** The ground state energy of an off-center hydrogenic impurity as a function of the relative position of the impurity for different dot radii. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Figure 35.** The binding state energy of an off-center hydrogenic impurity as a function of the relative position of the impurity for different dot radii. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

In Figure 36, the ground state energy for different radii of quantum dot versus the relative position of the off-center impurity ( $a/r_0$ ) is shown. For very large quantum dot radii Levine’s ground state energy of an atom located precisely on the surface of a semi-infinite medium is obtained; that is, the ground state energy changes gradually from its bulk value ( $-1$  Rydberg) into Levine’s state ( $-1/4$  Rydberg) as the impurity reaches the surface.

In Figure 37, the ground state binding energy for different radii of quantum dot versus the relative position of the off-center impurity ( $a/r_0$ ) was plotted. For the too large

**Figure 36.** The ground state energy of a hydrogenic impurity in a spherical quantum dot of very large radius. Note that the ground state changes gradually from its bulk value ( $-1R_y^*$ ) to the Levine state ( $-1/4R_y^*$ ). Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Figure 37.** The binding state energy of a hydrogenic impurity as a function of the relative position of the impurity for large dot radii. Note that there is a point from which the edge states start to appear. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

quantum dot radii considered here, binding energy curves cross one another and define a point from which the edge states begin to appear. This critical point corresponds to a hydrogenic impurity placed at the relative distance  $a/r_0 = 0.68$  from the center of the quantum dot. The associated binding energy with the quantum dot of largest radius ( $r_0 = 100$  effective Bohr) decreases from  $1R_y^*$  (effective Rydberg) for an impurity located far from a quantum dot surface to  $1/4R_y^*$  for an impurity located exactly at the surface of a quantum dot. The binding energy behavior is in reasonable agreement with that of Chen [103], who studied the problem of hydrogenic donors near semiconductor surfaces. Furthermore, starting from the critical point (near the quantum dot surface), there is an inversion of binding energy for quantum dots of different radii. This occurs because the boundary has a greater effect on binding energy when the quantum dot size increases, as a result of the strong spatial limitation due to the closeness of the impurity to the surface. When a magnetic field is applied, the critical point is removed and the binding energy curves cross one another at only one point. Moreover, crossing points are shifted away from the boundary as the magnetic field is increased, and finally a moderate field strength causes them to vanish.

### 3.7. Two-Electron Atomic Systems Confined within Spheroidal Boxes

The direct variational method is used to estimate some interesting physical properties of the He atom and  $Li^+$  ion confined within impenetrable spheroidal boxes. A comparative investigation of the ground state energy, pressure, polarizability, dipole moments, and quadrupole moments with those of He atom inside boxes with paraboloidal walls is made [104, 105]. The overall results show a similar qualitative behavior. However, for  $Li^+$  there are quantitative differences on such properties due to its major nuclear charge, as expected. The trial wavefunction is constructed as a product

of two hydrogenic wavefunctions adapted to the geometry of the confining boxes.

Nowadays there is special interest in investigation of atoms and molecules confined in nanostructures because their physical properties become highly dependent of the size and shape of the confinement volume [65, 77, 78, 105–111]. The reduction of space where the atom is located is equivalent to subjecting it to high pressures and the results of this new spatial condition are, besides other effects, the increase in total energy of the atom and the decrease of its polarizability.

The “atom in a box” model consists of replacing its interaction with neighboring particles by a potential wall. The simplest situation is to assume an infinite potential wall since for this case the wavefunction must vanish at the boundary of the box. The latter condition simplifies the calculations extremely. When a quantum system is localized in a box, the result is that the wavefunction of the system is constrained into that region.

The study of hydrogenic impurities trapped in solids has signaled the limitations of the model of confinement inside spherical boxes. For example, the observed hyperfine splitting of atomic hydrogen in  $\alpha$ -quartz shows the presence of nonvanishing anisotropic components [112], and moreover, the electron microscopy studies of semiconductor clusters show microparticles whose shapes vary from quasi-spherical to pyramidal [113]. This has motivated the use of other models involving nonspherical boxes.

The helium atom inside spherical boxes has been investigated for modeling the effect of pressure on atoms with more than one electron [106–108]. Recently the helium atom inside boxes with paraboloidal walls [105] and the helium atom in a semi-infinite space limited by a paraboloidal boundary [114] have been studied.

### 3.7.1. Variational Calculation of Ground State Energy

The prolate spheroidal coordinates  $(\xi, \eta, \varphi)$  are defined by

$$\xi = \frac{(r_1 + r_2)}{2R} \quad \eta = \frac{(r_1 - r_2)}{2R} \quad \varphi \equiv \varphi \quad (194)$$

where  $r_1$  and  $r_2$  are the distances from any point to two fixed points (foci) separated by a distance  $2R$ . In these coordinates

$$\{\xi = \text{const.} \quad -1 \leq \eta \leq 1 \quad 0 \leq \varphi \leq 2\pi\} \quad (195)$$

defines a family of ellipsoids of revolution around the  $z$ -axis, while

$$\{1 \leq \xi \leq \infty \quad \eta = \text{const.} \quad 0 \leq \varphi \leq 2\pi\} \quad (196)$$

defines a family of hyperboloids of revolution around the  $z$ -axis. In both cases  $2R$  is the focal distance and  $\varphi$  is the usual azimuth angle [115].

If the nucleus of the helium atom is located on one of the foci ( $z = -R\hat{e}_z$ ),  $r_1$  and  $r_2$  denote the location of the two electrons relative to the fixed nucleus, and  $r_{12}$  is the

interelectronic distance, then the Hamiltonian for this system formed by two electrons and one nucleus of charge  $Z$  ( $=2$ ) is given by

$$\hat{H} = -\frac{1}{2}\nabla_1^2 - \frac{1}{2}\nabla_2^2 - \frac{Z}{r_1} - \frac{Z}{r_2} + \frac{1}{r_{12}} \quad (197)$$

where it has been assumed that  $\hbar = m_e^* = e = 1$  (atomic units) and the mass of the nucleus is considered to be very large compared to the electron mass (Born–Oppenheimer approximation).

In spheroidal coordinates, the Laplacian operator can be written as

$$\nabla^2 = \frac{1}{R^2(\xi^2 - \eta^2)} \left\{ \frac{\partial}{\partial \xi} (\xi^2 - 1) \frac{\partial}{\partial \xi} + \frac{\partial}{\partial \eta} (1 - \eta^2) \frac{\partial}{\partial \eta} + \frac{\xi^2 - \eta^2}{(\xi^2 - 1)(1 - \eta^2)} \frac{\partial^2}{\partial \varphi^2} \right\} \quad (198)$$

and the electron–nucleus distances are, respectively,

$$r_1 = R(\xi + \eta) \quad r_2 = R(\xi' + \eta) \quad (199)$$

The electron–electron repulsive potential can be written as a series expansion in products of associate Legendre polynomials

$$\frac{1}{r_{12}} = \frac{1}{R} \sum_{l=0}^{\infty} (2l+1) \sum_{m=0}^l \epsilon_m i^m \left[ \frac{(l-m)!}{(l+m)!} \right]^2 \cos m(\varphi - \varphi') \times P_l^m(\eta) P_l^m(\eta') f_l^m(\xi, \xi') \quad (200)$$

where

$$f_l^m(\xi, \xi') = \begin{cases} P_l^m(\xi') Q_l^m(\xi) & \xi > \xi' \\ P_l^m(\xi) Q_l^m(\xi') & \xi < \xi' \end{cases} \quad (201)$$

$\epsilon_m$  is Neumann’s factor:  $\epsilon_0 = 1$ ,  $\epsilon_n = 2$  ( $n = 1, 2, 3, \dots$ ) [116].

If the atom is enclosed in an impenetrable prolate spheroidal box defined as

$$\{\xi = \xi_0 \quad -1 \leq \eta \leq 1 \quad 0 \leq \varphi \leq 2\pi\} \quad (202)$$

then the wavefunctions must fulfill the requirements

$$\begin{aligned} \psi(\xi = \xi_0, \eta, \varphi; \xi', \eta', \varphi') &= 0 \\ \psi(\xi, \eta, \varphi; \xi' = \xi_0, \eta', \varphi') &= 0 \end{aligned} \quad (203)$$

To obtain the ground state energy of a helium atom by using the direct variational method, the ansatz wavefunction is constructed as a product of two hydrogenic functions, namely,

$$\begin{aligned} \psi(\xi, \eta, \varphi; \xi', \eta', \varphi') &= A \exp[-\alpha R(\xi + \eta)] \\ &\quad \times \exp[-\alpha R(\xi' + \eta')] \\ &\quad \times (\xi - \xi_0)(\xi' - \xi_0) \end{aligned} \quad (204)$$

where  $A$  is a normalization constant, and  $\alpha$  is a variational parameter to be determined after minimizing the energy functional with the additional constrictions imposed by Eq. (203). To satisfy the latter, two auxiliary functions

have been included which have a similar contour to the spheroidal confinement box to allow the total wavefunction to cancel out at the boundary of the box. The kind of wavefunctions like those given in Eq. (204) have been used to investigate one- and two-electron atomic systems confined by spherical penetrable boxes [78], the H,  $H_2^+$ , and  $HeH^{2+}$  quantum systems within soft spheroidal boxes [111], and the helium atom inside boxes with paraboloidal walls [105]. In all of these confined quantum systems such simple functions can describe the symmetry in a qualitative way. Quantitatively, the results are close to those obtained by other methods [106, 107].

The evaluation of the matrix element for the electron-electron Coulomb repulsion with the trial wavefunction [Eq. (204)] involves integration over the azimuthal angles, which can be done immediately, and only the term with  $m = 0$  of Eq. (200) remains. The latter shows the symmetry of system under rotations around the  $z$ -axis. Additionally, the associate Legendre polynomials become ordinary Legendre polynomials. A complete evaluation of the leading expression for the matrix element is presented in Section 4.7.3.

The ground state energy of He and  $Li^+$  for  $R = 0.1, 0.5,$  and  $1.0$  Bohr as a function of volume of the enclosing box is displayed in Figure 38, where a comparison with results of Ley-Koo and Flores-Flores [105] for a He atom within a paraboloidal box is also made.

### 3.7.2. Pressure, Polarizability, and Dipole and Quadrupole Moments

The computed variational energy and trial wavefunctions allow calculation of some of the properties of the confined atom. The average pressure exerted by the boundary on the atom is given by

$$P = -\frac{d\varepsilon}{dV} = -\frac{3}{4\pi R^3(3\xi_0^2 - 1)} \frac{d\varepsilon}{d\xi_0} \quad (205)$$

**Figure 38.** Ground state energy for the helium atom and the lithium ion versus the volume of the spheroidal box and the interfocal distance. Energy units, Hartree; volume units, Bohr<sup>3</sup>. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

where  $V = 4\pi R^3 \xi_0 (\xi_0^2 - 1)/3$  is the volume of the spheroidal box and  $\varepsilon$  is the total ground state energy of the atom. The results obtained for pressure are displayed in Figure 39 for  $R = 0.1, 0.5,$  and  $1.0$  Bohr as a function of  $V$ ; they are also compared with the results of [105].

Following Ley-Koo and Flores-Flores, we used an adapted expression for the polarizability of atoms to molecules [117–119]; then the parallel and perpendicular components of the polarizability are given by

$$\alpha_{\parallel} \equiv \alpha_{zz} = \frac{4}{Z} \left\langle \sum_{i=1}^2 (z_i - \langle z \rangle)^2 \right\rangle = \frac{16}{Z} [\langle z^2 \rangle - \langle z \rangle^2]^2 \quad (206)$$

$$\alpha_{\perp} \equiv \alpha_{xx} = \alpha_{yy} = \frac{4}{Z} \left\langle \sum_{i=1}^2 x_i^2 \right\rangle = \frac{16}{Z} \langle x^2 \rangle^2 \quad (207)$$

Due to the asymmetric position of the nucleus and the asymmetric distribution of electrons inside the confinement box, the atom has an electric dipole moment, which is given by the expectation value of the electron position plus the nucleus contribution; that is,

$$\vec{d} = -RZ\hat{e}_z - \left\langle \psi \left| \sum_{i=1}^2 \vec{r}_i \right| \psi \right\rangle = -[ZR + 2\langle z \rangle]\hat{e}_z \quad (208)$$

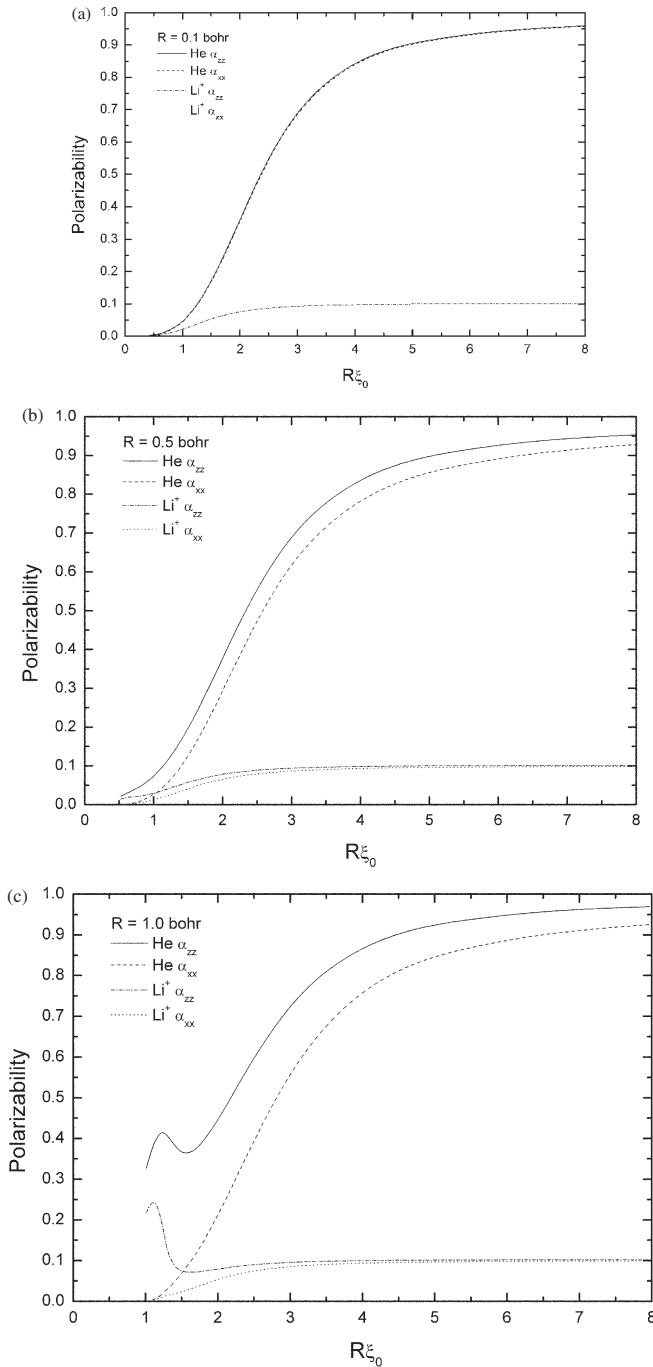

The components of the electric quadrupole moment tensor are given by

$$\begin{aligned} Q_{zz} &= Z(2R^2) - \left\langle \sum_{i=1}^2 [2z_i^2 - x_i^2 - y_i^2] \right\rangle \\ &= Z(2R^2) - 4[\langle z^2 \rangle - \langle x^2 \rangle] \\ Q_{xx} &= Q_{yy} = -\frac{1}{2}Q_{zz} \end{aligned} \quad (209)$$

Figure 40a–c shows the polarizability components for He and  $Li^+$  as a function of the major semiaxis,  $R\xi_0$ , for

**Figure 39.** Pressure of the helium atom and the lithium ion versus the volume of the spheroidal box and the interfocal distance. The atomic unit for pressure is equivalent to  $2.94 \times 10^{13}$  Pa. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Figure 40.** Polarizability tensor components versus major semiaxis of the spheroidal box. Polarizability units,  $\text{Bohr}^3$ ; distance units, Bohr. (a)  $R = 0.1$ , (b)  $R = 0.5$ , and (c)  $R = 1.0$ . Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

$R = 0.1, 0.5$ , and  $1.0$  Bohr, while Figure 41 shows the electric dipole moment as a function of  $R\xi_0$  (for the same  $R$  values given previously). Figure 42 shows the electric quadrupole moment as a function of  $R\xi_0$  for the same values of  $R\xi$ .

As can be seen in Figure 38, the qualitative behavior for confined helium atom is that the energy increases from

**Figure 41.** Electric dipole moment versus major semiaxis of the spheroidal box. The atomic unit for the dipole moment is equivalent to 2.54 Debye. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

$-2.847656$  Hartree (corresponding to “free” helium atom) to a large positive value as a consequence of volume reduction of the confinement box. It can be also noted that for large volumes of spheroidal boxes there is a weak confinement of the atom and the eccentricity of spheroid becomes irrelevant, but for small volumes of the spheroidal box there is a strong confinement and the eccentricity plays a very important role in the energy value as can be corroborated in Figure 38. For  $R = 0.5$  Bohr, the energy curve coincides in both boxes. The latter is an important situation because it has been compared to the energy of an atom enclosed within two boxes of different shape, where additionally the nucleus of the atom for a paraboloidal box is located in the

**Figure 42.** Electric quadrupole moment versus major semiaxis of the spheroidal box. The atomic unit for the quadrupole moment is equivalent to  $1.34 \times 10^{-26}$  esu  $\times$  cm<sup>2</sup>. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

common focus (origin of coordinates) of paraboloids (which corresponds to a symmetric case) while for the spheroidal box the nucleus is located out of the origin, leading to an asymmetric case. It seems that for  $R = 0.5$  Bohr there is no difference for the atom to be in either of these boxes (i.e., boundary shape changes the electron distribution so that both effects combine to give the same energy for the atom). Regarding the same figure, the ground state energy for  $\text{Li}^+$  increases from its asymptotic value of  $-7.222656$  Hartree as the volume of the confinement box decreases, showing the same qualitative behavior as in the helium case. For the same confinement volume, the energy of  $\text{Li}^+$  is smaller than the energy of He due to the Coulomb attraction between the nucleus of  $\text{Li}^+$  ( $Z = 3$ ) and the electrons being greater than in helium atoms ( $Z = 2$ ).

In Figure 39, curves of pressure applied on the atom by the spheroidal box walls are displayed. In this figure we again compare with the results for helium atoms inside impenetrable paraboloidal boxes. As can be noted, the pressure curve for  $R = 0.5$  Bohr is nearest to the corresponding pressure curve for helium enclosed within a paraboloidal box. In same figure, the pressure curves for a lithium ion are also displayed. For the same  $R$  and confinement volume, the pressure on  $\text{Li}^+$  ion is smaller than for He atoms because the Coulomb attraction for the former is greater, which forces the ion electrons to move closer to the nucleus (i.e., they are farther away from the confinement walls than the He electrons).

In Figure 40a–c, the polarizability tensor components  $\alpha_{xx}$  and  $\alpha_{zz}$  are shown. When  $R = 0.1$  Bohr, they begin to decrease from their asymptotic common value  $0.986540$  (corresponding to free helium atom) to zero as the volume of the enclosing box diminishes. It can also be noted that for a nearly spherical box no differences on values of polarizability tensor components are found. For  $R = 0.5$  Bohr, the parallel component of polarizability  $\alpha_{zz}$  (which always takes a value greater than value of transversal component  $\alpha_{xx}$ ) approaches a positive value near zero as the volume of the box diminishes. Moreover, the influence of nonsphericity of the box on values of polarizability tensor components can also be observed. When  $R = 1.0$  Bohr,  $\alpha_{zz}$  has a minimum at  $R\xi_0 \cong 1.52$  Bohr, then increases to a maximum located at  $R\xi_0 \cong 1.24$  Bohr, and finally diminishes approaching a positive value greater than for the other two  $R$  values considered before. This effect in polarizability is also present for  $\text{Li}^+$ , where its polarizability decreases from its asymptotic value of  $0.153354$ . The latter is a consequence of the combination of (a) the deformation of the spheroidal box by increasing its eccentricity (given by  $1/\xi_0$ ) as the volume diminishes and (b) the proximity of the wall to the nucleus, which makes the electrons align on the  $z$  axis; thus the system reaches the maximum of its polarizability. Then, its subsequent decrease (not to zero) is due to the asymmetric reduction of space where the electrons can move.

In Figure 41, the electric dipole moments for  $R = 0.1, 0.5,$  and  $1.0$  Bohr, respectively, are displayed. The feature of this physical quantity is its decreasing behavior from zero for He atoms and from an asymptotic value (different for each value of  $R$ ) for  $\text{Li}^+$  ions to limiting negative values as  $\xi_0 \rightarrow 1$ . All these asymptotic values can immediately be determined from Eq. (208). The nonzero value of the dipole moment

is due to the asymmetric position of the nucleus inside the spheroid, which makes a permanent dipole moment ( $-ZR$ ) since  $\langle z \rangle \rightarrow 0$  as the volume approaches zero. This behavior is qualitatively different from [114] where the electric dipole moment of helium atoms in a semi-infinite space limited by a paraboloidal boundary was investigated. In the latter case, the magnitude of the electric dipole moment seems to increase monotonically from zero (free helium atom) to a limiting value as the volume is reduced. These variations show the shifting of the electron distribution away from the boundary as the latter closes in around the nucleus.

Figure 42 displays the electric quadrupole moment of He atoms increasing from its asymptotic value (corresponding to the free atom), to a positive limiting value different for each value of  $R$ , as  $\xi_0 \rightarrow 1$ . In contrast to the case studied in [105], the positive sign of the quadrupole moment indicates that the electrons preferentially distribute themselves on the major axis of the spheroid. Additionally, for this kind of confinement box, due to the asymmetric nucleus position within the spheroid, there is not a maximum for this property as in the case of paraboloidal walls where the nucleus is located on the symmetry center of the box.

### 3.7.3. Explicit Evaluation of Coulombic Interaction Term

The evaluation of the expectation value of the electron–electron repulsive potential requires performing integrals of the form

$$\begin{aligned} \left\langle \frac{1}{r_{12}} \right\rangle &= (2\pi)^2 A^2 R^5 \sum_{l=0}^{\infty} (2l+1) \\ &\times \int_1^{\xi_0} \int_{-1}^1 \int_1^{\xi_0} \int_{-1}^1 \exp[-2\alpha R(\xi + \eta)] \\ &\times \exp[-2\alpha R(\xi' + \eta')] (\xi - \xi_0)^2 (\xi' - \xi_0)^2 \\ &\times P_l(\eta) P_l(\eta') f_l(\xi, \xi') \\ &\times (\xi^2 - \eta^2)(\xi'^2 - \eta'^2) d\xi d\eta d\xi' d\eta' \end{aligned} \quad (210)$$

where  $f_l^m(\xi, \xi')$  [Eq. (201)] has been reduced to

$$f_l(\xi, \xi') = \begin{cases} P_l(\xi') Q_l(\xi) & \xi > \xi' \\ P_l(\xi) Q_l(\xi') & \xi < \xi' \end{cases} \quad (211)$$

The integration over  $\eta$  and  $\eta'$  coordinates gives the result

$$\begin{aligned} \left\langle \frac{1}{r_{12}} \right\rangle &= (2\pi)^2 A^2 R^5 \sum_{l=0}^{\infty} (2l+1) \\ &\times \int_1^{\xi_0} \int_1^{\xi_0} \exp[-2\alpha R\xi] \exp[-2\alpha R\xi'] \\ &\times (\xi - \xi_0)^2 (\xi' - \xi_0)^2 f_l(\xi, \xi') \\ &\times [\xi^2 \xi'^2 I_0^2 - (\xi^2 + \xi'^2) I_0 I_2 + I_2^2] d\xi d\xi' \end{aligned} \quad (212)$$

where  $I_0$  and  $I_2$  are integrals which involve spherical Bessel functions. That is,

$$I_0 = \int_{-1}^1 \exp(-2\alpha R\eta) P_l(\eta) d\eta$$

$$\begin{aligned}
&= \sum_{l'=0}^{\infty} \int_{-1}^1 (2l'+1) i^{l'} j_{l'}(i2\alpha R) P_{l'}(\eta) P_l(\eta) d\eta \\
&= \frac{2}{2l+1} \sum_{l'=0}^{\infty} (2l'+1) i^{l'} j_{l'}(i2\alpha R) \delta_{l'l} = 2i^l j_l(i2\alpha R) \quad (213)
\end{aligned}$$

and

$$\begin{aligned}
I_2 &= \int_{-1}^1 \eta^2 \exp(-2\alpha R \eta) P_l(\eta) d\eta \\
&= \sum_{l'=0}^{\infty} \int_{-1}^1 (2l'+1) i^{l'} j_{l'}(i2\alpha R) P_{l'}(\eta) P_l(\eta) \eta^2 d\eta \quad (214)
\end{aligned}$$

With the recurrence relation

$$\eta P_k(\eta) = \frac{k+1}{2k+1} P_{k+1}(\eta) + \frac{k}{2k+1} P_{k-1}(\eta) \quad (215)$$

the  $I_2$  integral can be written as

$$\begin{aligned}
I_2 &= \sum_{l'=0}^{\infty} \int_{-1}^1 (2l'+1) i^{l'} j_{l'}(i2\alpha R) \left\{ \frac{(l'+1)(l+1)}{(2l'+1)(2l+1)} \right. \\
&\quad \times P_{l'+1}(\eta) P_{l+1}(\eta) + \frac{l'l}{(2l'+1)(2l+1)} P_{l'-1}(\eta) P_{l-1}(\eta) \\
&\quad + \frac{(l'+1)l}{(2l'+1)(2l+1)} P_{l'+1}(\eta) P_{l-1}(\eta) \\
&\quad \left. + \frac{l'(l+1)}{(2l'+1)(2l+1)} P_{l'-1}(\eta) P_{l+1}(\eta) \right\} d\eta \\
&= 2 \left\{ \frac{(l+1)(l+2)}{(2l+1)(2l+3)} i^{l+2} j_{l+2}(i2\alpha R) + \frac{(2l^2+2l-1)}{(2l-1)(2l+3)} \right. \\
&\quad \left. \times i^l j_l(i2\alpha R) + \frac{l(l-1)}{(2l-1)(2l+1)} i^{l-2} j_{l-2}(i2\alpha R) \right\} \quad (216)
\end{aligned}$$

The integrals of Eq. (212) are evaluated numerically.

### 3.8. Quantum Systems within Penetrable Spheroidal Boxes

In this section the direct variational method is used to study some physical properties of H,  $H_2^+$ , and  $HeH^{2+}$  enclosed within soft spheroidal boxes [111]. The ground state energy, polarizability, and pressure are calculated for these systems as a function of the size and penetrability of the boxes. For these systems the ground state energy as a function of box eccentricity for different values of the barrier height is calculated. Furthermore, in order to demonstrate the applicability of the variational method, other properties of physical interest directly involving the wavefunction, such as the polarizability and the pressure, are calculated.

#### 3.8.1. H, $H_2^+$ , and $HeH^{2+}$ within Penetrable Spheroidal Boxes

The Hamiltonian for a one-electron molecular ion in the Born–Oppenheimer approximation can be written as

$$\hat{H} = -\frac{1}{2} \nabla^2 - \frac{Z_1}{r_1} - \frac{Z_2}{r_2} + \frac{Z_1 Z_2}{2R} \quad (217)$$

where the units are chosen to make  $\hbar = e = m_e^* = 1$ . The subscripts 1 and 2 denote the nucleus of charges  $Z_1$  and  $Z_2$ , respectively.

The prolate spheroidal coordinates  $(\xi, \eta, \varphi)$  are defined as [115]

$$\xi = \frac{(r_1 + r_2)}{2R} \quad \eta = \frac{(r_1 - r_2)}{2R} \quad \varphi \equiv \varphi \quad (218)$$

where  $2R$  is the interfocal distance of the prolate spheroids of revolution  $\{\xi = \text{const.}; -1 \leq \eta \leq 1; 0 \leq \varphi \leq 2\pi\}$ .

If the nuclei are located in the foci of this coordinate system, the Hamiltonian of Eq. (217) can be now expressed as

$$\hat{H} = -\frac{1}{2} \nabla^2 - \frac{Z_1}{R(\xi + \eta)} - \frac{Z_2}{R(\xi - \eta)} + \frac{Z_1 Z_2}{2R} \quad (219)$$

where the Laplacian operator is then

$$\begin{aligned}
\nabla^2 &= \frac{1}{R^2(\xi^2 - \eta^2)} \left\{ \frac{\partial}{\partial \xi} \left[ (\xi^2 - 1) \frac{\partial}{\partial \xi} \right] + \frac{\partial}{\partial \eta} \left[ (1 - \eta^2) \frac{\partial}{\partial \eta} \right] \right\} \\
&\quad + \frac{1}{R^2(\xi^2 - 1)(1 - \eta^2)} \frac{\partial^2}{\partial \varphi^2} \quad (220)
\end{aligned}$$

We now consider the system as confined within a prolate spheroidal box of eccentricity  $1/\xi_0$  and barrier height  $V_0$ . The corresponding modified Hamiltonian is then

$$\hat{H} = -\frac{1}{2} \nabla^2 + V_b(\xi, \eta) \quad (221)$$

where

$$V_b(\xi, \eta) = \begin{cases} -Z_1/R(\xi + \eta) - Z_2/R(\xi - \eta) & (1 \leq \xi \leq \xi_0) \\ V_0 & (\xi_0 \leq \xi < \infty) \end{cases} \quad (222)$$

The formal solutions of the Schrödinger equation for the inner ( $\xi \leq \xi_0$ ) and outer ( $\xi \geq \xi_0$ ) regions must satisfy continuity conditions at the boundary ( $\xi = \xi_0$ ), which are equivalent to

$$\left. \frac{1}{\psi_i} \frac{\partial \psi_i}{\partial \xi} \right|_{\xi=\xi_0} = \left. \frac{1}{\psi_o} \frac{\partial \psi_o}{\partial \xi} \right|_{\xi=\xi_0} \quad (223)$$

Equation (223) allows us to find the energy of the system if an explicit form of the wavefunction is known.

The  $V_0 = \infty$  case was studied exactly by Ley-Koo and Cruz [120]. An approximate study of these systems for finite values of  $V_0$  can be performed using a direct variational method. In this case an ansatz wavefunction  $\chi$  must be constructed. Following Refs. [78, 121], we have

$$\chi_i(\xi, \eta, \varphi) = A_i \psi_i^0(\xi, \eta, \varphi; \alpha) f(\xi, \alpha) \quad (224)$$

and

$$\chi_o(\xi, \eta, \varphi) = A_o \psi_o^0(\xi, \eta, \varphi; \alpha) f(\xi, \alpha) \quad (225)$$

where  $\psi_i^0$  and  $\psi_o^0$  are the solutions of the Schrödinger equation for the free system [122, 123],  $f$  is an auxiliary function which allows the total wavefunction to satisfy the condition shown in Eq. (223), and  $\alpha$  is a variational parameter

to be determined once the corresponding energy functional is minimized with the additional constrictions improved by Eq. (223).

Following Coulson [122], the ansatz wavefunction for the ground state is constructed as

$$\chi_i(\xi, \eta, \varphi) = A_i(\xi_0 - \alpha\xi)\exp[-\alpha(\xi + \eta)] \quad (\xi \leq \xi_0) \quad (226)$$

and

$$\chi_o(\xi, \eta, \varphi) = A_o \exp(-\beta\xi)\exp(-\alpha\eta) \quad (\xi \geq \xi_0) \quad (227)$$

where  $A_i$  and  $A_o$  are two constants related through the normalization condition on the total wavefunction. A relation between the variational parameters  $\alpha$  and  $\beta$  can be obtained through the continuity condition at  $\xi = \xi_0$  so that the energy functional is to be minimized with respect to only one parameter, either  $\alpha$  or  $\beta$ .

The energy of the ground state of H,  $H_2^+$ , and  $HeH^{2+}$  for  $V_0 = 0, 2, 8, 20$  and  $\infty R_y^*$  is displayed in Figure 43 as a function of the size of the enclosing box  $\xi_0$ . As can be noted, good agreement is found with the exact results for the case of  $V_0 = \infty$ . When  $V_0$  has a finite value, the calculations show the correct qualitative behavior, similar to that found by Ley-Koo and Rubinstein [124] for hydrogen within penetrable spherical boxes. In order to gain some confidence in the value of the ansatz wavefunctions, we have calculated the polarizability and pressure for  $H_2^+$ . In the Kirkwood approximation [119] the parallel and perpendicular components of the polarizability are given by

$$\alpha_{\parallel} \equiv \alpha_{zz} = 4\langle z^2 \rangle^2 \quad \alpha_{\perp} \equiv \alpha_{xx} = \alpha_{yy} = 4\langle x^2 \rangle^2 \quad (228)$$

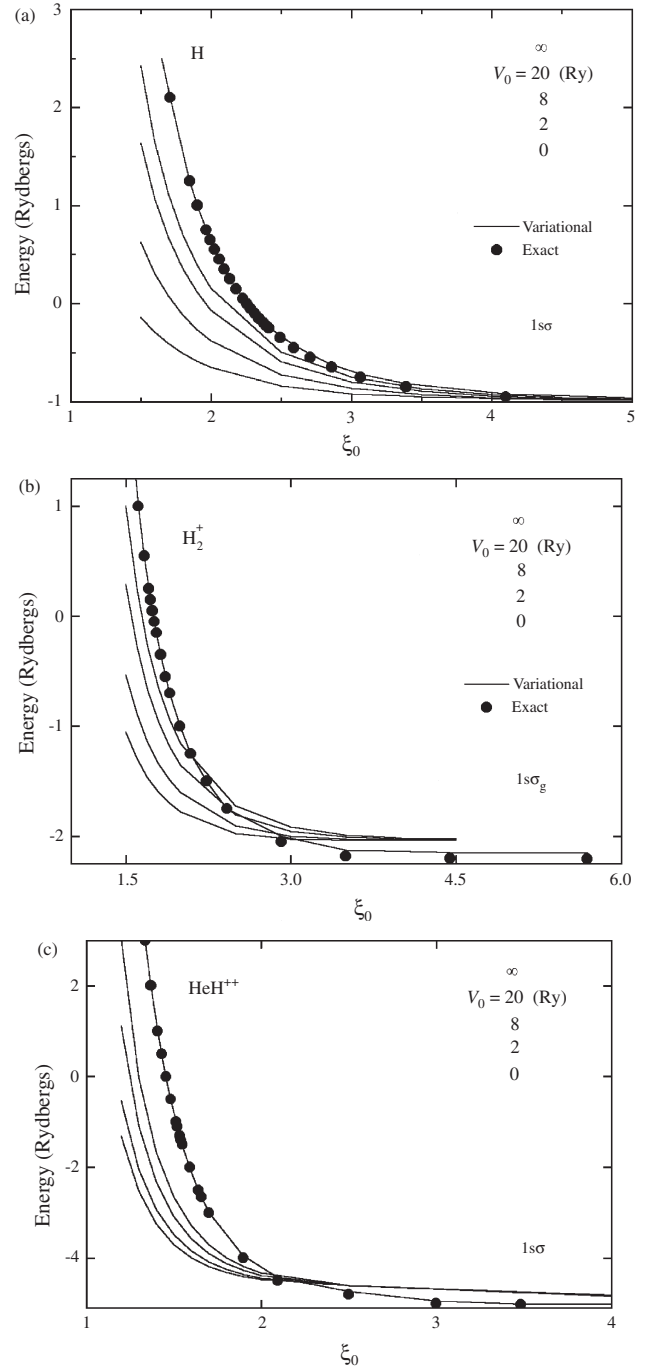

Finally, the pressure on the system due to the confinement can be calculated through the relationship

$$P = -\frac{d\varepsilon}{dV} \quad (229)$$

where  $V$  is the volume of the spheroidal box and  $\varepsilon$  is the total ground state energy of the system calculated at the equilibrium bond length. The results obtained for these properties are displayed in Figure 44 for  $V_0 = 0$  and  $\infty R_y^*$  as a function of  $\xi_0$ . As can be seen, good agreement is found when our results are compared for  $V_0 = \infty$  with the calculations reported by LeSar and Herschbach [109, 110], who used a five-term James-Coolidge variational wavefunction. For finite values of  $V_0$  the correct qualitative behavior is obtained [125].

### 3.9. Confinement of One- and Two-Electron Atomic Systems by Spherical Penetrable Boxes

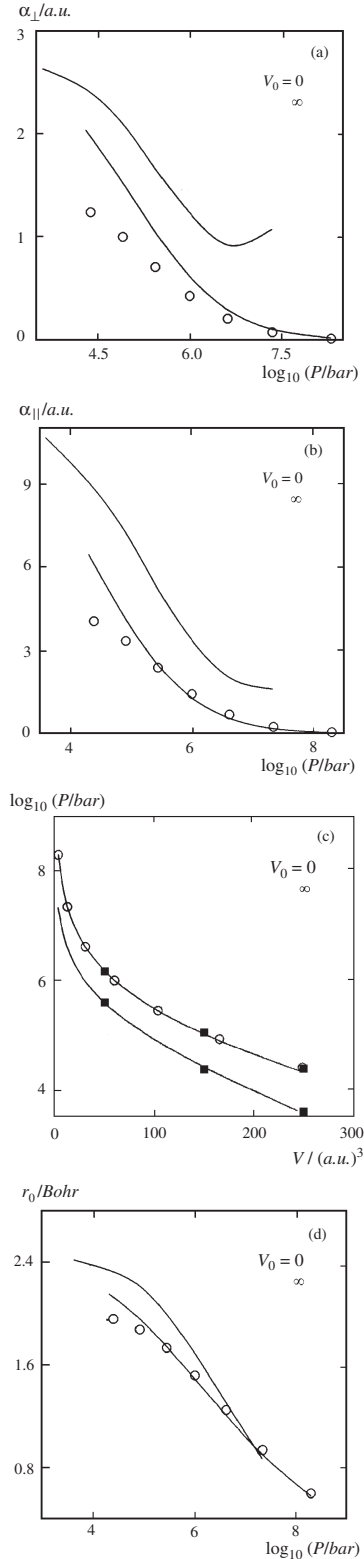

We explicitly treat the case of some one- and two-electron atomic systems (H,  $H^-$ , He,  $Li^{2+}$ , and  $Be^{2+}$ ) in their ground state within spherical confining barriers [66]. In all cases, a simple representation for the ansatz wavefunction is employed and the corresponding energies are given as a function of size and height of the barrier. Additionally, some

**Figure 43.** Ground state energies for H (a),  $H_2^+$  (b), and  $HeH^{2+}$  (c) enclosed within penetrable spherical boxes as a function of box size  $\xi_0$ . The nucleus are clamped and  $R = 1$  a.u. The continuous lines represent the variational calculations of this subsection. The circles are the exact results for  $V_0 = \infty$  reported in [120]. Academic Press, San Diego, 2001. © 2001, Academic Press.

quantities of physical interest are evaluated for the case of hydrogen.

The case of hydrogen has been thoroughly analyzed by Ley-Koo and Rubinstein [124]. Proper comparison with their

**Figure 44.** Physical properties of  $H_2^+$  enclosed within penetrable spheroidal boxes as a function of box size  $\xi_0$ . The continuous lines represent the variational calculations of this subsection. The circles are the results of [109, 110], while the squares are those of [125]. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.), Academic Press, San Diego, 2001. © 2001, Academic Press.

results will yield some confidence on the capability of the procedure proposed in this work to account for the behavior of certain physical properties of the system as a function of box size and barrier height. Accordingly, for this system, in addition to the energy we evaluate the Fermi contact term, polarizability, pressure, and magnetic shielding constant.

For the rest of the systems, the estimated energies as a function of the characteristics of the confining potential and a comparison of their qualitative and quantitative behavior with available calculations for the impenetrable case by Ludeña and Gregori [107] are presented.

### 3.9.1. Model and Theory

For penetrable walls, let the ansatz wavefunction in the interior of the box be given as

$$\chi_i = \chi_{0,i} f \quad (230)$$

where  $\chi_{0,i}$  denotes the wavefunction of the free system and  $f$  denotes an auxiliary function that guarantees the adequate matching at the boundary with the exterior wavefunction

$$\chi_o = \chi_{0,e} \quad (231)$$

such that  $\chi_{0,e}$  keeps the proper asymptotic behavior characteristic of the system under study. Furthermore, the choice of the auxiliary function  $f$  must be such that it reduces to the familiar cutoff function proposed previously for an infinitely high confining potential. These requirements, together with the fulfillment of the virial theorem [126], constitute the key assumptions to be employed in order to construct our ansatz wavefunctions.

According to the direct variational method, an upper bound to the energy for a particular state may be found by requiring that

$$\langle \chi_i | \hat{H}_i | \chi_i \rangle_{\Omega} + \langle \chi_o | \hat{H}_o | \chi_o \rangle_{\Omega'} = \text{minimum} \quad (232)$$

where

$$\begin{aligned} \hat{H}_i &= -\frac{1}{2} \nabla_q^2 + V(q) & q \in \Omega \\ \hat{H}_o &= -\frac{1}{2} \nabla_q^2 + V_0 & q \in \Omega' \end{aligned} \quad (233)$$

$\Omega$  and  $\Omega'$  are the interior and exterior regions, respectively, and  $\{q\}$  represents the set of coordinates used.  $V(q)$  is the acting potential within the interior region and  $V_0$  is the height of the confining potential.

In addition to Eqs. (232) and (233), the normalization condition

$$\langle \chi_i | \chi_i \rangle_{\Omega} + \langle \chi_o | \chi_o \rangle_{\Omega'} = 1 \quad (234)$$

must be satisfied together with the requirement for continuity of the logarithmic derivative at the boundary ( $q = q_0$ ):

$$\frac{1}{\chi_i} \frac{\partial \chi_i}{\partial q} \Big|_{q=q_0} = \frac{1}{\chi_o} \frac{\partial \chi_o}{\partial q} \Big|_{q=q_0} \quad (235)$$

Indeed, if we are going to consider several states, we must impose the constraint of orthogonality among them,

both in the interior as well as in the exterior region. Note that the preceding arguments are of a general character and should apply to any system whether confined by penetrable or impenetrable walls.

### 3.9.2. Ground State of the Confined Hydrogen Atom

The potential energy associated with the Hamiltonian of the hydrogen atom confined by a spherical box with penetrable walls is given by a Coulomb term inside the box

$$V(r) = -\frac{Ze^2}{r} \quad r < r_0 \quad (236)$$

and a constant barrier height outside the box,

$$V(r) = V_0 \quad r > r_0 \quad (237)$$

with  $r_0$  the radius of the confining box.

For the purposes of this section we consider now the 1s state. For this case, the corresponding wavefunctions are chosen as

$$\begin{aligned} \chi_i(1s) &= N_i(r_0 - \gamma r)\exp(-\alpha r) & r < r_0 \\ \chi_o(1s) &= N_o r^{-1}\exp(-\beta r) & r > r_0 \end{aligned} \quad (238)$$

with  $\alpha$ ,  $\beta$ , and  $\gamma$  variational parameters and  $N_i$  and  $N_o$  normalization constants.

In contrast to the impenetrable case, we have considered three variational parameters in order to allow for more flexibility in the matching procedure at the boundary. In fact, only two of these parameters ( $\alpha$ ,  $\gamma$ ) need to be found, the third one being defined through Eq. (235) as

$$\beta = \frac{\alpha r_0(1 - \gamma) + 2\gamma - 1}{r_0(1 - \gamma)} \quad (239)$$

Following Ley-Koo and Rubinstein [124], some quantities of physical interest such as the Fermi contact term ( $A$ ), diamagnetic screening constant ( $\sigma$ ), polarizability ( $\alpha$ ), and pressure ( $P$ ) are defined, respectively, as

$$\begin{aligned} A &= \frac{2}{3}g\beta g_n\beta_n|\chi_i(1s)|_{r=0}^2 & \sigma &= \frac{e^2}{3\mu c^2}\left\langle\frac{1}{r}\right\rangle \\ \alpha &= \frac{4}{9}a_B^{-1}\langle r^2 \rangle^2 \\ P &= -\frac{1}{4\pi r_0^2}\frac{d\varepsilon}{dr_0} = \frac{1}{4\pi r_0^3}(2\varepsilon - \langle V \rangle) \end{aligned} \quad (240)$$

Fernandez and Castro [127] showed that the virial theorem for systems with sectionally defined potentials must be reformulated as compared to the case of systems constrained by Dirichlet boundary conditions. Hence, the use of Eq. (240) for  $P$  is not correct for confining potentials with finite barrier heights but, for comparative purposes, Eq. (240) will be employed for the evaluation of  $P$ .

Figures 45–49 show the values obtained by this method for the energy ( $\varepsilon$ ),  $A$ ,  $\sigma$ ,  $\alpha$ , and  $P$  for the 1s state with barrier heights of 0, 4, and 10 Ryd ( $e^2/2a_B$ ). For comparison, the corresponding exact values calculated by Ley-Koo and Rubinstein are also shown. As the reader must be aware,

**Figure 45.** Ground state energy of H as a function of confining radius  $r_0$ , for different barrier heights. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

there is a fair agreement between the energy values obtained by the method used here and the exact calculations. Also, regarding the values estimated for the various physical quantities, the agreement is also fairly good.

### 3.9.3. Ground State of Confined Two-Electron Systems

The Hamiltonian for a confined atomic system with two electrons is given as

$$\hat{H} = -\frac{1}{2}\nabla_1^2 - \frac{1}{2}\nabla_2^2 + V(\vec{r}_1, \vec{r}_2) \quad (241)$$

**Figure 46.** Fermi contact term ( $A$ ) for H as a function of confining radius  $r_0$ , for different barrier heights. In units of  $(2/3)g\beta g_n\beta_n = 12.690$  mT. Considering each electron in a  $1s$  state the interior wavefunction is chosen as

$$\chi_i(r_1, r_2) = A(r_0 - \alpha r_1)(r_0 - \alpha r_2)\exp[-\alpha(r_1 + r_2)] \quad (243)$$

and the exterior function as

$$\chi_o(r_1, r_2) = B \frac{\exp[-\beta(r_1 + r_2)]}{r_1 r_2} \quad (244)$$

with  $A$  and  $B$  normalizing constants. Note that in this case we are using only two variational parameters. This choice will certainly make the trial wavefunction too rigid. However, as will be seen, even with this crude approximation fair results may be obtained.

Following the procedure outlined by Eqs. (232)–(235) the energy values for  $\text{H}^-$ ,  $\text{He}$ ,  $\text{Li}^+$ , and  $\text{Be}^{2+}$  are obtained as a function of  $r_0$  and  $V_0$ . Table 4 displays the results of this exercise for some selected barrier heights. We note first the cases of  $\text{He}$ ,  $\text{Li}^+$ , and  $\text{Be}^{2+}$  for which the qualitative and quantitative behavior of the energies tend to the correct values [107] as the barrier height approaches infinity. Note, however, that for relatively large box sizes the energy values obtained for the penetrable case lie slightly lower than those for the impenetrable case. This effect is attributed to the rigidity imposed on the input wavefunction through the assignment of a single variational parameter for the interior as well as the exterior regions.

Interestingly enough, the  $\text{H}^-$  system shows a particular sensitivity to the confining effect as may be verified from the overall trend of the energy values. Unfortunately, there are no other calculations to compare with for this confined system. The energies obtained in this work for large values of  $r_0$  correspond to the value of  $\epsilon = -0.473$  Hartree reported by Wu and Falicov [128] in their variational treatment of free  $\text{H}^-$  with a single exponential parameter. Furthermore, these authors have shown that using two exponential parameters in their trial wavefunction, the ground state energy

for H<sup>-</sup> becomes  $\varepsilon = -0.513$  Hartree, a value closer to that of  $-0.527$  reported by Pekeris [129] using a 1078-parameter wavefunction. Hence, we believe that a more flexible trial wavefunction in our treatment of two-electron confined atoms will improve the quality of the predictions.

### 3.10. Optical Properties of Impurity States in Semiconductor Quantum Dots

The optical absorption spectra associated with transitions between the  $n = 1$  valence level and the donor impurity band have been calculated for spherical GaAs quantum dots with infinite potential confinement, using a variational procedure within the effective mass approximation, following [130]. We show results either for one impurity or for a homogeneous distribution of impurities inside of the quantum dot. The interaction between the impurities has been neglected. The main features found in the theoretical spectra were an absorption edge associated with transitions involving impurities at the center and a peak related to impurities at the edge of the dot. For all sizes of the quantum dot the peak

associated with impurities located next to the edge always governs the total absorption probability.

Oliveira and Perez-Alvarez [131], Porrás-Montenegro and Oliveira [132], and Porrás-Montenegro et al. [133] have studied the optical absorption spectra associated with shallow donor impurities for both finite and infinite barrier GaAs–GaAlAs quantum wells and quantum well wires. The main features were an absorption edge associated with transitions involving impurities at the center and a peak related to impurities at the edge of the wire. For quantum well wires the situation of the bulk material is reached for radii of 1000 Å and the peak associated with transitions involving impurities at the center decreases as the radius of the structure is diminished.

Porrás-Montenegro et al. [134, 135] have calculated the impurity binding energies as functions of the radius, impurity position as well as the density of impurity states in spherical GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As quantum dots, finding two structures associated with impurities located at the center and at the edge of the quantum dots, which are expected to show up in absorption and photoluminescence spectra associated with shallow hydrogenic impurities in quantum dots, as was the

case in detailed calculations of the impurity-related optical absorption spectra in GaAs–GaAlAs quantum wells [131] and quantum well wires [133, 136].

Helm et al. [137] performed a far-infrared absorption study in lightly doped GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As superlattices and found that, at low temperatures, the absorption spectra are dominated by donor transitions. They studied the  $1s-2p_z$  donor transitions experimentally and theoretically, obtaining excellent agreement.

Otherwise experimental progress through spectroscopic techniques made possible a detailed analysis of the effects of confinement on shallow impurities in quantum wells. Far-infrared magnetospectroscopy measurements on shallow donor impurities in GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As multiple quantum well structures were performed by Jarosik et al. [138], who assigned structures in the transmission spectra to intrimpurity  $1s-2p_{\pm}$  transitions. Work on magnetic field effects on shallow impurities in GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As multiple quantum well structures was also recently reported by Yoo et al. [139].

### 3.10.1. Model and Theory

The Hamiltonian of a shallow hydrogenic impurity in a spherical quantum dot of GaAs can be written in the effective mass approximation as

$$\hat{H} = \frac{\hat{p}^2}{2m_e^*} - \frac{e^2}{\kappa|\vec{r} - \vec{R}|} + V_b(\vec{r}) \quad (245)$$

where  $V_b(\vec{r})$  is the confining potential which is zero for  $r < r_0$  and infinite for  $r > r_0$ ,  $r_0$  being the radius of the dot. The impurity position is denoted by  $\vec{R}$ .

The eigenfunction of the Hamiltonian in the absence of the impurity for the ground state ( $n = 1$  and  $l = 0$ ) and for the infinite potential well is [134]

$$\psi(\vec{r}) = \frac{\sin(k_{10}r)}{(2\pi r_0)^{1/2}r} \quad (246)$$

where  $\vec{r}$  is  $(r, \theta, \varphi)$ . In order to satisfy the boundary conditions  $\psi(r = r_0) = 0$ , the eigenenergies corresponding to Eqs. (245) and (246) are  $\varepsilon_{10} = \hbar^2 k_{10}^2 / 2m_e^*$  with  $k_{10} = \pi/r_0$ .

With inclusion of the impurity potential, one should use a variational approach to determine the ground state binding energy. The trial wavefunction considered is

$$\psi(\vec{r}) = \begin{cases} N(\vec{R}, \lambda) \frac{\sin(k_{10}r)}{r} \exp(-\lambda|\vec{r} - \vec{R}|) & r \leq r_0 \\ 0 & r > r_0 \end{cases} \quad (247)$$

with  $\lambda$  being a variational parameter and  $N(R, \lambda)$  the normalization factor. The binding energy of the impurity is given by

$$\varepsilon_b(r_0, \vec{R}) = \varepsilon_{10} - (\langle T \rangle + \langle V \rangle) \quad (248)$$

where  $\langle T \rangle$  and  $\langle V \rangle$  are kinetic and potential energies.

For transitions from the first valence level to a donor impurity level, we have, for the initial and final states,

$$\psi_{10}^i = \frac{\sin(k_{10}r)}{(2\pi r_0)^{1/2}r} u_i(\vec{r}) \quad (249)$$

$$\psi_{10}^f = N(\vec{r}, \lambda) \frac{\sin(k_{10}r)}{r} \exp(-\lambda|\vec{r} - \vec{R}|) u_f(\vec{r}) \quad (250)$$

where  $u_i(\vec{r})$ ,  $u_f(\vec{r})$  are the periodic parts of the Bloch states for the initial and final states.

Taking the energy origin at the first conduction subband as depicted in Figure 50, we have for the energy of the initial (first valence level) state

$$\varepsilon_i = -E_g \quad (251)$$

where  $E_g$  is given by

$$E_g = \varepsilon_g + \frac{\hbar^2 k_{10}^2}{2m_e^*} + \frac{\hbar^2 k_{10}^2}{2m_h^*} \quad (252)$$

with  $\varepsilon_g$  being the bulk GaAs bandgap.

The energy of the final state is

$$\varepsilon_f = -\varepsilon_b(r_0, \vec{R}) \quad (253)$$

The transition probability per unit time for valence-to-donor transitions associated with a donor impurity located at  $\vec{R}$  is proportional to the square of the matrix element of the electron–photon interaction  $\hat{H}_{el}$  between the wavefunctions of the initial state (first valence level) and final (impurity) states. That is,

$$W = \frac{2\pi}{\hbar} \sum |\langle f | \hat{H}_{el} | i \rangle|^2 \delta(\varepsilon_f - \varepsilon_i - \hbar\omega) \quad (254)$$

with  $\hat{H}_{el} = C \vec{e}_r \cdot \hat{p}$ , where  $\vec{e}_r$  is the polarization vector in the direction of the electric field of the radiation,  $\hat{p}$  is the momentum operator, and  $C$  is a prefactor which contains

**Figure 50.** Schematic of some possible absorption transitions in an infinite GaAs–(Ga,Al)As quantum dot of radius  $r_0 = 300 \text{ \AA}$  with a donor impurity band. The density of state,  $\rho(\varepsilon)$ , from the positional dependent donor binding energy is shown schematically on the left-hand side. The dependence of the binding energy as a function of the donor impurity position is shown on the right-hand side.

the photon vector potential. Following the effective mass approximation, the foregoing matrix element may be written as [140]

$$\langle f | \widehat{H}_{e-l} | i \rangle \cong C \vec{e}_r \cdot \vec{P}_{fi} S_{fi} \quad (255)$$

with

$$\vec{P}_{fi} = \frac{1}{\Omega} \int_{\Omega} d\vec{r} u_f^*(\vec{r}) \hat{p} u_i(\vec{r}) \quad (256)$$

and

$$S_{fi} = \int d\vec{r} f_f^*(\vec{r}) f_i(\vec{r}) \quad (257)$$

where  $\Omega$  is the volume of the unit cell and  $f_f(f_i)$  is the envelope function for the final (initial) state. For the case of the donor impurity we have, for  $S_{fi} = S_{fi}(\vec{R}, \lambda)$ ,

$$S_{fi} = \left( \frac{2\pi}{r_0} \right)^{1/2} N(\vec{R}, \lambda) \int_0^{r_0} dr \sin^2(k_{10}r) \times \int_0^\pi d\theta \sin \theta \exp[-\lambda|\vec{r} - \vec{R}|] \quad (258)$$

For an infinite GaAs quantum dot of radius  $r_0$  with one impurity inside, the transition probability per unit time for valence to donor transitions is given by

$$W(\omega, \vec{R}) = W_0 \left( \frac{\pi \hbar^2}{2m_0 a_B^2} \right) S_{fi}^2 Y(\Delta) \quad (259)$$

where  $a_B$  is the Bohr radius and  $Y(\Delta)$  is the step function. In this expression we have for  $\Delta$  and  $W_0$

$$\Delta = \hbar\omega - E_g + \varepsilon_g(r_0, R) \quad (260)$$

$$W_0 = \frac{4m_0}{\hbar^3} a_B^2 |C|^2 |\vec{e}_r \cdot \vec{P}_{fi}|^2 \quad (261)$$

For a homogeneous distribution of impurities and assuming that the quantum dot radius is much larger than the lattice parameter one has for the total transition probability per unit of time

$$W_T(\omega) = \frac{3}{r_0^3} \int_0^{r_0} dR W(\omega, \vec{R}) R^2 \quad (262)$$

For the numerical computing, we used  $\kappa = 12.58$ ,  $m_c^* = 0.0665m_0$ ,  $m_h^* = 0.30m_0$ , where  $\varepsilon_g = 1.424$  eV.

A schematic representation of a GaAs quantum dot doped with a homogeneous distribution of the donor impurities is shown in Figure 50. The edges for optical absorption from the first valence subband to the donor impurity band are represented by  $\hbar\omega_1$ , and to the first conduction subband by  $E_g$ . The transition  $\hbar\omega_2$  corresponds to absorption to an impurity level associated with donors at the edges of the quantum dot. At the right we also show the density of the states for the impurity band.

In Figure 51, we display the donor binding energy as a function of the donor position inside the quantum dot for infinite potential well with different radii. The donor binding energy decreases as the donor position increases reaching a

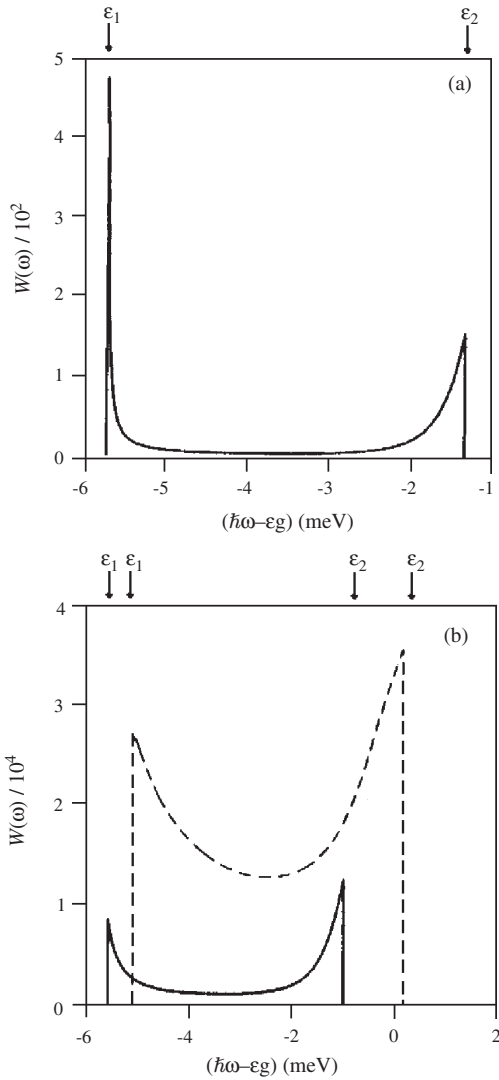

**Figure 51.** Donor binding energy as a function of the impurity position for infinite GaAs-(Ga,Al)As quantum dots with distinct dot radii. From top to bottom,  $r_0 = 50, 100, 200, 1000$  Å. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

minimum as the donor position is equal to the radii of the quantum dot. The absorption probability  $W(\omega, \vec{R})$  for an infinite quantum dot with one single impurity as a function of  $\hbar\omega - \varepsilon_g$  is shown in Figure 52. In Figure 52a, we present the absorption probability for an infinite GaAs quantum dot of radius  $r_0 = 3000$  Å. We observe that there is a noticeable peak structure associated with a single impurity located at the center of the dot, which is much larger than the structure associated with a single impurity next to the edge of the dot, meaning that we have essentially reached the bulk limit. Our results for an  $r_0 = 1000$  Å and  $r_0 = 500$  Å quantum dots are shown in Figure 52b; the structure associated with a single impurity located at the center of the dot is smaller than the structure associated with a single impurity at the edge of the dot.

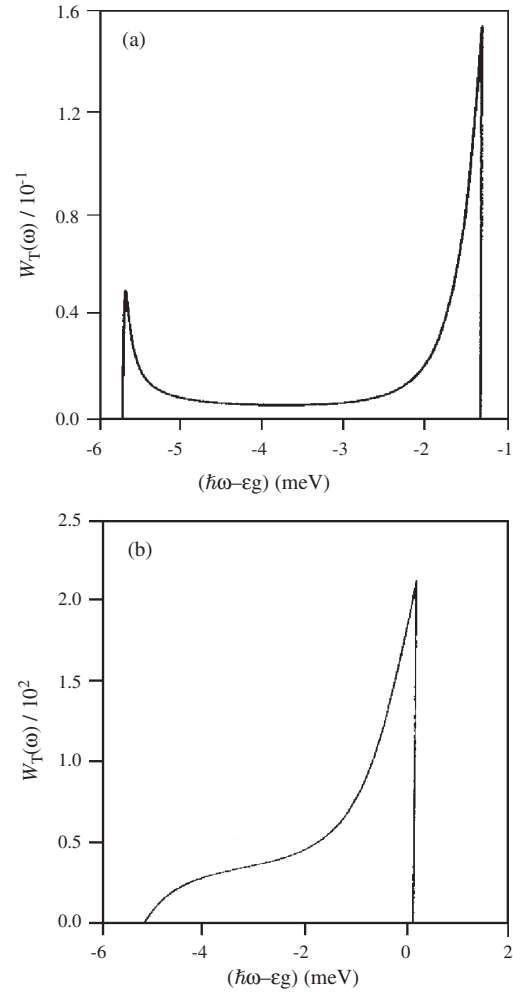

In Figure 53, we display the total absorption probability for an infinite GaAs quantum dot with a homogeneous distribution of impurities. For a quantum dot of  $r_0 = 3000$  Å the total absorption probability as a function of  $\hbar\omega - \varepsilon_g$  is shown in Figure 53a. An absorption edge associated with transitions involving impurities at the center of the well and a peak related with impurities next to edge of the dot are observed. The peak associated with impurities located next to the edge of the dot is much larger than the peak associated with impurities located next to the center of the dot. This behavior is quite different from that found for GaAs quantum wells and quantum well wires of comparable dimensions. This is a consequence of the quantum confinement and the homogeneous distribution of the impurities in the quantum dot.

When the radius of the quantum dot decreases we observe that the peak associated with impurities located next to the center diminishes (see Fig. 53b), which may be understood by means of the behavior of the density of the states as a function of the binding energy (see Fig. 3 in [135]). In this figure, it is seen that for small radii the density of the states

**Figure 52.** Optical absorption spectra (in units of  $W_0$ ), as a function of the  $\hbar\omega - \varepsilon_g$ , for valence to donor transitions in infinite GaAs-(Ga,Al)As quantum dots of different radii.  $r_0 = 3000 \text{ \AA}$  (a),  $r_0 = 1000 \text{ \AA}$  (full curve), and  $r_0 = 500 \text{ \AA}$  (dashed curve) (b).  $\varepsilon_1$  and  $\varepsilon'_1$  ( $\varepsilon_2$  and  $\varepsilon'_2$ ) correspond, respectively, to the onset of transitions from the first valence subband to the lower (upper) edge of the impurity band. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

is a smooth function which exhibits a well-defined peak at the binding energy associated with on-edge donors. When the radius is very large, the structure of the  $\varepsilon_i^{\max}$  Van Hove-like singularity is clearly a peak associated with on-center donors, which corresponds to the bulk limit. For quantum dots of  $r_0 > 1000 \text{ \AA}$  it is observed that the peak related to on-edge donors is still significant, a situation that is very well reflected in our results. On the other hand, a remarkable difference in the total absorption probability is the absence of the peak structure associated with impurities located at wells for quantum dots with radii less than  $500 \text{ \AA}$  with quantum wells and quantum well wires.

**Figure 53.** Total optical absorption spectra (in units of  $W_0$ ), as a function of the  $\hbar\omega - \varepsilon_g$ , for valence to donor transitions in infinite GaAs-(Ga,Al)As quantum dots of different radii.  $r_0 = 3000 \text{ \AA}$  (a) and  $r_0 = 500 \text{ \AA}$  (b) for a quantum dot with a homogeneous distribution of impurities, where there is no interaction between them. ## 4. NONCONVENTIONAL AND ATOMIC IDEALIZED CONFINED SYSTEMS IN NANOSTRUCTURES

### 4.1. Ground State Energy of the Two-Dimensional Hydrogen Atom Confined within Conical Curves

In this section the variational method is used to calculate the ground state energy of the two-dimensional hydrogen atom confined by impenetrable conical curves [141]. The confinement of the atom in a region limited by two intersecting parabolas as well as within a cone was also considered. The results show the transition of this system to a quasi-one-dimensional hydrogen atom when the curves are open. In the case of closed curves, a transition to a quasi-zero-dimensional hydrogen atom is observed. These limiting

cases, as well as other intermediate situations, are discussed within this section.

In particular, the ground state energy of this kind of system is calculated for different confining situations. Moreover, the behavior of the ground state energy is analyzed, as the confining region reaches an extreme value, that is, when the system becomes quasi-one-dimensional (open curves) or quasi-zero-dimensional (closed curves) as well as other intermediate situations.

The results show a very interesting behavior of this property depending upon the confinement region as well as the closed or open character of the curves.

The latter would represent an interesting research topic concerning the study of other properties of this system such as its polarizability, pressure due to the boundaries, dipole moment, etc.

#### 4.1.1. Schrödinger Equation

In atomic units ( $\hbar = e = m_e^* = 1$ ), the Schrödinger equation for the two-dimensional confined hydrogen atom in orthogonal curvilinear coordinates can be written as

$$-\frac{1}{2} \frac{1}{h_1 h_2} \left[ \frac{\partial}{\partial q_1} \left( \frac{h_2}{h_1} \frac{\partial}{\partial q_1} \right) + \frac{\partial}{\partial q_2} \left( \frac{h_2}{h_1} \frac{\partial}{\partial q_2} \right) \right] + V_{en}(q_1, q_2) + V_b(q_1, q_2) \} \psi(q_1, q_2) = \varepsilon \psi(q_1, q_2) \quad (263)$$

where  $(q_1, q_2)$  is the orthogonal curvilinear coordinate system in the plane and  $\{h_i\}$  is the scale factor, given by

$$h_i^2 = \left( \frac{\partial x}{\partial q_i} \right)^2 + \left( \frac{\partial y}{\partial q_i} \right)^2 \quad (264)$$

$V_{en}(q_1, q_2)$  is the Coulombic interaction

$$V_{en}(q_1, q_2) = -\frac{1}{r(q_1, q_2)} \quad (265)$$

while  $r(q_1, q_2)$  is the electron–nucleus separation, in this set of coordinates.

The confining potential that it will be assumed is of the form

$$V_b(q_1, q_2) = \begin{cases} +\infty & (q_1, q_2) \notin D \\ 0 & (q_1, q_2) \in D \end{cases} \quad (266)$$

where  $D$  is a given finite (or infinite) confining domain of the plane.

The solution of Eq. (263) must satisfy

$$\psi(q_1, q_2) = 0 \quad q \in \partial D \quad (267)$$

where  $\partial D$  is the boundary of  $D$ .

The model Hamiltonian for the confined quantum system under study can be written, in atomic units, as

$$\hat{H} = -\frac{1}{2} \nabla_q^2 + V_{en}(q) + V_b(q) \quad (268)$$

where  $V_{en}(q)$  and  $V_b(q)$  are given by Eqs. (265) and (266), and  $\nabla_q^2$  is derived from Eq. (263).

At this point, the variational method can be implemented to calculate the ground state energy of the system by constructing the functional

$$\varepsilon(\alpha) = \int_D \chi_i^* \left\{ -\frac{1}{2} \nabla_q^2 + V_{en}(q) \right\} \chi_i d^2 q \quad (269)$$

and minimizing it with respect to  $\alpha$ , restricted to

$$\int_D \chi_i^* \chi_i d^2 q = 1 \quad (270)$$

as usual.

The area element is given as  $d^2 q = h_1 h_2 dq_1 dq_2$ .

To this extent, the method described previously can be used to study a confined system for which the interactions with the surrounding medium are not considered (i.e., enclosed within a potential barrier of infinite depth). The next subsection is restricted to deal with the case of a typical one-electron confined system in two dimensions, namely, the case of hydrogen atoms confined within a given region of the plane with different geometries.

#### 4.1.2. Variational Wavefunctions for Different Geometries

As is well known, the Schrödinger equation for the unconfined two-dimensional hydrogen atom is separable in polar coordinates  $(r, \theta)$ ; its ground state wavefunction can be written as

$$\phi(r, \theta) = C_0 \exp(-k_0 r) \quad (271)$$

where  $C_0$  is a normalization constant,  $r$  is the electron–nucleus distance,  $k_0 = \sqrt{-2\varepsilon_0}$ ,  $\varepsilon_0 = -2$  Hartrees is its ground state energy, and the nucleus was assumed to be located at the origin.

When the atom in the plane is restricted to a given open or closed domain  $D$ ,  $\phi$  and  $\varepsilon_0$  must change to fit the new conditions accordingly. If the boundary,  $\partial D$  of  $D$ , is impenetrable for the electron, then  $\phi = 0$  at  $\partial D$ . The latter means that due to confinement, new quantization rules must be found; that is, the old “good” quantum numbers used to define the energy of the unconfined system are no longer useful to characterize the energy of the now confined system. Moreover, as the region of confinement was assumed arbitrary (in shape and size), the energy of a given state would depend on a continuous parameter associated with the size (or shape) of the domain  $D$  (or its boundary  $\partial D$ ).

In the case of the confined two-dimensional hydrogen atom, the approximate (variational) ground state energy would involve the use of a trial wavefunction given by

$$\chi(q_1, q_2) = A f(q_i, q_0) \exp[-\alpha r(q_1, q_2)] \quad (272)$$

where  $(q_1, q_2)$  is the system of coordinates compatible with the symmetry of the confining boundary,  $r(q_1, q_2)$  is the electron–nucleus distance in these coordinates,  $f(q_i, q_0)$  is a geometry-adapted auxiliary function such that  $f = 0$  at  $q_i = q_0$ ,  $q_i$  is a coordinate associated with the geometry of the boundary, and  $\alpha$  is a variational parameter.

The geometry of the confining boundary allows one to choose  $f$  in a quite simple way, namely, similar to its contours. To exemplify the latter, if the assumed confining boundary is a circle of radius  $r_0$ , then  $f = r_0 - r$  (i.e., this function maps all circles of radius  $0 \leq r \leq r_0$ , that is, the allowed region for the atomic electron). Similarly, if the confining boundary is an ellipse of “size”  $\xi_0$  (eccentricity =  $1/\xi_0$ ), then  $f = \xi_0 - \xi$  and the function would map all ellipses of size consistent with  $1 \leq \xi \leq \xi_0$ , thus generating the allowed space for the atomic electron in the plane. The definition of  $f$  can be done for other confining symmetries accordingly.

A description on the flexibility of so-constructed trial wavefunctions, to deal with a variety of confining situations, can be found in [65, 66, 78, 111, 121]. In particular, in [78, 111] other physical properties for one- and two-electron confined atoms are calculated to test the goodness of the wavefunctions. The results show good agreement compared with exact or more elaborate approximated methods.

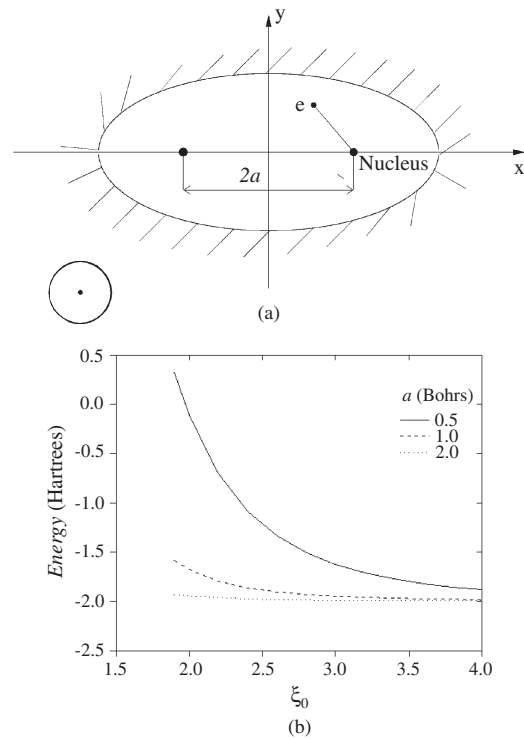

Hence, once that coordinate system  $(q_1, q_2)$  is chosen, all necessary elements for constructing the trial wavefunction are defined and the procedure outlined in the previous section can immediately be used to calculate and minimize the energy functional. Of course, the transformation equations defining the chosen coordinate system are assumed to be known; indeed, it is usually the case and they can be found elsewhere.

It is worth mentioning that the binding energy, defined as the absolute value of the difference between the energies of the electron with and without the Coulombic interaction, has only meaning in the case of closed curves. In the case of open curves, the electron energy belongs to the continuum spectrum and the binding energy is meaningless. Moreover, in the former situation, the binding energy would behave as the total energy, that is, as the confining region becomes smaller or either grows without limit, due to the closed and impenetrable property of the confining boundary.

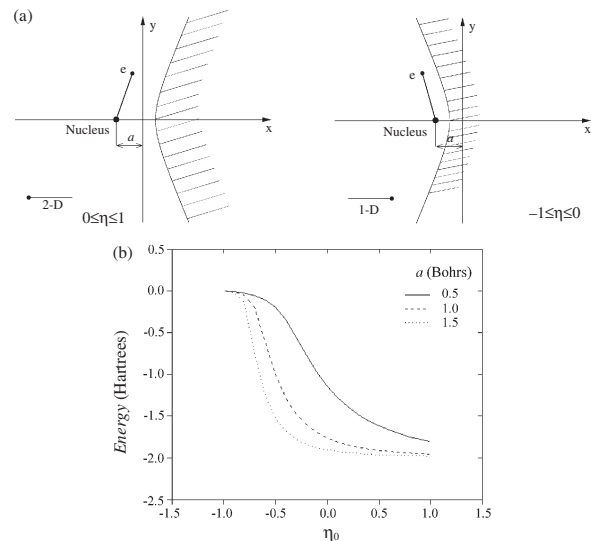

Figures 54a, 55a, 56a, 57a, 58a, and 59a display the confining geometries considered in this section, while Figures 54b, 55b, 56b, 57b, 58b, and 59b show the behavior of their corresponding ground state energies as a function of confining parameter, respectively.

The ground state energy of the two-dimensional hydrogen atom confined within an ellipse is displayed in Figure 54b as a function of parameter  $\xi_0$  (which defines the degree of confinement) for  $a = 0.5, 1.0,$  and  $2.0$  Bohrs, respectively. Notice that for a given  $\xi_0$  different than 1 and  $\infty$ , when  $a$  decreases, the major and minor semiaxes also decrease (i.e., the region of confinement is smaller and the energy increases). If  $\xi_0 \rightarrow 1$ , the two-dimensional hydrogen atom becomes a quasi-zero-dimensional system and the ground state energy goes to  $\infty$  (see Fig. 54a). In the case that  $\xi_0 \rightarrow \infty$ , the atom is allowed to occupy the whole plane for any value of  $a$ , thus recovering the case of an unconfined two-dimensional hydrogen atom, as expected.

In Figure 55b, the energy for the ground state of the two-dimensional hydrogen atom confined in a region of the plane limited by a hyperbola (see Fig. 55a) is displayed as a function of  $\eta_0$  (which defines the degree of confinement) for  $a = 0.5, 1.0,$  and  $1.5$  Bohrs, respectively. As can be observed, for  $\eta_0 = 0$ , the hyperbola becomes degenerate and their two

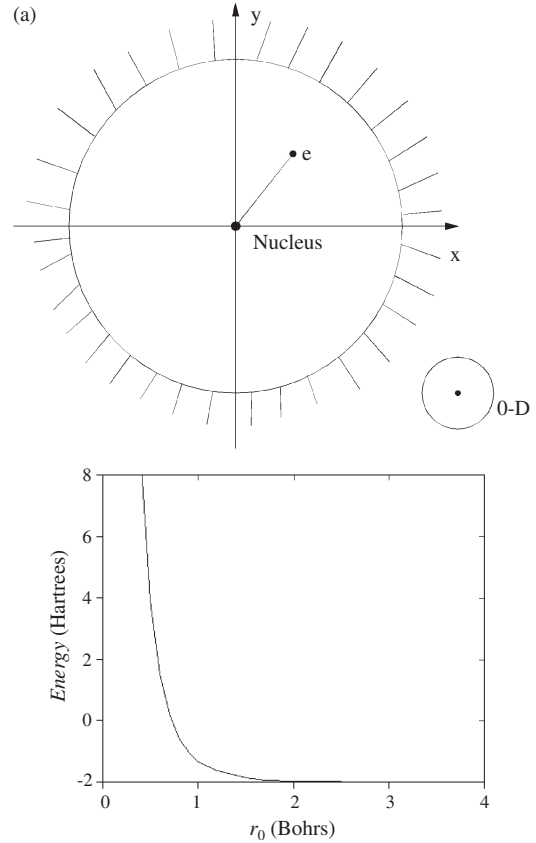

**Figure 56.** (a) Region of parabolic confinement. Limiting case: Q-one-dimensional. (b) Ground state energy of the two-dimensional hydrogen atom confined within a region of the plane limited by a parabola, as a function of  $\xi_0$ . Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

branches coincide with the  $y$ -axis, so that the confinement region becomes a half plane for any value of  $a$  different from zero and infinity. When  $\eta_0$  and  $a \rightarrow 0$ , the coalescence of the two branches of the hyperbola ( $\eta_0 \rightarrow 0^-$  and  $\eta_0 \rightarrow 0^+$ ) leads to a quasi-two-dimensional hydrogen atom with its nucleus at the  $y$ -axis; the ground state energy approaches  $-2/9$  Hartree. When  $a \rightarrow \infty$ , the whole plane becomes available for the atom, thus leading to the unconfined two-dimensional hydrogen atom (see Fig. 55a). Another observation is that for  $\eta_0 \rightarrow -1$  the whole plane is forbidden ( $x$ -axis is excluded), thus resulting in the one-dimensional hydrogen atom with zero energy (see Fig. 55b), which physically means that all excited states belong to the continuous spectrum or to the ionized atom. A similar behavior was found in [142, 143] for a three-dimensional hydrogen atom limited by paraboloidal or hyperboloidal surfaces.

Figure 56b shows the energy for the ground state of the two-dimensional hydrogen atom confined in a region of the plane limited by a parabola (see Fig. 56a) as a function of  $\xi_0$  (which defines the degree of confining). Notice that as  $\xi_0 \rightarrow \infty$  the parabola opens and the confinement region decreases until the whole plane is available; thus a transition occurs from a confined two-dimensional system to an unconfined two-dimensional system (see Fig. 56a), whose energy is  $-2$  Hartrees. In the same way, if  $\xi_0 \rightarrow 0$  the parabola closes

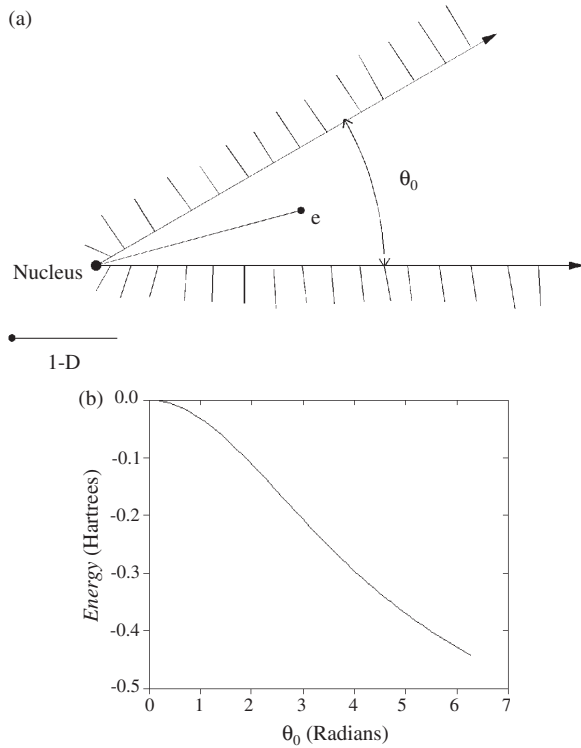

**Figure 57.** (a) Region of circular confinement. Limiting case: Q-zero-dimensional. (b) Ground state energy of the two-dimensional hydrogen atom confined within a region of the plane limited by a circle, as a function of its radius  $r_0$ . Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

and the forbidden region increases, confining the system in the  $-y$ -axis, thus realizing the transition from a confined two-dimensional system to a confined quasi-one-dimensional system, whose energy approaches zero (see Fig. 56b).

In Figure 57b, the ground state energy of the two-dimensional hydrogen atom confined in a circular region of the plane is depicted as a function of  $r_0$  (radius of the circle in atomic units). As can be observed, for  $r_0 \rightarrow \infty$ , the allowed space approaches the whole plane (i.e., the system becomes the unconfined two-dimensional hydrogen atom whose ground state energy is  $-2$  Hartrees). Another observation is that, when  $r_0 \rightarrow 0$ , the forbidden circular region becomes a point and a transition of the two-dimensional system to a quasi-zero-dimensional system (see Fig. 57a) with energy  $\varepsilon \rightarrow \infty$  occurs.

Figure 58b displays the ground state energy of the two-dimensional hydrogen atom confined in a region of the plane limited to a cone obtained when  $\theta = \theta_0$  and  $0 \leq r < \infty$ , as a function of  $\theta_0$  (polar angle in radians). In the limit when  $\theta_0 \rightarrow 0$  the cone decreases; then the transition of the confined two-dimensional system to the quasi-one-dimensional system with energy  $\varepsilon \rightarrow 0$  occurs, as in the previous situations. When  $\theta_0$  increases to  $2\pi$ , the allowed region grows

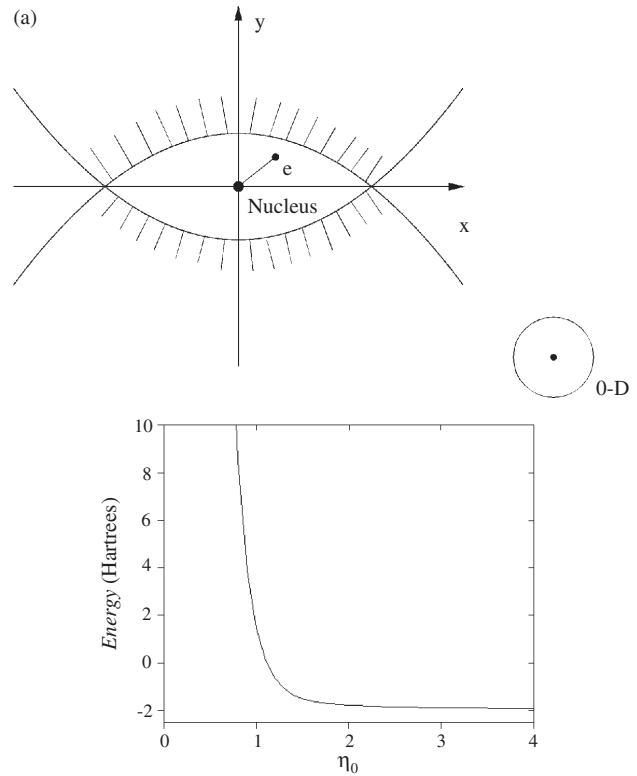

**Figure 58.** (a) Region of conical confinement. Limiting case: Q-two-dimensional. (b) Ground state energy of the two-dimensional hydrogen atom confined within a region of the plane limited by a cone, as a function of the opening angle  $\theta_0$ . Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

and the system behaves as a quasi-two-dimensional system; the edges of the cone are still a forbidden region (see Fig. 58a). The latter case corresponds to the minimum of the curve at 6.2856 radians ( $2\pi$ ) where the energy is  $\approx -2/9$  Hartree and coincides with the case of hyperbolic confinement in the limit  $\eta_0 \rightarrow 1$ ,  $a \rightarrow 0$  (see Figs. 55a and 58a), as expected.

Figure 59b shows the ground state energy of the two-dimensional hydrogen atom confined in a region of the plane given by the intersection of two symmetrical confocal parabolas (see Fig. 59a), as a function of  $\xi_0$  (root of the distance to the foci, in atomic units). As can be observed, when  $\xi_0 \rightarrow 0$  the two parabolas (and their intersections) are closer to the origin. The allowed region is almost a point, the transition of a confined two-dimensional system to a quasi-zero-dimensional one occurs, and accordingly, the energy becomes infinite, as expected. Moreover, in the case when  $\xi_0 \rightarrow \infty$ , the available space enlarges until the unconfined two-dimensional atom is recovered, that is, the energy approaches  $-2$  Hartrees (see Fig. 59b).

The overall results show that the ground state energy of the two-dimensional hydrogen atom confined by an impenetrable potential has two extreme limiting cases, namely: (a) In the case of closed conical curves, a transition to a quasi-zero-dimensional system occurs where the ground state energy becomes infinite, that is, the confinement region approaches a point; (b) in the case of open conical curves,

**Figure 59.** (a) Region of confinement given by the intersection of two symmetrical parabolas. Limiting case: Q-zero-dimensional. (b) Ground state energy of the two-dimensional hydrogen atom confined within a region of the plane limited by the intersection of two symmetrical confocal parabolas, as a function of  $\xi_0$ . Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

a transition to a quasi-one-dimensional system occurs in which the atom is confined to a straight line with origin at the nucleus and whose ground state energy becomes zero. Case (b) is closely related to the one-dimensional hydrogen atom discussed in [144–149], except that the binding energy is found to be infinite in [148]. The main difference between the limiting case (b) and the so-called Loudon one-dimensional atom [148] rests in the fact that Loudon did not take into account the energy due to the confinement because his model is one-dimensional and our limit case is quasi-one-dimensional. A discussion of this matter is made in next section. Moreover, since the binding energy of Loudon’s one-dimensional atoms is greater than the rest mass energy of the electron, the treatment of the atom should be done in a relativistic scheme, which renders a large, but finite, binding energy [150].

In summary, the confining geometries studied in this section lead us to conclude following extreme behavior:

- Circular:  $r_0 \rightarrow 0$       $\varepsilon \rightarrow \infty$
- [quasi-zero dimensional (Q-0D)]
- Elliptic:  $\xi_0 \rightarrow 1$       $\varepsilon \rightarrow \infty$      (Q-0D)

$$\text{Hyperbolic: } \begin{cases} \eta_0 \rightarrow 0 & \varepsilon = \varepsilon(a) \quad (a \neq 0) & \text{(Q-2D)} \\ \eta_0 \rightarrow 1 & \varepsilon = \varepsilon(a) & \text{(Q-2D)} \\ (\eta_0, a) \rightarrow 0 & \varepsilon \rightarrow -2/9 & \text{(Q-2D)} \\ \eta_0 \rightarrow -1 & \varepsilon \rightarrow 0 & \text{(Q-1D)} \end{cases}$$

$$\text{Parabolic (one): } \eta_0(\xi_0) \rightarrow 0 \quad \varepsilon \rightarrow 0 \quad \text{(Q-1D)}$$

$$\text{Parabolic (two): } \eta_0(\xi_0) \rightarrow 0 \quad \varepsilon \rightarrow \infty \quad \text{(Q-0D)}$$

$$\text{Cone: } \begin{cases} \theta_0 \rightarrow 0 & \varepsilon \rightarrow 0 & \text{(Q-1D)} \\ \theta_0 \rightarrow 2\pi & \varepsilon \approx -2/9 & \text{(Q-2D)} \end{cases}$$

### 4.1.3. One-Dimensional Hydrogen Atom, as a Limiting Situation

The behavior of the ground state energy of the confined two-dimensional hydrogen atom, when one dimension becomes infinitely small, will be analyzed in this section.

If the nucleus of the atom is located at the origin and the confining region is a symmetrical narrow strip of width  $2y_0$ , the Hamiltonian for the system is (in atomic units)

$$\hat{H} = -\frac{1}{2} \frac{\partial^2}{\partial x^2} - \frac{1}{2} \frac{\partial^2}{\partial y^2} + V_b(y) - \frac{1}{\sqrt{x^2 + y^2}} \quad (273)$$

where  $V_b(y)$  is the confining potential, defined as

$$V_b(y) = \begin{cases} 0 & -y_0 \leq y \leq y_0 \\ \infty & \text{otherwise} \end{cases} \quad (274)$$

The corresponding Schrödinger equation can be written as

$$\left\{ -\frac{1}{2} \frac{\partial^2}{\partial x^2} - \frac{1}{2} \frac{\partial^2}{\partial y^2} + V_b(y) - \frac{1}{\sqrt{x^2 + y^2}} \right\} \psi(x, y) = \varepsilon \psi(x, y) \quad (275)$$

where  $\varepsilon$  is the total energy and the wavefunction  $\psi(x, y)$  must satisfy the boundary condition

$$\psi(x, \pm y_0) = 0 \quad (276)$$

As has been pointed out by Jan and Lee [151], as the strip becomes very narrow (i.e.,  $y_0$  is very small), the fast motion in the  $y$ -direction allows the wavefunction to be written, approximately, as

$$\psi(x, y) \approx \chi(y) \Phi(x) \quad (277)$$

Since  $\psi(x, y)$  must satisfy the boundary condition (276), then

$$\chi(y) \approx \cos(k_0 y) \quad (278)$$

with  $k_0 = \pi/2y_0$ .

Introducing Eq. (277) into Eq. (275) and multiplying the result by  $\cos(k_0 y)$ , the integration over  $y$  from  $-y_0$  to  $y_0$  yields the equation

$$\left\{ -\frac{d^2}{dx^2} + N^2 \int_{-y_0}^{y_0} \frac{-2}{\sqrt{x^2 + y^2}} \cos^2(k_0 y) dy \right\} \Phi(x) = (\varepsilon - \varepsilon_y) \Phi(x) \quad (279)$$

where

$$N^2 = \left[ \int_{-y_0}^{y_0} \cos^2(k_0 y) dy \right]^{-1} = y_0^{-1} \quad (280)$$

is a normalization constant and  $\varepsilon_y = k_0^2 = \pi^2/4y_0^2$  is the kinetic energy of the fast motion in the  $y$ -direction due to confinement.

Equation (279) can be rewritten as

$$\left[ -\frac{d^2}{dx^2} + V_{\text{eff}}(x) \right] \Phi(x) = \varepsilon_x \Phi(x) \quad (281)$$

where  $\varepsilon_x = \varepsilon - \varepsilon_y$  and

$$V_{\text{eff}}(x) = N^2 \int_{-y_0}^{y_0} \left[ \frac{-2}{\sqrt{x^2 + y^2}} \right] \cos^2(k_0 y) dy \quad (282)$$

A similar equation was found in [151] for a hydrogenic impurity confined within a quantum well wire.

The result of averaging the two-dimensional Coulombic attraction over the fast  $y$  motion is such that Eq. (281) can be interpreted as Schrödinger equation for the one-dimensional atom under the potential  $V_{\text{eff}}(x)$ .

Moreover, a careful analysis of  $V_{\text{eff}}(x)$  in the limit  $y_0 \rightarrow 0$  reveals that this potential has the same behavior as the one-dimensional Coulomb potential, as was also pointed out by Jan and Lee [151] in the case of a three-dimensional hydrogen atom confined within a cylinder whose radius approaches zero. The energy  $\varepsilon_x$  in this limiting situation becomes the same as that obtained by Loudon [148], that is,  $-\infty$ . It can also be noted that when  $y_0 \rightarrow 0$ ,  $\varepsilon_y \rightarrow \infty$  and thus the total energy for the confined one-dimensional atom  $\varepsilon = \varepsilon_x + \varepsilon_y \rightarrow 0$ . The latter fact supports the results obtained in cases when the open confining curve approaches a straight line.

## 4.2. Geometrical Effects on the Ground State Energy of Hydrogenic Impurities in Quantum dots

The effect of nonsphericity of quantum dots on the ground state energy of hydrogenic impurities is studied in the frame of the effective mass approximation and the variational method [152]. The difference in composition of the quantum dot and the host material is modeled with a potential barrier at the boundary of the dot. To make the analysis, two symmetries are considered for the quantum dot: spherical and spheroidal. In this way, the ground state energy is calculated as a function of the volume of the quantum dot, for different barrier heights. The results show that the ground state is strongly influenced by the geometry of the dot; that is, for a given volume and barrier height, the energy is clearly different if the dot is spherical or spheroidal in shape when the volume of the dot is small (strong confinement regime). As the volume of the dot increases (weak confinement regime) the geometry becomes irrelevant, as expected.

The confinement of excitons in quantum dots and other microstructures such as quantum wells, quantum well

wires, etc. was corroborated experimentally in the past [113, 153–156]. The main feature of this effect corresponds to a frequency shift of the first excitonic peak to higher energy, compared to the mean bulk electronic peak. There have been many theoretical efforts to explain quantitatively this quantum mechanical effect [92, 157–163]. However, in all these works, the dot is assumed to be of spherical shape. This last assumption is not strictly true, since the electron microscopy studies of these systems show microparticles whose shapes vary from quasi-spherical to pyramidal [113]. The aim of this work is to analyze quantitatively the dependence of the ground state energy of a hydrogenic impurity on the geometry of the quantum dot. The latter would be of interest since it might constitute a qualitative study of the behavior of excitons confined within these microstructures. We assume that the impurity is confined within a potential barrier of finite depth, which emulates, on the average, the surrounding medium in which the dot is embedded. The calculation of the impurity ground state energy is performed using a variational approach, which previously was shown to be useful in dealing with this type of confined system in a fairly good fashion [66, 78, 111, 121]. The model Hamiltonian for the impurity is assumed to be valid within the effective mass approximation and we have considered, for the sake of comparison, spherical and spheroidal dots of the same volume and confining barrier. In this way, the ground state energy of the impurity is calculated as a function of the volume and the confining barrier heights.

#### 4.2.1. Brief Description of the Method

If  $\{q_i\}$  denotes the orthogonal set of coordinates compatible with the symmetry of the confining boundary, the trial wavefunctions can then be written as

$$\chi_i(q, \alpha) = Af(q, q_0, \alpha)\phi_i^0(q, \alpha) \quad q < q_0 \quad (283)$$

and

$$\chi_0(q, \beta) = B\phi(q, \beta) \quad q > q_0 \quad (284)$$

where  $\alpha$  and  $\beta$  are parameters to be determined,  $q_0$  is associated with the size and symmetry of the confining boundary,  $A$  and  $B$  are normalization constants,  $\phi_i^0$  is the free system wavefunction,  $\phi$  is a function with the proper asymptotic behavior as  $q_0 \rightarrow \infty$ , and  $f$  is an auxiliary function that allows the condition

$$\frac{1}{\chi_i} \frac{\partial \chi_i}{\partial q} = \frac{1}{\chi_0} \frac{\partial \chi_0}{\partial q} \quad (285)$$

at  $q = q_0$  to be satisfied.

The model Hamiltonian for the confined quantum system under study, in the effective mass approximation, can be written, in atomic units, as

$$\hat{H} = -\frac{1}{2}\nabla_q^2 + V(q) + V_b(q) \quad (286)$$

where  $V$  is the potential that accounts for the internal interactions of the components of the system and  $V_b$  is the confining potential. Here we shall assume that  $V_b$  has the form

$$V_b = \begin{cases} 0 & q < q_0 \\ V_0 & q > q_0 \end{cases} \quad (287)$$

At this point, the variational method can be implemented to calculate the energy of the ground state of the system by construing the functional

$$\varepsilon(\alpha, \beta) = \int \chi_i^* \left\{ -\frac{1}{2}\nabla_q^2 + V(q) \right\} \chi_i d^3q + \int \chi_o^* \left\{ -\frac{1}{2}\nabla_q^2 + V_0 + V(q) \right\} \chi_o d^3q \quad (288)$$

and minimizing it with respect to  $(\alpha, \beta)$ , restricted to

$$\int \chi_i^* \chi_i d^3q + \int \chi_o^* \chi_o d^3q = 1 \quad (289)$$

as usual.

#### 4.2.2. Geometry Adapted Trial Wavefunctions

In the effective mass approximation, the model Hamiltonian for an hydrogenic impurity ( $m_n^* = \infty$ ) confined within a quantum dot, in the context of the later section, can be written as

$$\hat{H} = -\frac{1}{2}\nabla_q^2 + V(q) + V_b(q) \quad (290)$$

where

$$V_b = \begin{cases} 0 & q < q_0 \\ V_0 & q > q_0 \end{cases} \quad (291)$$

and

$$V(q) = -\frac{1}{r_q} \quad (292)$$

Here  $r_q$  is the electron–nucleus separation and we have used effective atomic units. The symmetry of the confining domain determines the form of  $r_q$  in the set of coordinates compatible with it. In the following, we construct explicitly the trial wavefunctions for the chosen symmetries.

First, if we assume that the hole is located at the center of a confining sphere of radius  $r_0$ , the trial wavefunction in spherical coordinates can be written as [66]

$$\chi_i = A \exp(-\alpha r)(r_0 - \alpha r) \quad r < r_0 \quad (293)$$

and

$$\chi_o = B \exp(-\beta r)/r \quad r > r_0 \quad (294)$$

The continuity of the logarithmic derivative at  $r = r_0$ , given in Eq. (285), allows one relate  $\alpha$  and  $\beta$  by

$$\beta = \frac{\alpha r_0(1 - \alpha) + (2\alpha - 1)}{r_0(1 - \alpha)} \quad (295)$$

in such a way that only a variational parameter needs to be determined, once that the energy functional is minimized in the standard way.

If we now consider the exciton confined within the prolate spheroid

$$\{\xi = \xi_0 \quad -1 \leq \eta \leq 1 \quad 0 \leq \varphi \leq 2\pi\} \quad (296)$$

with the nucleus located at a foci, the electron–nucleus separation can then be written as

$$r_1 = R(\xi - \eta) \quad (297)$$

where  $2R$  is the interfocal distance of the spheroid. Following the solutions of Coulson and Robinson [122] for the free hydrogen atom in this coordinate system, the trial wavefunction is of the form

$$\chi_i = A \exp[-\alpha(\xi - \eta)](\xi - \alpha\xi_0) \quad \xi < \xi_0 \quad (298)$$

and

$$\chi_o = B \exp(-\beta\xi - \alpha\eta) \quad \xi > \xi_0 \quad (299)$$

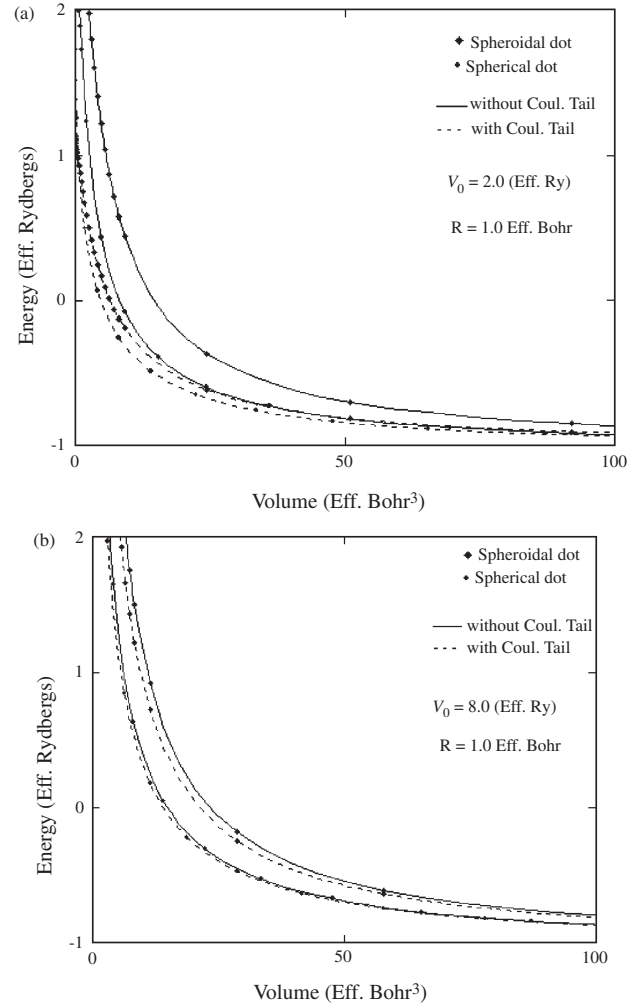

Once again, the boundary condition given by Eq. (285) allows one to connect  $\alpha$  and  $\beta$  through

$$\beta = \frac{\alpha\xi_0(1 - \alpha) + \alpha}{\xi_0(1 - \alpha)} \quad (300)$$

As the reader must be aware, this form for the trial wavefunction satisfies automatically the boundary condition on its logarithmic derivative with respect to  $\eta$ , at  $\xi = \xi_0$ . As in the previous case, only a variational parameter needs to be determined when we use the variational approach.

We have to point out that the auxiliary function of the form  $(q_0 - \alpha q)$ , which was used to construct the trial wavefunction for two symmetries, is flexible enough to describe the situation in which  $V_0 \rightarrow \infty$ . In that case  $\alpha \rightarrow 1$  and correspondingly  $\beta \rightarrow \infty$  [see Eqs. (295) and (300)] so that the external wavefunction becomes vanishingly small in this limit, as expected.

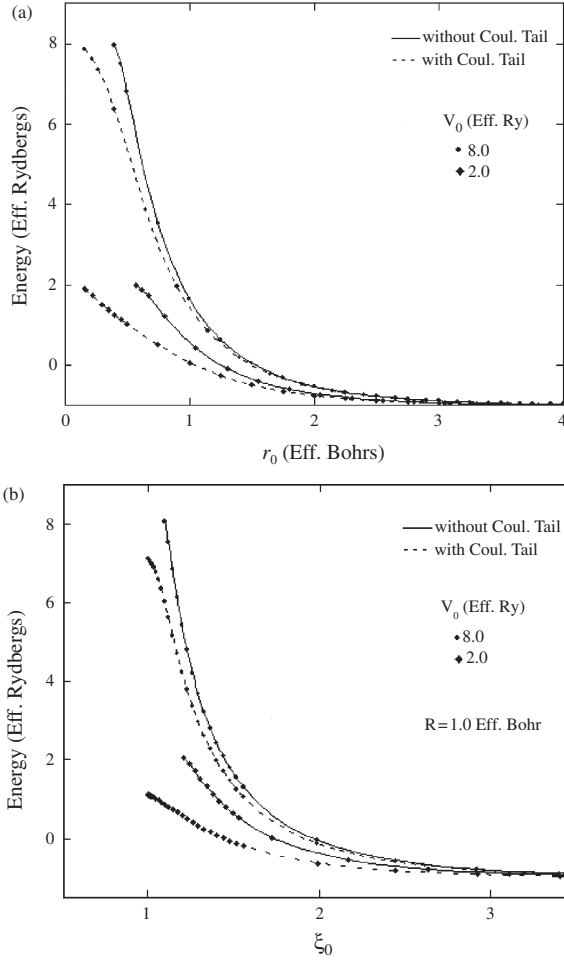

In Figure 60a and b, the energy for the ground state of the hydrogenic impurity confined within spherical and prolate spheroidal quantum dots is displayed as a function of the volume, for  $V_0 = 2.0$  and  $8.0$  effective Rydbergs respectively. In both figures we have assumed an  $R = 1$  effective Bohr for the case of the prolate spheroidal dot. The effect of considering a different geometry can be noticed immediately from these figures, which supports that, for a given volume of the dot and barrier height, the ground state energy shows a dependence on the shape of the confining box that is particularly stronger for smaller sizes of the dot. The effect of including the internal interaction potential (Coulomb term) of the components of the system (electron–nucleus) in both regions (inside and outside the quantum dot) is also shown in the figures. When the Coulomb term is considered in the exterior of the quantum dot, a remarkable difference can be noticed for the smaller barrier height potential and smaller sizes of quantum dot. The latter is due to the fact that the confining capability of the box decreases and correspondingly, the probability of finding the electron in the exterior of the quantum dot is increased (see Fig. 60a). In Figure 60b, this effect is smaller. In Figure 60a, we can also observe a stronger dependence, by including the Coulomb term in the exterior of the quantum dot, for the spheroidal symmetry than for spherical one. Another observation is that, for the spheroidal symmetry, we have considered the nucleus of the impurity placed in a focus not in the origin, but in the latter case, keeping in mind the work of Marín et al. [65], the resulting geometrical effect would be stronger.

**Figure 60.** Ground state energy for a hydrogenic impurity within quantum dots of a spherical and prolate spheroidal shape as a function of their volume for a fixed value of the barrier height. (a)  $V_0 = 2.0R_y^*$ , (b)  $V_0 = 8.0R_y^*$ . Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

In Figure 61a, we show the energy for the ground state of the hydrogenic impurity confined in a spherical quantum dot as a function of the volume, for  $V_0 = 8.0$  and  $2.0$  effective Rydbergs. In the solid curves, the Coulomb term is not included in the external region of the quantum dot while in the dashed ones we have considered it. Figure 61b shows the same curves as in Figure 61a for the prolate spheroidal quantum dot with  $R = 1.0$  effective Bohr. A difference between the curves with and without the Coulomb term in the exterior of the quantum dot can be noticed. This difference is greater for the smaller barrier height potential and in the region of strong confinement regime (small sizes of the quantum dot). This effect is similar to that discussed earlier for Figure 60.

In Figure 62, we make a comparison of the ground state energy of the hydrogenic impurity confined within a prolate spheroidal quantum dot, for  $V_0 = 2.0$  effective Rydbergs and

**Figure 61.** Ground state energy for a hydrogenic impurity within quantum dots of: (a) spherical symmetry as a function of the dot radius and barrier height, (b) prolate spheroidal symmetry as a function of the eccentricity and barrier height. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

different interfocal distances ( $2R$ ). The solid curves correspond to  $R = 0.5$  and  $R = 1.0$  effective Rydbergs without the Coulomb term, while dashed ones are for the same values of  $R$  but the Coulomb term in the exterior of the quantum dot is included. The latter figure confirms that there is a significant variation of the energy for different interfocal distances of the spheroidal quantum dot and that the difference is greater for the lower value of  $R$  and even more significant when the Coulomb term in the exterior of the quantum dot is not included.

Thus, the previous results show that a quantitative fitting of the energy-size curves for the impurity (or, qualitatively, for the exciton) to experimental results (for a given value of  $V_0$ ) must be taken with caution, independently of the model used to make comparison. This is the case in most of the theoretical approaches dealing with semiconductor crystallites, since a spherical shape is assumed to fit the experimental results.

### 4.3. Hydrogen Atom and Harmonic Oscillator Confined by Impenetrable Spherical Boxes

The direct variational method is used to study two simple confined systems, namely, the hydrogen atom and the harmonic oscillator within impenetrable spherical boxes. The trial wavefunctions have been assumed as the product of the “free” solutions of the corresponding Schrödinger equation and a simple function that satisfies the respective boundary conditions. The energy levels obtained in this way are extremely close to the exact ones, thus proving the utility of the proposed method.

#### 4.3.1. Direct Variational Approach

The exact solution for the free system can be found in any text of quantum mechanics [94]. Indeed, the corresponding energy and wavefunctions are given as

$$\varepsilon_n = -\frac{1}{n^2} \quad n = 1, 2, \dots \quad (301)$$

$$\psi_{nlm}(r, \theta, \varphi) = N_{nl}(2r/n)^l F(-n+l+1, 2l+2, 2r/n) \times \exp\left(-\frac{r}{n}\right) Y_l^m(\theta, \varphi) \quad (302)$$

where  $\hbar = m = 1$ ,  $Y_l^m(\theta, \varphi)$  are the spherical harmonics,  $F(a, b, z)$  is the confluent hypergeometric function [164], and  $N_{nl}$  is a normalization constant.

When we impose confinement on this system, the Hamiltonian is slightly modified and can be written as

$$\hat{H}' = -\frac{1}{2}\nabla^2 - \frac{1}{r} + V'(r) \quad (303)$$

where

$$V'(r) = \begin{cases} +\infty & r > r_0 \\ 0 & r \leq r_0 \end{cases} \quad (304)$$

and  $r_0$  is the radius of the confining spherical box.

The corresponding Schrödinger equation is still separable, but the resulting radial equation

$$\left[ \frac{d^2}{dr^2} + \frac{2}{r} \frac{d}{dr} - \frac{l(l+1)}{r^2} + \frac{2}{r} + 2\varepsilon \right] R(r) = 0 \quad (305)$$

must be solved with the following boundary condition:

$$R(r_0) = 0 \quad (306)$$

This means that, in order to obtain the energy spectrum, we must find the roots of Eq. (306). The new situation must be tackled in a more complicated way since we must construct a convergent series representation of  $R(r)$  and then solve it numerically.

Alternatively, we solve the same problem approximately, with the aid of the modified variational method discussed previously. We exploit the fact that the solutions of the “free” hydrogen atom are known [see Eq. (302)] in order to choose the trial wavefunctions as

$$\chi'_{nlm}(r, \theta, \varphi) = N(r_0 - r)(2\alpha r)^l F(-n + l + 1, 2l + 2, 2\alpha r) \times \exp(-\alpha r) Y_l^m(\theta, \varphi) \quad (307)$$

where  $N$  is a normalization constant that depends on  $r_0$  and  $\alpha$ , as well as on  $n$  and  $l$ .

We can note that  $1/n$  is replaced by  $\alpha$  in this choice for  $\chi'$ . The reason is that, as a result of confinement, the number  $n$  is no longer a good quantum number to specify the state of the system ( $l$  is still a good quantum number since symmetry has not been broken). This ansatz gives more flexibility to the variational wavefunctions, allowing for the calculation not only of the ground state energy, but also of excited states, with only one variational parameter. Furthermore, the quantum virial theorem for enclosed systems [165] is satisfied by these functions.

In order to show the adequacy of the method, in the following we shall restrict ourselves to states described by nodeless wavefunctions involving different symmetries.

When we use Eq. (307) as a trial wavefunction, together with the Hamiltonian given by Eq. (303), the energy can be readily found by minimizing the functional

$$\int_{\Omega} \chi'^* \hat{H} \chi' d\tau \quad (308)$$

with respect to  $\alpha$ , within the bounded volume  $\Omega$ , restricted to satisfy the constraints implied by

$$\int_{\Omega} \chi_n'^* \chi_m' d\tau = \delta_{nm} \quad (309)$$

This procedure is straightforward and can be done through direct algebraic manipulation.

Figure 63 shows the results obtained after minimizing Eq. (308) as compared to the “exact” values obtained by numerically solving Eq. (306) [124] for the ground state and the  $2p$  and  $3d$  excited states. Also shown in this figure are the results due to Fernandez and Castro [166] who used a method based on both hypervirial theorems and perturbation theory [167]. A remarkable agreement can be noticed, showing that the problem can be tackled in the simpler

**Figure 63.** Energy levels of the enclosed hydrogen atom as a function of the radius of the box  $r_0$ . Exact and variational calculations are compared (see text). Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

fashion proposed here. Note that, in contrast to the hypervirial treatment, the energy values obtained by the variational method always lie as an upper bound to the exact results for all box sizes, as expected.

Incidentally, Fernandez and Castro [165] were the first to obtain the ground state energies shown in Figure 63 variationally. These authors used a trial wavefunction identical to Eq. (307) while analyzing the fulfillment of the quantum virial theorem for enclosed systems by approximate wavefunctions.

We now turn our attention to the case of the enclosed harmonic oscillator following a procedure similar to the case of the enclosed hydrogen atom.

Once again, the problem of the “free” oscillator is exactly solved and the energy and wavefunctions are given by [94]

$$\varepsilon_{nl} = 2n + l + 3/2 \quad n = 0, 1, 2, \dots \quad (310)$$

$$\psi_{nl}(r, \theta, \varphi) = N r^l F(-n, l + 3/2, r^2) \times \exp(-r^2/2) Y_l^m(\theta, \varphi) \quad (311)$$

where we have set  $\hbar = m = \omega = 1$ ,  $Y_l^m(\theta, \varphi)$  are the spherical harmonics,  $F(a, b, z)$  is the hypergeometric function, and  $N$  is a normalization constant.

As in the case of the hydrogen atom, when we impose the confinement, the Hamiltonian is modified to give

$$\hat{H}' = -\frac{1}{2} \nabla^2 + \frac{r^2}{2} + V'(r) \quad (312)$$

where

$$V'(r) = \begin{cases} +\infty & r > r_0 \\ 0 & r \leq r_0 \end{cases} \quad (313)$$

$r_0$  being the radius of the confining spherical box in units of  $(\hbar/m\omega)^{1/2}$ .

Once again, if we were to solve the problem exactly, the Schrödinger equation is separable and the resulting radial equation

$$\left[ \frac{d^2}{dr^2} + \frac{2}{r} \frac{d}{dr} - \frac{l(l+1)}{r^2} - r^2 + 2\varepsilon \right] R(r) = 0 \quad (314)$$

should be solved with the condition

$$R(r_0) = 0 \quad (315)$$

which would force us to use a numerical treatment. In the modified variational method (as in the case of the confined hydrogen atom) the symmetry of the enclosed harmonic oscillator is not broken by the confinement and  $l$  is still a good quantum number but  $n$  ceases to be so. To construct the trial wavefunctions, we simply replace  $r^2$  by  $\alpha r^2$  in the argument of the functions in Eq. (311) and we proceed, as in our previous example, to find the energy of the system for each box size.

In Table 5 we compare the exact results obtained from Eq. (315) [124] and those obtained by the application of the variational procedure, for the ground state and the first excited state. For completeness, we also show the results for the ground state, obtained through the hypervirial perturbational method using an 11-term perturbation expansion [168]. Once again, a very good agreement is observed.

An important criterion for this selection is the fulfillment of the virial theorem for these systems [165]. At this stage it is important to note that there are several papers in the literature dealing with different techniques to tackle these problems [125].

In this connection, Fernandez et al. [165, 169–171] have done a thorough study of the use of the virial theorem for quantum systems subject to Dirichlet and/or Neumann boundary conditions. As we have mentioned before, in both examples, the agreement of the results obtained by the proposed modification of the direct variational approach is remarkable, in spite of the simplicity of the method.

We note that the symmetry of the systems and their confinement were intentionally chosen to be compatible (i.e., both being of spherical symmetry).

#### 4.4. Energy States of Two Electrons in a Parabolic Quantum Dot in Magnetic Field

The energy spectra of two interacting electrons in a quantum dot confined by a parabolic potential in an applied magnetic field of arbitrary strength are obtained in this section. The

<sup>a</sup> Reference [168].

shifted  $1/N$  expansion method is used to solve the effective mass Hamiltonian [172]. The influence of the electron–electron interaction on the ground state energy and its significant effect on the energy level crossings in states with different angular momentum are shown. The dependence of the ground state energy on the magnetic field strength for various confinement energies is presented.

The magnetic field dependence plays a useful role in identifying the absorption features. The effects of the magnetic field on the state of the impurity [173] and excitons [95, 159, 161, 174–176] confined in quantum dots have been extensively studied. Kumar et al. [177] have self-consistently solved the Poisson and Schrödinger equations and obtained the electron states in GaAs–GaAlAs for both cases: in zero and for magnetic fields applied perpendicular to the heterojunctions. The results of their work [177] indicated that the confinement potential can be approximated by a simple one-parameter adjustable parabolic potential. Merkt et al. [178] have presented a study of quantum dots in which both the magnetic field and the electron–electron interaction terms were taken into account. Pfannkuche and Gerhaxdts [179] have devoted a theoretical study to the magneto-optical response to far-infrared radiation (FIR) of quantum dot helium, accounting for deviations from the parabolic confinement. More recently, De Groote et al. [180] have investigated the thermodynamic properties of quantum dots taking into consideration the spin effect, in addition to the electron–electron interaction and magnetic field terms. The purpose of this section is to show the effect of the electron–electron interaction on the spectra of the quantum dot states with nonvanishing azimuthal quantum numbers and the transitions in the ground state of the system as the magnetic field strength increases.

Here we shall use the shifted  $1/N$  expansion method to obtain an energy expression for the spectra of two confined electrons in a quantum dot by solving the effective mass Hamiltonian including the following terms: the electron–electron interaction, the applied field, and the parabolic confinement potential.

##### 4.4.1. Theory and Model

Within the effective mass approximation, the Hamiltonian for an interacting pair of electrons confined in a quantum dot by parabolic potential of the form  $m_e^* \omega_0^2 r^2/2$  in a magnetic field applied parallel to the  $z$ -axis (and perpendicular to the plane where the electrons are restricted to move) in the symmetric gauge is written as

$$\hat{H} = \sum_{i=1}^2 \left\{ -\frac{\hbar^2 \nabla_i^2}{2m_e^*} + \frac{1}{2} m_e^* \omega_0^2 r_i^2 + \frac{\hbar \omega_c}{2} L_i^z \right\} + \frac{e^2}{\kappa |\vec{r}_1 - \vec{r}_2|} \quad (316)$$

where the two-dimensional vectors  $\vec{r}_1$  and  $\vec{r}_2$  describe the positions of the first and the second electron in the  $(x, y)$  plane, respectively.  $L_i^z$  stands for the  $z$ -component of the orbital angular momentum for each electron and  $\omega_c = eB/m_e^*c$ ,  $m_e^*$ , and  $\kappa$  are the cyclotron frequency, effective mass, and dielectric constant of the medium, respectively.

The frequency  $\omega$  depends on both the magnetic field  $B$  and the confinement frequency  $\omega_0$  and is given by

$$\omega = \left( \omega_0^2 + \frac{\omega_c^2}{4} \right)^{1/2} \quad (317)$$

The natural units of length and energy to be used are the effective Bohr radius  $a_B^* = \kappa \hbar^2 / m_e^* e^2$  and effective Rydberg  $R_y^* = \hbar^2 / 2m_e^* a_B^{*2}$ . The dimensionless constant  $\gamma = \hbar \omega_c / 2R_y^*$  plays the role of an effective magnetic field strength.

Upon introducing the center of mass  $\vec{R} = (\vec{r}_1 + \vec{r}_2) / \sqrt{2}$  and the relative coordinates  $\vec{r} = (\vec{r}_1 - \vec{r}_2) / \sqrt{2}$ , the Hamiltonian [180] in Eq. (316) can be written as a sum of two separable parts that represent the center of mass motion Hamiltonian,

$$\hat{H}_R = -\frac{\hbar^2}{2m_e^*} \nabla_R^2 + \frac{m_e^*}{2} \omega^2 R^2 + \frac{\hbar \omega_c}{2} L_z^R \quad (318)$$

and the relative motion Hamiltonian,

$$\hat{H}_r = -\frac{\hbar^2}{2m_e^*} \nabla_r^2 + \frac{m_e^*}{2} \omega^2 r^2 + \frac{\hbar \omega_c}{2} L_z^r + \frac{e^2}{r} \quad (319)$$

Equation (318) describes the Hamiltonian of the harmonic oscillator with the well-known eigenenergies

$$\varepsilon_{n_{cm}, m_{cm}} = (2n_{cm} + |m_{cm}| + 1) \hbar \omega + \frac{\hbar \omega_c}{2} m_{cm} \quad (320)$$

labeled by the radial ( $n_{cm} = 0, 1, 2, \dots$ ) and azimuthal ( $m_{cm} = 0, \pm 1, \pm 2, \pm 3, \dots$ ) quantum numbers. The problem is reduced to obtaining eigenenergies  $\varepsilon_{n_r, m}$  of the relative motion Hamiltonian. The energy states of the total Hamiltonian are labeled by  $CM$  and relative quantum numbers,  $|n_{cm} m_{cm}; n_r m\rangle$ . The coexistence of the electron–electron and the oscillator terms makes the exact analytic solution with the present special functions not possible.

#### 4.4.2. Shifted 1/N Expansion Method

The shifted 1/ $N$  expansion method,  $N$  being the spatial dimensions, is a pseudo-perturbative technique in the sense that it proposes a perturbation parameter that is not directly related to the coupling constant [181–184]. The aspect of this method has been clearly stated by Imbo et al. [181–183] who had displayed step-by-step calculations relevant to this method. Following their work, here we only present the analytic expressions that are required to determine the energy states.

The method starts by writing the radial Schrödinger equation, for an arbitrary cylindrically symmetric potential, in a  $N$ -dimensional space as

$$\left\{ -\frac{d^2}{dr^2} + \frac{(k-1)(k-3)}{4r^2} + V(r) \right\} \psi(r) = \varepsilon_r \psi(r) \quad (321)$$

where  $k = N + 2m$ .

In order to get useful results from 1/ $\bar{k}$  expansion, where  $\bar{k} = k - a$  and  $a$  is a suitable shift parameter, the large  $\bar{k}$ -limit of the potential must be suitably defined [185]. Since the angular momentum barrier term behaves like  $\bar{k}^2$  at large  $\bar{k}$ , so the potential should behave similarly. This will give rise

to an effective potential, which does not vary with  $\bar{k}$  at large values of  $\bar{k}$  resulting in a sensible zeroth-order classical result. Hence, Eq. (321) in terms of the shift parameter becomes

$$\left\{ -\frac{d^2}{dr^2} + \frac{\bar{k}^2 [1 - (1-a)/\bar{k}] [1 - (3-a)/\bar{k}]}{4r^2} + \frac{V(r)}{Q} \right\} \psi(r) = \varepsilon_r \psi(r) \quad (322)$$

where

$$V(r) = \frac{2}{r} + \frac{1}{4} \omega^2 r^2 + m \frac{\omega_c}{2} \quad (323)$$

and  $Q$  is a scaling constant to be specified from Eq. (325). The shifted 1/ $N$  expansion method consists of solving Eq. (322) systematically in terms of the expansion parameter  $1/\bar{k}$ . The leading contribution term to the energy comes from

$$\bar{k}^2 V_{\text{eff}}(r) = \frac{\bar{k}^2}{r_0^2} \left( \frac{1}{4} + \frac{r_0^2 V(r_0)}{Q} \right) \quad (324)$$

where  $r_0$  is the minimum of the effective potential, given by

$$2r_0^3 V'(r_0) = Q \quad (325)$$

It is convenient to shift the origin to  $r_0$  by the definition

$$x = \bar{k}^{1/2} (r - r_0) / r_0 \quad (326)$$

and expanding Eq. (322) about  $x = 0$  in powers of  $x$ . Comparing the coefficients of powers of  $x$  in the series with the corresponding ones of the same order in the Schrödinger equation for one-dimensional anharmonic oscillator, we determine the anharmonic oscillator frequency, the energy eigenvalue, and the scaling constant in terms of  $\bar{k}$ ,  $Q$ ,  $r_0$  and the potential derivatives. The anharmonic frequency parameter is

$$\bar{\omega} = \left[ 3 + \frac{V''(r_0)}{V'(r_0)} \right]^{1/2} \quad (327)$$

and the energy eigenvalues in powers of 1/ $\bar{k}$  (up to third order) read

$$\varepsilon_{n_r, m} = V(r_0) + \frac{\bar{k}^2}{4r_0} + \frac{1}{r_0^3} \left[ \frac{(1-a)(3-a)}{4} + \gamma_1 \right] + \frac{\gamma_2}{\bar{k} r_0^2} \quad (328)$$

The explicit forms of  $\gamma_1$  and  $\gamma_2$  are given in next section. The shift parameter  $a$ , which introduces an additional degree of freedom, is chosen so as to make the first term in the energy series of order  $\bar{k}$  vanish, namely,

$$\frac{\bar{k}}{r_0^2} \left[ \left( n_r + \frac{1}{2} \right) \bar{\omega} - \frac{(2-a)}{2} \right] = 0 \quad (329)$$

by requiring an agreement between  $1/\bar{k}$  expansion and the exact analytic results for the harmonic and Coulomb potentials. From Eq. (329) we obtain

$$a = 2 - (2n_r + 1)\bar{\omega} \quad (330)$$

where  $n_r$  is the radial quantum number related to the principal  $n$  and magnetic  $m$  quantum numbers by the relation  $n_r = n - |m| - 1$ . Energies and lengths in Eqs. (321)–(330) are expressed in units of  $R_y^*$  and  $a_B^*$ , respectively.

For the two-dimensional case,  $N = 2$ , Eq. (325) takes the following form:

$$\sqrt{2r_0 V'(r_0)} = 2 + 2m - a = Q^{1/2} \quad (331)$$

Once  $r_0$  (for a particular quantum state and confining frequency) is determined, the task of computing the energy is relatively simple.

The results are presented in Figures 64–68 and Tables 6 and 7. The relative ground state energy  $|00\rangle$  of the relative motion, for the zero magnetic field case, against the confinement length is displayed in Figure 64. The present results (black dots) clearly show an excellent agreement with the numerical results of [178] (dashed line). In Figure 65, the first low energy levels  $|00\rangle$ ,  $|10\rangle$ , and  $|20\rangle$  of the relative Hamiltonian are presented as a function of the effective confinement frequency  $\omega$ , using parameters appropriate to InSb, where the dielectric constant  $\kappa = 17.88$ , electron effective mass  $m_e^* = 0.014m_0$ , and confinement energy  $\hbar\omega_0 = 7.5$  meV [180]. The energy levels obviously show a linear dependence on the effective frequency. As the effective frequency  $\omega$  increases the confining energy term dominates the interaction energy term and thus the linear relationship between the energy and the frequency is maintained. This result is consistent with [180].

To investigate the effect of the electron–electron interaction on the energy spectra of the quantum dot, we plotted

**Figure 64.** The relative ground state energy  $|00\rangle$  for the electrons in a quantum dot as a function of confinement length  $\ell_0 = (\hbar/m_e^*\omega_0)^{1/2}$  for the zero magnetic field. in Figure 66 the total ground state energy  $|00; 00\rangle$  of the full Hamiltonian for independent (solid line) and interacting (dashed line) electrons as a function of the ratio  $\omega_c/\omega_0$ . The figure shows, as we expect, a significant energy enhancement when the electron–electron Coulombic interaction term is turned on. Furthermore, as the magnetic field increases, the electrons are further squeezed in the quantum dot, resulting in an increase of the repulsive electron–electron Coulombic energy and in effect the energy levels.

**Figure 66.** The total ground state energy  $|00; 00\rangle$  for two electrons in a quantum dot as a function of the ratio  $\omega_c/\omega_0$ . The energy level crossings are shown in Figure 67. We have displayed the eigenenergies of the states  $|00; 0m\rangle$ ,  $m = 0, -1, -2, \dots, -5$ , for two interacting electrons parabolically confined in the quantum dot of size  $\ell_0 = 3a_B^*$  as a function of the ratio  $\omega_c/\omega_0$ . As the magnetic field strength increases the energy of the state  $m = 0$  increases while the energy of the states with nonvanishing quantum number  $m$  decreases, thus leading to a sequence of different ground states, as reported in [185]. In the interacting system, the higher the angular momentum of the relative motion, the lower the interaction energy. This is caused by the structure of the relative wavefunction: The larger the angular

**Figure 68.** The relative ground state  $|00\rangle$  energy versus the magnetic field strength for two different confinement energies. Reprinted with permission from [205], J. L. Marín et al., in “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Table 6.** The roots  $r_0$  determined by Eq. (684) for quantum dot states with nonvanishing azimuthal quantum number ( $m$ ) against the ratio  $\omega_c/\omega_0$ .

$m$	$\omega_c/\omega_0$	0	-1	-2	-3	-4	-5
1		4.262	4.827	5.457	6.075	6.659	7.209
2		3.692	3.682	4.212	4.719	5.193	5.635
3		3.188	2.943	3.398	3.825	4.229	4.586

momentum the larger the spatial extent and therefore, the larger the distance between the electrons [186]. To confirm this numerically, we list in Table 6 the roots  $r_0$  of the potential for the interacting electrons in the quantum dot, for states with different angular momenta. At particular values of the ratio  $\omega_c/\omega_0$ , as the azimuthal quantum number  $|m|$  increases, the root  $r_0$  also increases and thus the electron–electron interaction  $V_{ee}(r) = 2/r_0$ , in the leading term of the energy series expression, decreases.

In Figure 68, we showed the dependence of the ground state energy on the magnetic field strength for confinement energies:  $\hbar\omega_0 = 6$  and 12 meV. For constant values of the magnetic field, the larger the confinement energy, the greater the energy of the interacting electrons in the quantum dot. The spin effect can be included in the Hamiltonian, Eq. (316), added to the center of mass part as a space independent term, and Eq. (318) is still an analytically solvable harmonic oscillator Hamiltonian [180].

We have compared, in Table 7, the calculated results for the ground state energies  $|00\rangle$  of the relative Hamiltonian at different confining frequencies with the results of Taut [187]. In a very recent work, Taut has reported a particular analytical solution of the Schrödinger equation for two interacting electrons in an external harmonic potential. The table shows that as  $1/\omega$  increases the difference between both results noticeably decreases until it becomes  $\approx 1.4 \times 10^{-3}$  at  $1/\omega = 1419.47$ .

Quantum dots with more than two electrons can also be studied. The Hamiltonian for  $n_e$ -interacting electrons, provided that the electron–electron interaction term depends only on the relative coordinates between electrons  $V(|r_i - r_j|) = e^2/\kappa|r_{ij}|$ , and parabolically confined in the quantum dot, is separable into  $CM$  and relative Hamiltonians. The parabolic potential form  $V(r_i) = m_i\omega_0^2 r_i^2/2$ ,  $i = 1, 2, 3, \dots, n_e$ , is the only potential which leads to a separable Hamiltonian. The  $CM$  motion part is described by

**Table 7.** The ground state energies (in atomic units) of the relative Hamiltonian calculated by  $1/N$  expansion at different frequencies, compared with the results of Taut [187].

4	0.4220	0.6250
20	0.1305	0.1750
54.7386	0.0635	0.0822
115.299	0.0375	0.0477
523.102	0.0131	0.0162
1054.54	0.0081	0.0100
1419.47	0.0067	0.0081

the one-particle Hamiltonian, Eq. (318), with the electron mass replaced by the total mass  $M = n_e m_e^*$  and the electron charge replaced by the total charge  $Q = n_e e$ . The relative Hamiltonian part, which involves only the relative coordinates and momenta, has a cylindrically symmetric potential and can be handled by the  $1/N$ -expansion technique. When the confining potential is quadratic, FIR spectroscopy is insensitive to the interaction effects because of  $CM$  and relative motions. The radiation dipole operator  $\sum_i e_i \vec{r}_i = Q\vec{R}$ , being a pure  $CM$  variable, then it does not couple to  $\hat{H}_r$ , which contains all the electron–electron interactions. The dipole operator then induces transitions between the states of the  $CM$  but does not affect the states of the relative Hamiltonian. The eigenenergies for the  $CM$  Hamiltonian, Eq. (320), do not change because  $\omega_c$  in the energy expression remains the same; namely,  $QB/Mc = eB/m_e^*c$ . Consequently, the FIR absorption experiments see only the feature of the single electron energies. There are only two allowed dipole transitions ( $\Delta m = \pm 1$ ) and the FIR resonance occurs at frequencies

$$\omega_{\pm} = \sqrt{\left(\frac{\omega_c}{2}\right)^2 + \omega_0^2} \pm \frac{\omega_c}{2} \quad (332)$$

Many different experiments on quantum dots have proved the validity of Kohn's theorem and that the observed resonance frequency of an electron system in a parabolic potential is independent of electron–electron interactions and thus the actual number of electrons in the well, as reported by Wixforth et al. in a very recent review article [188].

In conclusion we have obtained the energy spectra of two interacting electrons as a function of confinement energies and magnetic field strength. The method has shown good agreement with the numerical results of Merkt et al. [178], Taut [187], and Wagner et al. [185]. Our calculations have also shown the effect of the electron–electron interaction term on the ground state energy and its significance on the energy level crossings in states with different azimuthal quantum numbers. The shifted  $1/N$  expansion method yields quick results without putting restrictions on the Hamiltonian of the system.

#### 4.4.3. Calculation of Parameters $\gamma_1$ and $\gamma_2$

The explicit forms of the parameters  $\gamma_1$  and  $\gamma_2$  are given in the following. Here  $R_y^*$  and  $a_b^*$  are used as units of energy and length, respectively

$$\gamma_1 = c_1 e_2 + 3c_2 e_4 - \bar{\omega}^{-1} [e_1^2 + 6c_1 e_1 e_3 + c_4 e_2^3] \quad (333)$$

and

$$\gamma_2 = T_7 + T_{12} + T_{16} \quad (334)$$

where

$$\begin{aligned} T_7 &= T_1 - \bar{\omega}^{-1} [T_2 + T_3 + T_4 + T_5 + T_6] \\ T_{12} &= \bar{\omega}^{-2} [T_8 + T_9 + T_{10} + T_{11}] \\ T_{16} &= \bar{\omega}^{-2} [T_{13} + T_{14} + T_{15}] \end{aligned} \quad (335)$$

with

$$\begin{aligned} T_1 &= c_1 d_2 + 3c_2 d_4 + c_3 d_6 & T_2 &= c_1 e_2^2 + 12c_2 e_2 e_4 \\ T_3 &= 2e_1 d_1 + 2c_5 e_4^2 & T_4 &= 6c_1 e_1 d_3 + 30c_2 e_1 d_5 \\ T_5 &= 6c_1 e_1 d_3 + 2c_4 e_3 d_3 & T_6 &= 10c_6 e_3 d_5 \\ T_8 &= 4e_2^2 e_2 + 36c_1 e_1 e_2 e_3 & T_9 &= 8c_4 e_2 e_3^2 \\ T_{10} &= 24c e_1^2 e_4 + 8c_7 e_1 e_3 e_4 & T_{11} &= 12c_8 e_3^2 e_4 \\ T_{13} &= 8e_1 e_3 + 108c_1 e_1 e_3 & T_{14} &= 48c_4 e_1 e_3 \\ T_{15} &= 30c_9 e_3 \end{aligned} \quad (336)$$

where  $c$ ,  $d$ , and  $e$  are parameters given as

$$\begin{aligned} c_1 &= 1 + 2n_r & c_4 &= 11 + 30n_r + 30n_r^2 \\ c_8 &= 57 + 189n_r + 225n_r^2 + 150n_r^3 & c_2 &= 1 + 2n_r + 2n_r^2 \\ c_5 &= 21 + 59n_r + 51n_r^2 + 34n_r^3 & c_3 &= 3 + 8n_r + 6n_r^2 + 4n_r^3 \\ c_6 &= 13 + 40n_r + 42n_r^2 + 28n_r^3 \\ c_9 &= 31 + 109n_r + 141n_r^2 + 94n_r^3 \\ c_7 &= 31 + 78n_r^2 + 78n_r^3 & e_j &= \kappa_j / \bar{\omega}^{j/2} & d_i &= \delta_i / \bar{\omega}^{i/2} \end{aligned} \quad (337)$$

where  $j = 1, 2, 3, 4$  and  $i = 1, 2, 3, 4, 5, 6$ :

$$\begin{aligned} \kappa_1 &= (2 - a) & \kappa_2 &= -\frac{3(2 - a)}{2} \\ \kappa_3 &= -1 - \frac{2r_0}{Q} & \kappa_4 &= \frac{5}{4} + \frac{2r_0}{Q} \\ \delta_1 &= -\frac{(1 - a)(3 - a)}{2} & \delta_2 &= -\frac{3(1 - a)(3 - a)}{4} \\ \delta_3 &= 2(2 - a) & \delta_4 &= -\frac{5(2 - a)}{2} \\ \delta_5 &= -\frac{3}{2} - \frac{2r_0}{Q} & \delta_6 &= \frac{7}{4} + \frac{2r_0}{Q} \end{aligned} \quad (338)$$

## 5. MECHANISM OF TERAHERTZ LASING IN SiGe/Si QUANTUM WELLS

Blom et al. [189] presented a theoretical calculation, which showed the formation of resonant states, and explained the origin of the observed temperature dependence of the dc conductivity under low bias voltage. Thus, it was shown that the mechanism of terahertz (THz) lasing is population inversion of the resonant state with respect to the localized impurity state. This is the same mechanism of lasing as in uniaxially stressed  $p$ -Ge THz lasers.

In an early experiment [190] published in 1992, THz radiation was observed from bulk  $p$ -Ge under uniaxial stress and a dc electric field, both applied along the same crystal axis. Eight years later measurements of the radiation spectrum characterized the observed radiation as pulse mode lasing under pumping of a strong electric field [191]. A theoretical explanation of the lasing phenomenon followed almost immediately [192], which proved the formation of resonant states as the required mechanism for achieving population inversion. Shortly thereafter, a tunable continuous

wave  $p$ -Ge THz laser was realized [193] under weak electric field pumping, accompanied by a complete theoretical interpretation [194].

The theory of population inversion based on the formation of resonant states has been given in detail very recently [195]. Under uniaxial stress the heavy hole band (HHB) in  $p$ -Ge lies lower than the light hole band (LHB) by an amount  $E_{\text{def}}$ . Dictated by the symmetry properties, one set of impurity levels is attached to the edge of the HHB, and another set is attached to the edge of the LHB. If  $E_{\text{def}}$  is greater than the hole binding energy of the lowest impurity level attached to the HHB edge, this impurity level overlaps the Bloch states in the LHB. Resonant states are then formed. Under an external electric field, the impact-ionized holes are accelerated toward the resonant level. With the proper combination of impurity concentration, temperature, electric field, stress, and scattering strength of phonons and impurities, holes have a large probability of occupying resonant states [192, 194, 195]. A resonant level population inversion with respect to those impurity levels which attach to the LHB edge is then formed, and THz lasing occurs [191, 193].

The externally applied uniaxial stress can be replaced by the strain in a QW with lattice mismatch, and a  $\text{Si}/\text{Ge}_x\text{Si}_{1-x}/\text{Si}$  QW with  $x < 0.2$  and a boron-doped well was proposed [196, 197]. In such a structure the well is stretched along the growth direction, so the HHB lies above the LHB. When impurities are added to the  $\text{SiGe}/\text{Si}$  QW system, all relevant energy levels are affected by the electric field produced by the charge redistribution in the system. It is plausible that a strong electric field in the QW may favor the formation of resonant states for THz lasing. Such a field can be achieved by employing two aspects of the sample structure. First, the Si buffer layer and the Si cap layer on each side of the well will be  $\delta$  doped with boron acceptors. Second, the existence of a thin  $\text{SiO}_2$  layer on top of the cap layer creates interface states between them. In such a structure THz lasing was indeed detected [198].

Because the carriers in a  $\text{SiGe}/\text{Si}$  QW are electrically pumped, electric transport in the well has been investigated in detail in order to clarify the relevant physical processes [197, 199]. Under a weak dc bias, the temperature behavior of the conductivity  $\sigma$ , plotted as  $\ln(\sigma)$  as a function of the inverse temperature  $1/T$ , exhibits two different linear regimes, below and above  $T \approx 20$  K, respectively, as shown by Figure 1 in [197]. Further experiments on magnetoconductivity and Hall mobility [197, 199] have indicated that the low temperature conductivity may be due to hopping. In the high temperature region, the slope of the  $\ln(\sigma)$  vs  $1/T$  curves suggests an activation energy of about 12 meV for Ge content  $x = 0.1$  and 18 meV for  $x = 0.15$ , if indeed the activation process exists. It was suggested in [197, 199] that the possible hole activation is between the two impurity levels  $E_{1s}^h$  and  $E_{1s}^l$  attached to each respective band. The present study has disproved this suggestion. The mechanism of the high temperature conductivity and its relation to the THz lasing are the questions to be answered.

In [189] an extensive numerical study of a  $\text{Si}/\text{Ge}_{0.15}\text{Si}_{0.85}/\text{Si}$  QW was performed. The system structure consisted of, in sequence, an  $n$ -Si substrate, an  $i$ -Si buffer layer of 130 nm thickness, a  $\text{Ge}_{0.15}\text{Si}_{0.85}$  well of 20 nm thickness, and an  $i$ -Si

cap layer of 60 nm thickness. Over the cap layer a thin layer of  $\text{SiO}_2$  typically appears, on which ohmic contacts were installed. The middle of the well was  $\delta$  doped with a boron concentration of  $6 \times 10^{11} \text{ cm}^{-2}$ . In both the buffer layer and the cap layer, at a distance of 30 nm from the respective QW interface, a  $\delta$  layer of boron was doped with a concentration of  $3 \times 10^{11} \text{ cm}^{-2}$ . In this system  $E_{\text{def}} = 31$  meV [200]. Using a one band variational approach given in [201], the binding energies  $E_{1s}^l$  and  $E_{1s}^h$  of the impurity levels attached to the LHB edge and the HHB edge, respectively, were calculated and both were found to have a value of about 27 meV.

One very important feature of the QW system is the interface states between the  $\text{SiO}_2$  layer and the Si cap layer, which can accumulate almost all holes from the  $\delta$  doping in the cap layer. This resulted in pinning of the chemical potential at the interface state energy level, which lay in the bandgap at  $\Delta \approx 0.4$  eV measured from the valence band top [202]. This charge redistribution inside the sample built up a strong electric field in the QW, which was detected experimentally [197, 199].

The energy level structure in the QW calculated is shown in Figure 69. The zero energy was set at the chemical potential  $\mu$ . The solid curve marks the HHB edge and the dotted curve the LHB edge. The lowest quantization energy levels  $E_1^{\text{hhb}}$  in the HHB and  $E_1^{\text{hbl}}$  in the LHB were indicated, along with the lowest impurity states attached to each band. In the case depicted ( $T = 4$  K), the electric field strength in the QW was 19 kV/cm, and  $E_1^{\text{hhb}} - E_{1s}^l = 5$  meV. The overlap of the impurity level  $E_{1s}^l$  with the  $E_1^{\text{hhb}}$  2D subband made it possible to form the resonant state required for THz lasing. Once they proved that a resonant impurity state could be formed in the structure, the theory of population inversion developed for strained bulk  $p$ -Ge [195] could be applied directly to explain the origin of the observed lasing in the  $\text{SiGe}/\text{Si}$  QW.

In order to understand the transport properties of the  $\text{SiGe}/\text{Si}$  QW system, which is relevant for the electric pumping of carriers into the resonant states, they also calculated the concentration of free holes,  $p_v(T)$ , as a function of the temperature, and their results are plotted as the solid curve in the upper panel of Figure 70. The temperature

**Figure 70.** Upper panel showing the calculated temperature dependencies of the free hole concentration  $p_v(T)$  (solid curve) and the number concentration of charged acceptors in the QW (dotted curve). The dashed curve is the energy separation  $E_1^{\text{hhb}} - \mu$ . The lower panel displays the measured current as function of the temperature. Reprinted with permission from [189], A. Blom et al., *Appl. Phys. Lett.* 79, 713 (2001). © 2001, American Institute of Physics.

dependence of  $p_v(T)$  was due to the thermal excitation of holes from the chemical potential into the 2D subbands. This was governed by the energy separation  $E_1^{\text{hhb}} - \mu$ , which depends strongly on the temperature, as shown in the upper panel of Figure 70. These theoretical findings and the following experimental data will support their conjectured mechanism of THz lasing in the SiGe/Si QW.

A Si/Ge<sub>0.15</sub>Si<sub>0.85</sub>/Si QW sample with the previously specified structure was fabricated with a MBE machine. High voltage pulses of 0.3 μs duration were applied parallel to the QW via the deposited ohmic contacts. Since the δ layer of boron in the buffer layer also supplies holes to the substrate, a *pn* junction type of carrier distribution is formed, which prevents the bypass of current through the substrate. When opposite surfaces parallel to the growth direction were polished to serve as an optical resonator, strong THz radiation was detected at liquid helium temperature. The radiation intensity is orders of magnitude stronger than the intensity of spontaneous emission. In Figure 71 the radiation intensity and the corresponding electric pumping current as functions of the pulse voltage are plotted. The abrupt increase of the current around 100 V marks the onset of impact ionization of the boron acceptors in the QW. A threshold current for the radiation is clearly seen. The characteristic features of the observed THz radiation are exactly the same as those of THz lasing reported recently [203]. This was expected, because the only difference between their sample and the sample in [198, 203]

**Figure 71.** Radiation intensity and electric pumping current as functions of the pulse voltage. Reprinted with permission from [189], A. Blom et al., *Appl. Phys. Lett.* 79, 713 (2001). © 2001, American Institute of Physics.

was the concentration of δ doping in the buffer and cap layers:  $3 \times 10^{11} \text{ cm}^{-2}$  in their sample and  $4 \times 10^{11} \text{ cm}^{-2}$  in the other ones.

At a low dc bias of 2 V the current  $I$  flowing parallel to the QW was measured as a function of the temperature. The result is plotted in the lower panel of Figure 70. Similar to the temperature behavior of the free hole concentration  $p_v(T)$ , the curve  $\ln(I)$  vs  $1/T$  also displays different characteristic features below and above  $T \approx 20$  K. In fact, in the high temperature region, the slope of the  $\ln(I)$  vs  $1/T$  curve is almost the same as the slope of the  $\ln(p_v)$  vs  $1/T$  curve. They then concluded that, in this temperature region, the dependence of the current  $I$  on  $1/T$  was caused by the temperature dependence of the thermal population in the free hole levels but does not suggest an activation process as stated in [197, 199].

Then, they turned to the transport process in the low temperature region. Their calculated free hole concentration  $p_v(T)$  shown in Figure 70, although small, is non-negligible at low temperatures. However, for such low temperatures and low concentration, the mobility may be very small [204], resulting in a decrease in the current of an order of magnitude. Nevertheless, they cannot rule out completely the possibility of hopping transport for the following reason. The charged impurity ions in both the buffer layer and the cap layer create a long range random potential in the QW. At the same time the spatial variation of the alloy composition produces a short range random potential. Both effects cause fluctuation of the 2D subband edge, and their calculations gave an energy fluctuation of about 5 meV. The transport of holes in the 2D subband would then exhibit hopping behavior with an activation energy of about 2–3 meV. It is important to emphasize that such a hopping process is entirely different from that stated in [197, 199], where the transport is ascribed to the hopping of holes from one acceptor to the other within the δ layer in the well. Such a process requires partially charged acceptors. In conclusion in [189] Blom et al. calculated the number concentration of charged

acceptors in the QW and plotted it as the dotted curve in the upper panel of Figure 70. At low temperatures, the number concentration of charge acceptors in the QW is far too small to produce a measurable hopping conductivity.

It can be emphasized that the mechanism of population inversion through the formation of resonant states is essential for the realization of semiconductor QW THz lasers. A full understanding of this mechanism will allow the design of advanced THz lasers using various lattice mismatched heterostructures with different semiconductors.

## GLOSSARY

**Conduction band** Energy band in a crystalline solid partially filled by electrons.

**Confined system** A quantum system in which carriers, atoms or molecules are restricted to exist in one, two or three dimensions of the order of a few nanometers.

**Effective mass** The mass of a particle in a crystalline solid.

**Gap** Forbidden region for the electrons, which it is determined by the difference of energies between conduction and valence bands.

**Idealized confined systems** A non-real isolated quantum system whose size is of the order of few nanometers.

**Impurity** An atom or molecule embedded in a different material.

**Impurity states** The additional electron levels which appears due to the presence of an impurity.

**MBE, MOCVD and Lithography** Methods of synthesis used to the fabrication of the nanostructured materials.

**Nanostructure** Material medium whose size is of the order of few nanometers.

**Quantum dot** A quantum system, in which the carriers are confined in all directions.

**Quantum well** A quantum system, in which the carriers are confined in only one direction, the other dimensions remain free.

**Quantum well wire** A quantum system, in which the carriers are confined in two directions, the other remains free.

**Valence band** Energy band in a crystalline solid completely filled by electrons.

## 1. INTRODUCTION

Inherently conducting polymers (ICPs) such as polypyrroles, polythiophenes, and polyanilines (I–III shown in Scheme 1) are extremely useful organic electronic conductors. The applications of these materials have been reviewed recently [1–3], spanning areas as diverse as nanomaterials [4], electrochromics [5], sensors [6], artificial muscles [7, 8], smart membranes [9, 10], platforms for cell culturing [11, 12] and corrosion protection [13]. Many of these applications involve electrochemical switching processes (to be discussed in more detail). In the quest to improve electrochemical switching speeds of ICPs, researchers have recently turned attention to control of the structure at the nanodomain.

It is also interesting to note that ICP macrostructures are actually composed of nanodomains of much higher conductivity than the bulk material [14–17] suggesting that nano-dimensional control will also improve the bulk conductivity of ICPs.

### 1.1. What Are ICPs?

The synthesis and electrochemical switching properties of ICPs such as polypyrroles (PPy), polythiophenes (PTh), and polyanilines (PAn) have been reviewed in recent monographs [18, 19].

The polymerization can be initiated chemically or electrochemically and involves formation of lower molecular weight oligomers via oxidation. These are then further oxidized

(at lower potentials than the initial monomer) to form a polymer that eventually precipitates or deposits onto the anode in an electrochemical cell as a critical molecular weight is exceeded:

A counterion ( $\text{A}^-$ ) is incorporated during synthesis to balance the charge on the polymer backbone. The anion of the chemical oxidants used provides the dopant  $\text{A}^-$ . Electrochemical oxidation provides greater flexibility in terms of the anion that can be incorporated from the electrolyte used as the polymerization medium. Polypyrroles can be formed from neutral aqueous solutions while acidic conditions are required for aniline solubilization and polymerization. Thiophene polymerization is commonly undertaken in organic solvents due to poor monomer solubility in aqueous solutions.

#### 1.1.1. Polypyrroles

The mild oxidation potentials needed to initiate formation of polypyrrole in aqueous solution have enabled the formation of a wide range of polypyrrole structures by simply varying the dopant.

Simple metal recognition capabilities are introduced by incorporation of metal complexing groups as dopants [20, 21], or electrocatalytic effects are induced by use of appropriate dopants [22], covalently attached redox sites [23, 24], and/or inclusion of micron-sized metallic particles [25, 26]. Conducting polymers are also known to promote electron transfer into/out of biological entities [27]. Biomolecular/recognition can be introduced by incorporation of antibodies or enzymes or even nerve growth factors into the polymer at the time of synthesis, as reviewed recently [28].

The incorporation of complex biomolecules as dopants can be accomplished while retaining the unique electronic properties of the polymer backbone. For example, the

**Scheme 1.** For polypyrroles and polythiophenes,  $n$  is usually ca. 3–4. For optimal conductivity, there is a positive charge on every third or fourth pyrrole or thiophene unit along the polymer chain. For the conducting emeraldine salt form of polyaniline (III) a radical cation resides at alternate N sites.

ultraviolet-visible (UV-vis) spectrum for PPy containing DNA as dopant is shown in Figure 1. This UV-vis spectrum shows the typical polaron/bipolaron 475 nm bands of doped polypyrrole at ca. 500 nm and 900 nm. The exact location of these bands is dependent on the dopant used. As illustrated in Figure 2, when 8-hydroxyquinoline-5-sulfonic acid (HQS) is used as dopant, the lower wavelength peak is even further blueshifted. The dopant also influences the degree of absorption in the near infrared beyond 900 nm and this is attributed to changes in polymer conformation (tight coil versus expanded coil). The polymer conformation has been found to be substrate dependent, with polypyrroles deposited on hydrophilic glass displaying an absorption band at 1180 nm, which is replaced by a free carrier tail extending to 2600 nm for polymers deposited on hydrophobic surfaces [29].

As well as varying the functional properties of ICPs, the dopant plays a key role in determining the electronic (conductivity) and mechanical properties (e.g., tensile strength) of the resultant material. For example, even slight changes in the molecular structure [30] of a range of sulfonated aromatic dopants influence these properties (Table 1). The incorporation of surfactant-like dopants such as dodecylbenzene sulfonate has also proved useful in sol-

**Figure 2.** UV-visible spectrum of a PPy HQS film grown galvanostatically onto ITO glass from a solution containing 0.2 M pyrrole and 0.1 M HQS. Reprinted with permission from [188], V. Misoska, Ph.D. Thesis, University of Wollongong, 2002.

ubilizing polypyrrole in organic solvents [31, 32]. The presence of alkyl and alkoxy substituents on the backbone of polypyrrole also increases their solubility in organic solvents. In contrast, polymerization of pyrrole monomers bearing sulfonated substituents has provided water soluble polypyrroles [33]. A very useful recent advance has been the development of a facile route for the modification of pre-formed polypyrroles containing good leaving group such as *N*-hydroxysuccinamide [34].

An important feature of these ICP structures is that they are amenable to facile oxidation/reduction processes that can be initiated at moderate potentials. For polypyrrole the oxidation state can be reversibly switched, as shown in Eq. (2). The doped oxidized forms exhibit good electrical conductivity ( $\sigma = 1\text{--}100 \text{ S cm}^{-1}$ ), while the reduced forms have very low conductivity ( $\sigma \sim 10^{-8} \text{ S cm}^{-1}$ ). The dynamic character of these polymer systems, with chemical, physical, and mechanical properties being a function of applied potential, is intriguing and is the basis of their proposed use in intelligent material systems [19].

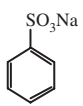

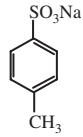

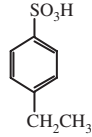

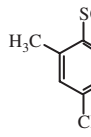

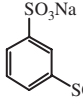

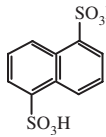

If the dopant anion ( $\text{A}^-$ ) is small and mobile (e.g.,  $\text{Cl}^-$ ), then upon reduction the anion will be efficiently ejected from the polymer [Eq. (2)]. However, extensive studies with polypyrroles have shown that if the dopant is large and immobile (e.g., if  $\text{A}^-$  is a polyelectrolyte such as polystyrene sulfonate), an electrically induced cation exchange process occurs, according to

where the cation ( $\text{X}^+$ ) is incorporated from the supporting electrolyte solution. The effect of the original dopant incorporated as well as the other ions in the electrolyte on the electrochemical switching characteristics of polypyrroles has been clearly demonstrated [30].

**Table 1.** Effect of the counterion on the tensile strength and conductivity of polypyrrole membranes [30].

Membrane	PPy/BSA	PPy/PTS	PPy/EBS	PPy/MS	PPy/BS	PPy/NPS
Counterions						
Tensile strength (MPa)	17–23	70–80	60–70	36–47	40–55	40–50
Conductivity (S/cm)	19–20	90–110	90–110	50–70	47–70	50–70

The redox processes described have a dramatic effect on the physical and chemical properties of the polymer. Conductivity will decrease, anion exchange capacity will diminish [Eq. (2)], cation exchange capacity may increase [(Eq. 3)] and hydrophobicity will be altered in a manner determined by which ion exchange process predominates. The mechanical properties are also influenced by the oxidation state with a greater elongation-to-break usually observed in the reduced materials [35]. The polymer also undergoes dramatic color changes upon redox switching (see Section 1.1.2) which is the basis of electrochromic devices based on ICPs [5].

### 1.1.2. Polythiophenes

The direct polymerization of thiophene is more complicated in that the monomer oxidation occurs at potentials more positive than required to overoxidize the polymer. Hence monomers with alkyl groups attached to the 3-position [36], bithiophene [37, 38], or terthiophenes [39] are often used as starting materials since they have lower oxidation potentials.

To avoid use of organic solvents for polythiophene synthesis, monomers can be dissolved in aqueous solution using surfactants [40] or molecular inclusion compounds such as cyclodextrins [41]. While the inclusion of the extensive range of dopants available with polypyrrole is not available with polythiophenes, some functional dopants have been incorporated [42]. Specific dopants such as the polyether [43] shown in Scheme 2 induce exceptional mechanical properties into polythiophenes, with tensile strengths of the order of 120 MPa readily obtained.

The UV-visible absorption spectra obtained (Fig. 3) after polymerization of bithiophene clearly show polaron/ bipolaron absorption bands that are eliminated once the polymer is electrochemically reduced.

Given the simple synthetic chemistries available to covalently attach functional groups to thiophene substrates prior to polymerization, this has been the preferred approach to introduce functionality into polythiophenes [44]. In conjunction with our collaborators at Massey University,

**Scheme 2.** Structure of the S-PHE used in this work. TBA = tetrabutylammonium.

New Zealand, we have produced a range of substituted terthiophene precursors (Fig. 4), from which functional polymers have been produced [45].

As discussed for polypyrroles, the polythiophenes undergo reversible oxidation/reduction processes (Fig. 5). Oxidation/reduction usually occurs at more positive potentials than for the polypyrroles and is not readily achieved in aqueous solutions [45], presumably due to the hydrophobic nature of the thiophene based polymer. Some workers have attached ether groups to the polymer backbone, increasing hydrophilicity and the rate of switching in aqueous media [46].

Another interesting feature of polythiophenes is that the *n*-doped state is more readily accessible than with either polypyrroles or polyanilines. This enables the polymer to be rendered conductive at more negative potentials. A number of authors [47, 48] have highlighted the importance of substituents on the polythiophene backbone in determining the accessibility (potential required for reduction) and stability of the *n*-doped state.

### 1.1.3. Polyanilines

Like polypyrrole, conducting polyaniline (PAn) and its ring-substituted analogs are generally prepared via either chemical or electrochemical oxidation/polymerization of the appropriate aniline monomer in aqueous solution. However, acidic conditions (pH generally 0–1) are required both

**Figure 3.** UV-vis spectra of PBT/S-PHE composite galvanostatically deposited ( $1 \text{ mA cm}^{-2}$  for 50 s) onto ITO coated glass from a solution containing 0.2 M 2,2' bithiophene and 2% S-PHE. Figure 4. Styryl terthiophene monomers synthesized.

to solubilize the aniline monomer and to ensure that the conducting emeraldine salt  $\text{PAn} \cdot \text{HA}$  form of the polymer is produced [see structure (III)]. The most common chemical oxidants are ammonium persulfate or ferric chloride, in which cases  $\text{HSO}_4^-/\text{SO}_4^{2-}$  or  $\text{Cl}^-$  anions are incorporated as the dopant anions  $\text{A}^-$  at the radical cation nitrogen sites along the PAn chains.

Using electrochemical polymerization, a much wider range of dopant anions may be incorporated along the polyaniline chains, depending on the electrolyte employed. After deposition on the working electrode, films of the  $\text{PAn} \cdot \text{HA}$  may often be removed as mechanically robust, stand-alone membranes. On the other hand, chemical polymerization has the advantage of being a simple process capable of producing bulk quantities of  $\text{PAn} \cdot \text{HA}$  powders on a batch basis.

In both chemical and electrochemical polymerization the initial and rate-determining step is believed [49–51] to

be oxidation of the aniline monomer to give the radical cation of aniline. This is followed by coupling of the radicals, predominantly *N* and *para* forms, and subsequent re-aromatization to give a dimer. This undergoes more facile oxidation than the aniline monomer, leading to chain propagation and eventual deposition of the emeraldine salt from solution.

The nature of the dopant anion incorporated along the growing polymer chain during polymerization has a profound effect upon the morphology [52], conductivity [53], switching characteristics, and solubility of the resulting polyaniline salts. Incorporation of polyelectrolyte dopant anions during either chemical or electrochemical oxidation of aniline has been an area of intense recent interest. These large anions can often be preferentially incorporated even when an acid such as  $\text{HClO}_4$  is present in large excess [54]. As will be discussed further in Section 3, this can induce water “solubility” onto the resultant emeraldine salt when the anion is a polyelectrolyte such as poly(styrenesulfonate) or polyacrylate [55–57]. This approach has helped in overcoming one of the problems previously associated with polyanilines, namely their insolubility in most common solvents. It has also provided a convenient route to aqueous nanosized dispersions of conducting emeraldine salts (see Section 4). Biological polyelectrolytes such as DNA have also been incorporated into emeraldine salts using this approach [58, 59].

On the other hand, organic solvent solubility has been induced in polyanilines via the incorporation of surfactant-type dopant anions such as dodecylbenzenesulfonate, racemic 10-camphorsulfonate ( $\text{CSA}^-$ ) [60], and dinonylnaphthalene sulfonate [61]. Another significant development has been the facile generation of optically active emeraldine salts such as  $\text{PAn} \cdot (+)\text{-HCSA}$  or  $\text{PAn} \cdot (-)\text{-HCSA}$  by the simple expedience of employing chiral acids such as (+)- or (-)-HCSA as the electrolyte during electrochemical polymerization [62, 63]. These chiral conducting polyanilines are believed to preferentially adopt single-handed helical structures for their polymer chains depending on which hand of the dopant HCSA acid is employed.

A large range of substituted anilines are available. Polymerization of these has given emeraldine salts whose properties differ significantly from those of the parent unsubstituted  $\text{PAn} \cdot \text{HA}$  salts. For example, the presence of alkyl or alkoxy substituents [64] on the aniline rings imparts enhanced solubility in organic solvents on the resultant polymers. On the other hand, sulfonate groups lead to water solubility, as in poly(2-methoxyaniline-5-sulfonic acid) [65].

Postpolymerization modification of polyanilines has also been pursued to introduce added functionality into the polymer for a variety of applications. For example, treatment of the emeraldine base (EB) or leucoemeraldine base (LB) forms of polyaniline with fuming sulfuric acid has led to water-soluble, sulfonated polyanilines (SPANs) in which 50–75% of the aniline rings bear sulfonate groups [66]. These latter emeraldine salts are self-doped (i.e., ring-bound sulfonate groups provide the dopant anion for the radical cation nitrogen sites along the chain). An exciting recent development has been the synthesis of poly(aniline boronic acid) [67]. This promises to be a convenient precursor for

Figure 5. Cyclic voltammogram of a PBT/S-PHE coated platinum electrode obtained after immersion in a propylene carbonate solution containing 0.5 M  $\text{LiClO}_4$ , scan rate =  $100 \text{ mV s}^{-1}$ . PBT/S-PHE was prepared galvanostatically ( $1 \text{ mA cm}^{-2}$  for 3 min) using a solution containing 0.2 M 2,2'-bithiophene and 2% S-PHE.

the facile synthesis of a wide range of substituted polyanilines that are difficult to synthesize directly from their respective monomers.

Doped PAN · HA emeraldine salts are good electrical conductors, with conductivities typically in the range 1–10 S cm<sup>-1</sup>. It is generally agreed that polarons are the charge carriers responsible for this high conductivity. Evidence includes the observation of a strong electron spin resonance signal associated with the radical cation sites in structure (III) [68]. It has also been shown that bipolaron states exist in polyaniline, but these are few in number and are not associated with the conducting regions of the polymer [69].

The attachment of functional groups to the aniline rings generally decreases the conductivity of polyaniline emeraldine salts. This is attributed to steric crowding causing a marked twisting of the polymer backbone from planarity, leading to decreased conjugation along the chains. Structural defects such as those arising from undesirable *ortho*-coupling of aniline radical cations during the polymerization also lead to impaired electrical conductivity. There has been considerable recent interest in enhancing the conductivity of emeraldine salts via their exposure to “secondary dopants” such as *m*-cresol. This can cause an increase in conductivity of several orders of magnitude. The enhanced conductivity has been attributed to the adoption of an “extended coil” conformation by the polyaniline backbone, with the polarons delocalized along the chains [70].

The UV-visible near-infrared spectra of polyanilines are very sensitive to the polymer chain conformation. For example, when PAN · HCSA emeraldine salts are generated by acid doping the EB form with camphorsulfonic acid in organic solvents such as chloroform, DMSO, or NMP [Eq. (4); See Fig. 8], they typically exhibit three absorption bands in the visible region, as shown in Figure 6. The strong band observed in these cases at 750–850 nm has been assigned as a localized polaron band, while the two bands at ca. 430 and 340 nm are attributed to a second polaron band and a  $\pi$ - $\pi^*$  (bandgap) band, respectively [71]. These spectral features and the moderate electrical conductivity of such salts (ca. 1 S cm<sup>-1</sup>) are considered diagnostic of a “compact coil” conformation for the polyaniline chains. In contrast, no long wavelength localized polaron band is observed in the visible region for PAN · HCSA salts generated by analogous

**Figure 6.** UV spectra showing EB–ES. Reprinted with permission from [189], C. Boonchu, Ph.D. Thesis, University of Wollongong, 2002.

acid doping in “secondary dopant” solvents such as *m*-cresol. These much more conducting salts ( $\delta > 100$  S cm<sup>-1</sup>) instead exhibit an intense free carrier tail in the near infrared region with an absorption maximum at ca. 2500 nm. These latter features are considered diagnostic of an “extended coil” conformation for the polyaniline backbone:

Circular dichroism (CD) spectroscopy provides a particularly powerful tool for probing the polymer chain conformation in related optically active emeraldine salts. For example, the “compact coil” form of PAN-(+)-HCSA in NMP solvent shows the characteristic bands seen in Figure 7. The strong bisignate CD bands at ca. 795 and 720 nm are associated with the localized polaron absorption at ca. 775 nm for this polymer in NMP (see Fig. 6) [72, 73]. Overlapping bisignate CD bands are also observed at lower wavelengths associated with the other two lower absorption bands seen for PAN-(+)-HCSA in Figure 6. The CD spectrum of “extended coil” PAN-(+)-HCSA (not shown) bears no similarity whatsoever to that seen in Figure 7 for the “compact coil” form [74].

Polyaniline contrasts with other ICPs in that it has three readily accessible oxidation states (fully reduced leucoemeraldine, partly oxidized emeraldine, and fully oxidized pernigraniline), as shown in Figure 8 [75]. In addition, reversible protonation/deprotonation equilibria occur for two of these oxidation states. Thus, the emeraldine salt form (ES), which is the only electrically conducting form of polyaniline, is typically dedoped at pH > 4 to give nonconducting EB. Conversely, the reverse acid doping of EB with HA acids [Eq. (4)] provides a convenient route to conducting PAN · HA emeraldine salts with a wide range of acids. The pernigraniline oxidation state of PAN can similarly exist as both a protonated pernigraniline salt or as a neutral pernigraniline base (Fig. 8). On the other hand, the fully reduced leucoemeraldine oxidation state appears to exist only in the neutral base form.

Polyaniline can be rapidly and reversibly switched between the various forms shown in Figure 8. The pH and redox switching is accompanied by marked changes in colour. For example, alkaline treatment of green PAN · HA emeraldine salts rapidly generates the blue color of EB. The associated UV-visible spectral changes caused by such alkaline dedoping are shown in Figure 8. Emeraldine base exhibits a characteristic exciton band at ca. 600 nm as well

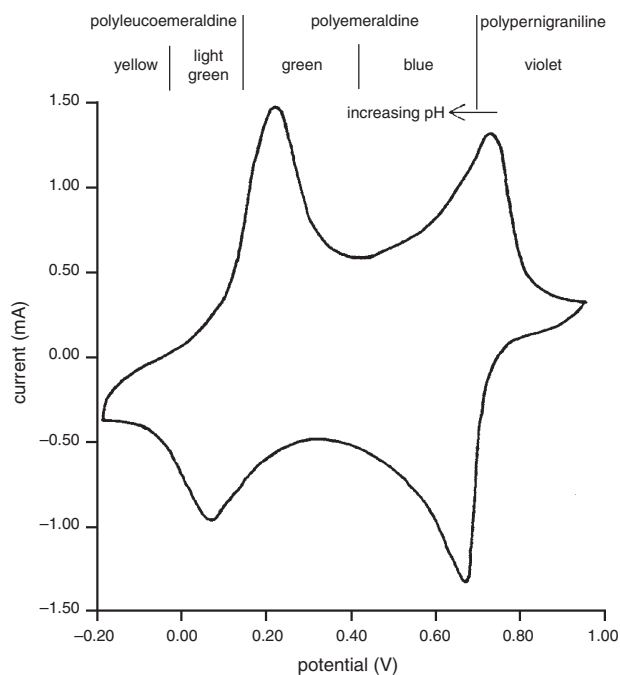

**Figure 7.** CD spectrum of PAN-(+)-HCSA.

**Figure 8.** Chemical transitions observed in the oxidation/reduction of polyaniline.

as a  $\pi-\pi^*$  band at ca. 330 nm [76]. Such alkaline dedoping when performed on PAN · HA films also leads to a dramatic reduction in electrical conductivity, the EB form being an insulator.

The reversible redox switching of polyaniline films can also be readily monitored by cyclic voltammetry. For example, the cyclic voltammogram of PAN · HCl in 1 M HCl is shown in Figure 9. In the cathodic sweep, oxidation peaks are observed at ca. 0.2 and 0.7 V (vs Ag/AgCl) that may be attributed to the successive oxidations of leucoemeraldine to emeraldine to pernigraniline.

**Figure 9.** Cyclic voltammogram of polyaniline (HCl) on a glassy carbon electrode; 1 M HCl(aq); 50 mV/s. The potentials at which structure and color changes occur and the change in the potential of the second redox reaction with pH are shown as well. The second oxidation peak moves to a less positive potential with increasing pH.

## 2. SYNTHESIS OF INHERENTLY CONDUCTING POLYMERS NANOSTRUCTURES

A number of approaches have been used to produce inherently conducting polymer nanocomponents.

### 2.1. Use of Steric Stabilizers

With a view to improving the processability of inherently conducting polymers, a range of colloidal materials have been produced over the past 10 years. The conventional approach involves chemical oxidation of the monomer in the presence of a steric stabilizer such as PVA to produce stable colloidal dispersions [77–79] with particle sizes typically 10–200  $\mu\text{m}$ .

Recently this approach has been refined and oxidation of aniline in DMSO in the presence of PVA has been used to produce dispersions containing particles as small as 5 nm [80].

In our laboratory we have developed an electrohydrodynamic approach for the synthesis of inherently conducting polymer colloids [81]. This involves the use of a flow-through electrochemical reactor using a high surface area vitreous carbon electrode. Using appropriate flow-through conditions, stable colloidal dispersions containing 100–200 nm spherical particles are readily produced (Fig. 10). This electrochemical approach allows facile incorporation of a wide range of dopants during colloid formation. For example, protein-containing colloids [82], colloids containing corrosion inhibitors [83], and, more recently, optically active colloids [84] have been produced.

**Figure 10.** Transmission electron micrograph of colloidal polypyrrole nitrate. Reprinted with permission from [4], G. G. Wallace and P. C. Innis, *J. Nanosci. Nanotech.* 2, 441 (2002). © 2002, American Scientific Publishers.

More recent work [85] has shown that the use of Tiron (Scheme 3) as dopant enables production of monodispersed polypyrrole particles of 50 nm (Fig. 11). Tiron has previously been shown to act as an electrocatalyst in the formation of polypyrrole [86].

## 2.2. Micellar Polymerization and Microemulsion Routes

A novel approach to the formation of ICP nanoparticles has been developed through the use of micellar polymerization and microemulsion techniques. The advantage of such an approach is that the particle size can be predefined by establishing the appropriate size and geometry of the templating micelle (Fig. 12). For example, formation of polyaniline nanoparticles has been achieved via polymerization in a micelle approach using either sodium dodecyl sulfate (SDS) [87] or dodecylbenzenesulfonic acid [88–90] as the surfactant stabilizer. Particle sizes in the range of 10–30 nm with conductivities as high as  $24 \text{ S cm}^{-1}$  have been reported.

Poly(3,4-ethylenedioxythiophene) (PEDOT) and polyaniline nanoparticles have also been synthesised via the micellar route with sodium dodecyl sulfate and dodecylbenzenesulfonic acid [91]. Polyaniline nanoparticles were spherical and 20 to 60 nm in diameter and PEDOT was from 35 to 100 nm. The observed conductivities of 20 to  $50 \text{ S cm}^{-1}$  (by pellet) were higher than those observed for larger micrometer sized particles prepared in bulk solutions.

Control of the micelle size utilized in the formation of polyaniline nanoparticles has been achieved by tailoring the stabilizer to modify the resulting micelle dimensions. Kim et al. [92, 93] have used amphiphilic polymer molecules, hydrophobically end-capped poly(ethylene oxide), and varied the hydrophilic PEO midsection length to control the final micelle size. The micelle structures formed were referred to as flower type, with the aniline monomer and hexane cosolvent interacting with the hydrophobic end groups. The resultant nanostructures ranged from 20 to approximately 300 nm in size depending on the molecular weight of the hydrophilic PEO midsection.

Metallic and semiconducting nanoparticles have been routinely produced at the sub-5 nm scale for some time but it has been a challenge to produce polymer nanoparticles smaller than this. Jang et al. [94] have reported the synthesis of polypyrrole nanoparticles at the 2 nm scale via a microemulsion route carried out at  $3 \text{ }^\circ\text{C}$ . Pyrrole monomer was initially formed into micelles and then oxidized by ferric chloride. Typical surfactants used in

Scheme 3. Tiron.

Figure 11. Transmission electron micrograph of aggregated polypyrrole tiron colloid particles ( $\times 150 \text{ K}$ ). Reprinted with permission from [4], G. G. Wallace and P. C. Innis, *J. Nanosci. Nanotech.* 2, 441 (2002). © 2002, American Scientific Publishers.

the preparation of these sub-5 nm particles were quaternary ammonium based cations such as octyltrimethylammonium bromide, decyltrimethylammonium bromide, and dodecyltrimethylammonium bromide. At room temperature these surfactants produced nanoparticles larger than 10 nm while at  $70 \text{ }^\circ\text{C}$  ca. 50 nm particles were observed.

Nanoscale patterning of polypyrrole dot structures of 80 to 180 nm diameter in self-organized arrays has also been achieved via a block copolymer surface-micelle templated approach [95]. Using this approach, micelle templates were prepared using the Langmuir–Blodgett (LB) technique to deposit an AB diblock copolymer onto a mica substrate followed by the selective chemical deposition of polypyrrole onto these templating structures. Selective deposition is achieved by exploiting the preference of polypyrrole to deposit onto hydrophobic surfaces rather than hydrophilic substrates. An advantage of this approach is that lithographic patterning techniques can be avoided due to the self-assembly of the micelle via the LB technique. Inverse structures of these PPy dots have also been prepared

Figure 12. Schematic illustrating micellar/microemulsion nanoparticle synthesis. Reprinted with permission from [4], G. G. Wallace and P. C. Innis, *J. Nanosci. Nanotech.* 2, 441 (2002). © 2002, American Scientific Publishers.

by extended polymer synthesis in the presence of self-assembled polystyrene cores that are selectively removed by toluene.

Selvan et al. [96, 97] utilized a block copolymer micelle of polystyrene-block-poly(2-vinylpyridine) in toluene exposed to tetrachloroauric acid which was selectively adsorbed by the micelle structure. On exposure of this solution to pyrrole monomer, doped polypyrrole was observed to be synthesized concurrently with the formation of gold nanoparticles as a result of the reduction of the bound  $\text{AuCl}_4^-$ . The nanoparticles formed had a monodispersed (7–9 nm) gold core surrounded by a PPy shell after annealing at 130 °C for 1 hour. Depending on the postsynthesis treatment, different shaped nanoparticles such as spherical, cubic, tetrahedral, and octahedral shapes were formed due to micelle coagulation. Dendritic nanoaggregate structures were also reported to form via a vapor phase polymerisation of the pyrrole monomer onto cast films of the block copolymer. In related work by Zhou et al. [98, 99] metal ion reduction of Au, Pd, and Pt salts with a  $\pi$ -conjugated polymer, poly(dithiafulvene) (PDF), capable of electron donating to the metal salts thereby reducing them and itself being oxidized to provide steric and electrosteric stabilization of the nanoparticle. The resultant metal cores of the composite nanoparticles were 5–6 nm in size. Interestingly, the surface plasmon absorption band in the UV-vis spectrum for a metal nanoparticle (Pd, Pt) was significantly redshifted to 550 nm from an anticipated 510–525 nm. This shift was attributed to the electronic interaction of the oxidized PDF with the metallized cores.

Using a chemical approach involving inverse microemulsions, it has been shown that small monodisperse polyaniline particles can be produced [100–102]. Inverse microemulsion polymerization of polyaniline by Chan et al. [101] was reported to give particles of 10–35 nm diameter that were spherical and could be synthesized using either the chemical or electrochemical route. The presence of stabilizing surfactant was found to be detrimental to the electrical conductivity of these particles when dried, due to formation of an insulating barrier around the nanoparticles in the bulk. After washing to remove the surfactant, chemically prepared materials exhibited conductivities of up to 10  $\text{S cm}^{-1}$  while for electrochemically prepared materials conductivities as high as 200  $\text{S cm}^{-1}$  were reported. Gan and co-workers have used [102] an inverse microemulsion approach that involves formation of barium sulfate nanoparticles, which are then coated by polyaniline. These composite nanoparticles had a reported conductivity from 0.017 to 5  $\text{S cm}^{-1}$ , with particles ranging in size from 10 to 20 nm. Xia and Wang [103] have used ultrasonication during inverse microemulsion polymerization of polyaniline to produce spherical nanoparticles with diameters of 10–50 nm and conductivities in the order of 10  $\text{S cm}^{-1}$ . The ultrasonication was found to increase the rate of polymerization of aniline which is typically slow when the microemulsion route is used. Rate increases are obtained by acceleration of the heterogeneous liquid–liquid chemical reactions in solution. A secondary advantage is the prevention of aggregation due to particle agitation induced by ultrasonication.

Polypyrrole nanotubes have also been synthesised via an inverse microemulsion self-assembly route by Jang and

Yoon [104]. Nanotubes were synthesised by using bis(2-ethylhexyl)sulfosuccinate (20.3 mmol) in hexane (40 mL) which form tube- or rodlike micelles, due to the presence of a double tail on a small hydrophilic head group, when aqueous  $\text{FeCl}_3$  (1 mL, 9.0 M) was added. The  $\text{Fe}^{3+}$  cations are effectively trapped in the center core of the micelle. Addition of pyrrole (7.5 mmol) to this solution then results in interfacial polymerization at the micelle surface, resulting in hollow nanotubes 95 nm in diameter and up to 5  $\mu\text{m}$  in length. The electrical conductivity of these nanotubes was up to 30  $\text{S cm}^{-1}$  and was observed to be a function of the  $\text{FeCl}_3$  oxidant concentration. More interestingly, the conductivity of these materials did not appear to be limited by the presence of the surfactant molecule, which in other emulsion polymerization routes tends to lead to a thick insulating coating that limits the observable conductivity.

### 2.3. Physical Templates

Conducting polymers have been grown within zeolites [105, 106]. With channels as small as 0.3 nm this allows assembly of single molecular wires. Conductivities of  $10^{-9}$   $\text{S cm}^{-1}$  for such wires contained within zeolites have been reported and this increases to  $10^{-2}$   $\text{S cm}^{-1}$  when the polymer is extracted from the host structure.

Martin and co-workers [107–109] have used controlled pore size membranes as templates to electrochemically grow fibrillar mats of ICPs. Similar structures have also been produced using nanoporous particle track-etched polycarbonate membranes with both polypyrrole [110–113] and polyaniline [114] via chemical and electrochemical techniques. The approach involves oxidation of the monomer within the pores of a template. This is achieved electrochemically as illustrated in Figure 13. The electrode substrate used can be either a conventional flat surface system such as solid gold, platinum, or glassy carbon, resulting in structures such as shown in Figure 14a. Alternatively, more novel electrode substrates such as platinized PVDF membranes with nominal pore size of 0.45  $\mu\text{m}$  can be used (Fig. 14b).

Carbon nanotubes (CNTs) have been directly synthesized via a template carbonization of polypyrrole on an alumina template membrane (Whatman Anopore) with 0.2  $\mu\text{m}$  diameter pores and 60  $\mu\text{m}$  in total thickness [115]. Polypyrrole was chemically deposited on and through the membrane

**Figure 13.** Assembly of fibrillar ICPs using controlled pore size templates. Reprinted with permission from [4], G. G. Wallace and P. C. Innis, *J. Nanosci. Nanotech.* 2, 441 (2002). © 2002, American Scientific Publishers.

**Figure 14.** Scanning electron micrographs of fibrillar structure of PPy/pTS on (a) a flat electrode surface and (b) a PVDF membrane. Reprinted with permission from [188], V. Misoska, Ph.D. Thesis, University of Wollongong, 2002.

via a chemical oxidative process. Surface deposited polymer was removed by polishing with alumina powder and ultrasonication. This membrane was then carbonized in an Ar atmosphere and then etched in 48% HF to remove the alumina template. Metal CNTs impregnated with Pt, Pt–Ru, and Pt–WO<sub>3</sub> were prepared by treatment with the appropriate metal salt solutions prior to etching. The resulting CNTs were single wall type with diameters ranging from 1 to 5 nm. The application of these nanostructures as electrode substrates for methanol fuel cell was explored, utilizing the presence of dispersed metals such as Pt<sup>0</sup> and Ru<sup>0</sup> metal and W<sup>6+</sup> in the CNT, providing catalytic regions for methanol oxidation.

Freestanding nanotubes are formed by the selective dissolution of the templating membrane. Hollow tubes of polypyrrole are initially formed in the templating structure followed by the in-filling of these tubes at longer synthesis times. Electrical conductivities of these structures

(e.g., 375 S cm<sup>-1</sup> at 20 nm) show an enhancement over that of the bulk material (1.5 S cm<sup>-1</sup>) grown under similar conditions [110]. A similar conductivity enhancement effect based on tube diameter has also been reported by Cai et al. with conductivities up to 10<sup>3</sup> S cm<sup>-1</sup> [116, 117].

Applications of template-assisted growth of aligned polyaniline nanofibril arrays in the area of field emission have been explored by Wang et al. [118]. Nanofibril arrays were prepared by chemically depositing polyaniline into 20–200 nm pores in anodic aluminum oxide film 30 to 60 μm thick that was subsequently etched away with 0.3 M H<sub>3</sub>PO<sub>4</sub> or by ultrasonication [119]. Field emission studies revealed a low electric field threshold of 5–6 V/μm, with a minimum emission current density of ca. 0.01 mA/cm<sup>2</sup> and a maximum emission current density of 5 mA/cm<sup>2</sup>. Comparisons to other materials with lower emission current densities, such as diamond and CNTs, were made and the authors noted that aligned nanofibril arrays were attractive due to their high surface area, lower manufacturing cost, and robust mechanical properties.

Hollow ICP cigar-shaped nanotubes with sealed ends, synthesized via the track-etched polycarbonate template route, have also been reported by Mativetsky and Datars [113]. These materials exhibited a small drop in conductivity as the diameter decreased from 400 to 50 nm, contrary to the previous reports [110–112]. The small decrease in conductivity of the order of 50 mS cm<sup>-1</sup> is believed to result from an increase in the electron scattering within the nanocylinder walls or from the presence of large impedances in the nanostructure. The authors attributed this different dependence on tube diameter by treating the tube as a solid cylinder, resulting in conductivity trends observed by others, or as reported in this instance as a hollow nanostructure which gave these results.

Others have shown that the electrochemical properties of polyanilines grown in a template such as sol–gel silica or PVDF are greatly improved [120]. This is attributed to improved order at the molecular level.

Other templates used to assist assembly of nanostructured conducting polymers are synthetic opals [121–126] based on polystyrene or silica spheres. The area of synthetic opals is of interest for use as photonic bandgap crystals: materials in which photons of a given energy cannot travel through or propagate in a crystal but rather are reflected by the lattice structure [125]. Of further interest is that opal templates provide a route to establishing high range order in the nanodomain, resulting in high surface-to-volume ratios. Template opal structures (Fig. 15) are preformed from monodisperse spherical colloidal particles that are permitted to self-assemble into close packed arrays via a sedimentation process assisted by either gravity or pressure/microfiltration. After template formation, conducting polymer is formed by infiltration of monomer into the void spaces within the crystal structure, followed by subsequent oxidative polymerization. The final stage is the removal of the templating core to leave an inverse structure from the templating material with essentially the same optical properties as the original host [123] (Fig. 16). Others [121, 122] used a similar templating approach, but prepared self-assembled polystyrene (PS) latex opals onto gold substrates followed by the direct electropolymerization of PPy, PAN, and polybithiophene (PBT)

**Figure 15.** Self-assembly of opal structures onto electrode substrates via monodisperse colloidal dispersions. Reprinted with permission from [188], V. Misoska, Ph.D. Thesis, University of Wollongong, 2002.

into the interstitial void spaces of the host matrix. Upon removal of the PS, structural shrinkage was observed for PPy and PAN but PBT exhibited no such effect. Using this approach, interchanneling between adjacent template layers was evident, giving evidence for the formation of a three-dimensional (3D) macroporous nanostructure. Yoshino et al. [124] utilized  $\text{SiO}_2$  opal templates followed by the infiltration of soluble preformed poly(3-alkylthiophene) and poly(2,5-dialkoxy-*p*-phenylene vinylene) and finally removal of the  $\text{SiO}_2$  spheres by HF etching. These nanostructured materials were then investigated for photoluminescence (PL) and electroluminescence properties. A spectral narrowing of the PL and an increase in excitation intensity was observed with respect to the solution form of these polymers.

## 2.4. Molecular Templates

Distinctly different from the templating techniques described previously, this approach relies on the interaction at the molecular scale of the conducting polymer and a templating dopant or surfactant/polyelectrolyte to form a nanoparticle. The molecular template not only functions to direct morphology but it can also impart other properties to the ICP nanoparticle, as will be discussed.

Others have shown that molecular templates, such as a polyacrylate film predeposited on a carbon electrode, can be used effectively to create polypyrrole nanowires via electrochemical oxidation of pyrrole [127, 128].

Choi and Park [129] have modified surfaces with cyclodextrins to assist in the electroformation of polyaniline nanowires. Others have utilized the concept of molecular templates to form polyaniline supramolecular rods with electrical conductivity improved by 2 orders of magnitude [130].

**Figure 16.** Schematic illustrating preparation of an inverse ICP opal using a synthetic opal template. Reprinted with permission from [4], G. G. Wallace and P. C. Innis, *J. Nanosci. Nanotech.* 2, 441 (2002). © 2002, American Scientific Publishers.

A template guided synthesis of water-soluble chiral conducting polyaniline in the presence of (S)-(-)- and (R)-(+)-2-pyrrolidone-5-carboxylic acid [(S)-PCA and (R)-PCA] has been reported to produce nanotubes [131]. The structures prepared have outer diameters of 80–220 nm with an inner tube diameter of 50–130 nm. It was proposed that the tubular structures form as a result of the interaction of the hydrophobic aniline being templated by the hydrophilic carboxylic acid groups of the PCA in aqueous media during chiral tube formation. The resultant tubes were shown to be optically active, suggesting that the polyaniline chains possess a preferred helical screw.

McCarthy et al. [132, 133] reported a template-guided synthesis of water-soluble chiral polyaniline nanocomposites. The nanoparticles were prepared by the physical adsorption of aniline monomer onto a templating poly(acrylic acid) in the presence of (+)- or (-)-CSA, followed by chemical oxidation. Using this approach, optically active nanocomposites of approximately 100 nm diameter were formed. Earlier work by Sun and Yang [134] using polyelectrolytes produced similar nonchiral dispersions in which the polyaniline chain is interwound with a water-soluble polymer by electrostatic forces [135]. Similar work by Samuelson et al. utilized DNA as a chiral template for polyaniline [89].

Shen and Wan [136] have shown that chemical oxidation of pyrrole (by APS) in the presence of  $\beta$ -naphthalene sulfonic acid ( $\beta$ -NSA) results in the formation of tubules down to ca. 200 nm in diameter. The tubular structures had reasonable conductivity ( $10 \text{ S cm}^{-1}$ ) and were soluble in *m*-cresol. In later work [137] it was reported that the morphology was significantly influenced by the concentration of the  $\beta$ -NSA. Granular morphologies were present when  $[\beta\text{-NSA}]$  was less than 0.2 M, while on increasing the  $\beta$ -NSA concentration fiber formation becomes the dominant morphology. At  $\beta$ -NSA concentrations above 2.9 M, a block-type morphology predominated with an associated drop in conductivity to  $2 \text{ mS cm}^{-1}$ . Monomer concentration was shown to have little effect on the resultant morphology and electrical conductivity. The morphological steps in tube formation were described as grain to short tube to long tube. Other morphology types have also been noted using the  $\beta$ -NSA anion, namely hollow microspheres ranging from 450 to 1370 nm (with inner wall thicknesses of 20 to 250 nm, respectively) and conductivities of up to  $190 \text{ mS cm}^{-1}$  [138]. A similar approach has been extended to polyaniline [139]. The influence of a secondary inorganic acid codopant has also been demonstrated, with conductivities from  $10^{-1}$  to  $10^0 \text{ S/cm}$  [140]. Others [141] have used lipid tubules as templates during chemical oxidation of pyrrole to form nanofibers with diameters between 10 and 50 nm and lengths reaching up to several hundred micrometers.

The concept of using molecular templates has been taken a step further by Zhang and Wan [142] by the incorporation of 10 nm  $\text{Fe}_3\text{O}_4$  nanomagnet particles into the  $\beta$ -NSA nanorods and nanotubes that are 80–100 nm in diameter. These PANi- $\beta$ -NSA/ $\text{Fe}_3\text{O}_4$  nanostructures were observed to exhibit superparamagnetic behavior (i.e., hysteresis loop effects). More importantly, both the electrical conductivity and magnetic properties of these nanoparticles could be

manipulated by control over the loading level of the nano-magnetic particles. Increased loading of the  $\text{Fe}_3\text{O}_4$  nanoparticle decreased the conductivity from ca.  $70 \text{ mS cm}^{-1}$  for no loading to ca.  $10 \text{ mS cm}^{-1}$  at 20 wt%, while inducing superparamagnetic behavior in the nanocomposite.

Self-assembled polyaniline nanofibers and nanotubes, which also exhibit photoisomerization functionality, have been described by Huang and Wan [143] using azobenzene-sulfonic acid (ABSA) as the molecular templating surfactant, dopant, and photoactive agent. Nanostructures formed were similar to those by Wan et al. [131, 136, 138, 140, 142] discussed previously, with diameters of 110–130 nm and fiber lengths of 3–8  $\mu\text{m}$ . The photoinduced isomerization, from *trans* to *cis*, of the ABSA dopant was observed by UV-vis spectroscopy at 430 nm ( $n-\pi^*$  transition) after irradiation of the nanocomposites at 365 nm (over 0, 2, 6, 10, and 12 min) by UV-vis spectroscopy from 300 to 800 nm. The photoisomerization of the composite material was observed to be slower than for ABSA due to steric hinderance as a result of the *trans*-ABSA interacting along the polymer backbone.

## 2.5. Nontemplated Routes

There are a number of synthetic routes that are capable of producing nanoparticles in the absence of a precursor substrate or a molecular template.

For example, He and co-workers [144] have described a technique wherein polyaniline is deposited between two nanoelectrodes to form a nanojunction. As the junction is decreased in size to just a few nanometers, abrupt switching characteristics are observed as opposed to the more gradual transition observed during electrochemical switching of polyaniline structures with larger dimensions. A further report from the same laboratory [145] added a new dimension by initiating growth of polyaniline between a scanning tunneling microscope (STM) tip and a gold substrate. The STM tip was modified to allow only a few nm to take part in the growth of the nanowire. During growth the tip and substrate were monitored at 20–100 nm resolution. After growth the nanowire could be stretched by moving the STM tip to produce wires up to 200 nm in length and with diameters as low as 6 nm. These structures had conductivities of about  $5 \text{ S cm}^{-1}$ .

Electrodeposition of polyaniline containing  $[\text{C}_{60}]$  fullerene as dopant [146, 147] has been shown to result in 2D or 3D fibrillar structures [147, 148]. Diameters from 10 to 100 nm with fibril lengths of up to 3000 nm were observed. The fibrillar network had conductivities in the range  $10\text{--}100 \text{ S cm}^{-1}$ . Two-dimensional networks have been prepared using pulsed potential techniques while 3D networks were observed to form over longer synthesis times. Via this approach there is apparent control over the density of contact points for the individual nanonetworks.

Others [148] have used electron beam lithography to create polythiophene-based nanopatterns with linewidths down to 50 nm and gaps of 10 nm. They have shown that after exposure to a 50 kV electron beam poly(3-octylthiophene) becomes less soluble in chlorobenzene, enabling development of nanotracks that have conductivity of the order of  $1 \text{ S cm}^{-1}$ .

Electrospinning [149, 150] is another recent nontemplated method. This simple approach is based on the electrostatic fiber spinning of composite fibers of polyaniline with polyethylene oxide, polystyrene, or polyacrylonitrile. These fibers are formed when a high electric field (5–14 kV) is placed between the tip of a metallic anodic spinning needle loaded with the dissolved polymer solution (0.5–4 wt% PAN and 2–4 wt% host polymer) and an opposing cathode plate separated by 20 cm. The presence of the high electric field results in the surface tension of the polymer-loaded solution at the needle tip to be exceeded, expelling a polymer fiber from the surface toward the opposing cathodic plate. The transit time from the anode tip to the cathode plate is accompanied by a desolvation and drying process in part assisted by the electrostatic charges placed upon the solvent molecules causing electrostatic repulsion. The resulting nanofiber composite is reported to have lengths in the meter range and is collected as an interwoven mesh with large surface-to-volume ratios ( $\sim 10^3 \text{ m}^2/\text{g}$ ). These fibers are ohmic in nature. Fiber dimensions of less than 100 nm have been routinely produced by this technique. More recently [149] fibers of PAN have been directly spun from a 20 wt% solution of PAN (Versicon<sup>TM</sup>) in 98% sulfuric acid at 5 kV. The electrospinning method has also been extended to produce continuous polyaniline/polyethylene oxide monofilament nanofibers down to 60 nm diameter at a maximum spin rate of 1130 m/min and a conductivity of  $33 \text{ S cm}^{-1}$  [151].

Aligned polymer nanowire structures have been developed using an electrochemical deposition technique to form aligned polyaniline arrays on smooth and textured electrode substrates without the need for a porous templating structure [152, 153]. Oriented polymer nanowires were formed using a preprogrammed constant-current deposition method where the current density was stepped down throughout the nanowire growth. In the initial stage of nanowire growth, 50 nm polymer nuclei were deposited from an aqueous electrolyte containing 0.5 M aniline and 1.0 M perchloric acid at a current density of  $0.08 \text{ mA cm}^{-2}$  over 30 min. The current density was subsequently stepped down over a 3 hr period from 0.04 to  $0.02 \text{ mA cm}^{-2}$ . Extended polyaniline growth in the initial nucleation phase resulted in the formation of a thick polymer deposit with randomly oriented, thick-branched polymer structures over the surface. Typical nanowire structures had diameters for 50 to 70 nm and lengths of approximately 0.8  $\mu\text{m}$ . Complex surface geometries have been demonstrated using this technique where nanowires have been deposited onto ordered silica spheres deposited onto the electrode substrate as well as onto textured surfaces to produce hierarchical structures. The potential for these surfaces in chemical sensing has been demonstrated for  $\text{H}_2\text{O}_2$  detection utilizing iron(III) hexacyanoferrate nanoparticle catalysts supported by the nanowire structure.

Polypyrrole nanowire have also been electrochemically synthesized on graphite/paraffin composite electrodes from a 0.2 M phosphate buffer (pH 6.86) electrolyte containing 0.2 to 2.0 M lithium perchlorate and 0.1 to 0.5 M pyrrole [154]. Nanowires were grown by cyclic voltammetry and potential step methods. Nanorod growth is directed by inducing microstructure at the electrode surface. This was achieved by predigesting the graphite rod electrode in

boiling 10% hydrochloric acid and then boiling 10% nitric acid for 30 min, respectively, resulting in a porous graphite rod surface which was subsequently in-filled with paraffin at 150 °C and finally polished. The resultant electrode surface was covered with nitro-groups to which the pyrrole monomer selectively adsorbs providing a nucleation zone for nanotube formation. The resultant tubes were unaligned and irregularly dispersed across the surface as an entangled mesh with diameters of ca. 50–200 nm.

Thin 50 to 100 nm freestanding polypyrrole nanofilms have been synthesized utilizing oxidative interfacial polymerization at a water–chloroform interface [155]. Thicker 3 to 4  $\mu\text{m}$  polypyrrole films have been produced via this method [156]. Control over the final film thickness was achieved by removal of the immiscible solvents from above and below the nucleating film after a few minutes of polymerization. Stirring of the interfacial solutions resulted in the inhibition of polymer nucleation at the interface. Thin 5 nm polypyrrole films on mica and graphite surfaces have been formed via a admicellar polymerization route [157]. The thin films were formed due to the surfactant (CTAB and SDS) in solution adsorbing to the substrate surface as a thin film micelle containing the pyrrole monomer, which was subsequently polymerized by ferric chloride solution. On the graphite surface the polypyrrole morphology consisted of thin discs and interlinked islands. On the mica surface the morphology consisted of randomly scattered islands with no continuous film formation evident.

Dip-pen nanolithography has been performed on a number of surfaces via a coated atomic force microscope (AFM) tip at the 130 nm scale up to several micrometers using SPAN as the writing ink [158]. Transfer of the conducting polymer ink from the AFM tip to the substrate is achieved via capillary action upon tip contact to the substrate surface with 0.5 nN contact force. The deposited SPAN tracks were found to electroactive.

Near-field optical lithography has also been performed to draw nanostructures of poly(*p*-phenylene vinylene) (PVP) using light delivered from a scanning near-field fiber probe, with a 40 or 80 nm optical aperture, on a scanning near-field optical microscope AFM device [159]. Polymer features are drawn by exposing the PVP soluble precursor to ultraviolet light (325 nm HeCd laser, 0.2 mW at the sample surface) rendering the exposed precursor insoluble and permitting the dissolution of the remaining polymer. Following chemical conversion for the exposed PVP precursor a fully conjugated polymer can be achieved. Two-dimensional photonic crystal arrays have been demonstrated by this method with pillars 32 nm tall, 200 nm wide (at half height) and a lattice constant of 333 nm (ca.  $30 \times 30$  dot lattice).

## 2.6. Nanocomposites

The final approach to be reviewed involves the use of preformed nanosized structures to assist in the formation of ICPs with nanodimensions. For example, Pope and co-workers introduced the concept of using silica nanoparticles to stabilize inherently conducting polymers [160]. We subsequently used this approach to produce polyaniline based silica nanocomposites [161] using an electrohydrodynamic synthesis technique. The electrochemical approach allows

direct incorporation of a wide range of dopants, including in this case the optically active camphor sulfonate ion to produce chiral particles with nanodimensional ICPs incorporated therein (Fig. 17).

Applications of conducting polymers to nanosized semiconductor particles, commonly referred to as quantum dots, have also been made to produce nanocomposite materials [162]. These materials are typically spherical semiconductor crystals of 5 to 10 nm in size, such that quantum confinement effects predominate within these structures. At this size, these nanocrystals have special optical and electronic properties resulting from these quantum effects. A prime application of these materials is that tight size control will influence the onset of absorption and the fluorescence wavelength, thereby affecting the color of the observed particles in solution. CdS and  $\text{Cu}_2\text{S}$  quantum dots were coated by mixing into an *N*-methylpyrrolidone (NMP) solution containing the EB form of polyaniline. Extended exposure of the EB to these nanoparticles resulted in the oxidation of the EB to the pernigraniline base form. Co-precipitation of the EB and nanocrystals in NMP was achieved by the addition of ethanol. For CdS, electron transfer from the polymer to the nanocrystals is energetically favorable. Similarly, excitons created on the nanocrystals can also be transferred to the polymer resulting in an electron on the nanoparticle and an electron hole in the polymer. This creates a potential to control the performance of photovoltaic devices by altering the nanocrystal's size and concentration.

In another example, Bremer and co-workers [163] polymerized polyaniline onto nanodimensional polyurethane particles dispersed using a steric stabilizer (Fig. 18). We

**Figure 18.** Cor-shell nanoparticles. Reprinted with permission from [4], G. G. Wallace and P. C. Innis, *J. Nanosci. Nanotech.* 2, 441 (2002). © 2002, American Scientific Publishers.

adapted this approach to produce highly optically active nanoparticles (20 nm) based on polyaniline doped with (+)-camphor sulfonate coated onto polyurethane particles [164].

A major disadvantage of using this approach is that these structures commonly aggregate to form raspberry-like structures during the polymerization process [161]. In an attempt to minimize this affect, Xia and Wang synthesized polyaniline nanosilica [165] and nanocrystalline titanium oxide composites [166] while applying ultrasonic irradiation during the chemical polymerization process. Although aggregation was evident, the resultant nanoclusters of 60 to 120 nm were obtained from the initial 15 to 40 nm SiO<sub>2</sub> cores. Similar results were observed for PAN-TiO<sub>2</sub> nanocomposites. Other morphologies that resulted from the ultrasonication included thread-like and sandwich-like aggregated structures.

Nanocomposites have also been fabricated utilizing aqueous vanadium or iron oxide sols and polyaniline to produce particles characterized by X-ray crystallography as ca. 9 and 13 nm in diameter, respectively [167]. Strong interaction between the inorganic V<sub>2</sub>O<sub>5</sub> core and its polyaniline shell indicates that the PAN-V<sub>2</sub>O<sub>5</sub> nanoparticle functions as an intercalation compound, with electron transfer from the unshared electron pair of the nitrogen atom to the V<sup>5+</sup> ion evidenced by electron paramagnetic resonance (EPR) spectroscopy. In the case of a Fe<sub>3</sub>O<sub>4</sub> core, the ferromagnetic character of the Fe<sub>3</sub>O<sub>4</sub> was the dominating feature of the EPR spectrum. However, infrared spectroscopy indicated that electronic interactions are occurring between the Fe<sub>3</sub>O<sub>4</sub> core and the conducting polymer shell.

Recent work aimed at other objectives may also provide an interesting route to the production of ICP-containing nanocomposites: this is in the use of CNTs as host “particles.” CNTs in their own right possess interesting electronic properties and when combined with other conjugated polymers synergistic effects have been observed [168, 169]. Our studies have focused on the use of aligned carbon nanotubes as templates for ICP deposition. Our recent work in this area [170] has revealed significant improvements when PPy glucose oxidase is coated onto aligned CNTs for use as biosensors (Fig. 19). We have also shown that ICPs can be highly effective dispersants for CNTs, presumably attaching

**Figure 19.** Aligned carbon nanotubes with a bioactive conducting polymer. (a) Pure CNT array before treatment. (b) Aligned CP-CNT coaxial nanowires; inset shows clear image of single tube coated with PPY. (c) PPY only deposited on the top of CNT surface due to high density of tubes. (d) Polymer formed on both outside of walls and the top of the surface of the CNT array. Reprinted with permission from [170], M. Gao et al., *Electroanalysis*, 15, 1089 (2003). © 2003, Wiley-VCH.

themselves to the CNT structure. The properties of these novel dispersants of nanomaterials are yet to be investigated.

The molecular template concept used to produce polyaniline nanotubes [136] (as discussed) has also been used prepare to sulfonated multiwalled carbon nanotubes [171]. In this instance, the sulfonated nanotube surface serves a dual role acting as an *in-situ* dopant for the polyaniline as well as providing a supramolecular template onto which the anilinium ions in solution bind. Polymerization therefore occurs predominantly at the sulfonated nanotube surface. The resultant hybrid structure consists of a 10 nm thick polyaniline coating on the CNT surface, providing a novel way of introducing and functionality of to CNTs.

## 2.7. ICP Surfaces for Facilitating Metal Nanoparticle Growth

Utilizing ICPs as potential platforms for supporting nanoscale structures has been investigated to provide novel supported catalysts. The concept of embedded metal nanoparticles was recently presented by Zhou et al. [98, 99]. In this instance the metal nanoparticles were embedded in the polymer matrix and therefore protected from the chemical environment. Wang and co-workers [172] employed a similar approach by chemical reduction of AuCl<sub>3</sub> or Pd(NO<sub>3</sub>)<sub>2</sub> by polyaniline powder in either aqueous dispersions or in NMP, a common solvent for the EB form of PAN. Reduction of palladium nanoparticles was slow with EB; hence the polyaniline was initially reduced to the leucoemeraldine base form in order to facilitate reduction of the Pd<sup>2+</sup> to its metallic state. The nanoparticle sizes for the Au and Pd were observed to be 20 nm from NMP solution and 50–200 nm from polyaniline powder. Gold-polyaniline nanocomposites have been prepared by the chemical reduction of

$\text{HAuCl}_4$  and simultaneous polymerization of aniline to produce 26 nm Au nanoparticles dispersed in the polyaniline powder matrix [173].

Platinum and platinum oxide nanoparticles, 4 nm in size, have been successfully deposited onto polypyrrole/polystyrene sulfonate colloidal dispersions (with dimensions ranging from 30 to 1000 nm) [174] for use as catalysts.  $\text{Pt}(\text{NH}_3)_4\text{Cl}_2$  and  $\text{Na}_6\text{Pt}(\text{SO}_3)_4$  metal salts were reduced by formaldehyde or  $\text{H}_2\text{O}_2$  respectively in order to form Pt nanoparticles on the ICP colloid surface. These nanocomposite dispersions have been reported to be effective catalysts for oxygen reduction in a proton exchange membrane fuel cell, indicating that the metal catalytic particles are accessible for chemical interaction.

Polythiophene has also been investigated as a potential substrate for the formation of catalytic platinum nanoparticles, 2–4 nm in size, for oxygen reduction. The Pt nanoparticles were homogeneously deposited across a predeposited polythiophene film by direct electrodeposition from a solution of 12.5 M  $\text{H}_2\text{SO}_4$  and 4 mM  $\text{H}_2\text{PO}_4$ . The resulting composite was produced in a similar fashion as other electrocatalysts such as carbon-supported platinum.

### 3. UNIQUE PROPERTIES AND APPLICATIONS OF INHERENTLY CONDUCTING POLYMERS NANOSTRUCTURES

As ICPs approach nanodimensions a number of trends become evident which involve either the preservation of the bulk properties of the ICP and/or the enhancement of the properties of the nanomaterial such as conductivity. Some of these influences of nanostructure reported in the literature are discussed.

He et al. [144, 145] have created a conducting polymer nanojunction switch with abrupt switching characteristics that are attributed to a single nanocrystalline domain in which the individual polymer strands collectively undergo the usual insulator–conductor transition.

Nanoelectronics will be an expanding area of application for ICPs. A recent example has been illustrated for the fabrication of organic photodiodes and light emitting diodes [175]. Fullerene derivatives grafted onto soluble polythiophene, based upon the PEDOT system, have been utilized to form an integrated donor–acceptor polymer system. Nanopatterned electrodes were prepared by using a silicone rubber replica stamp which was used to transfer an organic resist image of an optical grating (280 nm periodicity) on top of a metal film. This film was subsequently etched to form a nanopatterned metal electrode substrate, onto which the polymer was cast forming the electronic device. Short sub-micrometer/nanoscale distances between the metallic electrodes were important due to the polymer layer having a low charge carrier mobility (exciton), emphasizing the importance of nanofabrication for these devices.

Numerous reports have discussed the fact that nanocomponents have inherently greater conductivity than the macroscopic analog [111]. This is not surprising given the model described by Epstein [176] and Kaiser [177] in which the bulk properties of ICPs arise from crystalline (highly

conductive) nanodomains in a sea of amorphous (less conductive) material. A number of experimental approaches [178] have been used to verify the presence of these domains.

Formation of these nanodomains provides us with a unique opportunity to access these regions of high order and subsequently higher conductivity. A challenge in accessing enhanced electrical properties is that many approaches for the formation of nanoparticles require the use of an insulating surfactant. This was noted by Chan et al. [101] where removal of the insulating surfactant required for nanoparticle formation caused the conductivity to increase. Others [179] have shown that dramatic improvements in specific capacitance for polythiophene tubules can be obtained, increasing from 4 C/g polymer for a flat film up to 140 C/g polymer and 148 C/g polymer for micro- and nanotube formations, respectively.

The realization of efficient photovoltaic devices based on inherently conducting polymers also depends on the ability to control structure at the nanodimension [180, 181]. Such materials generate electron/hole pairs (excitons) upon irradiation. The ability to generate electricity from these charge pairs depends on our ability to split these charges at appropriate interfaces. Unfortunately, the lifetime of excitons is short and only those formed within 10 nm of an interface will ever reach it. The development of efficient nanostructures is therefore critical to this area.

Metallic nanoparticles exhibit well-documented phenomena of surface plasmon absorption processes where the free electrons at the surface of the nanoparticle generate a dipole moment to interact with visible wavelengths [182, 183] when the particle is too small itself to interact with light by Bragg scattering processes. It has been reported that the surface plasmon absorption can interact with an encapsulating  $\pi$ -conjugated polymer when it is oxidized [98, 99]. This interaction is reported to be due to the direct electronic communication of the surface electrons of the metal nanoparticle with the encapsulating polymer. The result of this interaction is a redshift of the optical plasmon absorption band with respect to a lone metal nanoparticle. This shift in absorption can be achieved by an aggregation process of the metal nanoparticle, but no such aggregation was evident implying direct electronic interaction with the polymer and metal electron.

Xia and Wang [103] elegantly demonstrated the advantages and pitfalls to be encountered as we enter the nanoworld. As particle size decreases the degree of doping and crystallinity increases, with a concomitant increase in conductivity. They also showed crystalline domain sizes ranging from 10 to 40 nm and that as size decreases lattice defects may occur causing the crystalline structure to be broken due to the smaller size.

An industrial application of polyaniline utilizing nanodispersions of the ICP into corrosion inhibiting paint latexes has been developed whereby 70 nm particles are dispersed to form a self-organised complex of ultrafine network [184]. For a number of years it has been demonstrated that ICPs can impart corrosion resistance to metal substrates. When these nanoparticles have been melt dispersed with a loading of 1% w/v in paint, the composite material is observed to have similar metallic properties to the bulk

material. This arises due to the nanoparticle forming a network structure permitting electron tunneling via a continuous conducting pathway [185]. A clear advantage of utilizing these nanodispersions is that a similar corrosion inhibitor activity is achieved to that found using larger particle sizes, requiring higher polymer loading, or coated films.

Mandal has shown that the use of polyaniline nano-components results in extraordinarily low (0.03 vol%) percolation thresholds in polyvinylalcohol [186].

Polypyrrole-iron oxide nanocomposites have been prepared for application as humidity and gas sensors [187]. Improved sensor sensitivity is achieved by increasing the surface area based upon microstructure. By this approach nanoparticles were prepared by the reaction of ferric nitrate and methoxyethanol in the presence of pyrrole to produce a nanostructured aggregate with the appropriate morphology and surface area to function as a sensor.

Recently we have used aligned carbon nanotube platforms to fabricate inherently conducting polymer based biosensors with excellent performance characteristics [170].

## 4. CONCLUSIONS

The unique properties of materials brought about by control of structure at the nanodimension have generated much excitement in the research community in recent times. Those of us interested in the modification and efficient utilization of inherently conducting polymers have not escaped the nanotechnology euphoria.

Potentially, the benefits to be reaped from control of the ICP structure from the nanoscale to the microdomain and beyond are substantial. The more highly ordered structures obtained are expected to yield novel electronic, electrochemical, mechanical, chemical, and photoelectrochemical properties. Researchers have developed innovative strategies and approaches that enable controlled dimension nanocomponents to be produced. As with all areas of nanotechnology, the challenge is to assemble these nanocomponents into devices or structures that display the benefits of nanodimensional control.

## GLOSSARY

**Dopant** An anionic additive incorporated into the matrix of an inherently conducting polymer to provide electrostatic neutrality to the cationic charges on the polymer backbone and to modulate the electrical properties of the polymer.

**Emeraldine (salt or base)** The half oxidized state of polyaniline. When protonated as the salt polyaniline is conducting. As the base the polymer is an insulator or poorly conducting.

**Inherently conducting polymer** A polymeric material which conducts and electrical current by means of its electronic structure, namely via  $\pi$ -bond conjugation along the polymer backbone, and has no other conducting fillers added. Conductivity can be modulated by the addition of dopant anions to the polymer matrix and controlling the polymer oxidation level.

**Leucoemeraldine (base)** The fully reduced and insulating form of polyaniline.

**Monomer** A single repeat unit within a polymer chain structure.

**Pernigraniline (salt or base)** The fully oxidized and non conducting form of polyaniline.

**Polyelectrolyte** A polymer which has either anionic or cationic functionality attached directly to or as a part of the monomer repeat unit. Anionic or cationic character can be controlled by the number of repeat units, with these functionalities, incorporated into the polyelectrolyte structure.

**Polymerization** The process whereby single monomer units are reacted to form a larger continuous molecular chain structure.

**Redox** Reduction (electron loss) and oxidation (electron gain) processes.

# Inorganic Nanomaterials from Molecular Templates

Sanjay Mathur, Hao Shen

*Institute of New Materials, Saarbrücken, Germany*

## CONTENTS

1. Introduction
  2. Chemical Synthesis of Nanomaterials
  3. The Metal-Organic Precursor Approach
  4. Methods for Molecule-to-Material Transformation
  5. Molecular Clusters as Building Blocks to Nanoparticles and Nanostructured Films
  6. Conclusions
- Glossary  
References

*All things began in order, so shall they end, and so shall they begin again; according to the ordainer of order and mystical mathematics of the city of heaven.*

—Sir Thomas Browne, 1658

## 1. INTRODUCTION

Typically, a nanostructure is a material structure assembled from a layer or cluster of atoms with size on the order of nanometers [1–5]. A number of methods exist for the synthesis of nanostructured materials, including synthesis from atomic or molecular precursors (chemical or physical vapor deposition, gas condensation, chemical precipitation, aerosol reactions, biological templating, etc.), processing of bulk precursors (mechanical attrition, crystallization from the amorphous state, phase separation, etc.), and processes

in nature (e.g., biological systems) [6–12]. Although it is general, this definition underlines the fact that a positional control over constituting atomic or molecular units is inherently associated with the synthesis of nanostructured materials. When evaluated dimensionally, the domain of nanoscale structures (<100 nm) lies between that of ordinary, macroscopic or mesoscale products and microdevices on the one hand, and single atoms or molecules on the other. For this reason, nanostructured materials comprising a countable number of polyatomic or molecular units represent a scale of matter where entirely new properties, not known in the bulk counterparts, are manifested and dominate their behaviors. The most well-known example is the change in color of CdS nanocrystals when their size is reduced to a few nanometers [13]. Such mechanisms include quantum effects, statistical time variations of properties and their scaling with structure size, dominant surface interactions, and the absence of defects in the volume of nanocrystals. These effects endow nanoscale particles and structures thereof with unique mechanical, electronic, magnetic, optical, chemical, etc. properties [6, 8, 14]. Bulk materials constructed from nanoparticles also exhibit new properties such as enhanced plasticity and surface reactivity, and more uniform structures [15].

The unique properties of assembled nanostructures largely attributed to their small size are responsible for the great strides in the development of new synthetic methodologies that would allow the prescribed synthesis of any desired nanostructured material. Methods for controlling the shape and size of inorganic nanocrystals are evolving rapidly with the increasing understanding of basic size-dependent scaling laws, which are important for a wide range of applications. Furthermore, nanoparticulate systems display some special properties like dispersability of an immiscible phase, light weight, extremely high surface area, control over the scattering of light and electronic states (useful in optoelectronic features), and the relatively higher energetic state of atoms and molecules present at the surface of a nanoparticle when compared with those in the bulk. The higher energy associated with the surface also drives

the growth of phases and poses the greatest challenge to the controlled synthesis of nanosized particles [7, 8].

The various possibilities for fabricating nanomaterials through the control of the sizes of their constituent clusters or particles can be broadly divided in the so-called *top-down* (transformative) and *bottom-up* (synthetic) approaches. The top-down processes are based on the transformation of bulk materials into nanoscaled components, largely by mechanical methods, whereas the bottom-up approach relies on the synthesis of large architectures from smaller, well-defined nanosized units. Conventional materials with a grain size anywhere from hundreds of microns ( $\mu\text{m}$ ) to millimeters (mm) are also made of polyatomic or molecular assemblies of matter, where the distribution (ordered or statistical) and multiplicity of such building units are responsible for the familiar averaged properties of bulk materials. Because these macroscale properties effectively extend down to the microscale, traditional manufacturing techniques are experiencing a miniaturization trend for the fabrication of microstructures (e.g., in microelectronics) in a top-down approach. On the other hand, well-known monoatomic or molecular units offer the ultimate building blocks for an atom-by-atom or molecule-by-molecule synthesis of nanostructures in a bottom-up fashion. However, the possibility of building extended solid-state structures from molecular building blocks demands a comprehensive and thorough analysis of synthesis and the composition-structure-property relationship. This review is intended to provide an overview of the efforts made in the chemical synthesis of nanomaterials with the use of molecular metal-organic precursors, with special emphasis given to single-source precursors (SSPs) [16–31]. The term “single source” in a strict sense applies to compounds containing all of the phase-forming elements in a single molecular source (e.g.,  $(\text{Me}_2\text{AlNH}_2)_3$  for AlN) that can be used to perform a one-step synthesis of the desired (nano)material. In addition to the inherent advantages (low-temperature synthesis, phase purity, better composition, and morphology control, etc.) of chemical methods, this concept allows the “preformation” of a solid-state material on the molecular scale.

The research work reviewed here is focused on molecular routes to inorganic nanomaterials and will not refer to the progress of molecular nanotechnology, which is largely related to the understanding of molecular phenomena involved in the self-assembly or self-organization of molecular building blocks to form supramolecular structures that interact to form a higher ordered material (aggregate or crystalline) [32–34]. The emphasis in this contribution will be on the state of the art of molecular concepts developed to obtain inorganic nanoparticles or nanostructured films by chemical routes.

## 2. CHEMICAL SYNTHESIS OF NANOMATERIALS

There is a growing realization that the knowledge of fundamental molecular interactions and processes (=chemistry) is of central importance for the progress of nanoscience, which deals with matter at a scale where the properties are dominated by molecular behaviors, including single molecules and molecular assemblies. Despite clear practical implications of nanocrystalline materials, there exists a deficit in

the ability to produce materials with desired intrinsic properties and a precise control over size, shape, and composition [35]. This situation is distressing, especially in view of the fact that most of the recent advances in nanomaterials are based on novel materials with extraordinary properties (e.g., fullerenes, carbon nanotubes, quantum dots, 1-D oxide wires, etc.) as well as new processing routes (e.g., aerosol nucleation, mechanochemistry, templated growth in mesoporous matrices, hydrothermal methods, etc.).

Chemistry has profoundly influenced the emergence of advanced materials through the development and application of novel chemical routes for the synthesis of nanosized powders and nanostructured films. The “nano-movement” in materials chemistry is partly triggered by the observation that the predefined metal stoichiometry and reaction chemistry of molecular precursors can enforce a molecular-level homogeneity in the obtained materials [36–38]. In solid-state processing, the solid precursors (such as metal oxides, carbonates, and salts) must be brought into contact by grinding and mixing and subsequently heat-treated at high temperatures to facilitate the diffusion of atoms or ions in the reaction mixture. Since the diffusion process depends on the temperature of the reaction and grain interfaces, the mixing and grinding steps are usually repeated throughout the heat treatments to prepare fresh surfaces for further reactions. When compared with solid-state processing, the diffusion of matter in the vapor or liquid phase is typically many orders of magnitude higher. Moreover, the chemical reactions allow a controlled interaction of atoms or molecules to form uniformly dispersed solid particles. The atomic-scale mixing of the phase-forming elements results in a faster nucleation of the product at low temperature, which makes kinetic control over the process possible. As a result it is possible to suppress the preferred formation of thermodynamically favored substances and to perform a phase-selective synthesis of metastable compounds.

Although the concept of synthesizing materials from molecules has long been suggested as a mild approach (the so-called soft chemistry methods), the interest, for a long period of time, was to apply these routes to known materials. It is only recently that attention has been shifted to the synthesis of new materials with novel compositions. To decipher how molecular interactions give rise to complexity, it is chemical synthesis that can provide new compounds to manipulate molecular interactions and thereby control the process of material formation as well as the properties of the resulting materials. The chemical techniques use direct, often very simple, chemical reactions to produce the solid of interest. In addition, chemical processing allows control of chemical structure, morphology, and dimension required on several scales of magnitude. For instance, with the manipulation of the reaction kinetics so as to encourage particle nucleation over particle growth, ultrafine particles can be obtained. The nucleation kinetics are easily regulated by varying the amounts or ratios of the reactants or reaction time, for example, by massively exceeding the supersaturation ratio in precipitation reactions or by increasing the amount of water added in an alkoxide-based sol-gel process to drive hydrolysis at the expense of condensation reactions. Furthermore, the reaction kinetics can also be influenced by adjustment of the thermal energy input or thermal energy

distribution in the reaction vessel. The enhanced degree of mixing achieved by ultrasonic irradiation can accelerate reaction kinetics by two orders of magnitude and yield nanometric particles [39]. Sonic and ultrasonic agitation methods are used to create small bubbles, in a reaction pool, to accelerate reaction kinetics by cavitation. This method, known as sonochemical synthesis, relies on the phenomenon of acoustic cavitation (a point where the intensity of ultrasound exceeds the intramolecular forces, and, as a result, the molecular structure collapses and a cavity is formed) that results from enormous stresses (500–1000 atm) and elevated temperatures ( $\sim 3000$  K) induced in the reaction medium by the application of ultrasound (20 kHz to 10 MHz). Another example of accelerated chemical reaction strategy is the straightforward synthesis of hexagonal gallium nitride (GaN) nanocrystals by detonation of gallium azides [40, 41].

In basic chemistry terms, the starting materials (input) of a chemical reaction are the *reactants* and the material (output) to which the reactants are converted, the *product*. In most of the chemical methods in practice, the starting materials are commonly available reagents, which are close to the desired composition but need a heat-treatment step to attain the final composition. For example, the calcination of  $\text{CaCO}_3$  eliminates  $\text{CO}_2$  and results in the formation of  $\text{CaO}$ . Similarly, firing  $\text{Al}(\text{OH})_3$  drives off water to produce  $\text{Al}_2\text{O}_3$ . In such cases, where the “precursor” is an infusible solid, the size of the particles in the precursor will impose a minimum limit for the size of the particles in the final calcined material. However, particles can grow larger because of fusion (necking) that takes place at elevated temperatures. Further problems associated with such powders are (i) that particles are rarely round (spherical powders pack better), (ii) the presence of dense agglomerates of much smaller crystallites formed during firing and crystallization, and (iii) the external contamination of particles during milling or grinding steps that are necessary to break down the larger agglomerates. For these reasons, minimizing the calcination temperature and steps is a prerequisite in the preparation of nanocrystalline materials by conventional chemical techniques. An elegant way to limit the particle size at the precursor stage is to use well-defined molecules that can be seen as “molecular fragments” of the solid-state structure. A number of methods have been devised to control the final particle size by performing the reactions in spatially confined reaction pools, for example, hydrolysis in aqueous reaction pools separated by an intervening liquid (water-in-oil micro(nano)emulsion) or pyrolysis of small droplets of precursor solution separated from each other by a gaseous phase (aerosol). The methods are not straightforward in predicting the final particle size because of chemical exchange and agglomeration between pools in the microemulsion method, whereas coalescence and drying of droplets in the case of aerosol technique lead to a size distribution and chemical inhomogeneities in the final material. In addition, the chemical reaction occurring within the droplets and the nature of different chemical intermediates can further complicate the synthesis. Since no *positional control* is offered, the different compounds present in the reaction mixture randomly collide to form various intermediate species with metal ratios unfavorable for obtaining

a single-phase material. As a consequence, phase separation and element segregation are present at the nanometer scale, although the global stoichiometry of the product corresponds to the desired composition. This is a common observation in the conventional material synthesis procedures (e.g., solid-state reactions, coprecipitations, combustion reactions, etc.) where the intrinsic chemical behaviors (e.g., different hydrolysis rates of the reactants in solution-phase reactions or different vapor pressure or thermal stability in the gas-phase reactions) of the different components present in a reaction mixture make the stoichiometry of the target material highly susceptible to inaccuracies. For instance, a simple mixing of two chemical precursors A and B, to produce the binary system AB (multisource precursor, MSP), may produce a visibly homogeneous mixture, but the molecular-level scenario can be different, and, despite a correct global stoichiometry, the precursor “cocktail” may have element segregation and non-ideal A:B ratios at the nanometer scale that may be carried forward to the end product (Scheme 1).

**Scheme 1.** Chemical aspects of multisource precursor (MSP) and single-source precursor (SSP) processes.

In this context, the SSP containing predetermined metal-ligand interactions (e.g., metal-carbon for carbides, metal-nitrogen for nitrides, metal-oxygen for oxides, etc.) are an attractive choice for obtaining materials that are homogeneous at the atomic level. The superior potential of molecular-level synthesis has been demonstrated in several cases. For instance, the metal organic chemical vapor deposition (MOCVD) of group III nitrides ( $\text{AlN}$ ,  $\text{GaN}$ ,  $\text{InN}$ ) has traditionally been carried out with mixtures of the corresponding metal alkyls with ammonia ( $\text{NH}_3$ ). However, the high thermal stability of  $\text{NH}_3$  (<5% pyrolyzed at  $700^\circ\text{C}$ ) necessitates very high substrate temperatures ( $>1000^\circ\text{C}$ ), and high  $\text{NH}_3:\text{MR}_3$  ( $\text{M} = \text{Al}, \text{Ga}, \text{In}$ ) ratios (e.g., 2000:1) are required to inhibit nitrogen desorption. This severely limits the choice of substrate material, and the inefficient use of toxic ammonia demands gas-scrubbing systems. On the other hand, the use of molecular sources  $[\text{Me}_2\text{AlNH}_2]_3$  and  $[\text{Et}_2\text{GaNH}_2]_3$  containing preformed aluminum-nitrogen and gallium-nitrogen bonds gives crystalline  $\text{AlN}$  and  $\text{GaN}$  films at  $400\text{--}800$  and  $650^\circ\text{C}$ , respectively.

Finally, the chemical routes are simple and thus cost-effective when compared with the physical methods, which require sophisticated technology and expensive experimental set-ups. The synthesis of materials is achieved at relatively lower temperatures than those required for conventional processing methods, and it is possible to process large quantities and high throughput. Moreover, they offer enormous versatility with respect to composition, allowing, for instance, tailoring of the composition. It is possible to cosynthesize another material in the same medium. For this reason, various chemical routes have been proposed based on the application of molecular compounds to produce inorganic materials. A brief description of the common chemical methods (sol-gel, CVD, aerosol, microemulsion, and hydrothermal synthesis) applied to the synthesis of nanophase materials from molecular precursors is presented in the following section. In addition, some other methods (coprecipitation and the polymeric precursor route) not using the single-source approach but based on a molecular-level mixing of the components are also discussed because examples taken for a comparative evaluation of conventional and molecular chemistry routes necessitates their understanding.

### 3. THE METAL-ORGANIC PRECURSOR APPROACH

The synthesis of materials prepared from molecular components is a growing research thrust in nanomaterials science because it allows the use of molecular building blocks for the rational design and construction of new materials [42]. Novel molecular and extended networks constructed from organic and inorganic building blocks have been found to behave like molecule-based conductors and superconductors, optically active compounds, and magnets. In addition, the versatility of molecular based materials allows for the design of hybrid materials with the possibility of synergy effects. At this stage it is necessary to differentiate between the two popular strategies of obtaining materials from molecules, namely molecule-based nanomaterials (MBNs) and molecule-derived nanomaterials (MDNs). Both approaches are based on the use of molecules or molecular ions and their interactions to design a (nano)material in a *bottom-up* fashion. However, in the case of molecule-based materials, the molecular integrity of the building units is maintained in the final configuration (Scheme 2), whereas in the case of molecule-derived synthesis the features of the parent molecular framework are not necessarily maintained in the final material (Scheme 3).

Scheme 2.

Scheme 3.

In addition, the nature of bonding is generally different in the two cases; the class of MBNs is dominated by molecular architectures and assemblies based largely on noncovalent interactions, where the main driving forces for the formation of a network are metal-ligand interaction, hydrogen bonding,  $\pi$ - $\pi$  stacking, ion templation, chiral interactions, etc. On the other hand, the MDNs are based on covalent and/or ionic interaction. Furthermore, in the case of an MBN, the common principles of synthetic organic, organometallic, inorganic, and polymer chemistry are used to obtain the desired material. This methodology is also used to obtain the precursors to MDNs; however, the target nanomaterial is obtained only after a few processing steps, which involve the loss of organic ligands, structural fragments, or elements to reach the final solid. Moreover, a molecular building block of an MDN may contain many more elements than those required to form the end product. For instance, iron pentacarbonyl ( $\text{Fe}(\text{CO})_5$ ) is used as a source of iron nanoparticles, and nanostructured films contain C and O as carbonyl ligands, which are knocked off during the processing steps to nanocrystalline iron. Similarly, titanium isopropoxide ( $\text{Ti}(\text{OPr}^i)_4$ ) loses the organic periphery in the formation of titanium dioxide ( $\text{TiO}_2$ ).

The molecular self-assembly, which can be seen as a case of MBN, seems to open new pathways to nanostructures formed by the organization of molecular building blocks through controlled molecular interactions. A representative example is shown in Figure 1, which displays a supramolecular ribbon structure based on hydrogen bonding between barbituric acid and 2,4,6-triaminopyrimidine units [32].

It must be emphasized that despite significant differences, the distinction between the MBN and MDN approaches is not absolute because examples are now known in which the structural features of an MDN source are carried forward to the extended solid network. For instance, the use of cubane precursor molecules,  $[(\text{Bu}^t)\text{GaS}]_4$ , in the MOCVD process results in the growth of a new cubic GaS phase, whereas using the dimeric species  $[(\text{Bu}^t)_2\text{GaS}]_2$  as molecular precursor forms the thermodynamically stable hexagonal GaS. It has been shown that the formation of cubic GaS is a consequence of the retention of the cubane  $\text{Ga}_4\text{S}_4$  core during the deposition and growth process (Scheme 4). Interestingly, the cubic phase is not obtained by other routes and precursors. In view of the general definitions applied to MBN and

Figure 1. Self-assembly of a supramolecular ribbon from barbituric acid and 2,4,6-triaminopyrimidine units. Reprinted with permission from [32], J. M. Lehn et al., *J. Chem. Soc., Perkin Trans. 2*, 461 (1992). © 1992, Royal Society of Chemistry.

MDN, the cubic phase of GaS might be termed an MBN and the hexagonal GaS an MDN.

Scheme 4.

### 3.1. The Single-Source Concept

When one considers that precursor structure and metal-ligand connectivity determine the composition of nanomaterial from a legal perspective, the role of suitable precursors in the designed synthesis of nanomaterials becomes immediately apparent. It is reasonable to assert that solid-state structures can be templated at the nanometer scale by employing well-defined molecular clusters containing metallic elements in a ratio compatible with the targeted ceramic or composite, the so-called SSPs [16–31, 43–51]. The defined metal-ligand interactions in such *nano-synthons* initiates the growth of nanomaterials at lower temperatures by providing intact nuclei for a bulk material. A large number of different expressions like molecular building blocks, molecular subunits, or modular building units are used to describe metal-organic compounds used as single molecular source.

However, the expression “single-source precursor” is also applied to a mixture of constituents mixed homogeneously either as a powdery mixture (solid) or in a common solvent (liquid) system. While the precursor system in the first case is a physical mixture, the validity of the expression is rather questionable in the second case because it is used to define a precursor cocktail, although no investigations of the nature of the species present in the solution is made, in most of the cases. The use of a mixture of different chemical compounds, corresponding to the elements present in the desired material (e.g., individual Y, Ba, and Cu sources to obtain  $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ ), complicates the situation in the multiple-precursor route, mainly because of the different chemical nature of the individual chemical species present in the precursor-complex. The composition and phase purity of the material are difficult to control because the intrinsic behaviors of single components, for example, solubility, susceptibility to hydrolysis, etc., in solution-based methods and differential vapor pressures, thermal stability, etc., in the gas-phase synthesis make the stoichiometry highly susceptible to inaccuracies due to an increased number of process variables. In view of the above, the examples described in this article are based on the conversion of defined molecular

clusters, which have been characterized with respect to their chemical structure and composition before being applied as molecular sources to nanostructured materials.

In the past few years, the use of molecular compounds as precursors to thin films and powders has been extensively explored. There are many excellent examples of the use of SSPs for one-, two-, three-, and four-component systems and even biphasic composites [16, 19, 20, 29, 43, 44, 47, 52–315].

The salient examples of compounds used as a single source to solid-state phases are assembled in Tables 1–4. A broad and arbitrary classification of the single molecular source,  $[\text{ABL}_1\text{L}_2]$ , based on experimental results, is presented in the following section (Eqs. 1–6, A and B, are the phase-forming elements;  $\text{L}_1$  and  $\text{L}_2$  are ligands that can be similar or different). The concept is elaborated on the basis of different Mg- and Al-containing alkoxides that have been used as precursors to  $\text{MgAl}_2\text{O}_4$  particles or films [104, 259, 260, 263, 316, 317].

#### 3.1.1. Case I: Stoichiometric Assembly of the Phase-Forming Elements

The SSPs belonging to the subcategory outlined in Eq. (1) are based on an appropriate ratio of the phase-forming elements that should be compatible with the desired inorganic phase. The chemical nature (neutral, anionic, chelating), steric bulk, and the decomposition chemistry of the ligand(s) are not the prime concern in the selection of a suitable precursor. Nevertheless, the existence of similar molecular frameworks with different ligands offers the possibility to choose the precursor most suited for a particular process or

application. For example, the mixed-metal Mg-Al alkoxide,  $[\text{MgAl}_2(\text{OPr}^i)_8(\text{Pr}^i\text{OH})_2]$ , possesses the cation ratio required for the formation of  $\text{MgAl}_2\text{O}_4$  spinel. The thermal decomposition of the precursor is associated with the formation of several products based on radical and/or ionic fragmentation of the ligands (Eq. (2)). The mutual stoichiometry of the by-products depends upon the reaction conditions. The molecule exists as an isopropyl alcohol adduct in the solid-state (Fig. 2a), and the observed arrangement of  $\text{Mg}^{2+}$  and  $\text{Al}^{3+}$  ions is also maintained in the solution, as confirmed by molecular weight studies [318]. Because of the appropriate Mg:Al ratio,  $[\text{MgAl}_2(\text{OPr}^i)_8(\text{Pr}^i\text{OH})_2]$  has been used for the synthesis of ultrafine spinel particles by the sol-gel method [260]. The hydrolysis of the heterometal precursor was investigated by rheological measurements and  $^{27}\text{Al}$  NMR spectroscopy, which suggested that the bimetallic unit survives

during hydrolysis and gelation and does not break down into constituent alkoxides.

Although [MgAl<sub>2</sub>(OPr<sup>i</sup>)<sub>8</sub>(Pr<sup>i</sup>OH)<sub>2</sub>] is suitable to produce stoichiometric powders or films of MgAl<sub>2</sub>O<sub>4</sub> by the sol-gel process, it is not a convenient precursor for gas-phase synthesis of spinel particles or films because of its thermal instability [263, 317]. When this compound is heated under low-pressure conditions (LP-MOCVD) or stored for long time periods, the coordinated isopropyl alcohol molecules are knocked off, creating a coordinative insaturation at the Mg center. As a result the compound undergoes a structural change, giving rise to new Mg-Al species such

Figure 2. Molecular structures of [MgAl<sub>2</sub>(OPr<sup>i</sup>)<sub>8</sub>(Pr<sup>i</sup>OH)<sub>2</sub>] (a) and [MgAl<sub>2</sub>(OBu<sup>t</sup>)<sub>8</sub>] (b), precursors to MgAl<sub>2</sub>O<sub>4</sub>.

as [Mg<sub>2</sub>Al<sub>3</sub>(OPr<sup>i</sup>)<sub>13</sub>], which do not possess the Mg:Al ratio ideal for MgAl<sub>2</sub>O<sub>4</sub> [263]. The problem of thermal instability can be overcome by replacing the isopropoxide ligands with bulkier *tert*-butoxide ligands. The *tert*-butoxide derivative, [MgAl<sub>2</sub>(OBu<sup>t</sup>)<sub>8</sub>] [319], contains no coordinated alcohol molecules (Fig. 2b) and is thermally robust. In view of the above, it can be used in gas-phase reactions to obtain stoichiometric spinel films. However, the thermal stability acquired through the introduction of the bulky *tert*-butoxy ligands (–OC<sub>4</sub>H<sub>9</sub>) also imparts a low vapor pressure and higher organic contamination in the final material. This necessitates treatment at higher temperatures to remove the residual carbon content, however, only at the expense of grain growth. Such problems are typical in the chemical or molecular synthesis of materials and represent an area that has not been investigated from the viewpoint of (nano)materials chemistry. A probable solution would be a judicious choice of ligands and/or novel ligand combinations that undergo a clean stripping by intramolecular mechanisms, a strategy that is still not popular in the context of inorganic materials. The principles of organometallic chemistry permit the engineering of a *new generation* of precursors; the designed decomposition opens up new routes to high-purity nanomaterials at low temperatures.

### 3.1.2. Case II: Controlled Stoichiometry and Designed Ligand Elimination

This class of precursors is based on a controlled ligand elimination pathway. With the use of the principles of organometallic chemistry, the ligands or combination of ligands in the precursor is judiciously chosen so that stripping of the organic periphery, which is usually the source of contamination in MDN, is simple and clean (Eq. (3)).

In the case of Mg-Al heterometal alkoxide precursors discussed here, the modification of the precursor by the introduction of hydride or alkyl ligands uses the  $\beta$ -elimination pathway on the metal centers. For example, Kim et al. have synthesized alkyl-modified derivatives of the general formula [Mg( $\mu$ -OR)<sub>2</sub>AlMe<sub>2</sub>]<sub>2</sub> (R = Pr<sup>i</sup>, Bu<sup>i</sup>) and successfully used them as single sources to deposit stoichiometric MgAl<sub>2</sub>O<sub>4</sub> films on Si(001) substrates [263]. Both of the precursors are much more volatile than MgAl<sub>2</sub>(OR)<sub>8</sub> compounds; Mg[( $\mu$ -O<sup>i</sup>Pr)<sub>2</sub>AlMe<sub>2</sub>]<sub>2</sub> can be vapor-transported at room temperature, whereas Mg[( $\mu$ -O<sup>i</sup>Bu)<sub>2</sub>AlMe<sub>2</sub>]<sub>2</sub> should be heated to 60 °C. Veith et al. have designed a more elegant

strategy in which the terminal alkoxide ligands on Al centers were replaced by hydride ligands [320] to obtain a hydride-modified Mg-Al *tert*-butoxide,  $[\text{MgAl}_2\text{H}_4(\text{O}i\text{Bu}^t)_4]$ . As a consequence of the drastic reduction in the molecular weight, an enhanced volatility is observed for the modified precursors ( $[\text{MgAl}_2(\text{O}i\text{Bu}^t)_8]$ , 100 °C;  $[\text{MgAl}_2\text{Me}_4(\text{O}i\text{Bu}^t)_4]$ , 60 °C;  $[\text{MgAl}_2\text{H}_4(\text{O}i\text{Bu}^t)_4]$ , 45 °C).

Both modification schemes are based on the abstraction of  $\beta$ -hydrogen (by an incipient carbanion) from the alkoxy group to eliminate methane ( $[\text{MgAl}_2\text{Me}_4(\text{O}i\text{Bu}^t)_4]$ ) or dihydrogen ( $[\text{MgAl}_2\text{H}_4(\text{O}i\text{Bu}^t)_4]$ ) and isobutene (Eq. (4)). This phenomenon is well established in organometallic chemistry and has been exploited for the deposition of ZnO and MgO from methyl zinc alkoxide and methyl magnesium alkoxide, respectively [233]. Figure 3 shows the ligand elimination mechanism operative in the alkyl- and hydride-modified Mg-Al alkoxides. The on-line mass spectral analysis performed during the chemical vapor deposition of  $[\text{MgAl}_2\text{H}_4(\text{O}i\text{Bu}^t)_4]$  revealed isobutylene and dihydrogen to be the only volatile by-products. Veith et al. verified further the proposed mechanism by investigating the thermal decomposition of deuterated compound,  $[\text{MgAl}_2\text{D}_4(\text{O}i\text{Bu}^t)_4]$  [320]. The observation of a new peak at  $m/z = 3$  instead of the peak due to molecular hydrogen ( $m/z = 2$ ) confirmed the abstraction of  $\beta$ -hydrogen by the terminal deuteride ligands, resulting in the formation of HD. The above example illustrates that a careful selection of ligands can be used to design the decomposition behavior of the precursor compound. Since all of the thermolysis products are volatile organic compounds, "organic-free" nanomaterials can be obtained at low temperatures.

### 3.1.3. Case III: Single-Step Formation of Multiphase Materials

This class of precursors represents a rather new strategy where two discrete solid phases can be obtained from a single molecular species. This approach uses precursors with unusual stoichiometry or oxidation states. In the first case, the driving force is often the phase separation from a metastable matrix to give two or more thermodynamically stable phases, whereas the disproportionation of a

**Figure 3.** Ligand elimination mechanism in hydride- and alkyl-modified Mg-Al *tert*-butoxides.

metastable precursor is responsible, in the latter case, for the formation of a composite material. The thermolysis of alkyl silicon alkoxides ( $\text{R}_x\text{-Si}(\text{OR})_{4-x}$ ) to produce SiC/SiO<sub>2</sub> composite or that of  $\text{LaAl}_3(\text{OPr}^i)_{12}$  to form  $\text{LaAlO}_3/\text{Al}_2\text{O}_3$  belongs to the first category, whereas the disproportionation of a Cu(I) precursor to give Cu(0) and Cu(II) species from a single source exemplifies the second category. Since these composites originate from a single chemically homogeneous source, the different phases are homogeneously interdispersed, and it is possible to control their three-dimensional structures and the grain sizes of the individual phases.

For instance, the Mg-Al isopropoxide,  $[\text{Mg}_2\text{Al}_3(\text{OPr}^i)_{13}]$  (Fig. 4), which can be prepared in good yield by reacting Mg and  $\text{Al}(\text{OPr}^i)_3$  in refluxing isopropyl alcohol [317], serves as a unimolecular source to obtain a biphasic oxide-oxide composite of composition  $\text{MgAl}_2\text{O}_4/\text{MgO}$  [321]. The X-ray powder diffractogram of the oxide-oxide nanocomposite

obtained from the above precursor shows that both phases are crystalline (Fig. 5). The TEM image revealed a homogeneous biphasic material in which MgO grains are evenly dispersed in a nanocrystalline matrix of spinel particles.

The current interest in the design of nanomaterials at the molecular scale is largely driven by the ability of chemical methods to permit the control of size, shape, and purity, which ultimately influence the final properties of the nanomaterials. In this context, the use of SSPs is highly favored to achieve an atomic-scale mixing of the elements in target nanomaterial. The concept of using a single molecular source or a molecular building block is derived in principle from biomolecular, supramolecular, or polymeric structures where a repetitive arrangement of one or more fundamental structural units can lead to novel architectures and properties [33]. However, for inorganic materials, the molecular

**Figure 4.** Molecular structure of  $[\text{Mg}_2\text{Al}_3(\text{OPr}^i)_{13}]$ . Reprinted with permission from [317], J. A. Meese-Marktscheffel et al., *Chem. Mater.* 5, 755 (1993). © 1993, American Chemical Society.

**Figure 5.** XRD pattern of  $\text{MgAl}_2\text{O}_4/\text{MgO}$  nanocomposite obtained from  $[\text{Mg}_2\text{Al}_3(\text{OPr})_{13}]$  precursor.

building units are intermediates between the extended network and the atoms forming it. Attention is paid to the connectivity between the elements that should be present in the final material after all of the processing steps have been performed. In other words, the molecular precursor for MDN provides intermediate control of the process of formation of large structures.

Some of the salient features and promises of the single molecular source approach are (i) the possibility of tuning the metal and organic contents in a molecule according to the requirements of the material; (ii) low decomposition/crystallization temperatures, since the metals are already mixed on a molecular scale and no diffusion of ions is necessary; and (iii) ultrahigh purity of the resulting ceramics or composites because of the neat decomposition processes that can be tuned by the appropriate ligand elimination mechanism. In addition, the use of a single molecular species avoids phenomena like preferential hydrolysis or crystallization during solution processing and selected pyrolysis of one of the constituents in thermolysis reactions, which are typical features of a multisource synthesis. A large number of chemical compounds belonging to different organometallic groups have been exploited to obtain solid materials of different compositions. The main classes of precursors used in (nano)material synthesis are presented in Table 5.

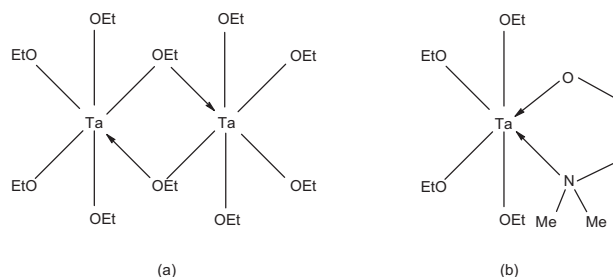

One of the major advantages of using metal-organics in processing new materials is the flexibility of varying both the organic and metallic parts of the molecular source. In the case of metal alkoxides, a common problem is their propensity to expand the coordination number at the metal center, either by intermolecular association (oligomerization) or by reaction with adventitious water or oxygen [45, 49–51, 322–326]. This adversely affects their properties, such as volatility, which is an important feature for their easy transport in the gas phase. A simple approach to preventing this is to modify the alkoxide precursor with chelating or donor functionalized ligands, that produces species with coordinatively saturated metal centers. Jones et al. have shown that dimeric Nb and Ta alkoxides can be modified by alkoxide groups containing one donor function, such as dimethyl

**Table 5.** Commonly used precursors<sup>a</sup> in the synthesis of (nano)-materials.

aminoethoxide ( $\text{OCH}_2\text{CH}_2\text{NMe}_2$ ), to obtain monomeric species (Scheme 5) with a 10-fold increase in the vapor pressure ( $\text{Ta}_2(\text{OEt})_{10}$ , 0.075 torr/108 °C;  $\text{Ta}(\text{OEt})_4(\text{OCH}_2\text{CH}_2\text{NMe}_2)$ , 0.75 torr/108 °C) [327]. Furthermore, multidentate ligands can be used to modify the reactivity of alkoxide precursors, for example, by decreasing the number of hydrolyzable (terminal) ligands. The modification of ligand sets not only alters the physical and chemical properties of the precursor systems, but also seems to have a pronounced influence on the properties of the resulting materials. Boyle et al. have investigated the densification behavior of  $\text{TiO}_2$  films obtained with the use of various carboxylic acid-modified titanium alkoxides in a sol-gel process. The structure of the Ti–O framework depends on the steric bulk of the ligands and the  $\text{Ti}(\text{OR})_4/\text{carboxylic acid}$  ratio [328]. The results indicate that small nuclearity clusters favored fully dense materials, which illustrates the relationship between precursor structure and final film properties. If the modification of precursor is achieved with polymerizable organic ligands such as methacrylic acid or methyl methacrylate, clusters capable of undergoing polymerization or cross-linking reactions are obtained. Such organically modified clusters entail a synergetic combination of the properties typical of each of the constituents, giving rise to the class of inorganic-organic hybrid materials [329].

**Scheme 5.**

Another significant advantage of the molecular precursor approach is the production of metastable materials. Since the molecule-to-material transformations operate far from equilibrium conditions, kinetically rather than thermodynamically favored products are formed. Barron et al. have shown that the easy formation of metastable cubic GaS is determined by the cubane structure of the precursor compound,  $[(t\text{Bu})\text{GaS}]_4$ , which is preserved under MOCVD conditions. The structure of the precursor was determined and found to be identical at 25 and 250 °C by single-crystal X-ray diffraction and gas-phase electron diffraction studies [149, 330]. Their work on several other gallium thiolates and selenolates is an elegant effort to elucidate the role of precursor structure in determining the phase of the material. The different GaS compounds (Scheme 6) were found to produce different solid-state phases in the films deposited by their chemical vapor deposition), which may be related to the symmetry of the core structures. For example, chemical vapor deposition) of the dimer  $[(\text{Bu}')_2\text{Ga}(\text{SBU}') ]_2$  (I), possessing a  $\text{Ga}_2\text{S}_2$  core of  $C_{2v}$  symmetry, yields poorly crystalline hexagonal GaS. On the other hand, the highly symmetrical  $\text{Ga}_4\text{S}_4$  core of  $[(t\text{Bu})\text{GaS}]_4$  (II) provides a template for a high-symmetry solid phase (cubic GaS). In a similar manner, the lack of any but  $C_3$  symmetry in heptameric  $[(t\text{Bu})\text{GaS}]_7$  (III) should result, if the core is retained during the deposition, in an amorphous film. The  $\text{Ga}_7\text{S}_7$  core of  $[(t\text{Bu})\text{GaS}]_7$  has a  $C_3$  axis with no possibility of ordered close packing. Thus, during CVD a random array of Ga and S atoms is incorporated into the film. Indeed, an amorphous film is obtained when  $[(t\text{Bu})\text{GaS}]_7$  is used in the MOCVD process [18].

Scheme 6.

Furthermore, the SSPs can facilitate the formation of those ceramic materials (e.g., nitrides) whose syntheses are severely constrained by the reaction conditions. Transition metal nitrides possess free energies of formation that are extremely less favorable than corresponding oxides, principally because of the tremendous strength of the  $\text{N}=\text{N}$  bond ( $227 \text{ kcal mol}^{-1}$ ) relative to  $\text{O}_2$  ( $119 \text{ kcal mol}^{-1}$ ). Consequently, the preparation of  $[\text{MN}_n]$  from the respective elements is entropically disfavored at the high temperatures necessary to ensure sufficient diffusion rates. In this case, the metal amides, given the covalent nature of metal–nitrogen bonds, act as convenient SSPs to obtain metal nitride phases at low temperatures.

Given the importance of molecular chemistry routes in the synthesis of nanomaterials, the challenge is to develop synthetic rationales for a customized assembly of molecular building blocks from the fundamental components (metals and ligands) that would facilitate a prefabrication of suitable precursor to any desired nanomaterial. However, it

would be overly simplistic to assume that a single molecular source is the only structure from which target material can be obtained. Given the versatility and development of synthetic chemistry, the range of potential molecular structures that can be used to obtain new materials and nanomaterials appears to be unlimited. A major bottleneck in this regard is the fact that molecular control of materials is not a predictive science, and it is difficult to anticipate the phase structure of the resulting solid from the knowledge of the precursor design. Most of the work performed to demonstrate the strength of molecular chemistry methods in achieving better control over the phase purity and composition of the materials is based on an explanation with hindsight, achieved after the experiment was concluded. In this context, there is an urgent need to develop an understanding of the precursor–material relationship based on the mechanism of precursor decomposition and the structural and chemical factors that govern (or disfavor) molecular control over the process of material formation. The ability to answer the question, Can the molecular structure of the precursor species influence the phase of the final solid product? is the driving force for the current quest for SSPs to nanoscale materials.

Despite the potential advantages of metal–organic precursors as molecular sources for the low-temperature synthesis of nanomaterials, their application to most of the materials is limited because of the unavailability of compounds containing all of the phase-forming elements in a single source. In most of the cases, the selection of a suitable precursor is dictated by the requirements of the material and the synthesis methods. Subject to the processing conditions (solid, solution, or gas phase), the inherent properties of the precursor can impose limitations on the building-block approach. For example, the pyrophoric nature, poor solubility, and extremely low vapor pressure of a compound can limit its application in solid-state, liquid, and gas-phase synthesis, respectively. The other related and equally important parameters are the stability of the molecular framework and stoichiometry of the cations. The fact that the construction of metal–organic species (e.g., alkoxides, amides, metal–metal bonded clusters, etc.) is based on the principles of charge neutrality and electron count limits the choice when precursors to nonstoichiometric compounds or doped materials are sought.

To understand what precursor chemistry implies, the isolation and characterization of preceramic aggregates are necessary, because similar molecular building blocks can arrange themselves in different ways to produce compounds with different metal stoichiometries. For example, heterometal alkoxides are invariably formed in a mixture of constituent alkoxides; however, a simple mixing of two alkoxides,  $\text{M}(\text{OR})_x$  and  $\text{M}'(\text{OR})_y$ , is no guarantee of the formation of a single precursor species  $\text{MM}'(\text{OR})_{x+y}$  mainly due to the structure potential (I, II, and III, Scheme 7) of alkoxide ligands. As a result, in addition to the desired precursor, several other compounds may be present in an uncharacterized precursor mixture, depending upon the chemical requirements of the individual components and reaction conditions. For example, Ba and Zr(Ti) alkoxides can combine in different ways to produce mixed-metal Ba–Zr(Ti) clusters with different structures and metal ratios [331]. Of course, the

formation of a particular framework is subject to the chemical nature (neutral or anionic) and steric profile of the ligands. Some examples of alkoxide clusters based on different Ba:Zr(Ti) ratios are shown in Figure 6. As a consequence of this combinatorial effect, the synthesis of BaZrO<sub>3</sub> from a mixture of Ba and Zr precursors was associated with traces of Ba and Zr phases or their products in the final ceramic material, whereas BaZrO<sub>3</sub> could be selectively synthesized from the single-source Ba-Zr precursor [BaZr(OH)(OPr<sup>i</sup>)<sub>5</sub>(Pr<sup>i</sup>OH)<sub>3</sub>]<sub>2</sub> (Eqs. (7) and (8)) [332].

Scheme 7.

To act as a suitable chemical source for material synthesis, the precursor compound should fulfill a set of requirements. The basic criteria for designing and synthesizing a metal-organic precursor are

- Simple and scalable synthesis
- High purity and purifiability by sublimation or distillation
- Easy handling and long shelf life
- Clean decomposition behavior

**Figure 6.** Molecular structure of different Ba-Zr(Ti) alkoxide clusters: (a) [BaZr<sub>2</sub>(OBU<sup>i</sup>)<sub>10</sub>] (Ba:Zr = 1:2), (b) [Ba<sub>2</sub>Zr(OBU<sup>i</sup>)<sub>8</sub>(HOBU<sup>i</sup>)<sub>2</sub>(THF)] (Ba:Zr = 2:1), (c) [BaTi<sub>3</sub>(OPr<sup>i</sup>)<sub>14</sub>] (Ba:Ti = 1:3) and (d) [BaZr(OPr<sup>i</sup>)<sub>5</sub>(OH)(HOPr<sup>i</sup>)<sub>3</sub>]<sub>2</sub> (Ba:Zr = 1:1). Reprinted with permission from [23], M. Veith, *J. Chem. Soc., Dalton Trans.* 2405 (2002). © 2002, Royal Society of Chemistry.

- Must not form stable residues
- Decomposition at low temperatures
- No(?) chemical hazards (nontoxic and noncorrosive by-products).

In addition to the above attributes, metal-organics should meet the following requirements to be SSPs:

- Appropriate element ratio compatible with the target material
- Sufficient stability of the molecular framework to survive different experimental conditions (e.g., thermolysis and hydrolysis)
- Low molecular weight and low nuclearity to achieve acceptable vapor pressure
- Predefined reaction/decomposition chemistry
- Minimum heteroatom content in the ligands used to build or stabilize the molecule.

Further properties of a “tailor-made” precursor are subject to the nature and condition of the processing methods. These specific criteria, for example, can be high vapor pressure, a large temperature window between evaporation and decomposition, and thermal lability for the methods involving gas-phase decomposition, whereas high solubility, stability in solution (no dissociations or rearrangements), and high reactivity are of interest for solution-based transformation. It must be pointed out that all of these conditions are seldom met in a single molecular species, and the quest for an “ideal” precursor is responsible for the rapidly increasing chemistry–material science interface.

Although a wealth of information on the synthesis and characterization of inorganic molecular derivatives is available, a continuous input based on new synthetic principles and reaction chemistry is desired to discover a provisional and plausible sequence of transformation that will convert a starting configuration (molecular precursor) into the desired final state (nanomaterial). The current approach of using molecular building blocks to grow nanomaterials is backward chaining, where the role of precursor chemistry in determining the structure and purity of the synthesized material is analyzed in a retrosynthetic manner. The concept of designing molecular precursors to mimic and act as preforms for known solid-state structures is still in its infancy and needs a systematic exploration to elucidate the potential of this methodology in terms of obtaining device-quality materials with improved performance when compared with materials obtained by conventional routes. Furthermore, the diversity of molecular structures and structural motifs available to synthetic chemists acts as a pointer for future research dealing with the synthesis of inorganic materials with unusual structures, new compositions, and possibly unknown properties.

#### 4. METHODS FOR MOLECULE-TO-MATERIAL TRANSFORMATION

The chemical methods commonly applied to the synthesis of nanomaterials involve reactions in different phases: solid (mechanical attrition, mechanochemical synthesis,

sonochemical treatment), solution (sol-gel, coprecipitation, hydrothermal synthesis, electrochemical, micro(nano)-emulsion and polymeric precursor methods), and gas (chemical vapor deposition, aerosol synthesis, atomic layer deposition). The methods described in the following section are only a subset of the wide variety of chemical routes being investigated for the preparation of nanomaterials. The underlying criterion for the selection of these chemical methods is the fact that either they rely on the availability of molecular chemical compounds as precursors or the inherent advantages of the method(s) are fortified by the use of metal-organic precursors. There has been no attempt to be comprehensive, but we have tried to provide an overall picture of the developments in material synthesis from chemical methods.

#### 4.1. Sol-Gel Process

The sol-gel technique refers to a room-temperature chemical route that is used for preparing oxide materials by the hydrolysis of metal-organic compounds (particularly metal alkoxides) carried out under controlled pH, amount of water, and alkoxide concentration [333]. The process involves initially a homogeneous solution of metal alkoxide derivatives such as  $M(OR)_x$  or  $MM'(OR)_{x+y}$ , which is “activated” by a careful hydrolysis to initiate inorganic polymerization reactions that produce species containing M–O–M or M–O–M’ linkages [194]. The fundamental reaction in the hydrolysis of metal alkoxides is a nucleophilic substitution ( $SN^2$ ) that involves a nucleophilic addition of an  $OH^-$  group to the electrophilic metal center ( $M^{+\delta}$ ). As a result, the coordination number of the metal atom is increased in the transition state, which leads to the migration of a proton toward an alkoxy group, consequently knocking off the protonated ROH ligand (Scheme 8).

Scheme 8.

The metal species bearing a terminal hydroxy group react with other species in the solution to form oligomeric structures linked by oxo- or hydroxo- ligands, which can be transformed into polymeric gels by aging. The polymerization reactions and the subsequent drying and thermal treatments result in the elimination of water (oxolation) and alcohol (alcoholation) to finally produce a solid material (Scheme 9). These modified molecular entities arrange themselves via hydrolysis and cross-condensation reactions

to form oxo- or hydroxo-macromolecular networks, thus favoring the gelation process.

Scheme 9.

The stage where the molecular structure of the precursor is no longer reversible is called a sol-gel transition. The gel is an elastic solid filling the same volume as the solution; it shrinks upon drying to give a rigid oxide skeleton with interconnected porosity that can be tailored in terms of size, shape, and volume. The natural drying of gels results in xerogels, whereas removal of the solvent under hypercritical conditions (without disturbing the gel structure) produces aerogels [334]. A schematic representation of the various steps of the sol-gel processing is given in Figure 7.

The partially hydrolyzed alkoxides can be viewed as molecular building blocks for the development of sol (particulate) or gel (polymeric), which can be used to obtain films by spin- or dip-coating and spray methods. Modifying the alkoxide precursors with less hydrolyzable or polymerizable groups can chemically control the condensation reactions [37, 335, 336]. Finally, the chemical reactivity of metal alkoxides toward nucleophilic reactions mainly depends on the strength of the nucleophile, the electrophilic character of the metal atom (an electronegativity-related property characterized by the positive charge on the metal atom), and its ability to increase the coordination number  $N$ : the degree of unsaturation at the metal center can be simply expressed by the difference  $N - Z$ , where  $N$  is the coordination number usually found in the oxide and  $Z$  is the oxidation state. A comparison of these values for some tetravalent metal alkoxides is made in Table 6. The above facts underline the critical role of the precursor chemistry when materials are

Figure 7. Various steps of sol-gel processing starting from a molecular alkoxide.

**Table 6.** A comparison of electronegativity, ionic radius, and preferred coordination number in some tetravalent metal alkoxides.

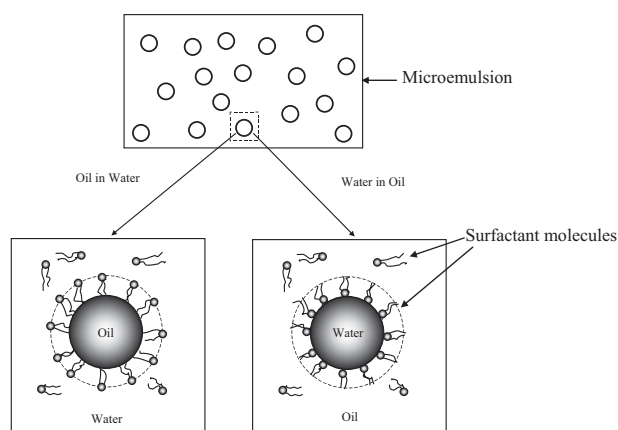

Alkoxide	Electronegativity ( $\chi$ )	Ionic radius ( $\text{\AA}$ )	Oxide	$N$	$N - Z$
$\text{Si}(\text{OPr}^i)_4$	1.74	0.40	$\text{SiO}_2$	4	0
$\text{Sn}(\text{OPr}^i)_4$	1.89	0.60	$\text{SnO}_2$	6	2
$\text{Ti}(\text{OPr}^i)_4$	1.32	0.64	$\text{TiO}_2$	6	2
$\text{Zr}(\text{OPr}^i)_4$	1.29	0.87	$\text{ZrO}_2$	7	3
$\text{Ce}(\text{OPr}^i)_4$	1.17	1.02	$\text{CeO}_2$	8	4

synthesized from chemical methods, but at the same time it offers the possibility of chemical control over the molecule-to-material transformation process.

The main advantages of sol-gel processing are easy control over the microstructure of the material from the earliest stages of the processing, higher purity, low or high porosity, and greater homogeneity. In addition, it allows facile synthesis of homogeneously doped systems, biphasic nanocomposites [337, 338]. In terms of economic potential, net-shape casting, extrusion, and coatings on large and complex surfaces are the major engineering advantages [194]. On the other hand, the long processing times, costs of the precursors, large shrinkage, production of volatiles, and fragmentation of the green body due to internal stresses are some of the limitations associated with this technique.

## 4.2. Microemulsion Technique

Microemulsions are transparent, isotropic dispersions of oil and water (two immiscible liquids) stabilized by the presence of carefully adjusted emulsifier(s) (surfactant molecules that can be cationic, anionic, or neutral), which are located at the interfaces between oil and water domains [339] (Scheme 10).

**Scheme 10.**

These systems are clear and thermodynamically stable, and they are prized for their stability and small particle size. The use of microemulsion technique in the synthesis of nanoparticles is based upon the use of two nonmiscible phases homogenized with the help of surface-active agents, ligands, and/or polymers, for assisting the growth of nanocrystals in small water droplets homogeneously entrapped in a hydrocarbon solvent. The most common examples are the water-in-oil (W/O) and the oil-in-water (O/W) micro-emulsions, as

shown in Scheme 10. The important properties are governed mainly by the water-to-surfactant molar ratio. Typically, the droplets are spherical and have a small polydispersity, in terms of size. The radii of the drops are usually one to four times the thickness of the surfactant film.

The reverse micelle technique is suitable for tailoring small and uniform nanoparticles of discrete nanoscaled oxides or hydroxides with controlled size distribution ( $<10$  nm) [244, 340–351]. The principal advantage of the method is that the concentration of metal-organic in the water droplets is very high, so that the reaction easily forms particles that are gelled throughout. This method has been used to prepare spherical submicrometer particles of titania, zirconia, and alumina [352]. However, a controlled formation of oxide materials is subject to the reactivity of the starting material with water and the reaction parameters, which actually determine the size and agglomeration effects in the final powder. As a consequence, the results can be different for similar precursors. For example, in the microemulsion-based hydrolysis of titanium, alkoxides have yielded uncontrolled aggregation and flocculation [353]; however,  $\text{TiO}_2$  particles with diameters less than 10 nm were prepared by controlled hydrolysis of titanium iso-propoxide in reverse micelles of sodium bis(2-ethylhexyl)sulfosuccinate-hexane-water [354]. Similarly, transition metal aluminum heterometal alkoxides of the general formula  $\text{MAI}_2(\text{OR})_8$  have been successfully used to perform a size-selective synthesis of nanocrystalline  $\text{MAI}_2\text{O}_4$  spinels (Scheme 11).

**Scheme 11.**

The emulsion method provides a physical means of controlling particle size and shape while still exploiting the advantages of sol-gel processing. The principal limitation of emulsion methods is that the emulsion structure is not at thermodynamic equilibrium and should be stabilized by the addition of surfactants that lower the interfacial tension between the phases and decrease the rate at which the droplets coalesce. Furthermore, the surfactant molecules have large molecular weights, and even a small amount of unremoved (uncracked) surfactant can result in significant organic contamination in the ceramic material.

## 4.3. Colloidal and Polymeric Routes

A well-known approach to the synthesis of multicomponent oxide powders is based on Pechini-type methods where the metal ions present in an aqueous solution are complexed with the help of organic ligands to form polybasic chelates [355–357]. This method generally allows for the use of readily available reagents such as oxides, carbonates, or nitrate as cation sources, with the added advantage that it requires no special apparatus or atmosphere control. The commonly used ligands are  $\alpha$ -hydroxycarboxylic acid (e.g., citric acid,

$\text{HOC}(\text{CH}_2\text{COOH})_2\text{-COOH}$ ). The polyhydroxy-metal complex, when treated with a polyfunctional alcohol (e.g., ethylene glycol,  $\text{HOCH}_2\text{CH}_2\text{OH}$ ), undergoes a polyesterification reaction with the concurrent formation of a water molecule and the formation of a mixed-cation precursor (Fig. 8).

A number of variations of this methodology are used to obtain stoichiometric powders, with the use of different chelating reagents like citric acid, tartaric acid, glycol, acrylic acid, etc. The common idea is to achieve an atomistic distribution of the cations within the polymer resin. The utility of the method relies on the chemical bonding of the cations to the polymer chains (Fig. 8). It is assumed that various cations are homogeneously mixed with little or no segregation of the components, and the rigid transparent glassy mass is a “single” preceramic precursor [356]. The organic molecules used as a complexing aid not only function as chelating agents and a resin vehicle but also provide combustion heat for calcinations; however, excess organic content can have a negative effect by raising the temperature too high during calcination. Moreover, the composition of the polymeric precursor is important for the final agglomerate morphology and particle size because when compared with a dense resin, a foamy, voluminous precursor is expected to produce loosely bound aggregates. Although these methods claim the advantages of molecular-level mixing and the formation of mixed-metal polymeric precursors, evidence is not always available. However, the characterization of a Ba-Ti precursor to  $\text{BaTiO}_3$  (Pechini method) by  $^{13}\text{C}$  NMR spectroscopy indicates that the coordination of Ba and Ti in the mixed-metal complex remains unchanged at both solution and resin stages. Nevertheless, this approach represents a low-temperature route to multicomponent material. For example, nanocrystalline yttrium aluminum garnet

**Figure 8.** Illustration of the formation of mixed-cation precursor in Pechini-type processes.

( $\text{Y}_3\text{Al}_5\text{O}_{12}$ ) could be obtained at  $1000\text{ }^\circ\text{C}$ , compared with the  $1600\text{ }^\circ\text{C}$  required for the solid-state reaction [358–360]. In another example, the refractory mixed oxide calcium aluminate ( $\text{CaAl}_2\text{O}_4$ ) was prepared in high purity at  $900\text{ }^\circ\text{C}$ , whereas the solid-state reaction between calcia ( $\text{CaO}$ ) or calcium carbonate ( $\text{CaCO}_3$ ) requires temperatures in excess of  $1400\text{ }^\circ\text{C}$  to complete the reaction, which still contains undesirable  $\text{CaAl}_4\text{O}_7$ ,  $\text{Ca}_{12}\text{Al}_{14}\text{O}_{33}$ , and unreacted starting materials [361]. Further advantages of the Pechini-type synthesis are the ability to prepare complex compositions, homogeneous mixing of the cations, and easy scalability.

Another strategy for the *in-situ* formation of single molecular species as precursors utilizes the complexing abilities of triethanol amine ( $\text{N}(\text{C}_2\text{H}_4\text{OH})_3$ ) and ethylene glycol ( $\text{C}_2\text{H}_4(\text{OH})_2$ ). This concept has been put forward as an inexpensive alternative to metal-organic precursors but is similar to the Pechini-type methods; the molecular structure of these alkoxide precursors remains ambiguous because of the lack of appropriate characterization. For example, Laine et al. have synthesized a precursor to Mg-Al spinel [362, 363] by heating  $\text{Al}(\text{OH})_3$ ,  $\text{MgO}$ , and a stoichiometric amount of  $\text{N}(\text{C}_2\text{H}_4\text{OH})_3$  in ethylene glycol. A plausible ionomer-like structure (Fig. 9) based on the mass spectral and NMR data [362] was proposed for the precursor compound wherein magnesium ion is encapsulated by a TEA molecule bridging two alumatrane units [364]. Following this approach, single precursors to mullite ( $\text{Al}_6\text{Si}_2\text{O}_{13}$ ) and cordierite ( $\text{Mg}_2\text{Al}_2\text{Si}_5\text{O}_{18}$ ) have been developed and used to synthesize high-purity phases [362].

The other commonly used solution method for the synthesis of multicomponent oxide ceramics is coprecipitation reactions producing a “mixed” precipitate comprising two or more insoluble species that are simultaneously removed from solution. The precursors used in this method are mostly inorganic salts (nitrate, chloride, sulfate, etc.) that are dissolved in water or any other suitable medium to form a homogeneous solution with clusters of ions. The solution is then subjected to pH adjustment or evaporation to force those salts to precipitate as hydroxides, hydrous oxides, or oxalates [365–367]. A careful control of pH is important for achieving a quantitative precipitation because the precipitating species is a product of the neutralization reaction between the inorganic precursor and the base. The crystal growth and their aggregation are influenced by the concentration of salt, temperature, the actual pH, and the rate of pH change. After precipitation, the solid mass is collected, washed, and gradually dried by heating to the boiling point of the medium. The washing and drying procedures applied for coprecipitated hydroxides affect the degree of agglomeration in the final powder and must be considered

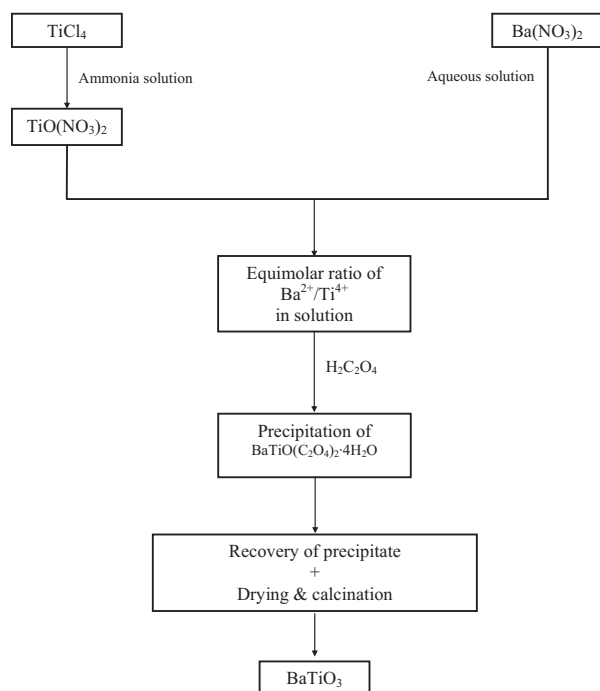

**Figure 9.** Proposed arrangements of cations in the trane precursor to  $\text{MgAl}_2\text{O}_4$  (adapted from [362]).

when nanosized powders are the intended product. Generally, a calcination step is necessary to transform the hydroxide into crystalline oxides. Although the precipitate is not structurally characterized, the association of ions to form mixed-metal hydroxides (e.g.,  $\text{MgAl}_2(\text{OH})_8$  for  $\text{MgAl}_2\text{O}_4$ ) offers the advantages of molecular-scale mixing of the components. This strategy is a commercially viable alternative method for obtaining high-quality oxide powders; however, the method is plagued by the problems of contamination due to anionic ligands (halides, nitrates, etc.), which are detrimental to the material properties if not removed during the calcination steps. In addition, an incomplete precipitation of one of the ions can lead to phase segregation or non-stoichiometric products. In most of the binary, ternary, and quaternary systems, a crystallization step is necessary, which is generally achieved by calcinations or, more elegantly, by a hydrothermal procedure in high-pressure autoclaves.

A large number of reports are available on the synthesis of ultrafine oxide powders ( $\text{Fe}_3\text{O}_4$  [368],  $\text{ZrO}_2$  [369],  $\text{BaTiO}_3$  [340],  $\text{NiTiO}_3$  [370],  $\text{MnFe}_2\text{O}_4$  [371],  $\text{ZnAl}_2\text{O}_4$  [372], oxide-oxide composites  $\text{CeO}_2/\text{ZrO}_2$  [373], and bio-material  $[\text{Ca}_5(\text{PO}_4)_3(\text{OH})_2$  [374]) by coprecipitation reactions. Nanocrystalline yttria-stabilized zirconia (grain size < 100 nm), consolidated and sintered to a nanostructured ceramic has been prepared by coprecipitation reactions [375]. Figure 10 shows the scheme employed to produce  $\text{BaTiO}_3$  nanopowders from a barium titanate oxalate precursor,  $\text{BaTiO}(\text{C}_2\text{O}_4)_2 \cdot 4\text{H}_2\text{O}$ .

The advantages of coprecipitation reactions are (i) the homogeneity of component distribution, (ii) the relatively low reaction temperature, (iii) the fine and uniform particle size with weakly agglomerated particles, and (iv) the low cost. However, these reactions are highly susceptible

**Figure 10.** A schematic of various steps involved in the preparation of  $\text{BaTiO}_3$  by a coprecipitation technique.

to the reaction conditions, and, because of incomplete precipitation of the metal ions, control over the stoichiometry of the precursors is rather difficult to achieve. In addition, the coprecipitation reactions are not suited for certain oxides/hydroxides, for instance, in the case of amphoteric systems.

#### 4.4. Solvothermal Synthesis

Solvothermal processes can be defined as chemical reactions or transformations in a solvent under supercritical conditions [36, 376]. The specific physico-chemical properties of solvents near such a pressure-temperature (100 MPa, 300 °C) domain can markedly improve the diffusion of chemical species [377]. These processes are used to synthesize new materials (meta-stable phases) as well as to develop new processes for obtaining functional materials and the shaping of materials, for example, monodispersed nanosized particles [378–380]. Although water is largely used as the reaction medium (hydrothermal synthesis) in most solvothermal reactions, several nonaqueous solvents (e.g., ammonia, hydrazine, alcohols) have been investigated for the preparation of different materials [381]. The first step of a hydrothermal reaction is either a sol-gel precipitation or a coprecipitation process, the precursors mostly being alkoxides, nitrates, chlorides, or sulfates, which are first dissolved in a suitable medium or water to form a homogeneous solution. Typically, sol-gel or coprecipitation-derived precipitates are amorphous in nature, which are hydrothermally treated in Teflon-lined steel autoclaves at constant temperature to induce crystallization (Scheme 12). Finally, the crystallized powders are repeatedly washed and dried at room temperature. Hydrothermal synthesis does not require expensive precursors and apparatus. Moreover, it is possible to predict the optimum synthesis conditions by theoretical methods based on electrolyte thermodynamics. One of the peculiar advantages of the hydrothermal synthesis is that besides the synthesis of inorganic materials, it is also possible to synthesize new crystalline precursors that can be structurally characterized. For example, a new hydroxo-stannate,  $\text{Sr}_2\text{Sn}(\text{OH})_8$ , has been obtained from hydrothermal studies of the  $\text{SrO-SnO}_2$  system. The compound acts as a single source for  $\text{SrSnO}_3$  (<700 °C) and  $\text{Sr}_2\text{SnO}_4$  (>900 °C) [382], subject to the thermal treatment.

**Scheme 12.**

Solvothermal methods offer a simple, direct, and low-temperature route for obtaining nanometric particles with narrow size dispersions and represent an alternative to calcinations for promoting crystallization under milder temperatures. Another feature of the hydrothermal treatment performed under near-supercritical conditions concerns the morphology of the materials that can be governed by monitoring temperature, pressure, reaction time, and the nature of the solvent. The easy access to the shaping of materials (crystal growth, preparation of fine microcrystallites) and low crystallization temperatures make hydrothermal synthesis an attractive method for producing submicrometer particles with a narrow size distribution, avoiding the firing steps required in sol-gel processing; however, interest in this method is limited compared with sol-gel methods. The drawbacks include the trial-and-error nature of the method to understand the chemical reactivity of supercritical fluids, which governs the course of the hydrothermal synthesis and consequently the composition, structure, and morphology of the nanomaterial. There are many experimental variables, like composition of the starting mixture (stoichiometric or not), choice of reagents, temperature, reaction time, and percentage fill of the reaction vessel. In addition, it remains difficult to predict the outcome of new reactions. Furthermore, observation of the reaction course is difficult because the reaction takes place in a sealed vessel. The future of hydrothermal processing for nanocrystal growth and materials synthesis requires lower pressure and temperature, which will facilitate *in-situ* observation of the reaction. Finally, the use of molecular compounds as stoichiometric synthons can substantially augment the advantages of solvothermal routes to produce nanopowders with high crystallinity and regular morphology.

#### 4.5. Chemical Vapor Deposition

The acronym MOCVD designates a gas-phase process in which metal-organic compounds (precursor) are converted into a solid film by their decomposition on a hot substrate [383–386]. In addition to the four important parameters (i.e., temperature, deposition time, pressure, and surface specificity), the chemical nature of the precursor substance is of paramount importance in determining the quality of the film in terms of homogeneity, morphology, and contamination. The film growth involves the conversion of atoms and/or molecules in the gas phase into atoms or molecules at the surface of the film, which can then be incorporated into it [52, 387]. This process takes place by adsorption of the gas-phase species on the substrate surface. Depending upon the interactions of the adatoms with the surface, the surface adsorption can be physical (essentially van der Waals interaction) or chemical (covalent linkage between the molecule and the surface) in nature. The adsorbed molecules may wander on the surface and react with other surface species to form the solid deposit. The mobility of surface species is largest on metallic and semiconducting surfaces, where bonding is not very directional. In the case of dielectrics, the highly directional covalent bonds tend to hold the chemisorbed molecules, thereby limiting their mobility. The volatile by-products released in the gas-phase decomposition, collision, and surface reactions can be removed in vacuum and

analyzed on-line by infrared spectroscopy or mass spectrometry to control the decomposition process as well as to elucidate the thermal decomposition of the precursor molecule. In a simplified view of the surface, it is assumed that there are a fixed total number of reactive sites upon which an incoming atom (“adatom”) or molecule can adsorb. Once a site is occupied, a second molecule will not adsorb on it. This is equivalent to the assumption that the number of atoms adsorbing is equal to those desorbing, if no reaction is taking place. The number of atoms or molecules adsorbing on the surface is proportional to the concentration of the gas-phase species or, in other words, equivalent to the partial pressure. Some of the fundamental processes occurring during the CVD of a metal-organic compound are depicted in Figure 11.

Since the conversion of an organometallic precursor to a useful thin film involves stripping most of the coordinated ligands, a well-understood decomposition chemistry is a prerequisite. The efficiency of the CVD process depends crucially on ligands that decompose by way of chemically productive pathways and with a low activation barrier. The precursors based on ligands with complex concomitant fragmentation reactions usually lead to the incorporation of heteroatoms such as C, B, N, O, or Si [383–386]. Furthermore, the intact vapor transport of the molecular precursor is highly essential to control over the process. The thermal instability or dissociative tendency of the precursor can initiate a cascade of reactions leading to nonideal geometry or undesirable deposits [305].

### 5. MOLECULAR CLUSTERS AS BUILDING BLOCKS TO NANOPARTICLES AND NANOSTRUCTURED FILMS

#### 5.1. One-Component Systems ( $E_x$ )

The nanoparticles (NPs) and nanostructured films of different metallic elements (Fe, Co, Ni, Cu, Ge, Ag, Au, Pd, Pt, Ru, etc.) have been the focus of intense research in recent years (Table 1) [12, 13, 386, 388]. A large number of methods have been devised for a controlled and size-tunable synthesis of colloidal nanoparticles. A variety of solution chemical methods such as laser pyrolysis and thermal

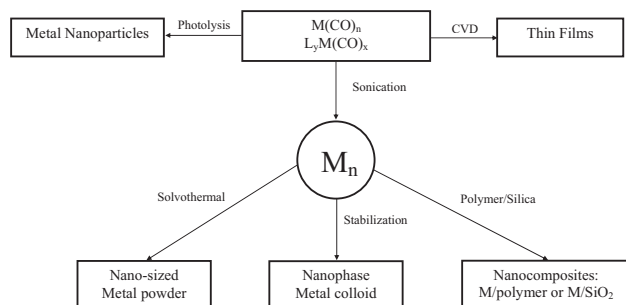

Figure 11. Fundamental processes active in the CVD process.

decomposition of organometallic compounds have recently been used to generate nanostructured materials [389, 390]. Fendler and Meldrum have reviewed the colloidal methods applied to generate nanostructured materials [391]. In terms of size selectivity and standardized procedures, this area has reached a certain level of maturity, due in particular to the large number of methods applied and efforts dedicated to the synthesis of monodisperse metal nanoparticles. However, the following section contains only selected examples that are related or show a close relevance to the scope of this article.

One general scheme for preparing nearly monodisperse (standard deviation, <5%) 3d transition metal nanoparticles relies on producing a single short nucleation event followed by slower growth on the nuclei formed. This is best achieved by introducing thermally unstable, zero-valent metal precursors, usually carbonyl compounds (e.g.,  $\text{Fe}(\text{CO})_5$ ,  $\text{Co}_2(\text{CO})_8$  [392, 393],  $\text{Ni}(\text{CO})_4$  for Fe, Co, and Ni NPs), into a hot solution containing colloidal stabilizers (Scheme 13) [394–396]. Alternatively, the metal precursors (e.g., acetates, halides) can be reduced by appropriate reagent (e.g., hydrides, polyols) to the elemental form [397, 398]. Metal carbonyls are interesting SSPs for the preparation of metallic nanoparticles and thin films (Table 1) because the metals within these compounds are formally in the zero-valent state and the departing CO ligand is by itself a stable noncondensable gas. For this reason, thermolysis, even in the absence of a reducing environment, can, in principle, produce high-quality metallic films or nanoparticles. The as-produced metal nanoparticles can be collected and consolidated to obtain nanopowders of metals. Alternatively, they can be capped with appropriate passivating agents to obtain stable colloids or can be incorporated within the pores of mesoporous organic or inorganic matrices to obtain composite materials (Scheme 13). Furthermore, a number of metal carbonyls are reasonably stable under ambient conditions and possess sufficient volatility to be transported in the vapor phase at relatively low temperatures. The volatility and stability of carbonyl compounds depend upon their nuclearity and can be altered through the stabilization of the metal center via donor ligands. Both simple and modified metal carbonyl precursors (Table 5) have been used in the CVD process to deposit metallic films of a huge number of metals (CVD BOOK).

Scheme 13.

Although the choice of metal precursor is commonly based on the ease of handling and ready availability of the starting material, a judicious choice may nevertheless affect the process parameters. For instance, the size of NPs in the case

of thermal or sonochemical reduction of metal sources can be controlled by adjusting the temperature and precursor-to-surfactant ratio, whereas the chemical reduction of metal ions (minimum two sources) is additionally subject to the influence of the concentration of the reducing agent and the kinetics of the reduction (e.g., a fast reduction step will produce a large number of nuclei). The presence of inert atmosphere and surfactant is necessary to avoid the oxidation of NPs, which otherwise results in the isolation of metal oxide particles [399]. The adsorbed surfactant molecules provide a dynamic organic shell that mediates growth, stabilizes the particles in solution, and limits oxidation after synthesis. The chemical strength of NP-surfactant interaction can also be used to monitor the size; for example, a combination of tight (e.g., long-chain carboxylic acid that binds strongly because of the strong affinity of metal for oxygen) and weak (e.g., tri-octyl or butyl phosphines) binding surfactants will favor slow and rapid growth, respectively. Although weak binding surfactants are important in mediating the growth of NPs, the surfactants that remain coordinated to the metal surface upon the isolation of NPs are the ones that bind tightly. Similarly, the steric profile of the surfactant molecules can be changed to tune the NP size. Furthermore, the surfactant can be exchanged for surfactants of different length or chemical functionality. In the case of transition metal NPs, the carbonyl decomposition methodology is scalable to large quantities for the production of magnetic fluids [400, 401]. With the use of molecular precursors, metal nanoparticles can be synthesized with a very narrow size dispersion that allows investigation of the scaling effect on the fundamental properties of the material. For instance, the magnetization data on cobalt nanoparticles of different sizes clearly show that the saturation magnetization decreases with the decreasing particle size (Fig. 12) [402, 403]. The coercivity  $H_c$ , the field required to reverse the magnetization, decreases with decreasing nanocrystal size, as seen in  $M$  versus  $H$  loops measured at 5 K (Fig. 12) for a series of hcp Co nanoparticles [401].

Figure 12. Magnetization versus applied field hysteresis ( $M$  vs.  $H$ ) loops of cobalt NPs of different sizes. Reprinted with permission from [401], C. B. Murray et al., *MRS Bull.* 26, 985 (2001). © 2001, Materials Research Society.

Suslick et al. have introduced the sonochemical reactions of volatile organometallic compounds as a general approach to the synthesis of nanophase materials [404]. The chemical effects of ultrasound result from acoustic cavitation, the formation, growth, and implosive collapse of bubbles within a liquid. The collapsing bubbles generate localized hot spots ( $T \approx 5000$  K) where molecular species decompose, and the resulting metal atoms agglomerate to form nanostructured metals that are often amorphous. A variety of metals, alloys and carbides have been produced using this approach [405]. A scanning electron micrograph of amorphous nanostructured iron obtained by the sonication of iron pentacarbonyl (Fig. 13) shows agglomerated nanometric particles (ca. 20 nm), which were shown by transmission electron microscopy to consist of smaller (4–6 nm) nanocrystals.

Thin films of Fe [406], Ru [407], and Os [407] have been formed by thermal decomposition of metal pentacarbonyls. Since pentacarbonyls are difficult to handle because of their air-, light-, and temperature-sensitive nature, Shore et al. have used trinuclear precursors  $M_3(CO)_{12}$  ( $M = Fe, Ru, Os$ ) to deposit metallic films; however, a dynamic vacuum of  $10^{-5}$  torr was necessary to transport the metal carbonyls to the heated substrate [408]. An exhaustive account of the CVD of a variety of metals, including the basic principles of precursor design and a classification of the precursors, is available in the book "The Chemistry of Metal CVD," authored by Kodas and Hampden-Smith [386].

The technological importance of films of single metals, multilayers, and alloys, together with the increasing demand of materials with improved performance, has led to a great deal of interest in nanostructured device-quality films. High-purity, dense metal films with controlled crystallite size and smooth surfaces deposited at relatively low temperatures with high deposition rates are required for microelectronic applications [409]. Precursors for CVD of metals (Table 1) can be broadly classified into three categories: (i) inorganic precursors, which do not contain carbon such as metal halides; (ii) metal-organic precursors, which contain organic

**Figure 13.** Scanning electron micrograph of nanostructured iron. Reprinted with permission from [403], K. S. Suslick et al., *Chem. Mater.* 8, 2172 (1996). © 1996, American Chemical Society.

ligands but do not possess metal-carbon bonds, such as metal alkoxides, metal amides, and metal hydrides; and (iii) organometallic precursors that contain organic ligands and metal-carbon bonds, for example, metal carbonyls, metal alkyls, and metallocenes [52, 387].

Inorganic precursors such as metal halides typically need high temperatures ( $>600$  °C) and a reducing agent such as  $H_2$  to produce pure metal films. Furthermore, they are inexpensive, commercially available precursors that can easily be purified. However, most of them are solids, and homogeneous precursor delivery into the CVD reactor is difficult. In contrast, the metal-organic or organometallic molecular precursors decompose at lower temperatures and possess high vapor pressures, and most of them are liquids or can be obtained as liquids by changing the ligands. The major disadvantage is the incorporation of heteroelements (C, O, F, N, P), which is difficult to control, particularly in the case of reactive metals. However, there are many examples where high-purity metal films have been deposited from single-source molecular precursors without coreactant like reactive (reducing) gas. This requires a decomposition mechanism where the organic ligands are removed intact from the reaction chamber or in which a reaction pathway exists to form volatile species that desorb easily from the surface [52, 387]. Disproportionation of Cu(I) compounds yields elemental Cu and a volatile Cu(II) species [410], and the metal-carbon bond is cleaved by  $\beta$ -hydrogen elimination in  $Al(iBu)_3$  [411], homolytic scission of Au–C bonds in  $(CH_3)Au(PMe_3)$  [412] and the use of precursors, which do not contain metal-carbon bonds such as  $AlH_3 \cdot NR_3$  [413]. The chemical transformations of these precursors are displayed in Eqs. (9)–(12).

In the case of metal CVD, precursors devoid of a metal-carbon bond or a low metal-carbon bond order are preferred because of the low carbon contamination in the deposits. The possibility of carbon incorporation is increased because of the increased strength of M–C bonding. For example, CVD of Fe using  $Fe(CO)_5$  produces relatively pure films when compared with the decomposition of ferrocene ( $Fe(C_5H_5)_2$ ), in the absence of any reducing agent [406].

Among elemental semiconductors, germanium crystals, wires, and films of nanoscopic dimensions are receiving increasing attention because of their novel electronic and optical properties that are intrinsically associated with the low dimensionality and quantum confinement effect in semiconductor materials. The quantum confinement effect enables indirect band gap semiconductors like Si and Ge to become more efficient light emitters. Compared with Si, Ge nanostructures are of particular interest, since the Bohr exciton radius is larger in Ge than in Si, which consequently should lead to more prominent quantum confinement effects. Ge nanocrystals have been synthesized by different physical, chemical transport [414–416], CVD [70], and sol-gel [417] methods. Yang et al. have used chemical

vapor transport for rational synthesis of random and aligned growth of 1-D structures [414–416, 418, 419]. In a typical synthesis, a mixture of Ge powder and I<sub>2</sub> and a gold-coated Si wafer were placed at the high-temperature (1000 °C) and low-temperature (800 °C) ends, respectively. Ge reacts with I<sub>2</sub> to form GeI<sub>2</sub> vapor at the hot end, which is then transported to the cold end. GeI<sub>2</sub> then decomposes into Ge and I<sub>2</sub> vapor to form Ge nanowires on the Au-coated Si substrate (Scheme 14). Although the starting material is a mixture of two different chemical species, the precursor to Ge nanowires is the single compound germanium diiodide, which is formed in the gas phase as a single source.

Scheme 14.

The molecular precursor strategy is less investigated for Ge-based nanostructures, largely because of the unavailability of suitable precursors. Chisholm et al. have used germanium bis(trimethyl)silylamide to deposit metallic Ge; however, the films were found to contain small amounts of N and O incorporated because of inefficient decomposition of precursor and partial oxidation of the films, respectively [47]. The most commonly used germanium precursor is tetrahydrogermane, GeH<sub>4</sub>. Since the germane precursor is pyrophoric in nature, the replacement of one of the hydrogen atoms in GeH<sub>4</sub> by appropriate organic groups with leaving group characteristics should lead to alternative germanium precursors. Jutzi et al. have synthesized the cyclopentadienyl germanes (RGeH<sub>3</sub>; R = substituted cyclopentadienyl groups) as new liquid precursors for the deposition of thin germanium films [70]. These precursors are easy to handle and decompose at low temperatures (<400 °C) to allow the deposition of Ge films under mild conditions; however, the films contain a significant amount of carbon (8 at.%). The quality of the films is comparable to the quality of those obtained from the decomposition of GeEt<sub>4</sub> above 500 °C [420]. The high organic contamination in Ge deposits (Ge: 92 at.%; C: 8 at.%) obtained from substituted cyclopentadienyl precursors was due to the high stability of the ligands and their fragments. We have used a simple germanium bis-cyclopentadienylide (Ge(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>) as a SSP to obtain high-purity germanium nanowires (Fig. 14a) as well as nanostructured films (Fig. 14b) at the lowest temperature (<350 °C) reported so far for the CVD of Ge [421]. Ge(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub> is different from GeH<sub>4</sub> or cyclopentadienyl germanes because of the weak dipolar interactions of the cyclopentadienyl groups with the metal centers, which results in the easy formation of metallic nanostructures. The micro-EDX analysis showed the Ge content to be more than 99 at.%, and carbon and oxygen contents were negligible. The

Figure 14. SEM image of (a) as-obtained Ge nanowires and (b) nanocrystalline Ge islands obtained by the CVD of Ge(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>.

thermal decomposition of Ge(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub> proceeds possibly by the cleavage of the Ge–Cp bond. This is supported by the observation of C<sub>5</sub>H<sub>5</sub><sup>+</sup>, (C<sub>5</sub>H<sub>5</sub>)<sub>2</sub><sup>+</sup>, and Ge<sup>+</sup> species in the mass spectral analysis of the gaseous products formed during the thermolysis of Ge(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub> [421].

A high-resolution transmission electron microscope (HR-TEM) image (Fig. 15) shows the wires to be homogeneous and straight, which indicates that they are free of defects. The average diameter of the wires was found to be 15 nm. The selective area diffraction pattern of these structures exhibits sharp spots corresponding to their highly crystalline nature. The preferred growth direction was found to be [112].

Molecular compounds, together with standard nanostructure fabrication methods, can be used for obtaining patterned nanowires or dots. For instance, Himpsel et al. have obtained self-assembled Fe nanowires by pyrolysis (nitrogen laser) of ferrocene (Fe(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>), selectively adsorbed between CaF<sub>2</sub> stripes on Si(111) [422]. Ferrocene is a suitable precursor because each molecule contains one Fe atom sandwiched between two cyclopentadienyl rings,

Figure 15. HR-TEM image showing the lattice fringes of a single-crystal Ge wire.

and, owing to the nonreactive nature of the precursor, the ferrocene-covered substrate is passive unless it is exposed to ultraviolet photons. The Fe nanowires were fabricated in three steps: (1) preparation of a Si template by annealing vicinal Si(111), (2) creation of continuous  $\text{CaF}_2$  stripes on a  $\text{CaF}_1/\text{Si}(111)$  surface by the growth of one or two monolayers of  $\text{CaF}_2$ , and (3) selective adsorption of ferrocene molecules in  $\text{CaF}_1$  trenches between the  $\text{CaF}_2$  stripes. Figure 16 shows the initial and final stages during Fe nanowire growth.

## 5.2. Two-Component Systems ( $\text{AE}_x$ )

In the context of monophasic binary materials (e.g.,  $\text{MgO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Y}_2\text{O}_3$ ,  $\text{AlN}$ ,  $\text{GaN}$ ,  $\text{CdS}$ ,  $\text{ZnSe}$ ,  $\text{SiC}$ ,  $\text{TiC}$ , etc.), the decomposition of metal-organic precursors has been successfully used to obtain nanoparticles and nanostructured films. The following text contains some outstanding examples of nanoparticles and nanostructured films obtained from well-defined single-source molecules.

### 5.2.1. Oxide Ceramics

The class of binary metal oxides represents a very important group of materials as both grains and coatings because of their mechanical (e.g.,  $\text{ZrO}_2$ ,  $\text{HfO}_2$ ), dielectric (e.g.,  $\text{Al}_2\text{O}_3$ ), conducting (e.g.,  $\text{SnO}_2$ ), photocatalytic (e.g.,  $\text{TiO}_2$ ), optical (e.g.,  $\text{Eu}_2\text{O}_3$ ), biocidal (e.g.,  $\text{ZnO}$ ), and magnetic (e.g.,  $\text{Fe}_3\text{O}_4$ ) applications. Nanocrystalline aluminum oxide is used for a large number of applications such as insulating layers, optical filters, wear-resistant coatings, and corrosion-protective films. In addition, high-surface-area aluminum oxides are used as catalyst support and adsorbents in industrial processes. The synthesis of so-called active aluminas by Yoldas [423] from aluminum alkoxides represents one of the fundamental steps taken toward the processing of high-performance materials from molecular precursors, which has been extended and modified during the last three decades, by several working groups (Tables 1–4).

Iron oxide films and nanoparticles are currently being extensively investigated because of their applications in catalysis, magnetic recording media, gas sensors, and anticorrosion protective paints [424–427]. Nanosized iron oxides

with a size of a few nanometers exhibit unique properties (e.g., high coercivity, superparamagnetism, enhanced surface sensitivity) not shown by their bulk phases, which has generated a great deal of technological and fundamental interest in the size and phase-selective synthesis of iron oxide particles and films. The functional properties of iron oxides are strongly dependent on their chemical composition, microstructure, and phase purity. The control over morphology, microstructure, and composition poses a synthetic challenge and is influenced by the preparation method, specific synthesis conditions, and pyrolytic or hydrolytic properties of the precursor [123] under processing conditions. The production of magnetic nanoparticles has improved enormously in recent years, although the synthesis of high-purity iron oxide nanoparticles a few nanometers in size with controlled size and distribution is still a challenging problem [124–127, 428–430] despite the application of different physical (e.g., molecular beam epitaxy (MBE) [431], reactive sputtering [432], and pulsed laser deposition (PLD) [433]) and chemical (e.g., sol–gel [434], electrochemical synthesis [435], ball milling [436], aerosol synthesis [437], and CVD [438]) methods. In view of the above, the use of iron alkoxide clusters as precursors to nanocrystalline oxides is a convenient route for controlling the composition and morphology of the target oxide. Furthermore, it allows a phase-selective synthesis, which is of significant importance, especially in the case of oxides, for instance, the  $\text{Fe}_x\text{-O}_y$  system, where several phases (hematite ( $\text{Fe}_2\text{O}_3$ ), maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ), magnetite ( $\text{Fe}_3\text{O}_4$ ), etc.) can be simultaneously formed in a narrow processing window.

Kiyomura and Gomi [127] has used iron (III) acetylacetonate complex (Fig. 17) in a plasma-assisted MOCVD process to grow magnetite films on Si(111) with a uniform morphology at 400 °C; however, the carbon content in the deposited film was rather high (2–6 at.%) because of the thermally robust nature of the precursor.

Armelaio and Artigliato [124] have used iron ethoxide  $[\text{Fe}(\text{OEt})_3]_n$  as a single molecular source for the sol–gel synthesis of nanocrystalline and transparent hematite thin films. The crystalline phase was obtained by thermal treatment of a homogeneous and amorphous material. The crystallite dimensions were controlled by varying the temperature, and the coatings were found to be nanostructured, even after

**Figure 16.** STM images of the initial and final stages in the self-assembly of Fe nanowires obtained by selective adsorption of ferrocene molecules. (a)  $\text{CaF}_2$  stripes separated by  $\text{CaF}_1/\text{Si}(111)$  trenches at a coverage of 1.9 monolayers of  $\text{CaF}_2$ . (b) Linear array of Fe nanowires 3 nm wide and 0.8 nm thick. **Figure 17.** Molecular structure of  $\text{Fe}(\text{acac})_3$ .

prolonged heating. The iron sites were found to be octahedrally coordinated in both the crystalline and amorphous states, which shows the inherent advantage of using a single molecular source, which results in a chemically homogeneous matrix. As a result, the microstructural evolution is consistent and stable [124]. Although iron ethoxide is an interesting precursor for solution methods, its application in gas-phase techniques is limited because of its poor volatility. The attempted volatilization ( $200\text{ }^{\circ}\text{C}/10^{-2}\text{ torr}$ ) results in the formation of a polynuclear iron cluster,  $\text{Fe}_9\text{O}_3(\text{OC}_2\text{H}_5)_{21}(\text{C}_2\text{H}_5\text{OH})$ , with low vapor pressure [439]. The molecular structure of this species reveals a cyclic arrangement of Fe–O rings based on the different coordination of Fe(III) centers (Fig. 18). The oxo-alkoxide species represent a molecular intermediate that is probably involved in the alkoxide-to-oxide conversion.

The thermal instability of iron ethoxide is related to the degree of association of the ethoxide molecule in the solid state. It is known that the corresponding aluminum compound is an infusible solid due to the extensive polymerization of  $\text{Al}(\text{OEt})_3$  through alkoxy-bridging. The bridging tendency in alkoxide species is governed by the propensity of the metal center to increase their coordination state [49–51], which can be tuned either through an increase in the steric bulk of the alkoxide ligands or through the use of chelating ligands [440, 441]. Indeed, the higher alkoxide analogue  $[\text{Fe}(\text{O}i\text{Bu})_3]_2$  was found to be an excellent precursor for the deposition of different iron oxide phases. The molecular structure of  $[\text{Fe}(\text{O}i\text{Bu})_3]_2$  exhibits a centrosymmetric dimer where two tetrahedrally coordinated Fe (III) centers are linked via bridging  $-\text{O}i\text{Bu}$  groups (Fig. 19).

The decomposition temperature of  $[\text{Fe}(\text{O}i\text{Bu})_3]_2$  needed to form iron oxide was determined by thermogravimetric analysis performed under nitrogen. The major weight loss occurs in a single decomposition step around  $180\text{ }^{\circ}\text{C}$  corresponding to the elimination of the organic ligands to form the inorganic oxide. This demonstrates the inherent advantage of SSPs in obtaining pure compounds with control over the phase purity and particle size in the resulting ceramic material. Such a single-step decomposition behavior is not observed in other precursor systems, for example, the organic derivatives of the inorganic iron salts like glycolates, citrates,  $\beta$ -diketonates, etc., where the precursor degrades in several

**Figure 18.** Molecular structure of  $\text{Fe}_9\text{O}_3(\text{OC}_2\text{H}_5)_{21}(\text{C}_2\text{H}_5\text{OH})$ .

**Figure 19.** Molecular structure of  $[\text{Fe}(\text{O}i\text{Bu})_3]_2$ .

steps, because of the stability of intermediate species; consequently higher temperatures are necessary for a complete decomposition of the precursor to form the oxide [442]. The DTA curve shows a small endothermic peak around  $150\text{ }^{\circ}\text{C}$  corresponding to the melting temperature of the precursor, and the exothermic transition at  $225\text{ }^{\circ}\text{C}$  is possibly due to the oxidative degradation of the iron alkoxide, resulting in the liberation of the organic by-products. The crystallization of hematite is observed as a small exothermal peak around  $370\text{ }^{\circ}\text{C}$ .  $[\text{Fe}(\text{O}i\text{Bu})_3]_2$  was used in a horizontal cold-wall reactor to deposit hematite films at  $400\text{ }^{\circ}\text{C}$ , whereas magnetite films were obtained at  $450$  and  $500\text{ }^{\circ}\text{C}$ , as confirmed by the X-ray diffraction (XRD) data (Fig. 20). It was shown that the  $\text{Fe}_3\text{O}_4$  phase results from the reduction of  $\alpha$  and  $\gamma$  ferric oxides [123, 428]. Apparently, the dangling oxygen bonds on the surface of ferric oxide nanocrystals cleave upon heating in a vacuum, thereby eliminating oxygen. However, the reduction of  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  by dihydrogen liberated during the decomposition of  $[\text{Fe}(\text{O}i\text{Bu})_3]_2$  cannot be ruled out (Eqs. (15) and (16)).

Subject to the nature of the metal atom, a thermally activated fragmentation of the metal *tert*-butoxides produces,

**Figure 20.** XRD patterns of magnetite (a) and hematite (b) iron oxide films deposited on silicon. Reprinted with permission from [428], S. Mathur, et al. *Chem. Vap. Deposition* 8, 277 (2002). © 2002, Wiley-VCH.

generally by an intramolecular process, *tert*-butyl alcohol, isobutene, and dihydrogen as the by-products [143]. This pathway was first proposed by Bradley and Maxfactor in their pioneering work on the thermolysis of Zr-*tert*-butoxide [443]. In other studies [227], it has been shown that isobutene results from  $\beta$ -H elimination of adsorbed *tert*-butoxy groups, whereas *tert*-butyl alcohol is formed by reaction of a *tert*-butoxide fragment with an adsorbed hydroxy group. All of these compounds are volatile and can easily be removed from the deposition zone to obtain oxides with minimum carbon contamination. The carbon content in the CVD deposits was shown to be low (<0.2 at.%), which exhibits a clean ligand stripping in the thermolysis of  $[\text{Fe}(\text{O}'\text{Bu})_3]_2$ . SEM analysis of the CVD films reveals characteristic morphologies for different iron oxide phases (Fig. 21). The hematite films display nanocrystalline spindle-like grains, whereas densely packed faceted crystallites were observed for the magnetite layers.

The nanostructured nature of the films is reflected in their magnetic behavior. The hysteresis loop of the  $\text{Fe}_3\text{O}_4$  film shown in Figure 22 can be considered as the superposition of a paramagnetic line a and a ferrimagnetic loop b. The weak magnetization when compared with polycrystalline  $\text{Fe}_3\text{O}_4$  probably results from the presence of a superparamagnetic phase. If a sample consists of small particles, its total magnetization decreases with particle size. As the size of the magnetic particle approaches the critical size required for a single-domain behavior, it becomes difficult to switch the magnetization from one direction to another. In the case of nanostructured materials (<50 nm), the total magnetization decreases with decreasing particle size, owing to the increased dispersion in the exchange integral and finally reaches the superparamagnetic state, where each particle acts as a spin with suppressed exchange interaction between the particles. In the case of magnetite films, the mean particle size (ca. 10–12 nm) is smaller than the critical (50–80 nm) size reported in the literature for single-domain behavior [444]. The higher coercivity of the  $\text{Fe}_3\text{O}_4$  film (4000 Oe) when compared with coarse-grained  $\text{Fe}_3\text{O}_4$  material (ca. 400 Oe) provides additional evidence for superparamagnetic behavior. The advantages of having molecular control over the growth process was also demonstrated by the deposition of different iron oxide phases on the silicon cantilever of an atomic force microscope with a conformal coverage and homogeneous morphology (Fig. 23).

$[\text{Fe}(\text{O}'\text{Bu})_3]_2$ , when used in a sol-gel process, produced hematite nanocrystals with a regular size and narrow size

**Figure 21.** SEM images of iron oxide phases. (a) Hematite. (b) Magnetite.

distribution. TEM images revealed a homogeneous distribution of highly faceted hematite particles (Fig. 24).

Although the magnetic properties of these samples reproduce reported data on  $\alpha$ - $\text{Fe}_2\text{O}_3$ , for the first time the existence of thermal hysteresis of both structural and magnetic hyperfine parameters at the Morin transition was observed (Fig. 25). The detailed Mössbauer measurements revealed a jump in hyperfine parameters (HPs) at  $T \sim T_M$ , a distinctive feature of Morin transition observed at 256(2) K [445]. The analysis of HPs as a function of temperature discards the coexistence of low- and high-temperature phases with different crystal symmetries as the possible origins of this hysteretic behavior.

Nanocrystalline  $\text{TiO}_2$  has received significant attention because of its improved properties and numerous potential applications, including nanoporous solar

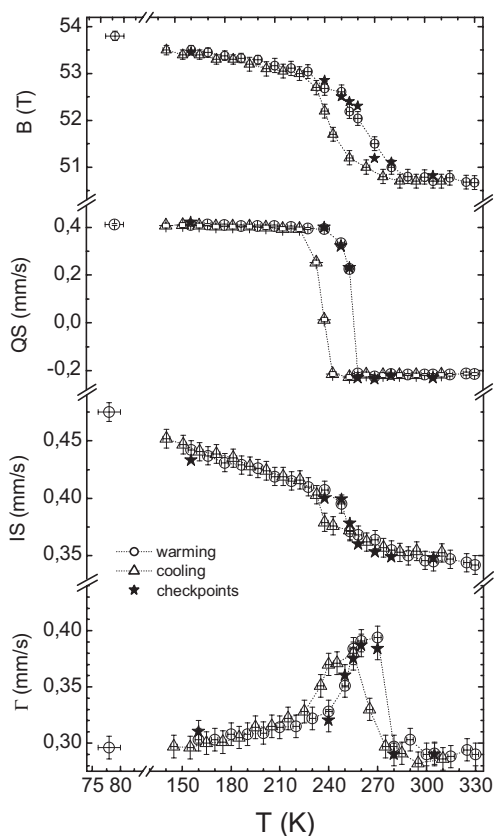

**Figure 23.** SEM images of AFM cantilever uncoated (a) and coated with hematite (b and d) and magnetite (c and e). Reprinted with permission from [428], S. Mathur et al., *Chem. Vap. Deposition* 8, 277 (2002). © 2002, Wiley-VCH.

**Figure 24.** HR-TEM micrographs and XRD pattern of the  $\alpha$ - $\text{Fe}_2\text{O}_3$  particles.

cells, photochemical applications and optical coatings, etc. [446–448]. The photocatalytically active  $\text{TiO}_2$  is currently used for so-called self-cleaning coatings in which titanium oxide nanocrystals are deposited as a porous film on the desired substrate. When illuminated, these materials oxidize the organic compounds present in the system, eventually degrading these compounds to water and carbon dioxide.

**Figure 25.** Mössbauer hyperfine parameters: (a) Hyperfine field  $B_{hyp}$ . (b) Quadrupole splitting (QS). (c) Isomer shift IS. (d) Linewidth  $\Gamma$  measured in heating and cooling cycles. The solid star-shaped symbols are checkpoints from the repeated measurements.

The energy of sunlight, mainly the UV part of the spectrum (360–380 nm), excites titanium dioxide nanoparticles, creating a photogenerated electron and a highly oxidizing hole in the conduction and valence band of the semiconductor [449, 450]. The electron can be scavenged by oxygen, and the hole can react with surface-bound OH on the  $\text{TiO}_2$ , creating a highly reactive  $\text{OH}^*$  radical that can completely mineralize organic components [451, 452] (Scheme 15).

**Scheme 15.**

In view of the growing technological potential of nanocrystalline titania, several chemical synthesis routes have been employed to prepare very fine particles [453–455]. The above-mentioned physical properties of  $\text{TiO}_2$  depend on the specific crystallographic structure (Scheme 16), as it is known to exhibit three different crystallographic forms, namely anatase, rutile, and brookite. In nanosized titania, anatase and rutile phases are inhomogeneously distributed, and postsynthesis thermal treatments are necessary to induce phase transformation and/or to improve the crystallinity. Solar energy conversion devices and chemical sensors make use of the anatase form of  $\text{TiO}_2$ , which is difficult to prepare in pure form and is generally accompanied by the rutile modification that dominates at high temperatures. For this reason, control over the solid-state structure is highly desirable. Although the anatase-to-rutile phase transformation in nanocrystalline samples is not well understood, a new kinetic model proposes the combined interface nucleation at certain contact areas between two anatase particles and formation and growth of rutile nuclei to be the transformation steps. Over shorter reaction times, the net transformation rate is determined by the rate of nucleation, which is initiated from rutile-like structural elements in the contact area. The activation energy of 165.6 kJ/mol for rutile nucleation within nanocrystalline anatase particles is much lower than values previously measured for rutile nucleation in coarse anatase samples (>330 kJ/mol). Over longer reaction times, the net transformation rate is determined by both nucleation and nuclei growth. These results quantitatively explain the origin of the size dependence of phase transformation rates in nanocrystalline  $\text{TiO}_2$ . However, the anatase phase can be selectively obtained when the material is formed under mild conditions; for example, Rambabu et al. have used titanium tetraisopropoxide,  $\text{Ti}(\text{OPr}^i)_4$ , as a SSP to obtain nanocrystalline oxide (5–7 nm) at temperatures as low as 85 °C by the *in-situ* conversion of titania sol [456]. Interestingly,  $\text{Ti}(\text{OPr}^i)_4$ , when used in a hydrothermal synthesis, produces rutile nanoparticles, indicating the role of high-temperature

and high-pressure conditions in the structure of the resulting nanoparticles.

**Scheme 16.**

It is well known that hydrolysis and condensation rates of alkoxide precursors can be tailored through the addition of multidentate ligands. However, the influence of the precursor structure on the physical properties of the resulting nanocrystalline material has received less attention. Boyle et al. have synthesized and characterized a series of carboxylic acid-modified titanium alkoxides [328] that display a rich structural diversity in the titanium-oxygen arrangements, depending upon the steric situation around the metal center (Scheme 17).

**Scheme 17.** Structural motifs of the titanium-oxygen cores in carboxylic acid-modified  $\text{Ti}(\text{OR})_4$ .

These compounds were used in a sol-gel process to obtain  $\text{TiO}_2$  films. The density of the films (Table 7) was found to vary for different precursors, which is probably related to the

**Table 7.** Influence of precursor structure on the density of resulting  $\text{TiO}_2$  films.

Compound	Core structure (Scheme 17)	$n_f$	$\rho$
$\text{Ti}_3(\text{O})(\text{ONep})_8(\text{OFC})_2$	g	2.185	101.8

$\text{Ti}_3(\text{O})(\text{ONep})_8(\text{ONc})_2$	g	1.966	87.46
$[\text{Ti}(\text{ONep})_3(\text{OBC})]_2$	h	1.923	86.52
$[\text{Ti}(\text{OPr}^i)_3(\text{OBC})]_2 \cdot \text{HOPr}^i$	h	1.802	78.26

gel structure and the geometry of the basic unit (Scheme 17) forming the three-dimensional network, which is corroborated by the fact that the solid-state structures are maintained in the solution. The most desirable precursors that were found to generate fully dense  $\text{TiO}_2$  films were those having small nuclearities, few terminal alkoxides, and a low overall carbon content. This study clearly shows the influence of precursor structure on material property.

### 5.2.2. Metal Chalcogenides, Nitrides, Pnictides

The changes in the fundamental properties of materials as a function of the size, evolving from the isolated atoms or molecular clusters to a bulk phase, are most remarkably manifested in the case of semiconductor nanoparticles. The observation of quantum-confinement effects has generated substantial interest in their applications in device technology based on their novel optical and transport properties [457, 458]. For example, the bandgap in CdS can be tuned between 4.5 and 2.5 eV as the size is varied from the molecular regime to the macroscopic crystal, and the radiative lifetime for the lowest allowed optical excitation ranges from tens of picoseconds to several nanoseconds [14, 459]. The colloidal processing methods, based on controlled nucleation and rapid termination of growth, are commonly used to prepare II-VI compound semiconductor nanoparticles. These methods allow easy access to large quantities of nanomaterials, but with relatively large dispersities ( $\sim 10\%$ ). In this context, the use of SSPs containing metal-chalcogen bonds templated in molecular compounds is a promising route for controlled growth of nanomaterials. These clusters exist as discrete molecular species and can be seen as a fragment of the bulk lattice [22, 110]. O'Brien et al. have studied the thermolysis of metal dithio- and diselenocarbamate complexes ( $\text{M}\{\text{E}_2\text{CNMe}(\text{C}_6\text{H}_{13})\}_2$ ) as single molecular precursors for a one-pot synthesis of CdS, ZnS, CdSe, and ZnSe nanoparticles [103, 105, 234]. The fabrication of semiconductor nanocrystals from these molecular precursors (Fig. 26) is a one-step process, typically performed in the temperature range of 200–250 °C. This approach has been extended to the synthesis of PbS and PbSe from lead(II) alkyldithio- or alkyldiselenocarbamates, respectively [22, 188, 460].

The importance of using small molecular clusters as synths to extended solid-state structures is especially evident in those examples where a structurally characterized molecular species reveals the metal-ligand interactions and coordination present in solid-state material. Several examples of well-defined polynuclear molecular clusters, possessing the elemental ratio suitable for the formation of a solid-state phase, are known; these represent the small (molecular) size regime where the properties are more like those of molecules than like those of bulk [461]. Farneth et al. have investigated the mechanism of the solid-state conversion of a series of II–VI precursors of general formula  $(R_4N^+)_4[S_4M_{10}(SPh)_{16}]^{4-}$  ( $R = Me, Et; M = Cd, Zn$ ) to the bulk metal sulphide structure [17]. The transformation as followed by combined TGA and mass spectroscopy proceeds in two discrete reaction steps: the first reaction, occurring around 200 °C, is characterized as a nucleophilic substitution or elimination reaction of a fragment ( $NMe_4SPh$ ) of the anion cluster with the tetraalkylammonium counterion. The loss of the cluster counteranions produces a new molecular solid of stoichiometry  $Cd_{10}S_{16}Ph_{12}$ , which has been isolated and characterized. This intermediate composition gave a broad XRD pattern that indicated very small (<25 Å) sphalerite-phase (cubic) crystals of CdS. It undergoes a second reaction around 350 °C, whereupon  $S_6Ph_{12}$  is eliminated, leaving a solid residue that was shown to be phase-pure CdS in the Wurtzite structure (Eq. (17)). The compound  $Cd_{10}S_{16}Ph_{12}$  is highly soluble in pyridine and was recrystallized by the addition of dimethylformamide (DMF). The solid-state structure determined by X-ray crystallography confirmed the formation

of a cluster with  $Cd_{32}S_{14}(SPh)_{36} \cdot (DMF)_4$  (Fig. 27). This molecule is much larger than the original  $Cd_{10}S_{16}Ph_{12}$  precursor-cluster, suggesting that the  $Cd_{32}$  cluster results from the assembly of CdS and  $SC_6H_5$  species of various nuclearities, which were shown by  $^{113}\text{Cd}$  NMR spectroscopy

**Figure 27.** Molecular structure of  $Cd_{32}S_{14}(SPh)_{36} \cdot (DMF)_4$  cluster (drawn after [461]).

to be in rapid exchange [17]. The structural details reveal a chunk of sphalerite form of bulk CdS whose dangling surface bonds have been terminated by wurtzite-like (hexagonal) CdS units at four tetrahedral corners (Fig. 27). This corresponds to an overall cluster size of  $\sim 15$  Å.

The lowest absorption band of  $Cd_{32}S_{14}(SPh)_{36} \cdot (DMF)_4$  located at 358 nm shows a significant “blue-shift” compared with the bulk CdS (Fig. 28).

The two main implications of this work are (i) the formation of molecular cluster solids as tractable intermediates, which display the features of nanocrystalline solids, and (ii) the possibility of exploiting the ligand chemistry to control the microstructure of the final nanocrystalline solids. Similarly, CdSe (2–9 nm) and ZnSe (2–5 nm) nanoparticles have been prepared from the corresponding selenides. Although the molecular precursors  $(R_4N^+)_4 \cdot [S_4M_{10}(SPh)_{16}]^{4-}$  and the resulting nanocrystals have been the subject of intensive investigations, the chemical reaction associated with this transformation, which could uncover the nucleation mechanism, has been not well studied. Strouse et al. [110] have investigated the decomposition of  $(R_4N^+)_4 \cdot [Se_4M_{10}(SPh)_{16}]^{4-}$  to form MSe ( $M = Zn, Cd$ ). The Cd:Se ratio in  $[Se_4Cd_{10}(SPh)_{16}]^{4-}$  is significantly higher

**Figure 28.** Absorption spectrum of  $Cd_{32}S_{14}(SPh)_{36} \cdot (DMF)_4$  in THF at room temperature compared with the bulk CdS absorption spectrum. Reprinted with permission from [461], N. Herron et al., *Science* 259, 1426 (1993). © 1993, American Association for the Advancement of Science.

(2.5:1) than required for the final product.  $\text{Cd}(\text{SPh})_3^-$  has been suggested as a labile fragment that would yield a Cd:Se stoichiometry of 1.5:1 based on the  $\text{Cd}_6\text{Se}_4$  core of the cluster. Since the CdSe nanomaterial grown in hexadecylamine is strictly stoichiometric, unidentified Cd by-products are required to balance the reaction stoichiometry. Several mechanisms for nucleus formation have been put forward, for instance, the fragmentation of the  $\text{M}_{10}$  cluster into  $\text{M}^{2+}$  and  $\text{Se}^{2-}$  or  $(\text{CdSe})_n$  species that can reassemble to form the nucleus or the alternative possibility that the cluster remains intact, acting as partial nuclei, and that the nanomaterial growth proceeds through scavenging of free M and Se atoms. Moreover, a combination of fragmentation via ring opening and subsequent ligand exchange, proposed for other metal chalcogenide clusters [462, 463], seems to be probable as well (Fig. 29). Apparently the  $\text{Cd}_{10}$  cluster grows (to  $\text{Cd}_{32}$ ) by ring opening followed by attack of the exposed Cd atom at the trigonally passivated chalcogenide ions and subsequent loss of the apical  $\text{Cd}(\text{SPh})_3^-$  caps (Fig. 29). As a consequence, nucleus formation occurs through ligand exchange, and in effect the cluster acts as a template for the formation of larger-nuclearity clusters. The transformation of molecular metal-chalcogenide systems into semiconductor nanocrystals with narrow size and shape dispersions demonstrates the versatility of templating nanomaterial growth by providing molecular inorganic clusters as intact nuclei. In view of the above, the use of SSPs in the deposition of thin film semiconductors by CVD techniques has been extensively studied [106, 464, 465]. Cadmium bis(diethylmonothiocarbamate),  $\text{Cd}(\text{Et}_2\text{mtc})_2$ , was shown to be a suitable source for the deposition of nanocrystalline and transparent CdS films at low temperatures (300–450 °C) (Fig. 30) [104].

Gallium nitride (GaN) has promising applications for blue and ultraviolet optoelectronic devices and has attracted much attention recently after the successful fabrication of high-efficiency blue light-emitting diodes [466]. GaN possesses a range of interesting properties, such as a wide bandgap (3.45 eV), high chemical inertness, radiation resistance, and capability of working at high temperatures, which make it an interesting candidate for optoelectronic devices.

For the above reasons, there is growing interest in the synthesis of GaN nanocrystals and nanostructured films. The established method of depositing device-quality GaN by MOCVD utilizes high-temperature interaction of  $(\text{CH}_3)_3\text{Ga}$ , with a large excess of  $\text{NH}_3$ . However, the high stability of the N–H bond in  $\text{NH}_3$  requires reaction temperatures in excess of 1000 °C and the inefficient use of toxic  $\text{NH}_3$ . Therefore, the choice of substrate material is limited by a high substrate temperature, which may result in residual strains in the deposited layers. To overcome the limitations of this process, alternative methods based on SSPs that incorporate direct Ga–N bonds and do not contain any strong N–H bonds, or even organic groups, offer the potential for significant improvements in the growth process and film quality [137, 467–469]. The major advantages of using molecular precursors with pre-formed Ga–N bonds include lower deposition temperatures, exclusion of  $\text{NH}_3$  from the process, reduction in N vacancies, and elimination or drastic reduction of carbon impurities [470, 471].

Recently, a large number of routes for synthesizing freestanding nanocrystals and films (nanostructured and epitaxial) of GaN have been reported. For example, the pyrolyses of  $[\text{Ga}(\text{NH}_2)_{3/2}]_n$  (450 °C) [472],  $[\text{H}_2\text{GaNH}_2]_3$  (600 °C) [473],  $[\text{Ga}\{\text{N}(\text{CH}_3)_2\}_3]_2$  (600 °C) [474],  $[\text{H}_2\text{GaN}_3]$  (350 °C) [467], and  $[\text{Ga}(\text{N}_3)_3]_n$  (280 °C) [475] gave nanocrystalline GaN powders. Although all of the precursors produced chemically homogeneous GaN, the temperature of crystallization and the amount of organic contamination depend on the organic content in the precursor molecule. In the case of large organic groups, high temperatures are required for their dissociation and complete decomposition. Despite several promises, the single-source route implies problems, such as low volatility of precursors and carbon contamination of the nitride films from undecomposed organic fragments. Therefore, a single precursor should be carefully designed so that it follows a clean decomposition pathway to produce the desired phase with a minimum level of impurities and the lowest possible decomposition temperature.

In a nonconventional approach, Fischer et al. have used detonation of gallium azides,  $(\text{R}_3\text{N})\text{-Ga}(\text{N}_3)_3$ , to obtain phase-pure nanocrystals of hexagonal GaN [137]. Kouvetakis et al. have reported several related routes for GaN synthesis

utilizing a carbon- and hydrogen-free SSP,  $\text{Cl}_2\text{GaN}_3$ , to grow thin oriented films of high-quality GaN on sapphire at 700 °C. The main limitation of this approach is the extremely low vapor pressure of  $\text{Cl}_2\text{GaN}_3$ , which is an involatile polymeric solid at room temperature, and the inherent loss of substantial quantities of  $\text{GaCl}_3$  (Eq. (18)) at the growth temperature:

In view of the above, an alternative monohydride precursor,  $(\text{HClGaN}_3)_3$ , was synthesized [136, 141], which is a moderately volatile molecular system consisting of interconnected tetrameric  $\text{Ga}_4\text{N}_4$  units (Fig. 31).

The compound decomposes easily at low temperatures by elimination of  $\text{HCl}$  and  $\text{N}_2$  to grow GaN on Si and sapphire (Eq. (19)).

An obvious extension of the above approach suggests the simpler dihydride analog of  $(\text{Cl}_2\text{GaN}_3)_3$  to be a potential precursor, as it could be expected to be more volatile (low molecular weight and increased covalent character). Indeed,  $[\text{H}_2\text{GaN}_3]_3$  is an air-sensitive liquid, volatile at room temperature, that can be distilled readily at 40 °C (0.2 torr). This simple hydride analog is particularly desirable as a CVD source [467] because it eliminates benign  $\text{H}_2$  and  $\text{N}_2$  by-products to yield stoichiometric GaN at temperatures as low as 150 °C (Eq. (20)).

$[\text{H}_2\text{GaN}_3]_3$  exists as a trimer of  $C_{3v}$  symmetry in the gas phase, as indicated by *ab initio* calculations. The  $\text{Ga}_3\text{N}_3$  cyclic core of the structure (Fig. 32) represents the basic building block that is structurally consistent with the tetrahedral structures of the group III nitrides, including those of GaN.

The dihydrido compound was successfully used to obtain high-purity GaN films free of carbon, oxygen, or hydrogen

**Figure 31.** Representation of the  $\text{Ga}_4\text{N}_4$  cyclic core of  $(\text{HClGaN}_3)_4$ . Reprinted with permission from [136], J. McMurran et al., *Inorg. Chem.* 37, 6638 (1998). © 1998, American Chemical Society.

**Figure 32.** Gas-phase structure of  $(\text{H}_2\text{GaN}_3)_3$ . The  $\text{N}_2$  portion of the  $\text{N}_3$  group is omitted for clarity (adapted from [467]).

impurities. Heteroepitaxial growth (Fig. 33) of wurzite GaN on sapphire was achieved at 650 °C [467].

Although  $[\text{H}_2\text{GaN}_3]_3$  is a versatile CVD source for GaN, the high reactivity of this molecule, which is a significant advantage with respect to the formation of GaN, requires a careful manipulation of the pure product. The pronounced tendency of this precursor to decompose in an exothermic reaction liberating nitrogen is a typical feature of metal azide chemistry. Nevertheless, it is possible to control the pyrophoric nature of the azide precursors by using ligands capable of intramolecular coordination [468, 476]. Kim et al. have synthesized mononuclear  $[\text{Et}_2\text{Ga}(\text{N}_3)\cdot\text{MeHNNH}_2]$  as a Lewis acid-base adduct for low-temperature deposition of *h*-GaN films on Si(111). The compound decomposes via loss of stable molecular species (Eq. (21)), yielding high-quality GaN films with little contamination [476].

In addition to the gas-phase synthesis, these precursors can be employed for the solution-based synthesis of GaN

**Figure 33.** High-resolution cross-sectional electron micrograph showing heteroepitaxial growth of wurzite GaN on sapphire at 650 °C. Reprinted with permission from [467], J. McMurran et al., *Appl. Phys. Lett.* 74, 883 (1999). © 1999, American Institute of Physics.

nanocrystals. Gladfelter et al. have used a cyclotrigallazane, prepared by the reaction of  $[\text{GaH}_3(\text{NMe}_3)]$  in supercritical ammonia. This compound dehydrogenates in the solid state to form nanocrystalline GaN. The thermal instability of gallium azides can be used to obtain colloids of GaN. Thermolysis of  $[\text{Et}_2\text{Ga}(\text{N}_3)]_3$ ,  $[(\text{N}_3)_3\text{Ga}\{\text{NMe}_2(\text{CH}_2)_3\}]$ , and  $[(\text{Et}_3\text{N})\text{Ga}(\text{N}_3)_3]$  in triglyme has produced nanometric GaN particles [469] (Scheme 18). Furthermore,  $[(\text{Et}_3\text{N})\text{Ga}(\text{N}_3)_3]$  has been used to grow nanocrystals of GaN in a regular porous matrix. For this purpose, the mesoporous molecular sieve MCM-41 was impregnated by the precursor solution and heat-treated ( $500\text{ }^\circ\text{C}$ ) to achieve a spatially confined nucleation of GaN nanoparticles [469] (Scheme 18).

**Scheme 18.**

The above examples clearly illustrate the potential of molecular-level design in controlling the vapor pressure and reactivity of the precursor compounds. Furthermore, an appropriate selection of ligands can enforce a neat thermal decomposition mechanism to offer high-purity inorganic materials at low temperatures. Another advantage of suitable liquid precursors is the possibility of growing nanoparticles by spatially restricting the molecular species in ordered channels or pores of mesoporous matrices.

Metal pnictides are best represented by the 13–15 compounds, such as GaAs, and are well known for their electronic and optoelectronic applications. The single-source approach to the preparation of these materials has been intensively investigated and reviewed by Maury [422] and Cowley [464], who have also actively contributed to the field [134, 477–486]. The use of III–V adducts as substitutes for highly reactive group III alkyls by Benz et al. [487, 488] was among the pioneering steps in this direction. Maury et al. have used Lewis acid-base adducts of formulae  $\text{ClR}_2\text{Ga} \leftarrow \text{ER}'_3$  ( $\text{E} = \text{As}, \text{P}$ ;  $\text{R}$  and  $\text{R}' = \text{Me}$  or  $\text{Et}$ ) to overcome the problem of the high reactivity and toxicity of conventional dual sources [487, 489]. Films of GaP [490, 491] and InP [491] were successfully grown from the cyclic trimers of general formula  $[\text{Et}_2\text{M}-\text{P}(\text{Et})_2]_3$  ( $\text{M} = \text{Ga}, \text{In}$ ) with covalent metal-phosphorus bonds [487, 492]. Epitaxial growth of GaAs was achieved with  $\text{ClR}_2\text{Ga} \leftarrow \text{AsR}'_3$  ( $\text{R} = \text{Me}, \text{Et}$ ). The thermal decomposition of two series of molecular precursors was achieved with the general formulae  $(\text{C}_6\text{F}_5)_{3-n}\text{Me}_n\text{Ga} \leftarrow \text{AsEt}_3$  ( $n = 0$  or  $2$ ) and  $[\text{ClR}_2\text{Ga} \leftarrow \text{AsEt}_2]_2\text{CH}_2$  ( $\text{R} = \text{Me}, \text{Et}$ ). The relative stabilities of the central M–E bond with respect to peripheral M–ligand and E–ligand interactions was evaluated by two different approaches. The first case deals with the use of Lewis acid-base dative bonds, whose strength can be tuned by means of the more or less electron-donating nature of the alkyl groups, and varied admixture of halogen (Cl) or pseudo-halogen ( $\text{C}_6\text{F}_5$ ) substituents; the rather fragile M–E bonds are a major limitation

in this approach, causing loss in volatility and surface mobility, whereas in the second approach complexes with covalent M–E bonds were used [289, 493, 494].

Cowley and Jones have used a variety of single-source organometallics that involve  $\sigma$ -bonding between group III and group V elements [16, 487, 495]. They have tested different Ga–As precursors, such as  $[\text{Me}_2\text{Ga}(\mu\text{-AsBu}'_2)]_2$  [484, 485, 487, 495–497],  $[\text{Me}_2\text{Ga}(\mu\text{-AsBu}'_2)]_2$  [487, 487, 498], and  $[\{\text{Ga}(\text{AsBu}'_2)\}_3]$  [487, 497]. The films deposited with the use of the methyl derivative  $[\text{Me}_2\text{Ga}(\mu\text{-AsBu}'_2)]_2$  were arsenic-deficient [487, 496]. On the other hand, epitaxial films could be obtained with  $[\text{Et}_2\text{Ga}(\mu\text{-AsBu}'_2)]_2$ ; however, the films exhibited anomalously low Hall mobilities due to the formation of gallium islands.

The antimonides of group 13 elements are narrow direct bandgap semiconductors with small bandgaps ( $E_g$  (eV) = 1.60 (AlSb), 0.67 (GaSb), 0.16 (InSb)) and high electron mobility that render them very attractive for potential applications in optoelectronic devices. For instance, GaSb is used for the production of light-emitting and light-detecting devices operating in the  $2\text{-}\mu\text{m}$  wavelength range (GaSb: 1), field effect transistors (GaSb: 2), and infrared detectors (GaSb: 3). The growth of thin films of group 13 nitrides, phosphides, and arsenides by CVD typically involves group 13 alkyls and group 15 hydrides; however, an analogous process is not possible for the preparation of group 15 antimonides because  $\text{SbH}_3$  is thermally very unstable (decomposes below  $-60\text{ }^\circ\text{C}$ ), which is also true for primary ( $\text{RSbH}_2$ ) and secondary stibines ( $\text{R}_2\text{SbH}$ ). Furthermore, an excess of stibine during film growth may lead to the formation of elemental Sb on the substrate, which has to be strictly avoided because of the low volatility of elemental Sb. For these reasons, group 13 trialkyls ( $\text{R}_3\text{M}$ ) and tri-organostibines ( $\text{R}_3\text{Sb}$ ) are used as the common precursors (GaAs: 12). However, the inability to produce atomic hydrogen during pyrolysis, as well as the high stability of metal-carbon bonds, favor the incorporation of large amounts of carbon in the resulting material. GaSb has been grown from  $\text{Sb}(\text{NMe}_2)_3$ , which contains weaker Sb–N bonds [499, 500]. The alternative pathway is based on the use of heterocycles  $[\text{R}_2\text{MER}'_2]_x$  that are attractive SSPs, particularly because of their lower metal-carbon bond energies when compared with pure group 13 and 15 alkyls. Schulz et al. have used  $\text{Bu}'_3\text{Ga}-\text{Sb}(\text{Bu}')_3$  and  $\text{Bu}'_3\text{Ga}-\text{Sb}(\text{Pr}')_3$  as single-molecule precursors for the synthesis of highly oriented carbon-free GaSb nanocrystals and whiskers [97].

### 5.2.3. Silicon Oxide, Nitride, and Carbide

Because of the covalent character of the chemical bonds, the nonoxide amorphous and nanocrystalline refractory ceramics exhibit a very high ( $\sim 3000\text{ }^\circ\text{C}$ ) melting point, low mobility of atoms, low plasticity, and high hardness at temperatures up to  $2000\text{ }^\circ\text{C}$ . Therefore these materials can substitute for metals, alloys, and intermetallics in many high-temperature engineering, chemical, and electronic applications. The synthesis of silicon-containing ceramics (oxide, carbide, nitride, etc.) is an active research field in its own right, and, since the early investigations of organometallic oligomers and polymers in the 1970s [501], numerous new organometallic compounds have been developed as precursors to all kinds of nonoxide ceramics like SiC,  $\text{Si}_3\text{N}_4$ , AlN, BN,  $\text{B}_4\text{C}$ , TiC, and TiN.

The low-temperature synthesis (without sintering aid) of two- and three-component silicon-containing ceramics that are homogeneous on an atomic scale is possible only through organometallic precursors [502]. The most salient application of organometallic precursors is in the liquid phase synthesis of silicon nitride and carbide ceramics, which are of significant technological interest because of their high strength and thermal and chemical stability. The use of molecular precursors for refractory materials affords potential advantages in terms of controlling the composition, deposition temperature, and microstructure of the deposited product [30]. The need to control these factors is critical to achieve the extraordinary properties of the above materials, which are sensitive to local variations in composition and/or microstructure. The choice of organometallic molecules for use as SSPs has been largely an empirical process, with few guidelines available relating to the molecular structure of the precursor and the chemical composition of the final material. In the preparation of silicon preceramic polymers, compounds containing Si-Si, Si-H, Si-N, Si-C, and Si-Cl bonds or molecular units based on these linkages are used as precursor species [503] that are derived from different alkyl chlorosilanes (Scheme 19). Since most of the precursor compounds are viscous or oily, their structural characterization is generally based on NMR and mass spectral data [504].

**Scheme 19.** The alkyl chlorosilanes used as building blocks in the synthesis of organometallic precursors.

The versatility of this class of polyceramic precursors originates from the facile chemical (cross-linking, dechlorination) reaction producing, sometimes by thermal treatments, tractable, soluble, and fusible precursor compounds. These stable coordinations are not always directly accessible. For example, the chlorosilanes  $\text{SiHCl}_3$ ,  $\text{SiH}_2\text{Cl}_2$ , and  $\text{SiH}_3\text{Cl}$  are stable compounds and do not split off HCl, whereas the corresponding aminosilane  $\text{SiCl}(\text{NH}_2)_3$  would decompose into  $\text{NH}_4\text{Cl}$  and solid diimide  $\text{Si}(\text{NH}_2)_2$ , which seems to be an attractive precursor from its chemical composition, but is unsuitable because of its physical properties. Similarly, the tetra-amide  $\text{Si}(\text{NH}_2)_4$  is an unstable compound. Although polymeric precursors for  $\text{Si}_3\text{N}_4$  with the ideal atomic ratio  $\text{Si}:\text{N}:\text{C} = 3:4:0$  cannot be directly prepared, various polysilazanes have been shown to convert to pure  $\text{Si}_3\text{N}_4$  [505–508].

This route offers the possibility of improving the compositional homogeneity and tailoring the composition and molecular structure of the ceramic powders. Furthermore, the solubility and rheology of polymeric precursors provide potential processing routes to binders, to sintering aids, and to the formation of nanosized thin films and fibers. In addition, this methodology produces nanosized powders, which are often difficult or impossible to achieve by the more traditional ceramic processing techniques. For example, a single class of preceramic polymer, polysilazanes, has been shown to convert to either pure  $\text{Si}_3\text{N}_4$  or a combination of  $\text{Si}_3\text{N}_4$  and SiC, depending on the chemistry of the polymer and pyrolysis conditions [509]. Polysilazanes are silicon compounds based

on an alternating Si–N backbone that may or may not contain organic substitutes (Scheme 20). The amount of carbon present in the polymer is decisive for the composition of the ceramic material. Minimizing the amount of carbon results in a ceramic with a stoichiometry closer to  $\text{Si}_3\text{N}_4$ , whereas the  $\text{Si}_3\text{N}_4/\text{SiC}$  composite is formed in the case of carbon-rich precursors [509]. In contrast to the sintering step applied for conventional ceramic powder processing, the polymeric precursors are solidified by pyrolysis, whereby the key concern is the ceramic yield determined by thermogravimetric analysis and corroborated by mass spectral studies of the pyrolysis products.

**Scheme 20.** General representation of organometallic precursors to silicon-containing ceramics.

Silicon carbide is an attractive material for demanding mechanical and high-temperature applications and is extensively used as an abrasive and erosive medium. In addition, it is tough, possesses low-friction characteristics, and is second only to diamond in wear resistance. Conventional SiC chemical vapor deposition processes generally utilize separate Si (e.g.,  $\text{SiH}_4$ ,  $\text{SiCl}_4$ ,  $\text{SiBr}_4$ ) and C (e.g.,  $\text{CH}_4$ ,  $\text{C}_2\text{H}_2$ ,  $\text{C}_3\text{H}_8$ ) sources and require temperatures in excess of  $1000^\circ\text{C}$  for the phase formation. High temperatures cause significant deformation of released polycrystalline-Si microstructures, making postprocess SiC coating challenging [510]. Moreover, control over microstructure and composition is difficult at high temperatures. Such limitations clearly illustrate the need for low-temperature alternatives. Lee and co-workers have obtained epitaxial cubic-SiC films with the use of 1,3-disilabutane ( $[\text{SiH}_2\text{CH}_2]_2$ , I, Scheme 21a) as a single precursor, at temperatures as low as  $900^\circ\text{C}$  [511]. Polycrystalline SiC films were obtained at  $650^\circ\text{C}$ . The molecular source, a liquid with high vapor pressure, simplifies the handling compared with conventional dual-source CVD, thereby eliminating the need for an elaborate gas-handling system and ensuring strict stoichiometry control. Using the same precursor, Maboudian et al. have deposited conformal SiC films on Si atomic force microscopy cantilevers at  $780^\circ\text{C}$ . Figure 35 displays a cross section of a SiC film deposited with the use of a molecular precursor on a Si AFM cantilever; an excellent conformal coverage with no void formation at the SiC/Si interface was observed. The disilacyclobutane CVD process was also successfully used to coat released poly-Si microstructures (Fig. 34). This observation reveals the potential for integrating this process into the fabrication technology for microelectromechanical systems (MEMS) [512].

Although 1,3-disilabutane is an ideal SiC precursor, it is not suitable for large-scale applications because it is expensive. Similarly, the simple carbosilanes such as  $\text{CH}_3\text{SiCl}_3$  afford little advantage in terms of either improved stoichiometry control or lowered deposition temperature [513]. Interrante et al. have used substituted disilacyclobutanes

**Figure 34.** SEM images of (a) the cross section of a 130-nm thick SiC film deposited on a Si AFM cantilever and (b) a released poly-Si lateral resonator coated with a thin SiC film. [MeSi(H)- $\mu$ -(CH<sub>2</sub>)<sub>2</sub>Si(Me)CH<sub>2</sub>SiH<sub>2</sub>Me] (II) and [Si(Me)-HCH<sub>2</sub>]<sub>2</sub> (III) (Scheme 21b, c) as alternative single precursors to SiC [514, 515]. Their results indicate that the decomposition chemistry is complicated in the case of II and III because of molecular rearrangements that adversely affect the product purity.

**Scheme 21.**

In contrast to the sol-gel and other processing methods, synthetic organometallic polymers obtained from well-defined building units can be used directly in applications such as coatings, fibers, or bulk shapes and subsequently pyrolyzed to the desired ceramic. The repetition and/or combination of modular units shown in Scheme 22 allows the fabrication of different organometallic precursors. Polycarbosilanes used as precursors to silicon carbide (SiC) can be synthesized with different alkyl groups according to the following equation [333]:

**Scheme 22.**

The polymeric route to silicon-based ceramics was developed by Yajima et al., who used polycarbosilane ( $-\text{[MeHSiCH}_2\text{]}_x-$ ) as a precursor to SiC [502, 516–518]. One of the drawbacks of this method was the initial Si:C ratio of 1:2, which resulted in excess carbon in the final product. The nonstoichiometric product offers mechanical properties inferior to those of bulk stoichiometric SiC [519]. To overcome these problems, pure and modified polymethylsilane (PMS) precursors with a Si:C ratio of 1:1 were successfully used by Laine et al. to obtain stoichiometric SiC [520]. Unmodified PMS,  $-\text{[MeSiH]}-$  [521, 522], with the stoichiometry required to form SiC, offers the potential to be the SSP to SiC. The only gaseous species that should be released in the pyrolytic conversion of PMS is H<sub>2</sub> with the retention of the Si:C ratio. However, unmodified PMS undergoes a rearrangement upon heating [520, 523] and loses 7–8 wt.% by releasing CH<sub>4</sub> and H<sub>2</sub> (Scheme 23). As a consequence, pyrolysis of unmodified PMS gives a mixture of SiC and excess Si, which shows the importance of molecular architecture and its inherent chemical behavior for the composition of the final material. The functionalization of PMS by vinyl groups was shown to compensate for the carbon loss by introducing additional carbon content. Depending upon the functionality of the vinyl groups, it is possible to adjust the composition from silicon rich to stoichiometric SiC and to carbon-rich ceramic.

**Scheme 23.**

Furthermore, new molecular precursors such as hydriodopolycarbosilane (Scheme 24), which is a single-component liquid source, have been developed to obtain high-purity SiC [524].

**Scheme 24.**

Polysilazanes are prepared in a straightforward reaction of  $(\text{CH}_3)_n\text{SiCl}_{4-n}$  with  $\text{NH}_2(\text{H}, \text{R})$ , whereby HCl is eliminated and a low-molecular compound is formed that can be polymerized by employing dehydrocoupling catalysts like KH,  $\text{Ru}_3(\text{CO})_{12}$ , etc. [525] (Scheme 25). The synthesis route

is especially suitable in the case where  $n = 1$  and  $R = \text{CH}_3$  [526, 527].

**Scheme 25.**

The pyrolysis of polysilazane II in a  $\text{NH}_3$  atmosphere produces colorless  $\text{Si}_3\text{N}_4$  in high yield (82%). The decomposition of polysilazanes involves different reaction products such as  $\text{CH}_4$  and  $\text{H}_2$ , which determine the ceramic yield. The highly branched polysilazanes with low carbon content exhibit higher ceramic yield. The split-off of oligosilazanes or loss of volatile silazanes by thermolytic retroversion and transamination should be suppressed to increase the ceramic yield.

Boron nitride has attracted a growing interest for technological applications because of its excellent characteristics, namely high hardness, chemical inertness, and dielectric behavior. Hexagonal boron nitride (*h*-BN) with a layered and  $sp^2$ -bonded structure is similar to graphite and is the stable ordered phase under ambient conditions. On the other hand, cubic boron nitride (*c*-BN) has a zinc blende structure with  $sp^3$ -bonding resembling that of diamond. In fact, *c*-BN is better suited for electronic device applications as a high-temperature semiconductor because of the wide direct energy bandgap (6.4 eV). Moreover, it can easily be doped both *n*-type and *p*-type with Si and Be, respectively. Significant progress has been made in the synthesis of *c*-BN by various physical and chemical deposition methods [528]. However, the major disadvantage of *c*-BN films is that they are much more difficult to synthesize than diamond because of their narrow phase stability region, high compression stress, and problems in controlling boron and nitrogen sources [529, 530]. To overcome these problems, Boo et al. have used isopropyl amine and *tert*-butylamine complexes of triethylborane ( $(i\text{Pr})\text{H}_2\text{NBET}_3$ ,  $(t\text{Bu})\text{H}_2\text{NBET}_3$ ) as SSPs with boron and nitrogen in a 1:1 ratio to grow a crack-free *h*-BN film on Si(100) at 850 °C [99].

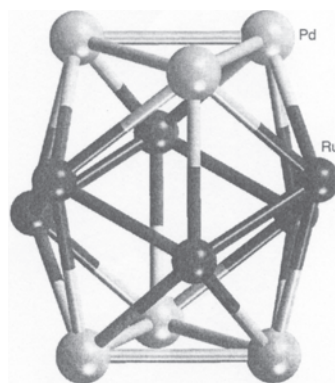

#### 5.2.4. Intermetallics

Heterometallic nanoparticle catalysts such as Pt-Re, Ir-Sn, Pt-Ru, Ag-Ru, Cu-Ru, and Pd-Ru occupy an important position in heterogeneous catalysis [531]. Published reports

[190, 532–534] on such catalyst systems reveal that enhanced catalytic performance apparently arises from the synergy between the component elements at the nanoscale, which is absent in solid solutions of the two bulk metals. Furthermore, the thin films of intermetallic combinations of a group 13 element and a transition metal are thermodynamically stable metal/semiconductor interfaces that can act as ohmic contacts or as Schottky barriers [535]. Although molecular beam epitaxy is used to deposit such materials, a large number of reports have appeared on the deposition of binary metal alloys by the gas-phase decomposition of single-source organometallic sources, which demonstrate the possibilities of controlling the stoichiometry of intermetallics.

Thomas and Johnson and co-workers have obtained discrete nanoparticles of the Pd-Ru bimetallic catalyst by gentle thermolysis of the mixed-metal Pd-Ru carbonylate cluster  $[\text{Pd}_6\text{Ru}_6(\text{CO})_{24}]^{2-}$  (Fig. 35) [190]. HR-TEM revealed that the Pd-Ru bimetallic nanoparticles were of uniform size (ca. 1.7 nm diameter). A uniform distribution of nanoparticles within the pores of mesoporous silica offers a highly active catalyst for hydrogenation of alkenes and unsaturated aromatic systems [190]. The easy formation of Pd-Ru nanoparticles is due to the ability of the anionic molecular precursor to shed its cloak of carbonyl groups under mild thermal treatment (180 °C). A comparison of the catalytic performance with monometallic Ru and Pd clusters reveals that the bimetallic catalysts are far superior in performance to their monometallic analogs, suggesting a possible synergism between the two bimetallic nanoparticles [190].

Kaeszi and co-workers have deposited stoichiometric films of intermetallics containing a group 14 element and a transition metal [536–538]. Precursor complexes with metal-metal bonds (e.g.,  $(\text{CO})_4\text{-CoGaCl}_2(\text{THF})$ ) [537] as well as those in which the metal centers are connected by bridging ligands such as  $[(\text{py})(\text{Et})\text{Co}(\text{dmg}\cdot\text{GaEt}_2)_2]$  [538],  $[\text{Ni}(\text{dmg}\cdot\text{GaEt}_2)_2]$  [538], and  $[\text{Pt}(\text{dmg})(\text{GaMe}_2)_2]$  [536] have been used to deposit CoGa, NiGa, and PtGa<sub>2</sub>, respectively. Since the Co–Ga phase diagram mainly comprises the  $\beta$ -CoGa phase, which extends on either side of the 1:1 atomic ratio, the CoGa films were consistently monophasic. On the other hand, the phase diagrams in the Ga–Pt and Ga–Ni systems comprise several phases, and as a result a small amount of Pt<sub>2</sub>Ga<sub>3</sub> is formed with the major and expected PtGa<sub>2</sub> phase

**Figure 35.** Structure of the  $\text{Pd}_6\text{Ru}_6$  core of the  $[\text{Pd}_6\text{Ru}_6(\text{CO})_{24}]^{2-}$  cluster. Reprinted with permission from [190], R. Raja et al., *Chem. Commun.* 1571 (1999). © 1999, Royal Society of Chemistry.

and the films obtained from the Ni-Ga precursor contained NiGa, NiGa<sub>4</sub>, Ni<sub>2</sub>Ga<sub>3</sub>, and NiGa<sub>4</sub>. Deposition from (CO)<sub>4</sub>-CoGaCl<sub>2</sub>(THF) in the temperature range 250–350 °C gave nearly stoichiometric CoGa films with some chlorine contamination. A mass spectral study (EI-MS) of the precursor showed the abundance (15%) of the stripped heterobimetallic species [CoGa]<sup>+</sup> corresponding to the stability of the Co–Ga bond [537]. The chlorine content in the films decreased at higher temperatures (350–400 °C), but the film became cobalt-rich, indicating that a decrease in the chlorine contamination is associated with a loss of gallium. This is probably due to the formation of volatile GaCl<sub>3</sub>, which is favored by the dissociation of Co–Ga bonds occurring above 350 °C. This example shows the relevance of investigating the gas-phase behavior of precursors, particularly in view of the different fragmentation mechanisms operative in the thermal degradation of the molecule, depending on the decomposition temperature.

Fischer et al. have performed extensive studies on the CVD of intermetallics from molecular precursors containing metal-metal bonds between *d* and *p* block elements [539–542]. Volatile heterodinuclear organometallic compounds L(CO)<sub>3</sub>Co–GaR<sub>2</sub>(D) and L(CO)<sub>3</sub>Co–Ga[(CH<sub>2</sub>)<sub>3</sub>NR<sub>1</sub>]<sub>2</sub>(R) (R = H, CH<sub>3</sub>, C<sub>2</sub>H<sub>5</sub>, CH<sub>2</sub>Bu', CH<sub>2</sub>SiMe<sub>3</sub>; D = THF, NMe<sub>3</sub>, NC<sub>7</sub>H<sub>13</sub>; L = CO, PMe<sub>3</sub>, PPh<sub>3</sub>; R<sup>1</sup> = CH<sub>3</sub>, C<sub>2</sub>H<sub>5</sub>) were studied as single molecular precursors for the deposition of binary CoGa alloy thin films. The films, grown in a hot wall reactor, had Co/Ga atomic ratios in the range of 1 to 3, depending upon the substrate temperature and the type of substituents at the gallium atom. The molecular structure of a prototype of the compound series L(CO)<sub>3</sub>Co–GaR<sub>2</sub>(D) is shown in Figure 36. The deviation in the Co:Ga ratio when compared with that in the precursor was observed when the deposition was performed at low temperatures. The formation of thermally stable gallium alkyl complexes was suggested as a probable reason for the Ga deficiency in the deposits [539].

**Figure 36.** Molecular structure of (CO)<sub>4</sub>Co-Ga(CH<sub>2</sub>'Bu)<sub>2</sub>(C<sub>8</sub>H<sub>8</sub>O). Reprinted with permission from [539], R. A. Fischer and A. Miehr, *Chem. Mater.* 8, 497 (1996). © 1996, American Chemical Society.

Similarly, a series of complexes based on Fe–Ga bonds [540] was used to deposit films with different Fe:Ga ratios. [(CO)<sub>4</sub>FeGa{(CH<sub>2</sub>)<sub>3</sub>NMe<sub>2</sub>}]<sub>2</sub>, a tetranuclear species with a preformed Fe<sub>2</sub>Ga<sub>2</sub> ring, and the gallium-rich complex [(CO)<sub>4</sub>Fe{Ga(CH<sub>2</sub>)<sub>3</sub>NMe<sub>2</sub>}(Bu')]<sub>2</sub> (Scheme 26) produced Fe-Ga films with strict control of the stoichiometry. The efficient elimination of ligands due to β-H elimination was proposed to be the reason for excellent film quality and low deposition temperatures (200–250 °C). Shore et al. have used HFeCo<sub>3</sub>(CO)<sub>12</sub> and H<sub>2</sub>FeRu<sub>3</sub>(CO)<sub>12</sub> as single sources for the CVD of FeCo<sub>3</sub> and FeRu<sub>3</sub> alloy films [408]. When occurring in cold wall reactors, partial decomposition of the HFeCo<sub>3</sub>(CO)<sub>12</sub> into volatile organo-iron compounds and less volatile cobalt species was observed, resulting in iron enrichment of the films. Nevertheless, pure heterobimetallic films could be obtained from photochemical vapor deposition by irradiation with a mercury arc lamp, with CO as a carrier gas. Chi et al. have used the Fe–Sn compounds (C<sub>5</sub>H<sub>5</sub>)Fe(CO)<sub>2</sub>(SnMe<sub>3</sub>) and *cis*-Fe(CO)<sub>4</sub>(SnMe<sub>3</sub>)<sub>2</sub> based on different Fe:Sn ratios to grow FeSn and FeSn<sub>2</sub> films [131]. Pure FeSn films were obtained with (C<sub>5</sub>H<sub>5</sub>)Fe(CO)<sub>2</sub>(SnMe<sub>3</sub>), whereas films composed of the FeSn<sub>2</sub> phase with a minor constituent of FeSn were obtained with *cis*-Fe(CO)<sub>4</sub>(SnMe<sub>3</sub>)<sub>2</sub>. Similarly, CoSn films with small amounts of α-Co<sub>3</sub>Sn<sub>2</sub> were prepared by CVD of Me<sub>3</sub>SnCo(CO)<sub>4</sub> and Ph<sub>3</sub>SnCo(CO)<sub>4</sub> [119].

**Scheme 26.**

The formation of intermetallic compounds from organometallic precursors is highly sensitive to the experimental conditions and requires an optimization of the deposition process for a phase-selective synthesis, especially in those cases where a large number of phases coexist in the binary phase diagrams.

### 5.3. Three-Component Systems (ABE<sub>x</sub>)

#### 5.3.1. Heterometal Oxides

The preparation of three-component systems poses a challenge for the molecular design of the precursor because of the compatibility of the intrinsic physicochemical properties of the individual building units. Moreover, it demands unambiguously characterized precursors with element ratios corresponding to that of the nanomaterial of choice. A variety

of interesting molecular precursors have been synthesized and/or modified for a size- and phase-selective synthesis of nanomaterials (Table 2), which provide the proof of the concept for the molecular-level synthesis of materials.

Stoichiometric  $\text{MgAl}_2\text{O}_4$  films have been successfully prepared from magnesium-aluminum isopropoxide containing the appropriate Mg:Al ratio (1:2) [259–261]. However, for the preparation of transition metal-aluminum, -gallium, or -iron spinels, the fusion of component oxides [543, 544] at high temperatures (1000–1600 °C), ball milling [545], self-propagating combustion synthesis [546], coprecipitation reactions [547], polymer route [548], and hydrothermal synthesis [549] have been used. Wickham et al. have used mixed acetates,  $\text{M}_3\text{Fe}_6(\text{OOCCH}_3)_{17}(\text{O})_3(\text{OH}) \cdot 12\text{pyridine}$  ( $\text{M} = \text{Ni}, \text{Co}, \text{Mn}$ ), as crystalline precursors to stoichiometric ferrites. These complexes contain a large number of pyridine molecules of crystallization, and rapid removal of the coordinated ligands can lead to the segregation of ions. Moreover, they require high temperatures (800–1000 °C) to transform into the respective ferrites. Apblett et al. synthesized a water-soluble Ni–Fe complex,  $[\text{Ni}(\text{H}_2\text{O})_6][\text{FeCl}(\text{EDTA})\text{H}]_2 \cdot 4\text{H}_2\text{O}$  [266], as a single precursor to nickel ferrite; however, the pyrolysis of this compound leads to phase separation, and the sample heat-treated at 600 °C shows  $\text{Fe}_2\text{O}_3$  and  $\text{NiFe}_2\text{O}_4$  as the crystalline phases. Further heating at 900 °C is essential for obtaining stoichiometric nickel ferrite.

Mathur et al. [244, 550] have used heterobimetallic precursors of the type  $[\text{MM}'_2(\text{OR})_8]$  ( $\text{M} = \text{Co}, \text{Zn}$ ;  $\text{M}' = \text{Al}, \text{Ga}, \text{Fe}$ ) for low-temperature synthesis of high-purity spinel particles by the microemulsion method. For a comparative evaluation of the single- and multicomponent approaches, the  $\text{CoAl}_2\text{O}_4$  spinel was synthesized from the single source  $[\text{CoAl}_2(\text{O}i\text{Pr})_8]$  (Fig. 37) and by the use of a stoichiometric mixture of  $[\text{Al}(\text{O}i\text{Pr})_3]_4$  and  $\text{Co}(\text{OR})_2$  ( $\text{R} = -\text{C}(\text{C}_6\text{H}_5)_3$ ). The XRD patterns (Fig. 38) of the two  $\text{CoAl}_2\text{O}_4$  samples reveal that the single-source synthesis yields, under similar experimental conditions, higher phase purity and crystallinity compared with the spinel obtained from a stoichiometric mixture of Al and Co sources. The expected differences in the hydrolysis susceptibility of the isopropoxide and phenoxide derivatives [551] cause different hydrolysis kinetics that adversely affect the homogeneity (with respect to the cation distribution) of the precursor solution. As a result, minor phase separation occurs in the dual-source system (Fig. 38).

Figure 37. Molecular structure of  $[\text{CoAl}_2(\text{O}i\text{Pr})_8]$ .

Figure 38. X-ray diffractograms of two  $\text{CoAl}_2\text{O}_4$  samples prepared by multicomponent (a) and single-source (b) precursor routes. Reprinted with permission from [244], F. Meyer et al., *J. Mater. Chem.* 9, 1755 (1999). © 1999, Royal Society of Chemistry.

Similarly, nanocrystalline  $\text{CuAl}_2\text{O}_4$  and  $\text{NiAl}_2\text{O}_4$  could be obtained by processing  $[\text{CuAl}_2(\text{O}i\text{Bu}')_8]$  and  $[\text{NiAl}_2(\text{O}i\text{Bu}')_8]$ , respectively.

Similarly, zinc aluminate ( $\text{ZnAl}_2\text{O}_4$ ), a well-known wide bandgap semiconductor with a spinel structure, was prepared by the sol-gel processing of the bimetallic precursor shown in Figure 39. Recent investigations of  $\text{ZnM}_2\text{O}_4$  ( $\text{M} = \text{Al}, \text{Ga}$ ) compounds have shown these systems to be new transparent and conductive materials [552]. The optical bandgap of polycrystalline  $\text{ZnAl}_2\text{O}_4$  (3.8 eV) indicates the material to be transparent for light with a wavelength larger than 320 nm. Thus it can be utilized for UV-photoelectronic devices. Moreover, the  $\text{ZnAl}_2\text{O}_4$  spinel is useful in many catalytic reactions, such as cracking, dehydration, hydrogenation, and dehydrogenation [553]. The XRD pattern of the sample calcined at 400 °C shows zinc aluminate (Gahnite) to be the only crystalline phase. This is the lowest reported temperature for the formation of single-phase crystalline  $\text{ZnAl}_2\text{O}_4$ . The crystallite size calculated from the line shape analysis of the diffraction peaks showed a log normal grain growth with increasing calcination temperature (Fig. 40). The above observations are in accordance with the TEM observations showing a systematic crystal growth (Fig. 41).

Figure 39. Molecular structure of  $[\text{ZnAl}_2(\text{O}i\text{Pr})_8]$ .

**Figure 40.** XRD traces of  $\text{ZnAl}_2\text{O}_4$  ceramic calcined at different temperatures. Reprinted with permission from [286], S. Mathur et al., *J. Am. Ceram. Soc.* 84, 1921 (2001). © 2001, American Ceramics Society.

The absorbance spectra (Fig. 42) of  $\text{ZnAl}_2\text{O}_4$  nanoparticles heat-treated (6 h) at 700, 800, 1000, 1200, and 1400 °C reveal a systematic shift in the absorption maxima. The absorbance edge became steeper with increasing the calcination temperature, and a “red shift” (4.5 to 4.0 eV) was observed (Fig. 42). Since the bandgap,  $E_g$ , of a nanocrystalline specimen scales with its diameter,  $d$ , as  $E_g \approx 1/d$ ,

**Figure 41.** TEM micrographs of  $\text{ZnAl}_2\text{O}_4$  ceramic calcined at 600 (a), 800 (b), 1000 (c), and 1200 °C (d). Reprinted with permission from [286], S. Mathur et al., *J. Am. Ceram. Soc.* 84, 1921 (2001). © 2001, American Ceramics Society.

**Figure 42.** Absorbance spectra of  $\text{ZnAl}_2\text{O}_4$  calcined at 700, 800, 1000, 1200, and 1400 °C, respectively. Reprinted with permission from [286], S. Mathur et al., *J. Am. Ceram. Soc.* 84, 1921 (2001). © 2001, American Ceramics Society.

it can be surmised that the observed variation in absorption is relevant to a strong change in the particle size, reflecting the transition of the spinel from nanocrystalline to the micron (bulk) state (inset, Fig. 42).

The class of spiro compounds with the general formula  $\text{M}^{\text{II}}\text{M}_2^{\text{III}}(\text{OR})_8$  was extended by introducing divalent cobalt and trivalent iron into a molecular framework to obtain a single molecular precursor to cobalt ferrite, which is the first example of a Co-Fe mixed-metal alkoxide (Fig. 43) [245]. The decomposition of the Co-Fe precursor in the sol-gel or CVD process produced stoichiometric  $\text{CoFe}_2\text{O}_4$  particles and films, respectively. The X-ray diffractogram (Fig. 44) of the sol-gel-derived material shows a monophasic spinel with nanosized grains ( $\langle d \rangle$ , 35 nm) [246].

One of the major strengths of the chemical methods is the selective synthesis of metastable phases. In contrast to the conventional processing that largely relies on brute force (mixing, milling, and firing), the molecular precursor approach provides a kinetic control over the process (see Section 2). A unique example in this regard is the selective synthesis of single-phase orthoferrite,  $\text{GdFeO}_3$ , which is difficult to obtain because of the easy formation of the thermodynamically favorable  $\text{Gd}_3\text{Fe}_5\text{O}_{12}$  (garnet) phase [554]. Orthoferrites are gaining attention as materials for

**Figure 43.** Molecular structure of  $\text{CoFe}_2(\text{O}'\text{Bu})_8$ .

**Figure 44.** XRD pattern of  $\text{CoFe}_2\text{O}_4$  derived by the sol-gel method.

magneto-optical data storage devices and because of their unique magnetic properties [555, 556]. Access to metastable rare earth iron perovskites with the general formula  $\text{LnFeO}_3$  ( $\text{Ln}$  = any lanthanide ion) was provided, for the first time, by a designed assembly of trivalent lanthanide and iron ions in a molecular framework [255] (Fig. 45). The problem commonly encountered in the selective synthesis of  $\text{LnFeO}_3$  compounds is the formation of thermodynamically favored garnet and secondary iron oxide phases resulting from the use of a mixture of  $\text{Ln}^{3+}$  and  $\text{Fe}^{3+}$  constituents as the precursor. In the absence of any chemical control (bonding) on the ions, the lanthanide and iron compounds in the admixture randomly collide to form various intermediate species with metal ratios unfavorable for obtaining a single-phase material. The result is the coexistence of undesired phases (e.g.,  $\text{Ln}_3\text{Fe}_5\text{O}_{12}$  and  $\text{Fe}_3\text{O}_4$  in the synthesis of  $\text{LnFeO}_3$ ) in the final ceramic material. In view of the above, more stable garnet ( $\text{Ln}_3\text{Fe}_5\text{O}_{12}$ ) and magnetite ( $\text{Fe}_3\text{O}_4$ ) phases are easily formed that, in view of their higher magnetic moments, hinder specific investigations of the weak ferrimagnetic behavior of the orthoferrite,  $\text{LnFeO}_3$ . In this context, the precursors with the required cation ratio and preformed  $\text{Ln-O-Fe}$  bonds are a major breakthrough in the selective synthesis of orthoferrite films and particles [255]. A controlled hydrolysis of Gd-Fe heterometal alkoxide produced

**Figure 45.** Molecular structure of  $[\{\text{GdFe}(\text{OPr}^i)_6\}(\text{HOPr}^i)]_2$ .

faceted nanocrystallites of nearly uniform size ( $\sim 60$  nm) (Fig. 46). The crystalline  $\text{GdFeO}_3$  is formed at a temperature much lower than those required for the solid-state reaction with  $\text{Gd}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  powders ( $\sim 1800$  °C). Furthermore, the crystalline  $\text{GdFeO}_3$  forms directly from an amorphous precursor without the crystallization of any intermediate phases, which in the absence of any phase segregation or crystallization of other stoichiometries confirms the compositional purity of the sample and the contention that the chemical mixing of the ions is retained during the various stages of the processing.

It is interesting to note that using a mixture of component alkoxides does not result in the formation of monophasic material. Kominami et al. have used a mixture of lanthanum and iron alkoxide in a glycothermal synthesis to obtain pure  $\text{LaFeO}_3$ , but the precursor was found to be contaminated by  $\text{LaCO}_3\text{OH}$  [557], whereas Traversa et al. could synthesize pure  $\text{LaFeO}_3$  powders by thermal decomposition of a heteronuclear cyanide complex,  $\text{La}\{\text{Fe}(\text{CN})_6\}\cdot 5\text{H}_2\text{O}$  [558]. In analogy,  $\text{Sm}\{\text{Fe}(\text{CN})_6\}\cdot 4\text{H}_2\text{O}$  was used as a single source for preparing  $\text{SmFeO}_3$  powders and to deposit films on alumina substrates [275]. They have also performed, for comparisons sake, a solid-state reaction between  $\text{Sm}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  powders. The XRD data (Fig. 47) for the two samples show that a single-phase  $\text{SmFeO}_3$  is present at 700 °C in the powder obtained from the Sm-Fe precursor, whereas single metal oxides were present as the major phases up to 1000 °C, in the ball-milled sample (Fig. 47).

Alkaline earth stannate, titanate, zirconate, and hafnate based on the perovskite structure are finding extensive applications as high dielectric constant, ferroelectric, and gas-sensing materials [559–562]. The conventional preparation of these electro-ceramics is based on the solid-state reactions of common inorganic precursors like oxides, chlorides, and carbonates, which require repeated cycles of milling and calcinations at high temperatures ( $>1400$  °C), to achieve complete diffusion and phase formation. Moreover, the

powders exhibit a wide grain size distribution and contamination due to impurities incorporated from abrasive particles or incomplete reactions. Many of these characteristics are symptomatic of inhomogeneous chemical reactions and exert an adverse effect on the useful properties of the material. In contrast to the powder-processing methods, liquid-phase processing (e.g., solution-sol-gel technique) provides a molecular-level mixing of the individual components, which reduces the diffusion path in the nanometer range to yield crystalline material at much lower temperatures than normally required for the solid-state reactions [563–566].

The alkoxide-based synthesis of perovskite powders has its origin in the pioneering works of Mazdiyasi et al., who utilized simultaneous hydrolytic decomposition of titanium and barium alkoxides [567]; however, the precise structure and composition of the precursor was not known in their studies. Several mechanisms have been suggested for the formation of perovskite phases in solution methods [566, 568]. Two mechanisms have been postulated for the formation of barium titanate. The first mechanism involves an acid-base-type reaction in which an anion with the formula  $\text{Ti}(\text{OH})_6^{2-}$  is initially formed during the hydrolysis of Ti alkoxide and later neutralized by the alkaline earth cations [569]. A second type of mechanism suggests the formation of negatively charged  $\text{TiO}_2$  particles (due to the absorption of hydroxyl groups) in which the alkaline earth cations diffuse to counterbalance the negative charge. The above mechanisms do not take into account the formation of heterometal species in the alkoxide or partially hydrolyzed solution, which is a prominent feature of alkoxide chemistry [45, 49, 50, 323, 570]. The nature and chemical composition of intermediate species play a dominant role in determining the purity and temperature of crystallization of the desired phase. For example, the formation of the ortho-titanate or zirconate phase ( $\text{Ba}_2\text{MO}_4$ ;  $\text{M} = \text{Ti}, \text{Zr}$ ) in sols containing individual Ba and Ti(Zr) precursors requires high ( $>1000^\circ\text{C}$ ) temperatures to decompose into  $\text{BaMO}_3$  [332].

The potential of heterometal alkoxide precursors to “preform” the ceramic on a molecular level is promising for nanoscaled perovskite powders (Tables 2–4). High-purity nanocrystalline  $\text{BaTiO}_3$  and  $\text{BaZrO}_3$  oxides [332] have been

synthesized from single-source Ba-Ti(Zr) alkoxide precursors. The improved homogeneity and phase purity and lower crystallization temperatures for gel  $\rightarrow$  oxide conversion are attributed to the use of mixed-metal compounds containing preformed Ba–O–Ti and Ba–O–Zr bonds. The TEM images of barium-titanate (Fig. 48) and zirconate powders revealed homogeneous nanoparticles, which were shown to be monophasic perovskites by powder XRD studies [332].

The strict control over the metal ratios through stoichiometric clusters allows the crystallization of perovskite nanoparticles at low temperatures. For comparative evaluation,  $\text{BaTiO}_3$  was also prepared through the use of common inorganic salts of individual elements in a classic sol-gel route. The X-ray powder diffractograms (Fig. 49) reveal that the powder obtained by the conventional method is contaminated even at  $1200^\circ\text{C}$  by undesired side products like  $\text{BaCO}_3$  and  $\text{Ba}_2\text{TiO}_4$ , whereas a single-phase material is obtained with the mixed-metal alkoxide precursor. In addition, the volume- and number-weighted size dispersion is significantly narrow for the perovskite powders obtained from alkoxide precursors (Fig. 50), which is not the case for powders obtained by the hydroxide route.

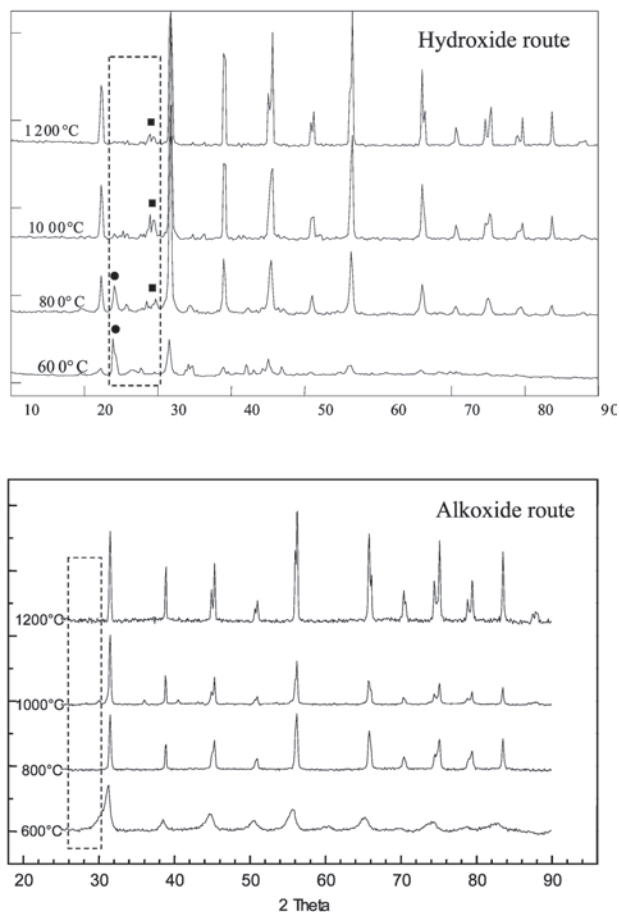

A large number of pure and  $\beta$ -diketonate-modified alkoxide derivatives of lead and alkaline earth metals with various tetravalent cations (Ti, Zr, Hf, Ce) are known [50, 267, 571–575], but most of them do not possess the cation ratio required for perovskite materials. The correct metal ratio in the molecular precursor with respect to the solid-state phase is a prerequisite for chemical control over the phase formation. For example, the decomposition of Pb-Ti heterometal precursor,  $[\text{PbTi}_2(\text{O})_4(\text{OOCCH}_3)(\text{OCH}_2\text{CH}_3)_7]_2$  [267], based on the Pb:Ti ratio 1:2, produced a mixture of  $\text{TiO}_2$ ,  $\text{PbTiO}_3$ , and  $\text{PbTi}_5\text{O}_7$  phases, whereas the precursor  $[\text{Pb}_2\text{Ti}_2(\text{O})_4(\text{OOCCH}_3)_2(\text{OCH}_2\text{CH}_3)_8]_2$  (Pb:Ti = 1:1), with similar ligands but an ideal cation ratio, could be converted into single-phase  $\text{PbTiO}_3$  at  $600^\circ\text{C}$  [575]. Figure 51 shows the molecular structures of the two precursors and the powder X-ray diffractograms of the residue obtained from their pyrolytic decomposition.

Hubert-Pfalzgraf et al. have prepared mixed-ligand Ba-Ti and Sr-Ti complexes (Fig. 52) that possess a metal ratio suitable for the synthesis of  $\text{BaTiO}_3$  and  $\text{SrTiO}_3$  [44, 564].

In an elegant study of the alkoxide-to-oxide transformation, Gaskins and Lannutti have prepared barium titanate at room temperature by reacting a barium titanium oxo-alkoxide,  $\text{Ba}_4\text{Ti}_4\text{O}_4(\text{OPr}^i)_{16}(\text{Pr}^i\text{OH})_3$  (Fig. 53), with acetone

[576]. The transient oxo species formed in the transformation of the molecular cluster possess oxygen coordination numbers for the metals that are necessarily lower than those found for the extended solid-state structure of  $\text{BaTiO}_3$ . As a consequence, the cluster grows (condenses) through oxygen supplied by the acetone molecules, a reaction called aldol condensation. The deficiency in oxygen coordination as the two alkoxide groups are replaced by an oxo unit provides a driving force for the cluster growth. A close look at the metal-oxygen core of the oxo-alkoxide molecule reveals a resemblance to a  $\text{BaTiO}_3$  structural subunit (Fig. 53). This structural similarity probably helps in lowering the barrier to a direct molecule-to-material conversion.

### 5.3.2. Heterometal Chalcogenides

Ternary chalcopyrite materials such as copper indium diselenide ( $\text{CuInSe}_2$ ), copper indium disulfide ( $\text{CuInS}_2$ ), and copper gallium diselenide ( $\text{CuGaSe}_2$ ) are potential solar cell materials, given that their direct bandgaps are nearly optimal for the absorption of the solar spectrum. High-quality thin films of solar-cell materials with high specific power ( $\text{W kg}^{-1}$ ) are required to fabricate efficient devices. Nanocrystalline films are an attractive alternative to single-crystalline devices that are currently used. Since the microstructure and secondary phases (surface layers) may have a large influence on the transport properties of the films [577], optimal control over the purity of films is necessary. Moreover, the current thin-film technologies are limited by the requirement of

**Figure 53.** (a) Molecular structure of Ba-Ti oxo-alkoxide. (b) Comparison of the core structure of monoclinic barium-titanium oxoisopropoxide with the  $\text{BaTiO}_3$  structure viewed along the 111 direction. Reprinted with permission from [576], B. C. Gaskins and J. J. Lannutti, *J. Mater. Res.* 11, 1953 (1996). © 1996, Materials Research Society.

high-temperature deposition processes that are incompatible with all polyimide or other polymer substrate materials. To eliminate or minimize the problems associated with differences between the coefficients of thermal expansion of the substrate and functional film, new approaches to depositing chalcopyrite materials at reduced temperatures are desired. One interesting solution to this problem is the use of ternary SSPs to obtain single-phase materials at low temperatures.

Banger et al. have tested molecular precursors with the general formula  $[\{\text{ER}_3\}_2\text{Cu}(\text{YR}')_2\text{In}(\text{YR}')_2]$  ( $\text{E} = \text{P, As, Sb}$ ;  $\text{Y} = \text{S, Se}$ ; and  $\text{R} = \text{alkyl, aryl}$ ). Besides the appropriate elemental ratio required to form the chalcopyrite phase, another key feature of this class of precursors is the number of tunable sites within the complex that allow engineering of the molecular architecture to direct properties (liquid state, high volatility, thermal stability) that best meet the requirements of the deposition process. An important illustration of the flexibility of the  $[\{\text{ER}_3\}_2\text{Cu}(\text{YR}')_2\text{In}(\text{YR}')_2]$  architecture is the phosphine stabilized complexes  $[\{\text{P}(\text{Bu}^n)_3\}_2\text{Cu}(\text{SEt})_2\text{In}(\text{SEt})_2]$  (**A**) and  $[\{\text{P}(\text{Bu}^n)_3\}_2\text{Cu}(\text{SPr}^n)_2\text{In}(\text{SPr}^n)_2]$  (**B**) that represent the first liquid precursor for the deposition of  $\text{CuInS}_2$ . The low-temperature differential scanning calorimetry (DSC) profiles of the two compounds (Fig. 54) show an absence of an endotherm assignable to a melting phase transition, thus confirming their liquid state. The exothermic peaks at 250 and 268 °C correspond to the decomposition of the samples.

$[\{\text{PPh}_3\}_2\text{Cu}(\text{SEt})_2\text{In}(\text{SEt})_2]$  was used to deposit well-adherent mirror-like films of  $\text{CuInS}_2$  at 390 °C [252] (Scheme 27). The films were dense, with a columnar grain growth and grain size of ca. 500 nm. No evidence of phosphorus or carbon contamination was obtained, indicating a clean decomposition of the precursor [250].

**Scheme 27.**

Vittal et al. have synthesized and structurally characterized molecular precursors (Fig. 55) to ternary silver indium sulfide phases,  $\text{AgInS}_2$  and  $\text{AgIn}_5\text{S}_8$ . Pyrolysis of  $[\{\text{PPh}_3\}_2\text{AgIn}(\text{SCOR})_4]$  ( $\text{R} = \text{Me, Ph}$ ) compounds results in the formation of  $\text{AgInS}_2$ , whereas aerosol-assisted CVD (AACVD) produced dark red films of  $\text{AgIn}_5\text{S}_8$ .

Mixed-metal perovskites are well known for their technological significance to electrochemical applications. In view of their unique ferroelectric, pyroelectric, piezoelectric, and dielectric properties, these materials are finding applications in transducers, light modulation, charge storage, and non-volatile memory devices [46, 559, 560]. The columbite-like phase of  $\text{MgNb}_2\text{O}_6$  (MN) has attracted interest because of

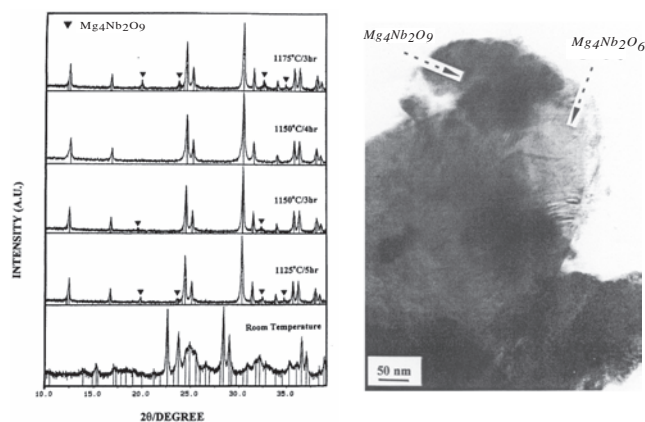

**Figure 54.** Low-temperature DSC for  $[\{P(\text{Bu}^n)_3\}_2\text{Cu}(\text{SET})_2\text{In}(\text{SET})_2]$  (A) and  $[\{P(\text{Bu}^n)_3\}_2\text{Cu}(\text{SPr}^n)_2\text{In}(\text{SPr}^n)_2]$  (B). its use in the synthesis of microwave dielectric materials such as  $\text{Ba}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$  (BMN). Moreover,  $\text{MgNb}_2\text{O}_6$  is the key material for the successful preparation of single-phase perovskite,  $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$  (PMN), which is becoming increasingly important for multilayer ceramic capacitor, electrostrictor, and actuator applications [578, 579]. However, the synthesis of single-phase  $\text{MgNb}_2\text{O}_6$  by solid-state methods is not straightforward, because of the formation of a corundum-like  $\text{Mg}_4\text{Nb}_2\text{O}_9$  phase [580], as observed in the XRD data for the powder calcined at high temperatures (Fig. 56). The transmission electron micrograph and selective area electron diffraction suggested the coexistence of orthorhombic  $\text{MgNb}_2\text{O}_6$  and hexagonal  $\text{Mg}_4\text{Nb}_2\text{O}_9$  phases, which was confirmed by micro-EDX analysis of the grains (Fig. 56).

The use of metal organic precursors ( $\beta$ -diketonate derivatives of Pb and Mg and  $\text{Nb}(\text{OR})_5$ ) also suffer from the problem of compatibility due to the differential hydrolysis rates of alkoxide and  $\beta$ -diketonate precursors [581]. A potential solution to this problem is mixed-metal precursors like

**Figure 55.** Molecular structure of  $[\{P\text{Ph}_3\}_2\text{AgIn}(\text{SCOPh})_4]$ . Reprinted with permission from [237], T. D. Devaraj et al., *Chem. Commun.* 2304 (2001). © 2001, Royal Society of Chemistry.

**Figure 56.** (a) Powder XRD patterns of the calcined  $\text{MgNb}_2\text{O}_6$  powders prepared from a dual source after calcination at different temperatures and times. (b) TEM micrograph of the calcined  $\text{MgNb}_2\text{O}_6$  powder, which shows the coexistence of a parasitic  $\text{Mg}_4\text{Nb}_2\text{O}_9$  phase. Reprinted with permission from [580], S. Ananta et al., *J. Eur. Ceram. Soc.* 19, 355 (1992). © 1992, Elsevier Science.

$\text{MgNb}_2(\text{OEt})_{12}(\text{EtOH})_2$  (Fig. 57) containing Mg and Nb in a single molecule and appropriate ratio [278]. The Mg-Nb ethoxide has been successfully used to deposit stoichiometric films of  $\text{MgNb}_2\text{O}_6$  [264]. The evaporation of  $\text{MgNb}_2(\text{OEt})_{12}(\text{EtOH})_2$  occurs in the range of 200–320 °C, which is comparable to the evaporation temperature of  $\text{Pb}(\text{thd})_2$  ( $\text{thd} = 2,2,6,6\text{-tetramethylheptane-3,5-dionate}$ ), showing that the volatilities of the two precursor systems (Mg-Nb and Pb) are well matched for liquid injection applications. This approach is of help, especially in the case of systems based on three or four different elements for which the precursor systems have not been investigated. The Mg-Nb bimetallic alkoxide is stable only at low deposition temperatures ( $<450$  °C); at higher temperatures the coordinating EtOH ligands dissociate to leave an unsaturated four-coordinate Mg center that is highly susceptible to attack by oxygen. This leads to interaction between the ligands (liberated from the  $\text{Pb}(\text{thd})_2$  precursor) to form Mg-thd species (e.g.,  $\text{Mg}(\text{thd})_2$  or  $\text{EtOMg}(\text{thd})$ ), which have a high thermal stability and lead to Mg-deficient films [264]. The reactivity of pure Mg-Nb alkoxide may be controlled by introducing chelating acetate ligands to obtain a modified acetato-alkoxide precursor,  $\text{MgNb}_2(\mu\text{-OAc})_2(\text{OPr}^i)_{10}$  (Fig. 58) [323]. Similarly,  $\text{Ba}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$  ceramics could

**Figure 57.** TGA data for (a)  $\text{Mg}[\text{Nb}(\text{OEt})_6]_2 \cdot 2\text{EtOH}$  and (b)  $\text{Pb}(\text{thd})_2$ . Reprinted with permission from [278], A. C. Jones et al., *J. Mater. Chem.* 11, 544 (2001). © 2001, Royal Society of Chemistry.

**Figure 58.** (a) Molecular structure of  $\text{Mg}\{\text{Nb}(\text{OEt})_6\}_2(2\text{EtOH})$ . Reprinted with permission from [264], H. O. Davies et al., *Adv. Mater. Opt. be prepared by a sol-gel method involving the reaction of the heterometallic  $\text{MgTa}_2(\text{OEt})_{12}$  with a barium precursor [582].

A SSP is not always a guarantee of control over stoichiometry, and heterometallic precursors may become a disadvantage when they disproportionate during the gas-phase transport, as observed for  $\text{SrTa}_2(\text{OR})_{12}$  compounds, because of the large disparity in the vapor pressure of the parent alkoxides [277]. Nevertheless, the replacement of simple (monoanionic) alkoxide ligands by chelating alkoxides (donor functionalized) offers the possibility of increasing the strength of the  $\text{Sr}(\text{O})\text{R}-\text{Ta}$  bridge. Jones et al. have used dimethyl aminoethanol (dmae) and bis(dimethylamino) isopropanol (bis-dmap) to obtain novel Sr-Ta heteroleptic alkoxides,  $\text{SrTa}_2(\text{OEt})_{10}(\text{R})_2$  ( $\text{R} = \text{dmae}, \text{bis}(\text{dmap})$ ). It can be discerned from the solid-state structure of the dmap derivative (Fig. 59) that in contrast to  $\text{SrTa}_2(\text{OPr}^i)_{12}(\text{Pr}^i\text{OH})_2$ , the Sr atom in  $\text{SrTa}_2(\text{OEt})_{10}(\text{bis-dmap})_2$  more highly coordinated (C. N. = 8) (Fig. 59). The use of  $\text{SrTa}_2(\text{OEt})_{10}(\text{dmae})$  in MOCVD has produced crystalline films of  $\text{SrTa}_2\text{O}_6$  [277].

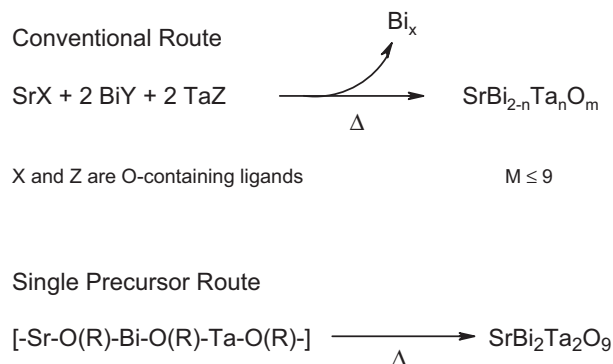

#### 5.4. Four-Component Systems ( $\text{ABCE}_x$ ) and Composites ( $\text{AE}_x/\text{ABE}_x$ )

In general, the synthesis of multicomponent nanomaterials such as  $(\text{Ba},\text{Zr})\text{TiO}_3$ ,  $\text{Pb}(\text{ZrTi})\text{O}_3$ , and  $\text{Pb}(\text{MgNb})\text{O}_3$  by chemical methods is plagued by the unavailability of suitable precursors. The mismatch in the compatibility (vapor pressure, decomposition temperature, chemical properties) of individual components often leads to unwanted side reactions that are unfavorable for obtaining a single-phase

**Figure 59.** (a) Molecular structure of  $\text{Sr}\{\text{Ta}(\text{OPr}^i)_6\}_2\cdot\text{Pr}^i\text{OH}$ . Reprinted with permission from [278], A. C. Jones et al., *J. Mater. Chem.* 11, 544 (2001). © 2001, Royal Society of Chemistry. (b) Molecular structure of  $[\text{Sr}\{\text{Ta}(\text{OEt})_5(\text{bis-dmap})\}_2]$ . Reprinted with permission from [277], M. J. Crosbie et al., *Chem. Vap. Deposition* 5, 9 (1999). © 1999, Wiley-VCH Publishers.

nanomaterial. For instance, the control of stoichiometry in the synthesis of strontium bismuth tantalite,  $\text{SrBi}_2\text{Ta}_2\text{O}_9$  (SBT), is still a knotty problem because of the relatively high volatility of the bismuth components. Recently attempts have been made to obtain SBT films and powders from a mixture of  $\text{SrTa}_2(\text{OEt})_{12}$  and  $\text{Bi}(\text{CH}_3)_3$  or by mixing of individual alkoxides, but none of these reports deals with a single-source SBT system [583, 584]. Lee et al. have prepared a complex alkoxide,  $[\text{SrBi}_2\text{Ta}_2(\text{OCH}_2\text{CH}_2\text{OCH}_3)_{18}]$ , which was characterized by solution NMR studies [292]. Since the complex exhibits just one set of alkoxide ligands indicating the same chemical environment, the formation of a single source was assumed. However, such a simplified spectrum may also result from a fast exchange of alkoxide groups present on different alkoxide centers. Nevertheless, the intrinsic role of a single alkoxide source is corroborated by the formation of single-phase SBT films. The common chemical routes to SBT (Scheme 28) employ a 20–30% excess of Bi component, which seems to be a must to compensate for the loss of Bi during the heat treatments [292, 585]. The use of Sr-Bi-Ta methoxyethoxide, however, shows that excess Bi is not necessary for the formation of a pure ferroelectric phase. The TGA analysis shows that the dried alkoxide precursor decomposed gradually and monotonously, with no abrupt heat release characteristic of a heterogeneous mixture. The low-temperature (350 °C) synthesis of SBT films with a homogeneous and dense grain structure, together with the TGA analysis, suggests a chemical network of Sr, Bi, and Ta ions that is responsible for retarding the loss of the Bi component.

**Scheme 28.**

The continuous quest to obtain materials with improved properties and the possibility of improving the compositional homogeneity and tailoring the composition through new organometallic molecular or polymeric precursors has led to investigations of new preceramic precursors based on additional elements (e.g., B-C-N and Si-B-N-C systems). The approach of synthesizing nonoxide ceramic materials from multicomponent precursor molecules already containing the basic structure (coordination) and bonds desired in the final ceramic product has proved to be of great value. Among ternary nonoxide ceramics, boron-carbon-nitrogen is gaining increasing attention because of the outstanding properties of boron carbonitride,  $\text{BC}_x\text{N}_y$ . These compounds are superhard like diamond and cubic boron nitride and show remarkable stability against oxidation at elevated temperatures [586].

When compared with diamond, which decomposes to carbon dioxide at 800 °C in air, cubic boron nitride (*c*-BN) is resistant to oxidation up to 1600 °C. However, the application of *c*-BN is complicated because of high internal stresses in thin films. Boron carbonitride possesses high hardness and oxidation resistance by low internal stresses; these properties make it an interesting alternative material. The starting materials pyridine borane ( $C_5H_5N \cdot BH_3$ ) and triazaborabicyclodecane ( $BN_3H_2(CH_2)_6$ ) containing boron, carbon, and nitrogen have been used as SSPs to deposit ultrahard  $BC_xN_y$  on low-melting-point materials like aluminum and polymers [240]. Riedel et al. have made a comparative evaluation of the suitability of  $C_5H_5N \cdot BH_3$  and  $BN_3H_2(CH_2)_6$  in a plasma-assisted CVD process. They found that the atomic hydrogen produced by the decomposition of precursor in the plasma reduces the carbon content in the films. Since  $BN_3H_2(CH_2)_6$  contains a higher amount of hydrogen, BCN films produced with this precursor revealed a lower carbon content. This example illustrates the role auxiliary elements (ligands) can play in the final composition of the material [271].

In view of the higher thermal stability of amorphous Si-C-N ceramics compared with binary Si-N or Si-C amorphous compounds, a large number of organometallic precursors such as polyorganosilazane [587], polymethyldisilazanes [588], and polyorganosilylcarbodiimides [589] have been used to obtain Si-C-N systems. It was observed that a dual-source precursor system consisting of polysilazane (Si-N) and polycarbosilane (Si-C) did not provide sufficiently homogeneous Si-C-N precursors to prevent the crystallization of SiC. On the other hand, single-source Si-C-N precursors with a similar C:Si ratio led to products that were amorphous at rather high temperatures [590].

Jansen et al. [591] have prepared amorphous ceramics with the chemical compositions  $Si_3B_3N_7$  and  $SiBN_3C$  by the pyrolysis of the single-source trichlorosilylamino-dichloroborane,  $Cl_3Si-NH-BCl_2$ , under ammonia and inert gas atmospheres, respectively. These ceramics possess optimized mechanical properties compared with material prepared from modified polymers or by copolymerization [592]. The borosilicon nitride  $Si_3B_3N_7$  and the borosilicon carbonitride  $SiBN_3C$  remain amorphous on heating in vacuum or in a  $N_2$  atmosphere up to 1800 and 1900 °C, respectively, and no separation into thermodynamically stable crystalline phases was observed. In addition, an extremely high resistance against oxidation up to 1550 °C was observed for  $SiBN_3C$ , which is simply too high for a metastable nonoxide ceramic [592]. The exceptional properties of these amorphous compounds seem to have their origin in the precursor chemistry and preorganized Si-N-B bonds. The atomic arrangement in the precursor (Fig. 60) is an important condition for the homogeneous elemental distribution, and it avoids regional inhomogeneity due to boron- or silicon-enriched clusters [593]. Si-B-N-C ceramics prepared from other precursors show segregation into crystalline  $Si_3N_4$  and turbostratic BN at temperatures over 1400 °C [594, 595].

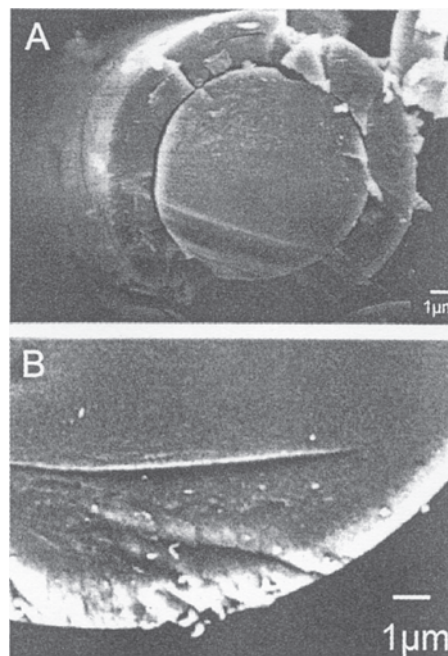

Whereas  $SiBN_3C$  fibers can easily withstand temperatures of up to 1800 °C in nonoxidizing atmospheres and up to 1500 °C under oxidizing conditions for long periods (<50 h), the commercial HiNicalon fibers (Nippon Carbon), when

**Figure 60.** (a) Synthesis of the precursor molecule TADB. (b) Pyrolysis and polymerization of TADB.

aged in air at 1500 °C for 15 h, develop a crystalline oxide layer that contains several cracks and debonds from the fiber core (Fig. 61). The above example shows the advantage of molecular precursors in achieving a high degree of connectivity in the amorphous ceramic that is responsible for the unusual properties of the fibers prepared from it.

The definition of nanocomposite material encompasses a large variety of systems, such as one-dimensional, two-dimensional, three-dimensional, and amorphous materials, made of distinctly dissimilar components and mixed at the nanometer scale [337] (Scheme 29). Nanocomposites are of intense current interest for potential applications

**Figure 61.** Oxidation resistance of Siboramic compared with HiNicalon fibers (Nippon Carbon). (A) Fracture surface of HiNicalon fibers after exposure to air (15 h, 1500 °C). (B) Fracture surface of  $SiBN_3C$  fibers after exposure to air (50 h, 1500 °C). Reprinted with permission from [616], P. Baldus et al., *Science* 285, 699 (1999). © 1999, American Association for the Advancement of Science.

in catalytic, magnetic, electronic, and optical applications [596–602].

**Scheme 29.**

The combination of two discrete phases with different properties, at the molecular level, provides an avenue to the design of new hybrid materials as well as the possibility of modulating the properties of one or more of the components. It is also a unique way to generate materials that have special properties that are unknown in the individual components or new compositions (materials) not known before. The concept of dispersing an active phase into a supporting phase (matrix) is not new, and a large number of examples are available where functional nanoparticles have been embedded in polymer, glass, or ceramic matrices to modify the properties [289, 296, 299, 301, 303, 306, 308, 309]. Since the properties of nanocomposite materials depend not only on the properties of their individual parents but also on their degree of mixing and interfacial characteristics, considerable efforts are focused on the development of new chemical routes for producing these systems. The phase segregation poses a challenge in the synthesis of compositionally different nanocomposites because a uniform intermingling of two different phases cannot be obtained by mechanical blending. The above problem nevertheless can be addressed by using single-molecule precursors in which the elements required to form the two phases (dispersoid and matrix) are assembled in a molecular framework.

Composites of a metal and metal oxide phase could be interesting in view of their special material properties, like hardness, plasticity, luminescence, conductivity, photoelectric properties etc. The strategy to obtain such biphasic nanocomposites in a *single-step* approach is based on the use of molecular precursors containing either a zerovalent or a meta-stable (unusual oxidation state) metallic center [410]. On thermal treatments, the meta-stable oxidation state disproportionates via a redox reaction to form a more stable higher oxidation state and the elemental form. For example, Cu(I) species have been used in sol-gel and CVD processes to obtain the Cu/Cu<sub>2</sub>O system.

A particularly interesting example is the formation of biphasic composites from the CVD of *tert*-butoxides of bivalent germanium, tin, and lead with the general formula

$M(\text{O}^t\text{Bu})_2$  ( $M(\text{II}) = \text{Ge, Sn, Pb}$ ) [143]. Veith et al. have studied the gas-phase pyrolysis (450–550 °C) of  $M^{\text{II}}(\text{O}^t\text{Bu})_2$  compounds to obtain composite films where metal particles are wrapped in oxide shells (Eq. (22)).

The molecular structure of the Ge precursor is shown in Figure 62. The formation of biphasic particles is chemically driven because the electron transfer necessary for the observed redox process ( $2M^{\text{II}} \rightarrow M^0 + M^{\text{IV}}$ ) occurs in a molecular entity, which enforces a narrow size distribution and self-organization of the two phases in the CVD deposit. The SEM images of the films show a regular distribution of spherical particles. The globular morphology of metal-metal oxide composite particles was investigated by nanoindentation and X-ray photoelectron spectroscopy (XPS) studies [603].

The Ge 3d XPS spectrum (Fig. 63) of the Ge/GeO<sub>2</sub> films exhibits two peaks, where the signal located at the lower binding energy is due to the germanium metal. Pure GeO<sub>2</sub> films (obtained by the CVD of Ge(OPr<sup>i</sup>)<sub>4</sub> under identical conditions) showed a peak corresponding only to the Ge-O phase (Fig. 63), which confirmed the formation of a composite material.

The Ge content in the composite film was found to increase upon argon sputtering. This suggested that the metal particles are possibly wrapped in an oxide matrix that was peeled off during the sputtering process. To confirm that the sputter process does not lead to the reduction of germanium oxide to elemental germanium, the GeO<sub>2</sub> sample was also sputtered with Ar<sup>+</sup> ions, but no Ge(0) was detected, even after a long sputtering time (Fig. 63). The nanomechanical characterization [603] of the Ge/GeO<sub>2</sub> films with an atomic force microscope-coupled nanoindenter (NI-AFM) supported a core-shell-type structure. Figure 64 shows the AFM images of the composite film before and after nanoindentation. The triangular impressions are due to indentations with different load forces. The applied force versus displacement (penetration depth) gave the hardness profile across the film. The hardness increased with increasing indented depth, reached a maximum value (7.2 GPa), and

**Figure 62.** Molecular structure of  $[\text{Ge}(\text{O}^t\text{Bu})_2]_2$ .

**Figure 63.** Ge 3d XPS spectra of the as-deposited and Ar<sup>+</sup>-sputtered Ge/GeO<sub>2</sub> and GeO<sub>2</sub> films. Reprinted with permission from [24], S. Mathur et al., *Mater. Sci. Forum* 386–388, 341 (2002). © 2002, Trans Tech Publications.

then gradually decreased to the initial value (6.0 GPa); the hardness value at the maximum corresponds to the hardness of bulk Ge (7.6 GPa). The indented depth-dependent variation of hardness (Fig. 64) indicated that the composite was composed of a harder constituent at the core. The indented depth corresponding to the maximum hardness can be assigned to the center of a spherical particle, which indicates that the mean particle diameter is about the twice the indented depth (ca. 120 nm), a fact borne out by the AFM image (Fig. 64), which shows the average particle size to be ca. 120–130 nm.

The redox chemistry observed for divalent Ge, Sn, and Pb species is also valid in their heterometal compounds;

**Figure 64.** AFM images of Ge/GeO<sub>2</sub> sample obtained before (a) and after (b) indentation experiments and the variation of the hardness with the contact depth. Reprinted with permission from [24], S. Mathur et al., *Mater. Sci. Forum* 386–388, 341 (2002). © 2002, Trans Tech Publications.

for example, thermolysis of BaSn<sub>2</sub>(OBU')<sub>6</sub> (formed by the Lewis acid-base reaction of Ba(OBU')<sub>2</sub> and Sn(OBU')<sub>2</sub> [325]) produces a two-phase material (Sn/BaSnO<sub>3</sub>) where metallic tin particles are dispersed in a barium stannate matrix [604]. Veith et al. have extended this approach to those metal centers for which a meta-stable oxidation state is not easily accessible [605] by incorporating reducing ligands into the precursor. Thus, hydride-modified aluminum *tert*-butoxide, [H<sub>2</sub>Al(OBU')]<sub>2</sub>, disproportionates upon pyrolysis (450–550 °C) to yield an Al/Al<sub>2</sub>O<sub>3</sub> composite [605]. A similar observation was made with the Ga compound [H<sub>2</sub>Ga(OBU')]<sub>2</sub> (Table 4), which produced a Ga/Ga<sub>2</sub>O<sub>3</sub> composite [302].

Silica-supported metal particles constitute a large class of important heterogeneous catalysts [532, 606]. The efficiency of such catalytic systems depends on the size and shape of the metal particles and on the nature of particle-support interactions. For this reason, considerable attention has been paid to the development of synthetic strategies to tailor metal/silica (M/SiO<sub>2</sub>) composite materials.

Lukehart et al. have incorporated complexes of various metals (Ge, Ag, Cu, Os, Pd, Pt, Re, and Ru) in silica xerogel matrices (Table 4) to obtain molecularly doped xerogels [294, 303].

**Scheme 30.**

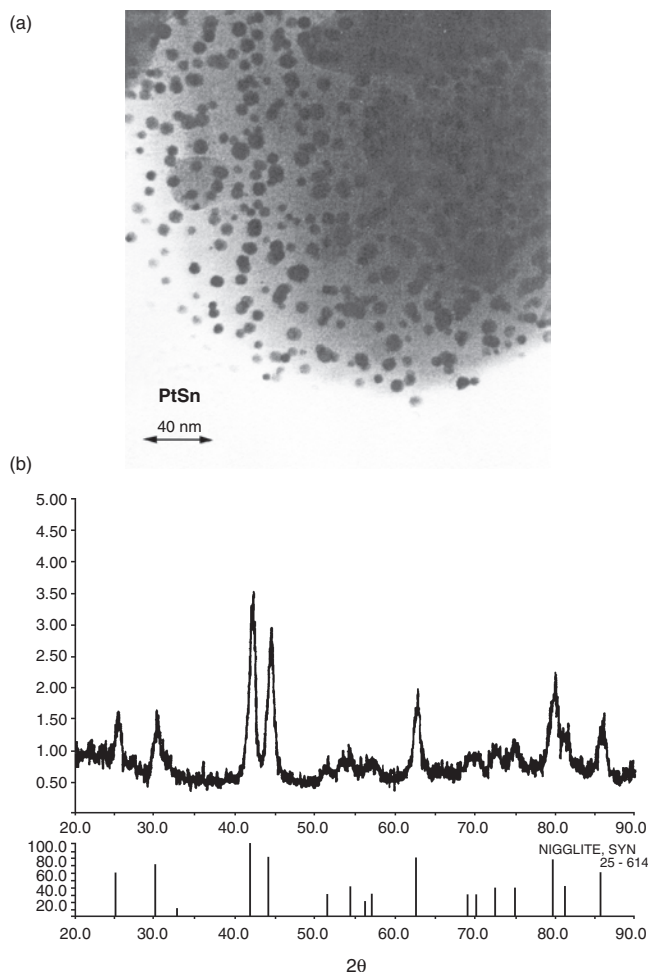

Subsequent thermal treatment of the doped xerogels afforded metal nanoclusters highly dispersed in the bulk of the xerogel matrix [294, 303], which is chemically controlled because of the covalent bonding of the metal complex in the matrix (Scheme 30). When a dinuclear complex such as *cis*-Pt(PPh<sub>3</sub>)<sub>2</sub>-(Ph)(SnPh<sub>2</sub>Cl), with a bimetallic core (Pt:Sn = 1:1) is used, a nanocomposite containing nanocrystals of PtSn (niggliite) intermetallic dispersed in silica matrix is formed (Fig. 65). The selective formation of single-phase PtSn particles demonstrates that control over the composition of the nanomaterial can be achieved through proper choice of the core structure of the molecular precursor [607].

Tilley et al. have used tris(alkoxy)siloxo derivatives of different metals such as Cu, Al, Ti, Zr, Hf, V, and Cr to obtain metal/silica and metal oxide/silica nanocomposites [103, 249, 299, 301, 311, 313] and have investigated their catalytic behavior. The molecular structure of the copper(I) derivative, [Cu(OSi(OBU')<sub>3</sub>)<sub>4</sub>], is shown in Figure 66.

The precursors of the general formula M[OSi(OBU')<sub>3</sub>]<sub>n</sub> are well-defined oxygen-rich compounds that can be thermolyzed to amorphous, homogeneous metal oxide/silica materials at low temperatures, via the elimination of isobutene and water. For example, the group 4 complexes, M[OSi(OBU')<sub>3</sub>]<sub>4</sub> (M = Ti, Zr, Hf), convert readily to high-surface-area MO<sub>2</sub> · 4SiO<sub>2</sub> materials at temperatures as low as 135 °C (Eq. (24)).

**Figure 65.** (a) TEM micrograph of silica xerogel nanocomposite containing PtSn nanoclusters and (b) the corresponding XRD trace. Reprinted with permission from [607], J. P. Carpenter et al., *Inorg. Chim. Acta* 251, 151 (1996). © 1996, Elsevier Science.

The thermolytic conversion of molecular precursors to metal oxide-silica materials occurs in theoretical yields with a homogeneous distribution of silicon and the transition metal in the oxide matrix that can be attributed to the preservation of molecular-level homogeneity in the transition from precursor to ceramic material. The solid-state transformation gives relatively ordered porous structures, indicating that the precursor's crystalline lattice may function as a template to orient the condensation reactions in particular directions. The microstructure of the heat-treated  $ZrO_2/SiO_2$  material shows a smooth silica matrix containing spherical  $ZrO_2$  particles that grow in size at higher temperatures (Fig. 67).

Roesky et al. have reported on the preparation and chemical properties of a large number of heterometallosiloxane compounds that represent an interesting class of model compounds and precursors to silica-based materials [608]. For example, Dhameincourt et al. have used eight-membered titanium-containing halo-siloxane rings  $[(TiX_2)_2O_4(SiBu_2)_2]$  ( $X = Cl, Br, I$ ) (Scheme 31) as SSPs, prepared according to Scheme 31, to homogeneous  $TiO_2/SiO_2$  material [310].

**Figure 66.** ORTEP view of the molecular structure of  $[Cu(OSi(OBu')_3)_4]$ . Reprinted with permission from [299], K. W. Terry et al., *Chem. Mater.* 8, 274 (1996). © 1996, American Chemical Society.

One of the interesting findings of their study is the role of halogen atoms, in the precursor, in determining the phase of the resulting ceramic. For instance, the precursors containing chloride and iodide ligands produced silica mixed with anatase, whereas the bromide derivative yielded silica mixed with rutile [310].

**Scheme 31.**

The (alkoxy)siloxides are also interesting precursors for depositing biphasic thin films. Narula et al. have used  $[(Bu'O)_3Si-O-Ti(OBu')_3]$  as a SSP for obtaining antireflection  $TiO_2-SiO_2$  coatings by atmospheric pressure CVD process [312]. Recently, Schubert et al. have prepared titanium alkoxides modified with a  $\beta$ -diketonate group

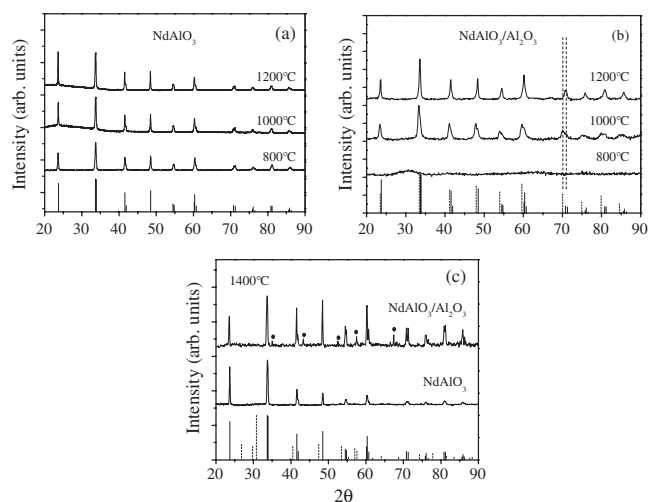

**Figure 67.** TEM photographs of xerogel derived from  $Zr[OSi(OBu')_3]_4$  after calcination under  $O_2$  at 1200 and 1400 °C. Reprinted with permission from [301], K. W. Terry et al., *J. Am. Chem. Soc.* 119, 9745 (1997). © 1997, American Chemical Society.

containing a hydrolyzable alkoxy silane moiety [609]. The hydrolytic conversion of these compounds produced dispersed silica-titania powders. The amount of silica in the final material could be tuned by increasing the number of alkoxy silane groups in the precursors. The presence of silica matrix inhibits the growth of titania nanoparticles; as a result, in the  $\text{TiO}_2\text{:2SiO}_2$  system the anatase phase was observed, whereas the formation of rutile was favored in the  $\text{TiO}_2\text{:SiO}_2$  system [609]. For anatase-rutile transformation, the titania particles must exceed a certain size, and particle growth is favored in the system containing lower silica content.

Recent reports on nanocomposite systems have shown that the matrix materials not only act as passive hosts in sustaining and protecting the nanocrystallites, but also provide a special environment the dispersoids [610–612]. For example, the change in the emission peak observed in the  $\text{CdSe/BaTiO}_3$  composite system has been attributed to the dielectric environment effects of the matrix on the electronic structure of the embedded  $\text{CdSe}$  quantum dots [613]. In the context of optical materials, composites containing lanthanide elements or their phases dispersed in an isotropic matrix are of immense technological value and current interest. The neodymium-doped materials are useful as solid-state laser media, phosphors, and optical amplifiers [600–602]. A homogeneous dispersion of high concentrations of  $\text{Nd}^{3+}$  ions in a fully connected host matrix like  $\text{SiO}_2$  is difficult because of the absence of nonbridging oxygen atoms. As a result, the coordinatively unsaturated  $\text{Nd}^{3+}$  ions form interaction clusters, resulting in quenching of the luminescence quantum yield. The addition of alumina as a codopant can control the clustering of rare-earth ions by forming  $\text{Nd-O-Al}$  bonds, which improves the ill-coordinated state of lanthanide centers [614]. Mathur et al. have put forward a new concept of controlling the quenching problem by restricting the movement of lanthanide ions in the host matrix. Since the  $\text{Nd-Nd}$  separation plays a decisive role in the quenching process, adding the dopant phase in the form of nanocrystals containing  $\text{Nd-O-Al}$  units is expected to offer positional control with respect to the minimum  $\text{Nd-Nd}$  separation. A higher amount of alumina can serve as an active matrix by interacting with the surface  $\text{Nd}$  atoms of the  $\text{NdAlO}_3$  nanocrystals to form further  $\text{Nd-O-Al}$  bonds. Moreover, alumina is a suitable matrix because it allows the incorporation of a high concentration of  $\text{Nd}^{3+}$  ions, and, in comparison to silica, alumina possesses a higher refractive index and optical transparency. To avoid short  $\text{Nd-Nd}$  distances, heterometallic precursors

**Figure 69.** X-ray diffraction profiles of  $\text{NdAlO}_3$  (a) and  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  (b and c) systems calcined at 800, 1000, 1200 and 1400 °C. Reprinted with permission from [265], S. Mathur et al., *Chem. Mater.* 14, 568 (2002). © 2002, American Chemical Society.

$[\text{NdAl}_3(\text{OPr}^i)_{12}(\text{Pr}^i\text{OH})]$ , containing single, isolated  $\text{Nd}$  ions surrounded by optically silent metal atoms, were used as precursors. The validity of this hypothesis was verified by investigation of the optical properties of (i) monophasic  $\text{NdAlO}_3$  and (ii)  $\text{NdAlO}_3$  nanocrystals evenly dispersed in alumina matrix ( $\text{NdAlO}_3/\text{Al}_2\text{O}_3$ ).

The precursors,  $[\text{NdAl}(\text{OPr}^i)_6(\text{Pr}^i\text{OH})]_2$  (NA) and  $[\text{NdAl}_3(\text{OPr}^i)_{12}(\text{Pr}^i\text{OH})]$  (NA3), possess the  $\text{Nd}:\text{Al}$  ratio required for the formation of  $\text{NdAlO}_3$  and  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  (Fig. 68). The molecular frameworks in NA and NA3 formed by the bidentate chelation of tetrahedral isopropoxo aluminate group(s) [297] fulfill the condition of preformed  $\text{Nd-O-Al}$  bonds.

Both compounds, when subject to controlled hydrolysis, produce homogeneous xerogels that can be calcined to obtain mono- and biphasic nanomaterials (Eqs. (25)–(26)).

The XRD patterns of the calcined powder obtained from NA show neodymium aluminate to be the only crystalline

**Figure 70.** TEM images of (a)  $\text{NdAlO}_3$  and (b)  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  calcined at 1000 and 1200 °C, respectively. Reprinted with permission from [265], S. Mathur, et al., *Chem. Mater.* 14, 568 (2002). © 2002, American Chemical Society.

**Figure 71.** Overview absorption spectra of  $\text{NdAlO}_3$  and  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  systems obtained at room temperature. Reprinted with permission from [265], S. Mathur et al., *Chem. Mater.* 14, 568 (2002). © 2002, American Chemical Society.

phase up to 1400 °C (Fig. 69), whereas in the case of the  $\text{NdAl}_3\text{O}_6$  sample, crystallization of aluminas (mixture of  $\gamma$ ,  $\kappa$ , and  $\delta$  phases) was observed around 1300 °C (Fig. 69). This observation was corroborated by the formal composition ( $\text{NdAl}_3\text{O}_6$ ) of the oxide material, indicating  $\text{Al}_2\text{O}_3$  to be amorphous up to 1200 °C. The TEM image of  $\text{NdAlO}_3$  exhibits crystallites with regular size and narrow size distribution, whereas a bimodal mixture of particles was present in calcined **NA3** powder (Fig. 70). The analytical electron microscopy of the composite material revealed large  $\text{NdAlO}_3$  grains (ca. 150 nm) regularly dispersed in an alumina matrix made up of tiny crystallites (ca. 20 nm) [265].

A comparative evaluation of the optical properties of  $\text{Nd}^{3+}$  ions in  $\text{NdAlO}_3$  and  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  revealed the absorption coefficient to be much larger (especially in the 350–700-nm region) for the  $\text{NdAlO}_3$  crystallites embedded in an  $\text{Al}_2\text{O}_3$  matrix than that observed for pure  $\text{NdAlO}_3$  (Fig. 71). The high-resolution absorption spectra (Fig. 72) of  $\text{NdAlO}_3$  and  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  recorded at 10 K correspond to the  $^4\text{I}_{9/2}(1) \rightarrow ^4\text{F}_{9/2}(1)$  transition. The  $\text{NdAlO}_3$  spectrum shows a single peak, whereas the  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  composite exhibits, besides the main peak, a series of satellites. The photoluminescence (PL) spectra (Fig. 72) of the two systems excited at 4 K by 351-nm radiation ( $\text{Ar}^+$  ion laser) reveal an enhanced PL intensity (X35 times) for the  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  sample. These improved optical properties of the oxide-oxide composite can be attributed to the influence of the  $\text{Al}_2\text{O}_3$  matrix on the electronic structure of  $\text{Nd}^{3+}$  ions in  $\text{NdAlO}_3$  particles. It is plausible that the much smaller alumina crystallites form a solvation shell around the  $\text{NdAlO}_3$

**Figure 72.** (a) High-resolution absorption and (b) photoluminescence spectra of  $\text{Nd } 4f \ ^4\text{F}_{3/2} \rightarrow ^4\text{I}_{9/2}$  emission in  $\text{NdAlO}_3$  and  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  systems. Reprinted with permission from [265], S. Mathur et al., *Chem. Mater.* 14, 568 (2002). © 2002, American Chemical Society.

**Figure 73.** HR-EM image of  $\text{NdAlO}_3/\text{Al}_2\text{O}_3$  composite showing crystalline and amorphous domains. Reprinted with permission from [265], S. Mathur et al., *Chem. Mater.* 14, 568 (2002). © 2002, American Chemical Society.

crystallites, thereby amending some of the surface defects of  $\text{NdAlO}_3$  nanocrystals and eliminating the clustering of Nd centers. Indeed, the high-resolution TEM images reveal crystalline domains of  $\text{NdAlO}_3$  linked together by amorphous alumina grains (Fig. 73). The observed higher absorption coefficient and photoluminescence of the **NA3** sample indicate that energy transfer from the alumina matrix to the  $\text{Nd}^{3+}$  cations is operative in the composite material, which additionally populates the excited state of  $\text{Nd}^{3+}$ , resulting in enhanced luminescence efficiency. The surface defects in the nanoparticles are the source of nonradiative quenching sites in the luminescent materials, which decrease the luminescence intensity. In the composite material, the  $\text{NdAlO}_3$  crystallites are in close contact with neighboring alumina grains (Fig. 73), which may compensate for some of the surface defects and simultaneously act as a passivating medium to

**Figure 74.** Molecular structure of  $\text{ErAl}_3(\text{OR})_{12}$ .

**Figure 75.** Commercial (a) and sol-gel (b) processed wash coat. Reprinted with permission from [256], C. K. Narula, *Mater. Res. Soc. Symp. Proc.* 271, 181 (1992). © 1992, Materials Research Society.

keep the neodymium aluminate centers effectively isolated (Scheme 32).

**Scheme 32.**

The lanthanide-containing oxide-oxide system represents a two-phase structure, where the optically active phase is crystalline and the matrix is amorphous. The processing of these composites can offer materials with properties that are glass-like in most respects, except for the spectroscopy, where they are crystal-like.

Westin et al. have used  $\text{ErAl}_3(\text{OPr}^i)_{12}$  in a sol-gel process to obtain Er-doped Al-Si-Ti oxide glasses (Fig. 74) [614]. The optical characterization of the material shows that using a SSP as the doping source endows a high homogeneity with respect to the cation dispersion, and the films were free from Er-rich clusters, which is the case in conventionally prepared Ln-doped material. The high dispersivity of Er ions in the matrix is reflected in the high emission in the infrared region.

Narula et al. have used lanthanum and cerium alkoxy-aluminates ( $\text{MAl}_3(\text{OPr}^i)_{12}$ ;  $\text{M} = \text{La}, \text{Ce}$ ) in a sol-gel process to obtain high-surface-area alumina incorporating lanthanum and cerium for automotive catalyst substrate applications [256, 297]. The NMR experiments performed to follow the hydrolysis reactions show that lanthanides remain bonded to aluminum in the early stages of hydrolysis. They have impregnated the wash coat of automotive catalysts with alkoxy-derived sols and compared it with the commercial wash coat for the oxidation of hydrocarbons and CO and the reduction of  $\text{NO}_x$ . As shown in Figure 75, a higher channel volume was achieved in the sol-gel-processed wash coat.

## 6. CONCLUSIONS

Nanotechnology demands maneuvering materials atom by atom, which renders the conventional macroscopic material processing methods (mixing, milling, and heating) crude and imprecise. The need for methods enabling controlled

growth of nanomaterial has led to the use of SSPs, which inherently possess the requirements of the nanomaterial (element combination and bonding features of the solid phase) in the molecular state. This review underlines the potential of molecular templating of nanomaterials of different compositions and shows that original solutions can be achieved through the chemical design of the precursor. The directed manipulation of molecular aggregates as elementary fragments of solid-state structure seems to be an efficient strategy for the preconceived synthesis of nanomaterials at the atomic level.

The incorporation of different elements into a molecular source to obtain the target material from a single source simplifies the material synthesis by drastically reducing the process parameters. The SSPs with a predefined metal stoichiometry and reaction (decomposition) chemistry can enforce a molecular-level homogeneity in the obtained materials. The hydrolytic or pyrolytic transformations of molecular derivatives have been used for the phase-selective synthesis of a large variety of ceramics and composites, which illustrates the potential of molecular clusters to “preform” the material on a molecular level (Tables 1–4). Although the field is still far from maturity, the continuing efforts of a large number of research groups in controlling various aspects of the molecule source strategy, such as enhanced volatility, low decomposition temperature, clean and efficient ligand elimination mechanisms, and control of stoichiometry, have boosted the use of single-molecule sources in the synthesis of functional nanomaterials, both films and particles, as is evident from the rapid increase in the publications dealing with this concept and the diversity of the composition of the materials synthesized (Tables 1–4). However, it should be noted that a significant number of reports have emerged from the material curiosity of a synthetic chemist, and the targeted development of experimental chemical methods, necessary to achieve nanoscopic structures by controlled and/or self-organized growth, needs greater attention.

A better understanding of underlying principles of chemical synthesis and the process of molecule-to-material conversion can make possible the rational synthesis of new inorganic materials. The current status of nanomaterials chemistry can be analyzed from two viewpoints: one corresponds to the synthesis of a material from an available precursor followed by the analysis of the nature of the precursor (chemical reactivity, stability, fragmentation, etc.) in light of the results obtained and can be termed as a *synthetic* approach; the other is from a *retrosynthetic* direction, which involves going backward from a target material to molecular starting materials by performing conceivable retro-reactions (subject to the knowledge base) to design the material at the molecular scale. The second case, which in principle forms the basis for illustrating the potential of molecular design, is less practiced for obvious reasons. Although the basic principles of the building-block approach to (nano)materials can obviously be extended to inorganic materials/phases hitherto “unknown,” the lack of systematic investigations regarding the molecular templating or the conditions under which a molecular compound can be transformed into an extended solid poses an application barrier. Consequently, a large number of metal-organic compounds are potential “assemblers” for the controlled assembly of meso- and nanoscopic

structures, yet remain underutilized synthons in the growth of nanomaterials. In view of the above, future research needs in the chemical synthesis of nanophase materials are:

- New synthesis strategies for a directed (chemically driven) synthesis
- Better control over chemical and structural homogeneity, the latter feature being crucial for nanocomposites
- Combinatorial methods for the exploration of complete thermodynamic space
- New chemical principles for designed texture, microstructure, and size-tuning
- Computational methods applicable to complex systems
- Development of precursor systems for nonstoichiometric compounds and doped materials
- Isolation and characterization of high-nuclearity molecular clusters (e.g., partially hydrolyzed species isolated from the sol-gel process), which can reveal the intermediate stages of the molecule-to-material conversion process
- Laboratory validation of discrete steps in the synthetic pathways and a knowledge base to guide the material scientist from the initial conception of a chemical synthesis to a reasonable strategy
- Up-scaling of laboratory procedures by development of commercially viable production methods.

The search for new materials is subject to rationales for providing chemical composition and structures, which constitute the feedback for new synthetic approaches and composition-structure-property relationships. This requires identification of new materials by both experimental (e.g., combinatorial materials synthesis) and computational (energy landscapes of different chemical systems to identify kinetically stable structures) methods. Finally, serious efforts at a complete characterization and proved improvement in the properties of the synthesized nanomaterial is needed from the chemistry community, especially to overcome mindsets and biases about molecular chemistry routes, for instance, the general (mis)conception that a multicomponent molecular precursor would definitely dissociate under experimental conditions to produce a mixture of individual components.

## GLOSSARY

**Chemical vapor deposition (CVD)** Chemical vapor deposition is a generic name for a group of processes that involve depositing a solid material from a gas-phase process by the decomposition of volatile precursors at a suitable temperature either in the gaseous state or on the substrate, thereby eliminating organic fragments as by-products.

**Molecule-based materials (MBM)** Material systems fabricated from molecular subunits, where the molecular integrity of the building units is maintained in the final configuration.

**Molecule-derived materials (MDM)** Materials derived from molecular precursors in which the parent molecular framework is not (necessarily) maintained in the final material.

**Single-source precursor (SSP)** A molecular source containing all of the phase-forming elements in a single chemical

compound, for example, gallium (*tris*)amide ( $\text{Ga}(\text{NR}_2)_3$ ) for gallium nitride (GaN).

**Sol-gel** A room-temperature chemical method used for preparing high-purity ceramics by the hydrolysis of metal-organic compounds in particular metal alkoxides carried out under controlled pH, amount of water, and alkoxide concentration, which involves the transition of a liquid “sol” into a solid “gel” phase.

## 1. INTRODUCTION

The detailed characterization of samples of nanoparticles and nanostructured materials presents a considerable challenge to the materials scientist. The importance of the task of determining basic characteristics such as size, structure, and chemical composition is in no doubt. However, the range of techniques available to comprehensively determine these properties in a single experiment is limited, and a survey of the published literature reveals an overwhelming emphasis on the use of electron microscopy, and in particular the transmission electron microscope (TEM).

The principal advantage of the TEM is its unprecedented spatial resolution, combined with the possibility of spatially localized reciprocal space examination using transmission electron diffraction. The ability to probe the local structure of a sample by electron diffraction is a unique advantage to the transmission electron microscopist. The reasonable penetration of high-energy electrons has enabled for example the characterization of buried interfacial structures, and this has been of immense importance to the development of our understanding of nucleation and growth mechanisms in heteroepitaxial thin films.

The TEM is ideally suited to the investigation of nanostructured materials; nanoparticles are among the simplest of TEM specimens, requiring no mechanical thinning to

achieve electron transparency and thus the least amount of sample preparation. Typically they need only be dispersed on a “holey” or “lacey” carbon support film prior to electron imaging.

In any situation involving materials characterization, an ideal microscopy technique will provide (1) sufficient spatial resolution to form interpretable images and (2) a method of preparing and mounting the sample that will avoid substantial modification and/or the introduction of artifacts. The first requirement is readily satisfied, since modern transmission electron microscopes typically have a resolution better than 2.5 Å. The second requirement, however, must be given careful consideration in any proposed experiment. One of the properties of nanoparticles that makes them attractive for certain key technologies, such as catalysis and biosensing, is their enhanced chemical activity due to their large surface area to volume ratio (a direct consequence of their small diameter). This has made nanoparticles of immense interest to the chemical and biomedical industries. However, as a consequence of this enhanced reactivity, atmospheric degradation (and in particular, oxidation) may substantially change the chemical and structural properties of the sample before analysis is complete.

Materials such as metal oxides and inert metals such as gold may suffer little or no effects. However, more reactive metals such as copper and many semiconductor materials such as silicon may experience substantial oxidation. Thus, in order to understand the structural properties of these nanomaterials as-synthesized, examination should ideally be made before exposure to ambient atmosphere occurs.

In situations where the examination of as-grown nanoparticles or nanoscale deposits is the main requirement, embedding of the particles or the film in a protective medium either during or immediately following growth has proved remarkably effective [1]. Sputtered silicon oxide layers have been widely used for this purpose. Metallic or semiconducting nanoparticles embedded in insulating media such as SiO<sub>2</sub> are an intrinsic part of the structure of some nanoelectronic device structures [2].

In addition to the characterization of the structures synthesized, we are also interested in understanding the dynamic processes that occur either during the growth of the nanomaterial or during subsequent processing. One of

the key advantages of dynamic observations is the ability to identify elusive metastable intermediate phases and probe structural evolution both within the bulk of a sample and at the sample surface. A comprehensive understanding of the influence of service environment on the bulk structure and surface morphology of the nanostructure is of immense interest. As our understanding of these processes and their mechanisms develop, we will become better able to intelligently design structures of the highest utility and efficiently predict the conditions most favorable to their realization.

We conclude then that there are situations where it is desirable to study the structure of nanoparticles before any exposure to atmosphere has taken place, in order to characterize the “intrinsic” properties of the nanomaterial. In addition, we wish to gain an understanding of the structural and morphological developments that may take place during exposure to a variety of service environments.

## 2. INSTRUMENTATION FOR DYNAMIC *IN-SITU* STUDIES

For our present purpose, we will define an *in-situ* observation as one that occurs either (a) during the *synthesis* of a nanostructured material, with no temporal interruption of the growth process, or (b) during postsynthesis *processing* of the nanostructure, such as during an anneal or other heat treatment. Depending upon the material and its specific application, the processing of interest may take place under conditions ranging from ultrahigh vacuum ( $<10^{-9}$  Torr), through high vacuum ( $\sim 10^{-8}$ – $10^{-6}$  Torr), to atmospheric or near-atmospheric pressure in a variety of different gases. We consider first the conditions our sample will experience during transmission electron imaging using conventional electron microscopes.

The gun, column, and camera chambers of an electron microscope are by necessity maintained in the high vacuum pressure regime or better, since electrons are scattered strongly in air. An ion-pumped TEM column will typically equilibrate at a pressure of order  $10^{-7}$ – $10^{-8}$  Torr during electron observation. Older and less well pumped systems may be at least an order of magnitude higher in pressure. The presence of a substantial partial pressure of hydrocarbon species in the high vacuum environment is almost unavoidable due to the presence of rotary oil pumps and perhaps oil diffusion pumps.

In addition, the area under observation is subjected to irradiation by fast electrons with energies typically in the range 100–300 keV. Hydrocarbon molecules are readily “cracked” by the electron beam, and anticontamination devices such as liquid nitrogen-cooled cold traps are commonly mounted close to the specimen to help reduce the total pressure.

## 3. SPECIAL CONCERNS FOR *IN-SITU* NANOSTRUCTURE STUDIES

Nanostructured materials are well known for their enhanced reactivity, due at least in part to their increased surface area:volume ratio. This has a positive influence on their catalytic properties; increased catalytic activity observed in

nanostructured materials such as supported metal particles in zeolite structures is a strong motivation to develop our understanding of the science, and thus the technology, of nanostructured materials.

However, as a consequence of their enhanced reactivity, atmospheric degradation (and in particular, oxidation) of nanostructured materials is an important consideration once they have been synthesized. Some materials are more sensitive to the effects of atmospheric exposure or electron irradiation than others. Ceramic materials, for example, are typically more stable under the electron beam and more resistant to chemical modification. Other materials such as metals and semiconductors, however, are rather more sensitive, and *in-situ* processing must be performed under ultrahigh vacuum (“ultraclean”) conditions.

In order to address the issues of (i) avoiding contamination for atmosphere-sensitive materials and (ii) achieving a controlled high pressure gaseous environment, two parallel streams of instrumentation development have developed. These are, respectively, instruments operating under ultrahigh vacuum conditions (with a base pressure below  $10^{-9}$  Torr), and instruments operating under controlled atmosphere conditions, enabling background gas pressures of up to 50 mbar or more to be sustained in the specimen region under electron irradiation.

In the following sections we provide a survey of published *in-situ* TEM studies of nanocrystals. The specific examples discussed are intended to illustrate some of the wide diversity of interests that exist and experiments that have been performed. Several examples are drawn from the author’s own research for reasons of familiarity. The interested reader is encouraged to refer to the references presented and those contained therein.

## 4. *IN-SITU* STUDIES USING CONVENTIONAL MICROSCOPES

At elevated temperatures, reaction and/or diffusion of atomic species often leads to significant modifications to the microstructure of the material. The ability to observe these in real time can often provide invaluable insight into nanoscale phenomena. The development of *in-situ* heating holders (or “hot stages”) capable of heating samples to medium or high temperatures has led to a number of exciting discoveries in materials science.

Hot stages most commonly comprise a resistively heated ring-shaped furnace, capable of receiving a standard TEM sample (3 mm disc). Temperatures between 800 and 1300 °C are generally attainable, at least for short periods of time, under electron observation.

Ceramic nanoparticles are typically reasonably robust to atmospheric exposure and may be readily prepared for TEM observation in atmosphere. Rankin [3] and Rankin and Boatner [4] studied the high-temperature sintering characteristics of nanoparticles of  $ZrO_2$  and  $MgO$  using a conventional TEM equipped with a furnace-type hot stage. Their investigations centered around direct observations of the development of interparticle contacts during sintering.

The evolution of neck profiles during high temperature annealing processes is not well characterized, due in

part to the experimental difficulties of neck profile inspection. There is particular interest in nanoscale sintering phenomena, where continuum theories of neck formation are expected to break down.

Rankin performed dynamic observations of the formation of neck growth between pairs of ceramic nanoparticles in point contact, at temperatures between  $\sim 830$  and  $890$  °C. The results revealed that the relative orientations of the particles prior to heat treatment are critical in determining the subsequent microstructural evolution.

The lowest energy configuration of two particles in contact is of course one in which the two particles coalesce to form a single particle with no grain boundaries and an equilibrium shape determined by the Wulff construction. Such a global equilibrium may not always be achievable, however, since substantial mass transport and particle rotation may be required; instead, the system may assume a local metastable equilibrium.

During the experimental observations, particles with relatively small misalignments showed evidence of rotation to full alignment and the formation of curved necks between the particles which were entirely epitaxial with both particles [3]. In the case of particle pairs with larger initial misorientations, in each case the orientation of one particle was found to dominate the neck formation, with a large faceted neck region forming in only one of the particles. In Figure 1a, the faceted edge of one particle (lower right corner) is initially in contact with the “rough” (highly stepped) surface of a second particle (upper left corner); after 15 minutes at high temperature, the neck region has almost completely filled. Further annealing apparently led to little change in the neck profile suggesting local equilibrium conditions had been achieved.

In Figure 2, two particles both with rough surfaces in contact are shown, after (a) 54 minutes and (b) 68 minutes annealing. Again, it is apparent that material is adding in registry with only one of the particles (the right hand particle in this case).

This study provides an excellent example of the breakdown of continuum theory as the dimensions of a material

move in to the nanoscale size regime, where expectations based on classical models must be revised.

Suspended wire-type holders have also been used for studies of nanoparticles, the advantage being that higher temperatures may be achieved for longer periods than with furnace-type holders [5]. Nanoparticles may be attached to a fine wire (e.g., W, of diameter  $20\text{--}30$   $\mu\text{m}$ ) by solvent evaporation, which can then be resistively heated to in excess of  $1500$  °C by a dc current. The relatively small mass of the heating element reduces significantly the thermal load on the electron microscope compared to other holders.

By placing a second wire in parallel with the first, and coating this second wire with a low melting point, high vapor pressure material such as gold, it is possible to perform relatively crude *in-situ* evaporation. Kamino and Saka [6] used this technique to vapor-deposit gold nanocrystals onto single crystal silicon particles. Upon annealing the particles wet the Si surface, resulting in the desorption of the native oxide and the formation of a reconstructed, highly faceted surface. Their experiments were performed in a conventional high resolution electron microscope with no vacuum modification, over a relatively short time scale. Portions of the surface could thus be preserved in a relatively clean condition for short periods. More well controlled conditions require the use of ultrahigh vacuum instrumentation.

## 5. IN-SITU STUDIES USING ULTRAHIGH VACUUM MICROSCOPES

Ultrahigh vacuum (UHV) electron microscopes have been developed in order to allow sample heating and *in-situ* deposition under ultraclean conditions similar to those found in molecular beam epitaxy (MBE) systems. Their development has occurred at a slower pace than conventional electron microscopes due in part to the hardware costs involved in following UHV design rules. To build a TEM entirely of UHV materials, from the gun to the viewing chamber, is still prohibitively expensive for most applications. One of the key design issues, then, becomes the ability to establish a continuous path for the electron beam between the gun ( $\sim 10^{-8}$  Torr), the specimen chamber ( $\sim 10^{-10}$  Torr), and the camera chamber ( $\sim 10^{-7}$  Torr). The same issue must be addressed for the environmental cell TEM where, in this case, the pressure in the specimen chamber (up to 50 mbar) is much higher than that in the gun and camera chambers.

The most common solution is to use a system of differential pumping apertures (see for example [7, 8] and references therein). Furthermore, to achieve base pressures in the region of  $10^{-10}$  Torr, only a select range of materials can be used for the specimen chamber, based on their propensity to outgas under UHV conditions. All components sharing the vacuum must be bakeable to in excess of 100 °C, to remove adsorbed water vapor from the interior surfaces of the vacuum chamber. The use of polymer-based vacuum seals is avoided due to outgassing and the need for high temperature baking; construction is dependent upon all-metal seals of high purity materials (such as low-oxygen copper). Since the sample is mounted in the polepiece of the objective lens, this also must be constructed with care.

The earliest UHV TEMs were developed in-house by modifying commercial high vacuum TEMs for UHV. To achieve UHV conditions, either local cryopumping of the sample chamber was employed, or a UHV sidechamber was attached to the microscope, or both [9–16]. More recently, UHV TEMs have become commercially available [17–22] with various modifications by different research groups, including an *in-situ* scanning tunneling microscope (STM) within the objective polepiece [23].

A number of studies of the structures of nanocrystals under electron beam irradiation have been published, both in UHV [24–26] and non-UHV [27–31] environments. Studies of nanoparticle structures by UHV TEM have focused on *in-situ* grown nanoparticles, prepared by either (i) condensation of a vapor onto the substrate surface, (ii) inert gas condensation of nanoparticles in a carrier gas, followed by deposition onto a surface, or (iii) chemical vapor deposition (CVD) onto a substrate. We consider examples of each of these experiments in the following sections.

### 5.1. MBE-Deposited Nanoparticles

One of the most technologically important materials today is silicon, and considerable attention has been given to the growth of materials for microelectronic device applications on the silicon surface. Native oxide which forms readily on the silicon surface is typically removed by heating to high temperature in order to form clean surfaces of reproducible structure. Upon cooling, a  $(7 \times 7)$  surface reconstruction is observed in the case of Si(111), and a  $(2 \times 1)$  reconstruction in the case of Si(100).

Using a UHV TEM with field emission gun (JEOL 2000VF), Tanaka et al. studied the formation of Pd islands on the Si(111) and Si(110) surfaces by electron beam evaporation of Pd [32]. Upon annealing at 673 K Pd<sub>2</sub>Si was observed to form, with a  $(3 \times 3)$  reconstructed surface as determined by an *in-situ* STM. The STM measurements were performed in a side chamber of the electron microscope sharing the same vacuum, following growth of the nanocrystals in the column of the electron microscope. Similar *in-situ* growth of Mo [20] and In [33] nanocrystals using MBE was also performed using the same instrument. HREM images identified size-dependent structural variations of the In nanocrystals. Crystals ~3 nm in diameter formed after relatively short deposition times were found to exhibit face-centered cubic (fcc) stacking; however, those formed after longer periods with diameters above 7 nm

exhibit the tetragonal structure similar to bulk In. Nanocrystals in excess of 10 nm in diameter were found to show transitions between single crystal, single twin, and decahedral multiply twinned structures.

### 5.2. Sputter-Deposited Nanoparticles

An alternative approach to nanoparticle synthesis is by Gleiter's inert gas condensation technique [34]. The technique involves the condensation of a vapor of the material of interest (formed, e.g., by evaporation, sputtering, etc.) by collision with inert gas molecules to form nanocrystals *prior* to deposition on a surface. Olynick and co-workers constructed a UHV sputtering chamber and connected the system directly to the column of a modified JEOL 200CX UHV TEM with *in-situ* sample heating and a base pressure of  $1 \times 10^{-9}$  Torr [35, 36]. Copper nanoparticles were synthesized by sputtering a high purity copper target (99.99%) in ~1 Torr of Ar (<1 ppb O<sub>2</sub>), producing particles in the size range ~5–20 nm and with a log-normal size distribution. The particles were then injected into the polepiece of the electron microscope. Upon entering the microscope, some of the particles were deposited on an electron transparent membrane mounted on the sample stage where they could be imaged under the electron beam. Immediately following deposition, the residual Ar gas was evacuated and electron observation performed within 30 s of deposition.

Sputtering of the Cu target was typically performed for a period of 30 s, before injection of the particles into the microscope column. If the particles were allowed to remain inside the sputtering chamber for a short period (30–120 s) following termination of the sputtering process, and before injection into the microscope, the as-deposited particles were found to have agglomerated, with up to 10 or more particles comprising each agglomerate.

In order to understand the effects of O<sub>2</sub> exposure on the sintering properties of nanocrystalline copper, a comparison was made between the structures of nanoparticle agglomerates prepared with and without a deliberate leak of O<sub>2</sub> during sputtering. In the absence of an O<sub>2</sub> leak, examination of the particles immediately after injection revealed the presence of “necks” between the particles, with some grain growth. The particles were icosahedral in shape and multiply twinned in structure, which is known from theory and experiment to be the lowest energy state for clean fcc particles with diameters less than 4–7 nm [37–39].

In the case of sputtering in Ar with trace amounts of O<sub>2</sub>, or in an unbaked system, the outlines of individual particles could be clearly discerned, with little or no “neck” growth between particles and no evidence of grain growth. It was concluded that trace amounts of oxygen slow the particle grain growth and sintering kinetics of icosahedral particles. This was shown to be consistent with a change in the kinetics of the surface diffusion of Cu in the presence of oxygen.

The ability to control grain growth and agglomeration in particle ensembles is attractive since these processes are detrimental to the properties of nanophase materials, leading to an increase in size and reduction in surface area. However, the formation of an oxide may not be beneficial to the particular application in view and thus the identification of a surfactant that might play the same role as oxygen in

reducing surface diffusivity would be an attractive solution to prevent particle sintering [35].

Having considered particle–particle interactions, particle–substrate interactions were then explored in a series of experiments using the same instrument. Cu [40], Ag [41], and Co [42, 43] nanoparticles were deposited onto single crystal copper as a model substrates. Electron transparent copper foils were prepared *ex-situ* by electron beam evaporation of copper onto cleaved NaCl(100), followed by flotation in deionized water onto 200  $\mu\text{m}$  thick silicon supports,  $\sim 3\text{ mm} \times 2\text{ mm}$  in size and with a central perforation. The portion of the copper foil overlying the perforated region could be imaged under the electron beam. The sample could also be resistively heated to several hundred Celsius; at a temperature of  $\sim 300\text{ }^\circ\text{C}$  an anomalous desorption of the native oxide covering the foil was observed leading to the formation of a clean, oxide-free Cu(100) surface [44]. Reproducible substrate surfaces could thus be obtained for each experiment.

For each material, the nanoparticles were found to assume random orientations on the Cu(100) substrate as determined by transmission electron diffraction. The particles were also stable in location and orientation until the substrate was heated.

In the case of Cu nanocrystals, upon heating to  $\sim 250\text{ }^\circ\text{C}$ , the particles appeared to vanish from the bright field images. Examination of the corresponding dark field images obtained using a  $\text{Cu}_{220}$  reflection revealed, however, that the particles were in fact still present in the same locations on the surface, being made visible by thickness fringe contrast as variations in the thickness of the substrate. An example of this contrast is presented in Figure 3. By slightly tilting the angle of incidence of the electron beam, the dark/bright thickness fringe contrast due to each particle (e.g., areas “A,” “B,” and “C” in Fig. 3a) can be reversed, as can be seen by comparing Figure 3a and b. The particles have thus reoriented, exhibiting the same crystallographic orientation as the substrate. A classical mechanism of sintering and grain growth was proposed.

The significance of the experiment was the observed time scale over which grain growth occurred. Gleiter and

co-workers studied the formation of low energy grain boundaries in copper by sintering a randomly oriented array of macroscopic single crystal copper spheres  $\sim 100\text{ }\mu\text{m}$  in diameter on a Cu(100) surface. Over a period of several hundred hours at a temperature close to the melting point, necks were found to form between the particles and the substrate. The sintering of spherical particles exhibits an  $r^4$  time dependence, where  $r$  is the radius of the sphere [45]. A time scale on the order of  $10^3$  hours was required for substantial neck formation in the case of a sphere  $\sim 100\text{ }\mu\text{m}$  in diameter. In the case of nanoparticles, however, where the radius is several orders of magnitude smaller, the time required for neck formation and grain growth is predicted to be  $< 1\text{ s}$  even at temperatures well below the melting point, consistent with the experimental observations [40].

When Ag nanoparticles were deposited instead of Cu, the results were a little different. An example of a selected area diffraction pattern recorded immediately after particle deposition on Cu(100) is shown in Figure 4a. The diffraction pattern again shows the Debye–Scherrer rings corresponding to randomly oriented nanocrystals as observed in the case of copper nanocrystals. However, superimposed on the Debye–Scherrer rings are two distinct single crystal diffraction patterns corresponding to the epitaxial orientation relationship:

$$(111)_{\text{Ag}} // (001)_{\text{Cu}}$$

$$[110]_{\text{Ag}} // [110]_{\text{Cu}}$$

This orientation relationship corresponds to four possible orientations of Ag, two of which are equivalent by a twin relationship. Two  $\text{Ag}_{220}$  reflections ( $^1\text{Ag}_{220}$  and  $^2\text{Ag}_{220}$ ) corresponding to these two distinct orientations are labeled in the figure. Dark field images were recorded using electrons from both the randomly oriented material and the epitaxially oriented material. In Figure 4b, we present an image recorded using the  $^1\text{Ag}_{220}$  reflection labeled in Figure 4a. From this and other images recorded using electrons from different portions of the Debye–Scherrer rings it was concluded that the majority of the Ag nanocrystals comprised both epitaxial and nonepitaxial material.

**Figure 3.** Weak-beam dark field image of the sample using a  $\text{Cu}_{220}$  reflection. The particles labeled A, B, and C show opposite contrast in images (a) and (b) due to a small change in the tilt of the electron beam, confirming that the particles have now assumed the same orientation as the substrate. Comparison of these findings with molecular dynamics computer simulations of “soft” landings of Ag nanocrystals on the Cu(100) surface showed remarkably consistent results. In Figure 5, the results of the simulations are presented in the form of [100] slices, 12 Å in thickness, through the nanoparticle and a portion of the substrate. After 5 ps of contact between the deposited Ag nanoparticle and the Cu surface, Figure 5a, ordering of Ag lattice planes close to the interface is occurring; after 2 ns, the first three lattice planes show good epitaxial registry with the substrate, Figure 5b. This phenomenon was termed “contact epitaxy” by the authors, since the epitaxial orientation is apparently established almost instantly upon contact. Neck growth then proceeds by stress-assisted diffusion (Fig. 5b), and the Ag atoms begin to “wet” the substrate surface.

The surface energy of Ag ( $\sim 1.25 \text{ J m}^{-2}$ ) is lower than that of Cu ( $\sim 1.8 \text{ J m}^{-2}$ ); in the final experiment, Co nanoparticles were deposited on the Cu(00) surface. Co is also immiscible in Cu, but the surface energy ( $\sim 2.55 \text{ J m}^{-2}$ ) is higher than that of Cu. One might therefore expect a tendency for the Cu substrate atoms to wet the Co particles in this case, rather than the particles wetting the substrate, as was observed in the case of Ag on Cu.

Upon annealing the Co nanoparticles, a significant change in the image contrast due to the particles was immediately observed. In Figure 6 we present bright field images of the sample (a) before and (b) after heating to 600 K. Inspection of electron diffraction patterns recorded following the anneal revealed that the particles were now entirely epitaxial with the substrate.

The image contrast in Figure 6b is similar to that observed by Ashby and Brown [46] and corresponds to strain contrast arising from the presence of Co particles coherently strained with the Cu(100) matrix. The lattice parameter mismatch between Cu and Co is small (Co is 1.9% smaller than Cu). The contrast is similar to that observed from self-assembled Ge quantum dots on Si(100), where the Ge epilayer is coherently strained with the underlying Si lattice.

The question as to where the particles were located, with respect to the substrate surface, was then considered. The strain state of the sample will vary depending upon the location of the nanoparticle (i.e., whether it is on the surface of the substrate, partially buried below the surface, or

**Figure 5.** Molecular dynamics simulations of the particle–substrate interactions, (a) 5 ps and (b) 2 ns after contact. Lett.* 73, 3208 (1998). © 1998, American Institute of Physics.

**Figure 6.** Bright-field images of Co nanoparticles on Cu(100) at (a) 300 K and (b) 600 K.

fully buried). Cross-sectional TEM of *in-situ* grown samples was inconclusive, and so a new quantitative TEM technique for strain measurement [47] was combined with molecular dynamics simulations of the strain state of particles as a function of depth below the surface. Quantitative comparison suggested that the particles were in fact fully buried in the copper substrate.

The driving force for burrowing was attributed to the reduction in free energy of the system by exchanging the Co–vacuum interface with a Co–substrate interface below the surface without increasing the substrate area or, significantly, the elastic strain. The process most likely occurred by (1) wetting of the particle by substrate material, followed by (2) burrowing. In both steps the total free energy of the system is reduced. Analysis of the burrowing time was also presented and was estimated to be less than 0.1 s at 600 K for a 13 nm diameter cluster. At room temperature, the time scale for burrowing to occur would be of the order of months [42].

### 5.3. CVD-Deposited Quantum Dots

Ross and co-workers studied the growth of Ge quantum dots on Si(100) using a Hitachi 9000UHV TEM modified for low-pressure chemical vapor deposition [48]. These and later low energy electron microscope studies brought new and exciting insights into the remarkable phenomenon of strain-mediated self-assembly. Self-assembled heteroepitaxial islands are of considerable technological interest for application in novel quantum dot optoelectronic and nanoelectronic systems and the model system Ge/Si(100) has attracted considerable attention [49–56].

The lattice mismatch between Ge and Si is similar to that between Co and Cu. Below a critical size, Ge islands grow under strained conditions to maintain a coherent interface between the island and substrate. Strain fields are generated in both the island and the substrate, and repulsive forces are exerted on neighboring islands through strain field interactions, reducing dramatically the probability of island coalescence events. Above a critical island size, it becomes energetically favorable for the introduction of dislocations to relieve the lattice strain.

In order to obtain data on the dynamics of island nucleation and growth, real-time observations of the nucleation and growth of Ge islands on the Si(100) surface were made. A partial pressure of  $2 \times 10^{-7}$  Torr of digermane was established in the microscope column and an electron transparent Si(100) substrate held at a temperature of 640 °C. Dark-field images of the sample were recorded on videotape as a function of digermane exposure [48]. Above a dose of  $\sim 50$  L of digermane, the nucleation and growth of Ge islands was observed. In Figure 7, a series of histograms of island size distribution are presented together with the corresponding dark field image. The images were recorded (a) 21, (b) 51, (c) 98, and (d) 180 s after the earliest evidence of strain contrast could be observed, corresponding to the nucleation of the islands.

From these data it is clear that the island size distribution, which is initially bimodal, becomes progressively narrower during growth, corresponding to extensive Ostwald ripening processes. The observed bimodal size distribution is known to correspond to two distinct island shapes—a pyramidal shape in the case of the smaller islands, and a dome shape in the case of the larger islands [56]. The processes involved in the transition between shapes have been the subject of much debate; these experiments provide direct evidence that the chemical potential of an island experiences an abrupt change when the equilibrium shape transitions between the pyramid and dome configurations. The model proposed by Ross and co-workers demonstrated that the shape transition could occur at a critical island volume where the dome energy becomes lower than the pyramid energy and may be

**Figure 7.** A series of histograms of island size distribution with corresponding dark field TEM images inset. The images were recorded after (a) 21, (b) 51, (c) 98, and (d) 180 s after the appearance of the earliest island strain contrast.

relevant to other heteroepitaxial systems involving bimodal size distributions.

## 6. IN-SITU STUDIES USING ENVIRONMENTAL MICROSCOPES

### 6.1. Catalyst Particles

Environmental electron microscopes permit controlled atmospheres of reducing, oxidizing, or other gases to be established in the polepiece and maintained for extended periods of time in the presence of the electron beam. Pressures of up to  $\sim 50$  mbar may be routinely achieved using modified microscopes [57].

Nanoscale particles find important applications in industrial catalysis for the chemical industry, constituting a critical component in a host of multibillion dollar global enterprises. Critical issues in the study of catalytic reactions and degradation mechanisms include metal–ceramic interfaces. Strong metal–support interactions (SMSI) in the gas environment, together with particle sintering, can lead to deactivation of the catalyst and loss of activity [57].

Gai and Boyes [57, 58] studied gas-phase reactions using a modified electron microscope at,  $N_2$  gas pressures of a few mbar, the instrument was capable of resolving gold and graphite lattice fringes at 700 °C [57]. Greater pressures of lighter gases such as  $H_2$  may in fact be tolerated, since electron scattering is strongly  $Z$ -dependent (where  $Z$  is the atomic mass of the scattering atom).

Recognizing the enormous potential of controlled environment TEM, Gai and Boyes studied the model intermetallic alloy catalyst Cu–Pd, supported on carbon. Fine particles were heated to 250 °C in both a  $H_2/He$  environment and a  $CO/He$  environment, for comparison. Particles were observed to be more strongly faceted in  $CO$  than in  $H_2$  and to sinter more quickly in a  $H_2$  atmosphere. High resolution imaging of the particles revealed that their (100) surfaces were also enriched with Pd.  $CO$  is known to bind more strongly to Pd than to Cu; the (110) surfaces, however, did not appear to show such enrichment [57–61].

Studies of nanoscale novel xerogel catalysts were also performed, important in the hydrogenation reaction of adiponitrile in Nylon 6,6 synthesis. Figure 8 shows a dynamic observation of Ru/titania xerogel catalyst in an  $H_2$  gas environment recorded (a) at room temperature and (b) during reaction at 280 °C after 2 hours. SMSI were not observed in the xerogel system, with the clusters appearing stable, with only very limited sintering and reaction. This has important implications for the use of xerogel catalysts in the selective hydrogenation reaction where stability is paramount.

Following the pioneering work of Gai and Boyes, Hansen and co-workers developed a similar *in-situ* environmental TEM capability, again based on the Philips CM300 [62]. They studied the shapes of Cu nanocrystals supported on ZnO and silica under different reaction conditions [63]. Copper nanocrystals find applications as catalysts in the synthesis of methanol, and in hydrocarbon conversion processes for fuel cells. They observed reversible shape changes of the nanocrystals, depending on the nature of the background gas.

The samples were prepared by impregnation of ZnO or silica supports with aqueous Cu-acetate solution, followed

**Figure 8.** *In-situ* environmental cell high resolution TEM image of a Ru/titania xerogel catalyst in  $H_2$  gas environment recorded (a) prior to reaction at room temperature, and (b) during reaction at  $280\text{ }^\circ\text{C}$  for 2 h.

by *in-situ* reduction of the CuO precursor by heating to  $\sim 280\text{ }^\circ\text{C}$  in flowing  $H_2$  (5 mbar). The influence of the gas composition on the structure and shape of the nanocrystals was then investigated by adding  $H_2O$  to the  $H_2$  flow (to produce more oxidizing conditions) or CO (to produce more reducing conditions).

The particles were observed to undergo significant shape changes with each change in gas composition. In Figure 9, the profile of a single copper nanocrystal supported on ZnO is presented, during exposure to sequential gas compositions of (a) 1.5 mbar  $H_2$ , (b) 1.5 mbar  $H_2:H_2O$  (3:1), and (c) 1.5 mbar  $H_2$ . A transition from a relatively high aspect-ratio profile to a pronounced low aspect-ratio profile is immediately apparent. From these and other HREM images, the faceted surfaces of the nanocrystals were identified, including that of the facet in contact with the substrate. The surface free energies and work of adhesion were subsequently calculated using the Wulff construction.

Under a pure  $H_2$  atmosphere, the majority of the Cu particles shared their (111) facet with the ZnO surface (as in the case of UHV deposition of Cu onto various atomically clean ZnO surfaces) indicating a weak particle-support interaction. With the addition of water vapor, the more spherical shape of the particles suggests that the (110) and (100) facets are stabilized with respect to the (111) planes, although the (111) facet in contact with the support remains unchanged.

The observations clearly suggest that water adsorption on the different exposed Cu facets is the main driving force for the gas-induced shape changes. This model is consistent with

**Figure 9.** TEM images showing the reversible shape change of a Cu nanocrystal. The same Cu nanocrystal is imaged at  $220\text{ }^\circ\text{C}$  under (a)  $H_2$  at 1.5 mbar, (b)  $H_2:H_2O$  (3:1) at a total pressure of 1.5 mbar, and (c)  $H_2$  at 1.5 mbar. Reprinted with permission from [63], P. L. Hansen et al., *Science* 295, 2053 (2002). © 2002, American Association for the Advancement of Science.

the reversible nature of the shape changes, and the observation that the same changes are also observed on silica supports [63].

## 6.2. Carbon Nanostructures

In 1985, Kroto and co-workers [64] made the exciting discovery of a third form of Carbon—the  $C_{60}$  fullerene molecule, comprising a spherical, closed “shell” of 60 carbon atoms. Since this discovery, there has been substantial interest in understanding the structure and mechanisms of formation of fullerenes and related nanostructures [65, 66]. Fullerenes, carbon nanotubes, and carbon nanocages are commonly synthesized in arc-discharge chambers in the presence of He gas [67]. Processing conditions in these chambers vary widely with location within the chamber [68], and a variety of processing conditions have been explored [69]. It is believed that fullerene formation takes place in a He atmosphere below 100 mbar, with nanotubes being formed at pressures of order 500 mbar [65], and current densities of between 200 and  $700\text{ A cm}^{-2}$ .

The TEM has played a crucial role in the discovery and exploration of carbon nanostructures. The high energy electron beam has also been used to stimulate microstructural changes in carbonaceous materials leading for example to the formation of Bucky-onions (continuous concentric spherical shells of C) under electron irradiation [70, 71]. Electron beam current densities of  $\sim 150\text{ A cm}^{-2}$  were employed in these experiments, similar to those found in arc-discharge chambers. Burden and Hutchison used a modified JEOL 4000 controlled environment high resolution TEM [72, 73] to study the *in-situ* growth of fullerenes under conditions as close as possible to those found in the arc-discharge chamber [74]. Single crystal graphite particles (with *c*-axis oriented normal to the electron beam) were irradiated in a partial pressure of He of 25 mbar. At room temperature, amorphous spheres of carbon of up to 50 nm in diameter were formed within the samples during irradiation. Upon heating to  $500\text{ }^\circ\text{C}$ , the crystalline stability of the graphite was enhanced dramatically, and under prolonged irradiation ( $\sim 1200\text{ s}$ ), single graphene sheets were observed to peel away from the single crystal particles, rolling up to form discrete single shells with circular profiles. The experiments provided initial evidence of the possibility of fullerene formation directly from graphene sheets, as opposed to condensed, amorphous carbon.

In later experiments, the formation of fullerene molecules on the surface of untreated carbon black was observed. The surface of carbon black comprises fragmented and overlapping graphene layers. The sample was subjected to 25 mbar of He gas and was heated to  $550\text{ }^\circ\text{C}$ . An electron beam current density of  $\sim 6.4\text{ A cm}^{-2}$  was applied [75], during which curling of the graphene sheets was again observed, with the formation of features consistent with closed fullerene shells of  $C_{60}$  and  $C_{70}$  bucky-balls [76]. In contrast to their prior observations of fullerene formation on single crystal graphite, none of the graphene sheets comprising the carbon black were large enough to roll up to form tubular structures. It was therefore concluded that the electron beam interaction with the He atmosphere led to a *sputtering* of fragments of graphene from the carbon black surface,

from which the growth of the observed fullerene molecules proceeded.

The authors also present a careful assessment of prior TEM experiments where, in some cases, formation of fullerene molecules in the absence of controlled environmental conditions was observed [70, 77–79], while in other cases (where very clean vacuum conditions were maintained), fullerene molecules did not form [77]. It was concluded that residual hydrocarbons present in the vacuum systems of some electron microscopes were likely a key factor determining the ability to synthesize fullerenes *in-situ*. This assessment is consistent with the results of their experiment, where ionized He ions cause local sputtering of the carbon black surface and provide a very high local density of C molecules for fullerene formation.

### 6.3. Boron Nitride Nanostructures

Burden and Hutchison also studied *h*-BN particles subjected to similar conditions as carbon black in their experiments [74, 75]. The structure of BN is analogous to that of graphite, the hexagonal polymorph possessing a comparable interlayer spacing. Evidence of curling of the *h*-BN sheets was also observed during irradiation; however, curling sufficient to result in closure was not observed even after extended periods of irradiation.

More recently, the synthesis of *h*-BN nanomaterials was investigated by Bengu and Marks [80] and Yeadon et al. [81] using ultrahigh vacuum transmission electron microscopes. Using a modified Hitachi 9000 UHV TEM Bengu and Marks synthesized single walled BN nanotubes in the sidechamber of the UHV TEM by electron beam evaporation of B in the presence of excited nitrogen. The profiles of the as-synthesized nanostructures were subsequently examined under the electron beam without atmospheric exposure. Comparison with computer simulations of shape as a function of structure led to a conclusive and elegant determination of their structure. In Figure 10, a high resolution TEM image of a typical BN “nanomountain” is shown, as grown on the tungsten substrate in the side chamber of the microscope. To the right, a structural model of the nanomountain determined using a molecular modeling software package is presented. Boron atoms are shown in red;

**Figure 10.** Single walled BN “nanomountain” grown on a tungsten substrate. The substrate lattice fringes correspond to W(100),  $d = 0.223$  nm. A computer model of the structure is shown to the right. Red spheres correspond to boron atoms; blue spheres correspond to nitrogen atoms.

nitrogen atoms are shown in blue. A high resolution image of a “nanodome” is presented in Figure 11, again with the corresponding structural model.

High resolution TEM images were subsequently simulated for the molecular models; it was found that only the presence of four-, six-, and eight-membered rings could lead to correct reproduction of the angles seen in the experimental high resolution images. Atomic models with five-, six-, and seven-membered rings (as per C nanostructures) failed to reproduce the observed angles, and this is believed to be due to the unfavorable nature of B–B and N–N bonds in odd-membered rings.

Using a modified JEOL 2000V UHV TEM with *in-situ* gas injection capability, Yeadon and co-workers synthesized *h*-BN nanocages under the electron beam by nitridation of FeB catalyst particles in an ammonia atmosphere. The UHV electron microscope was modified to permit reactive gas injection into the polepiece of the objective lens, thus enabling real time observations.

Nanoparticles of FeB were prepared by ball milling under an Ar atmosphere and then cast onto electron-transparent silicon supports by solvent evaporation. The Si supports could be resistively heated to  $\sim 1200$  °C.

In Figure 12a, a bright field image of a representative area of the sample is presented. Agglomerates of nanoparticles can be seen; the image was recorded at room temperature prior to  $\text{NH}_3$  injection. An electron energy loss spectroscopy (EELS) spectrum recorded from the sample at this stage is shown in Figure 12b (lower trace). The spectrum shows the presence of the B *K*-edge, together with a small peak due to C.

A partial pressure of  $\sim 5 \times 10^{-6}$  Torr  $\text{NH}_3$  was then stabilized in the sample chamber in the presence of the electron beam, and the sample was heated to 1000 °C. Sintering and agglomeration of the nanoparticles was observed during the ramp to 1000 °C, after which the particles appeared to stabilize. The particle profiles exhibited liquidlike fluctuations despite being several hundred Celsius below their melting temperature.

After a short period of time the profiles of the particles began to take on a faceted appearance, and the formation of a shell around the particles was observed. After further

**Figure 11.** Single walled BN “dome” grown on a tungsten substrate together with the corresponding structural model (right). Red spheres correspond to boron atoms; blue spheres correspond to nitrogen atoms.

**Figure 12.** (a) FeB nanocrystals at room temperature prior to ammonia exposure. (b) EELS spectra recorded before (lower trace) and after (upper trace) ammonia exposure at  $\sim 1000$  °C.

exposure ( $\sim 150$  s), in certain instances some of the particles were observed to spontaneously “eject” from their shells. The particles then remained in contact with the shell while a second shell formed around them. They were again spontaneously ejected from this second shell after a similar period of time.

In Figure 13, a bright field image recorded at room temperature after 4 of these events had occurred is presented. It is apparent that a chain of nanocages has formed, with the last nanocage still encapsulating the Fe–B particle (labelled “P”). The corresponding EELS spectrum is presented in Figure 12b (upper trace) and shows the characteristic energy loss peaks corresponding to *h*-BN. No evidence of the presence of C could be found.

Similar chains of nanocages and nanobamboo structures have been observed *ex-situ* by other groups for both carbon [82, 83] and BN [84, 85], although the exact mechanism by which the structures form is still not well understood. The *in-situ* data suggest that the nanocages grow by diffusion of nitrogen species to the FeB interface, where reaction with boron can occur. Ejection is most likely a consequence of compressive stress within the particle as a consequence of the inward growth of the *h*-BN layers. Cage growth and particle ejection continue until the B content of the nanoparticle is substantially depleted.

The liquidlike motion of the particles observed *in-situ* provides direct confirmation that, even at temperatures well below the melting point, substantial particle mobility is possible thus making possible the observed multiple expulsion mechanism of formation [86].

**Figure 13.** Bright field TEM image of the sample after cooling to room temperature showing the formation of a chain of *h*-BN nanocages. The particle responsible for the chain formation is labeled “P.”

## 7. CONCLUSIONS

*In-situ* transmission electron microscopy studies of the synthesis and processing of nanoparticles have considerably increased our understanding of fundamental materials processes in the science and technology of nanomaterials. The relative ease with which TEM samples of nanoparticles can typically be prepared has made electron microscope analysis more accessible to the nonspecialist and provided an efficient route to comprehensive nanoparticle characterization. As instrumentation of greater flexibility and enhanced performance continues to be developed, we can look forward to further exciting developments in the field of *in-situ* microscopy at the nanoscale.

## GLOSSARY

**Diffusion** Thermally activated movement of individual atoms through the crystal lattice or over the surface of a material.

**Inert gas condensation** The process of nanoparticle formation by which a vapour of atomic species cools by collision with an inert gas, the atomic species condensing to form fine particles of nanoscopic dimensions.

**In-situ** In the normal or natural position. In the present context, the characterization of materials synthesis and processing phenomena by reproducing the phenomena in a manner accessible to the characterisation technique of interest.

**Molecular beam epitaxy** The formation of crystals whose orientation is related to that of the substrate (i.e. epitaxial) by directing a molecular beam at a crystalline substrate under ultrahigh vacuum conditions.

**Sintering** The process by which fine particles of a material become chemically bonded by a process involving diffusion of atomic species at a temperature below the melting point.

**Sputtering** The emission of particles from a solid surface as a consequence of the impingement of energetic ionized particles with the surface.

## 1. INTRODUCTION

Due to the great size and structure selectivity of nanomaterials, their physical properties can be quite diverse, depending on their atomic-scale structure, size, and chemistry. To maintain and utilize the basic and technological advantages offered by the size specificity and selectivity of the nanomaterials, there are three key challenges that we need to overcome for future technological applications of nanomaterials. First, the synthesis of size, morphology, and structurally controlled nanomaterials, which are likely to have precisely designed and controlled properties [1]. Second, novel techniques for characterizing the properties of individual nanostructures and their collective properties. This is essential for understanding the characteristics of the nanostructures. Finally, the integration of nanomaterials with the existing technology is the most important step for their applications, especially in nanoscale electronics and optoelectronics.

Characterizing the physical properties of individual carbon nanotubes is a challenge for many existing testing and measuring techniques because of the following constraints [2]. First, the size (diameter and length) is rather small, prohibiting the application of well-established testing techniques. Second, the small size of the nanotubes makes their manipulation rather difficult, and specialized techniques are needed for picking up and installing an individual nanostructure. Therefore, new methods and methodologies must

be developed to quantify the properties of individual nanotubes. The objective of this chapter is to introduce the theory and techniques that have been developed for characterizing the mechanical, field emission, and electric transport properties of carbon nanotubes. Our study is based on *in-situ* transmission electron microscopy (TEM), so that the one-to-one correspondence of structure and property is maintained.

## 2. BENDING MODULUS OF CARBON NANOTUBES

### 2.1. Experimental Approach

In property measurement in nanoscale, the main challenge comes from the ultrasmall size of the nanotube that prohibits the application of conventional techniques. We first have to see the nanotube, and then measure its properties. Apparently, we must rely on electron microscopy. To carry out the property measurement of a nanotube, a specimen holder for a 100 kV TEM was built to apply a voltage across a nanotube and its counterelectrode (Fig. 1) [3, 4]. In the area that is loading a specimen in conventional TEM, an electromechanical system is built that allows not only the lateral movement of the tip, but also applying a voltage across the nanotube with the counterelectrode. This setup is similar to the integration of the scanning probe technique with TEM. The static and dynamic properties of the nanotubes can be obtained by applying a controllable static and alternating electric field.

The nanotubes used in the study are produced by an arc-discharge technique, and the as-prepared nanotubes are agglomerated into a fiber-like rod. The carbon nanotubes have diameters of 5–50 nm and lengths of 1–20  $\mu\text{m}$ , and most of them are nearly defect-free. The fiber is glued using silver paste onto a gold wire, through which the electric contact is made. The counterelectrode is an Au/Pt ball of diameter  $\sim 0.25$  mm. The nanotube to be used for property

**Figure 1.** Schematic diagram of the TEM specimen holder for *in-situ* measurements.

measurements is directly imaged under TEM (Fig. 2), and electron diffraction patterns and images can be recorded from the nanotube. The information provided by TEM directly reveals both the surface and the intrinsic structure of the nanotube. This is a unique advantage over scanning probe microscope (SPM) techniques. The distance from the nanotube to the counterelectrode is controllable.

## 2.2. The Fundamental Resonance Frequency and Nonlinear Effect

A carbon nanotube can be charged by an externally applied voltage; the induced charge is distributed mostly at the tip of the carbon nanotube, and the electrostatic force results in the deflection of the nanotube. Alternatively, if an applied voltage is an alternating voltage, the charge on the tip of the nanotube is also oscillating, and so is the force. If the applied frequency matches the natural resonance frequency of the nanotube, mechanical resonance is induced. By tuning the applied frequency, the first and second harmonic resonances can be observed (Fig. 3). The analysis of the information provided by the resonance experiments relies on the theoretical model for the system. The most established theory for modeling a mechanical system is the continuous elasticity theory, which is valid for a large-size object. For atomic scale mechanics, we may have to rely on molecular

**Figure 2.** TEM image showing carbon nanotubes at the end of the electrode and the other counterelectrode. A constant or alternating voltage can be applied to the two electrodes to induce electrostatic deflection or mechanical resonance.

**Figure 3.** A selected carbon nanotube at (A) stationary, (B) the first harmonic resonance ( $\nu_1 = 1.21$  MHz), and (C) the second harmonic resonance ( $\nu_2 = 5.06$  MHz). The right-hand side shows the shape predicted based on elasticity theory for a uniform macroscopic beam. Reprinted with permission from [3], P. Poncharal et al., *Science* 283, 1513 (1999). © 1999, American Association for the Advancement of Science.

dynamics. We first examine the validity of applying the classical elasticity theory for the data analysis.

We have compared the following three characteristics of the results predicted by the elasticity theory and the experimental results shown in Figure 3. First, the theoretical node for the second harmonic resonance occurs at  $0.8L$ , and the experiment showed  $\sim 0.76L$ . Second, the frequency ratio between the second and the first modes is  $\nu_2/\nu_{21} = 6.27$  theoretically, while the observed one is  $\nu_2/\nu_{21} = 5.7$ . The agreement is reasonably good if one looks into the assumptions made in the theoretical model: the nanotube is a uniform and homogeneous beam, and the root of the clamping side is rigid. The latter, however, may not be realistic in practical experiments. Finally, the shape of the nanotube during resonance has been compared quantitatively with the shape calculated by the elasticity theory, and the agreement is excellent. Therefore, we still can use the elasticity theory for the data analysis.

If the nanotube is approximated as a uniform solid bar with one end fixed on a substrate, from classical elasticity theory, the resonance frequency is given by [5]

$$\nu_i = \frac{\beta_i^2}{8\pi} \frac{1}{L^2} \sqrt{\frac{(D^2 + D_i^2)E_b}{\rho}} \quad (1)$$

where  $D$  is the tube outer diameter,  $D_i$  is the inner diameter,  $L$  is the length,  $\rho$  is the density, and  $E_b$  is the bending modulus. The resonance frequency is nanotube selective, and it is a specific number for a nanotube.

The correlation between the applied frequency and the resonance frequency of the nanotube is not trivial. We know that there are some electrostatic charges built on the tip of the carbon nanotube. With consideration of the difference between the surface work functions of the carbon nanotube and the counterelectrode (Au), a static charge exists even

when the applied voltage is withdrawn. Therefore, under an applied field, the induced charge on the carbon nanotube can be represented by  $Q = Q_0 + \alpha V_0 \cos \omega t$ , where  $Q_0$  represents the charge on the tip to balance the difference in surface work functions,  $\alpha$  is a geometrical factor, and  $V_0$  is the amplitude of the applied voltage. The force acting on the carbon nanotube is

$$F = \beta(Q_0 + \alpha V_0 \cos \omega t)V_0 \cos \omega t \\ = \alpha\beta V_0^2/2 + Q_0\beta V_0 \cos \omega t + \alpha\beta V_0^2/2 \cos 2\omega t \quad (2)$$

where  $\gamma$  is a proportional constant. Thus, resonance can be induced at  $\omega$  and  $2\omega$  at vibration amplitudes proportional to  $V_0$  and  $V_0^2$ , respectively. The former is a linear term in which the resonance frequency equals the applied frequency, while the latter is a nonlinear term, and the resonance frequency is twice the applied frequency. In practical experiments, the linear and nonlinear terms can be distinguished by observing the dependence of the vibration amplitude on the magnitude of the voltage  $V_0$ . This is an important process to ensure the detection of the linear term.

Another factor that one needs to consider is to identify the true fundamental resonance frequency [6]. From Eq. (1), the frequency ratio between the first two modes is 6.27. In practice, if resonance occurs at  $\omega$ , resonance could also occur at  $2\omega$ , which is the double harmonic. Figure 4 shows the resonance of a bent nanotube in such a case. To identify the fundamental frequency, one needs to examine the resonance at a frequency that is half or close to half of the observed resonance frequency; if no resonance occurs, the observed frequency is the true fundamental frequency.

The diameters of the tube can be directly determined from TEM images with a high accuracy. The determination of length has to consider the 2-D projection effect of the tube. It is essential to tilt the tube and to catch its maximum length in TEM, which is likely to be the true length. This requires a TEM that gives a tilting angle as large as  $\pm 60^\circ$ . Also, the operation voltage of the TEM is important to minimize radiation damage. The 100 kV TEM used in our experiments showed almost no detectable damage to a carbon nanotube, while 200 kV electrons could quickly

damage a nanotube. The threshold for radiation damage of carbon nanotubes is  $\sim 150$  kV.

After a systematic study of the multiwalled carbon nanotubes, the bending modulus of nanotubes was measured as a function of their diameters (Fig. 5). The bending modulus is as high as 1.2 TPa (as strong as diamond) for nanotubes with diameters smaller than 8 nm, and it drops to as low as 0.2 TPa for those with diameters larger than 30 nm. A decrease in the bending modulus with an increase of the tube diameter is attributed to the wrinkling effect of the wall of the nanotube during small bending [3]. The deformation is elastic, and the nanotube recovers its shape after relieving. This effect is pronounced, especially for larger size nanotubes; thus, the geometrical shape makes a significant contribution to the measured bending modulus (different from Young's modulus) [7]. However, with the decrease in the nanotube diameter, the bending modulus approaches Young's modulus.

The *in-situ* TEM technique demonstrated here provides a powerful approach toward nanomechanics of fiber-like nanomaterials with well-characterized structures. It can be applied to measure the mechanical properties of a wide range of nanowires, such as SiC, silica, and Si nanowires [8], and carbon nanotubes with defects [9]. This is a universal approach for nanomechanics.

### 2.3. Nanobalance

In analogy to a spring pendulum, the mass of a particle attached at the end of the spring can be determined if the vibration frequency is measured, provided that the spring constant is calibrated. This principle can be adopted to determine a very tiny mass attached at the tip of the free end of the nanotube. The resonance frequency drops more than  $\sim 40\%$  as a result of adding a small mass at its tip (Fig. 6). The mass of the particle thus can be derived by a simple calculation using an effective mass in the calculation of the momentum of inertia. This newly discovered "nanobalance" has been shown to be able to measure the mass of a particle as small as  $22 \pm 6$  fg ( $1f = 10^{-15}$ ).

### 3. FIELD EMISSION FROM CARBON NANOTUBES

Carbon nanotubes possess various superior properties for use as field emitters, such as sharp tips with a nanometer-scale radius of curvature [10], high mechanical stiffness [11–13], high chemical stability [14], and unique electrical properties [15, 16]. Due to the unique tip geometry of the carbon nanotubes, their field-emission property is one of the most attractive applications [17], which has been extensively studied using the classical technique. In this chapter, we introduce a few novel applications of TEM in characterizing the field-emission properties of carbon nanotubes, with focus on the characteristics of individual carbon nanotubes.

#### 3.1. Work Function at the Tips of Carbon Nanotubes

An important physical quantity in electron field emission is the surface work function, which is well documented for elemental materials. For emitters such as carbon nanotubes (NTs), most of the electrons are emitted from the tips of the carbon NTs, and it is the local work function that matters to the properties of the NT field emission. The work function is measured from the  $\ln(J/E^2)$  versus  $1/E$  characteristic curve, where  $E$  is the macroscopic applied electric field that is an average over all of the aligned carbon NTs that are structurally diverse in diameter, length, and helical angle, and  $J$  is the emitted current density. We have developed a technique for the measurement the work function at the tip of a single carbon nanotube [18].

Our measurement is based on the electric-field-induced mechanical resonance of carbon nanotubes, but with a slight modification. The principle for work function measurement is schematically shown in Figure 7a. We consider a simple case in which a carbon nanotube, partially soaked in a carbon fiber produced by arc discharge, is electrically connected to a gold ball. Due to the difference in the surface work functions between the NT and the counter Au electrode, a static charge  $Q_0$  exists at the tip of the NT to balance this potential difference, even at zero applied voltage [19]. The

**Figure 7.** (a) Schematic diagram showing the static charge at the tip of carbon nanotube as a result of difference in work functions between the nanotube and the gold electrode. (b) Schematic experimental approach for measuring the work function at the tip of a carbon nanotube.

magnitude of  $Q_0$  is proportional to the difference between work functions of the Au electrode and the NT tip (NTT),  $Q_0 = \alpha(W_{\text{Au}} - W_{\text{NTT}})$ , where  $\alpha$  is related to the geometry and distance between the NT and the electrode.

The measurement relies on the mechanical resonance of the carbon NT induced by an externally applied oscillating voltage with tunable frequency. In this case, a constant voltage  $V_{\text{DC}}$  and an oscillating voltage  $V_{\text{AC}} \cos 2\pi ft$  are applied onto the NT, as shown in Figure 7b, where  $f$  is the frequency and  $V_{\text{AC}}$  is the amplitude. The total induced charge on the NT is

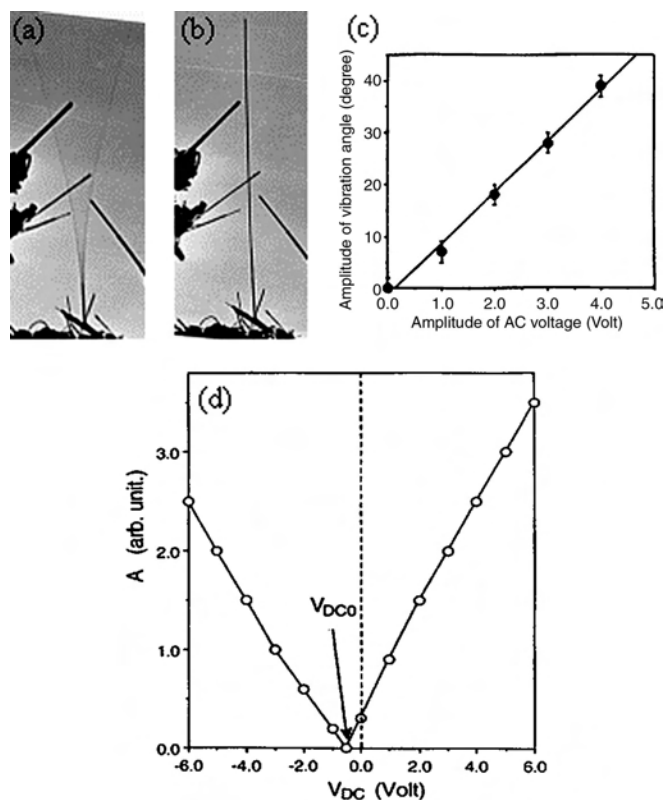

$$Q = Q_0 + \alpha e(V_{\text{DC}} + V_{\text{AC}} \cos 2\pi ft) \quad (3)$$

The force acting on the NT is proportional to the square of the total charge on the nanotube:

$$\begin{aligned} F &= \beta [Q_0 + \alpha e(V_{\text{DC}} + V_{\text{AC}} \cos 2\pi ft)]^2 \\ &= \alpha^2 \beta \{ [(W_{\text{Au}} - W_{\text{NTT}} + eV_{\text{DC}})^2 + e^2 V_{\text{AC}}^2 / 2] \\ &\quad + 2eV_{\text{AC}}(W_{\text{Au}} - W_{\text{NTT}} + eV_{\text{DC}}) \cos 2\pi ft \\ &\quad + e^2 V_{\text{AC}}^2 / 2 \cos 4\pi ft \} \end{aligned} \quad (4)$$

where  $\beta$  is a proportional constant. In Eq. (5), the first term is constant, and it causes a static deflection of the carbon NT; the second term is a linear term, and resonance occurs if the applied frequency  $f$  approaches the intrinsic mechanical resonance frequency  $f_0$  of the carbon NT (Fig. 8a). The last term in Eq. (4) is the second harmonics. The most important result of Eq. (4) is that, for the linear term, the resonance amplitude  $A$  of the NT is proportional to  $V_{\text{AC}}(W_{\text{Au}} - W_{\text{NTT}} + eV_{\text{DC}})$ . By fixing the  $V_{\text{DC}}$  and measuring the vibration amplitude as a function of  $V_{\text{AC}}$ , a linear curve is achieved (Fig. 8c).

Experimentally, we first set  $V_{\text{DC}} = 0$ , and tune the frequency  $f$  to find the mechanical resonance induced by the applied field. Secondly, under the resonance condition of keeping  $f = f_0$  and  $V_{\text{AC}}$  constant, slowly change the magnitude of  $V_{\text{DC}}$  from zero to a value that satisfies  $W_{\text{Au}} - W_{\text{NTT}} + eV_{\text{DC}0} = 0$  (Fig. 8b); the resonance amplitude  $A$  should be zero, although the oscillating voltage is still in effect.  $V_{\text{DC}0}$

**Figure 8.** (a) Mechanical resonance of a carbon nanotube induced by an oscillating electric field. (b) Halting the resonance by meeting the condition of  $W_{Au} - W_{NTT} + eV_{DC0} = 0$ . (c) Plot of vibration amplitude of a carbon nanotube as a function of the amplitude of the applied alternating voltage  $V_{AC}$ . (d) Plot of vibration amplitude of a carbon nanotube as a function of the applied direct current voltage  $V_{DC}$ , while the applied frequency is 0.493 MHz and  $V_{AC} = 5$  V.

is the  $x$ -axis interception in the  $A$ - $V_{DC}$  plot (Fig. 8d). Thus, the tip work function of the NT is  $W_{NTT} = W_{Au} + eV_{DC0}$  [18].

Several important factors must be carefully checked to ensure the accuracy of the measurements. The true fundamental resonance frequency must be examined to avoid higher order harmonic effects. The resonance stability and frequency drift of the carbon nanotubes must be examined prior to and after each measurement to ensure that the reduction of vibration amplitude is solely the result of  $V_{DC}$ . The NT structure suffers no radiation damage at 100 kV, and the beam dosage shows no effect on the stability of the resonance frequency. Figure 9 gives the plot of the experimentally measured  $V_{DC0}$  as a function of the outer diameter of the carbon NTs. The data show two distinct groups:  $-0.3$  to  $-0.5$  eV and  $\sim +0.5$  eV. The work function shows no sensitive dependence on the diameters of the NTs, at least in the range considered here. 75% of the data indicate that the tip work function of carbon NTs is 0.3–0.5 eV lower than the work function of gold ( $W_{Au} = 5.1$  eV), while 25% of the data show that the tip work function is  $\sim 0.5$  eV higher than that of gold. This discrepancy is likely due to the nature of some nanotubes being conductive and some being semiconductive, depending on their helical angles. In comparison to the work function of carbon ( $W_C = 5.0$  eV), the work function at the tip of a conductive multiwalled

**Figure 9.** Experimentally measured  $V_{DC0}$  as a function of the outer diameter of the carbon nanotube.

carbon NT is 0.2–0.4 eV lower. This is important for electron field emission.

### 3.2. Electrostatic Charges on Carbon Nanotubes

Using the *in-situ* TEM setup that we built, some of the interesting aspects of electron field emission from carbon nanotubes can be revealed. To observe the electrostatic field distribution due to the charges on a carbon nanotube, we use the beam deflection effect introduced by the electrostatic force. If the nanotube is positively charged (Fig. 10a), the electrons passing through the two sides of a nanotube are deflected toward each other due to electrostatic attraction, resulting in a weak diffuse scattering in the electron diffraction pattern around the central transmission beam. By selecting a portion of the diffusely scattered electrons using a small-size objective aperture, the field distribution around the nanotube can be revealed. Figure 10b and c shows two images of the nanotubes acquired by placing the objective aperture at the b and c positions, as indicated in Figure 10a, corresponding, respectively, to the dark-field and bright-field images of the nanotubes that are emitting electrons. The nonuniform contrast adjacent to a defect clearly shows the build up of charges. Therefore, electrostatic charges accumulate not only at the tips and bodies of the nanotubes, but

**Figure 10.** (a) Bright- and (b), (c) dark-field images of carbon nanotubes recorded by selecting the electrons scattered off the center beam due to the electrostatic deflection produced by the nanotubes under an applied voltage of 40 V, showing the electric field distribution at the tips, from where the electrons are emitting.

also at the defect sites. These observations are consistent with the expected results from electrostatics to preserve the carbon nanotube, if conductive, as an equal potential object.

### 3.3. Field-Emission-Induced Structural Damage

Due to the large aspect ratio of carbon nanotubes, the electric field at the tips of the nanotubes can be rather large; thus, the local temperature could be very high at field emission. It is possible to induce structural damage at the tips. The classical definition of turn-on field  $E_t = V/d$ , where  $V$  is the applied voltage and  $d$  is the distance from the tip of the field emitter to the surface of the counterelectrode, may not be an adequate measurement of the local field at the tips of the carbon nanotube due to its sharp needle geometry.

An important phenomenon of our study is the observation of the structural damage of a carbon nanotube during field emission under a higher voltage [20]. This study is useful in determining the structural stability of the nanotubes. Figure 11 shows a series of images of a nanotube that was being damaged by an applied voltage. The structural damage is apparent as the applied voltage increases. The damage occurs in such a way that the walls of the nanotubes are split patch by patch and segment by segment. A closer image of the splitting is shown in Figure 11e. This damage process is different from the unraveling process proposed by Rinzler et al. [21], who believed that the nanotubes are damaged following a string-by-string removal of the carbon atoms along the circumference of the graphitic layer.

Figure 12 shows a “stripping” process of a carbon nanotube under the applied electric field. The diameter and length of the nanotube  $A$  decrease as it being damaged by the field. This is a sharpening process of the multiwalled

nanotube. The structure of nanotube  $B$  is almost totally damaged by the field, and finally becomes a graphitic structure.

The mechanisms of the field-induced damage are believed to be due to two processes. First, the electrostatic force acting on the tip of the nanotube can split the nanotube piece by piece and segment by segment, such as the one shown in Figure 11. The second process is likely due to the local temperature created by the flow of emission current, which may “burn” the nanotube layer by layer, resulting in the sharpening process, as presented in Figure 12. The emission current is likely to flow along the nanotube through the most outer graphitic layers, which was first proposed by Frank et al. [22] for interpreting the quantum conductance of a multiwalled carbon nanotube at room temperature. This process has recently been used for removing the walls of carbon nanotubes [23, 24].

It was reported by Rinzler et al. [21] that the current emitted by nanotubes fluctuates almost randomly as a function of time at a time scale of a couple of seconds; this phenomenon was interpreted owing to an unraveling process of the carbon atom ring. Through *in-situ* TEM observation, we found that the fluctuation in emission current is due to a “head-shaking” effect of the nanotube while emitting electrons. The nanotube bends toward the counterelectrode at an applied voltage. The emission of electrons from a nanotube is likely to be a “ballistic” emission process in which the electrons are emitted as groups, although each emission can release many electrons. When the nanotube is fully charged prior to emission, the distance between the nanotube tip and the counterelectrode is the smallest due to the strongest electrostatic attraction; as soon as the electrons are emitted as a group, the electrostatic force between the nanotube

**Figure 11.** “Splitting” process in structural damage. (a)–(d) Series of TEM images showing the structural damage of a carbon nanotube during field emission, in which the applied voltage and the emission current are: (a)  $V = 80$  V,  $I = 10$   $\mu$ A, (b)  $V = 90$  V,  $I = 40$   $\mu$ A, (c)  $V = 110$  V,  $I = 100$   $\mu$ A, and (d)  $V = 130$  V,  $I = 250$   $\mu$ A. The distance from the tip of the nanotube to the counterelectrode was  $\sim 2$   $\mu$ m. (e) A nanotube that is experiencing the splitting of its outer layers during the damage. **Figure 12.** “Stripping” effect in structural damage. (a)–(e) Series of TEM images showing the structural damage of a carbon nanotube during field emission. The applied voltages were (a)  $V = 100$  V, (b)  $V = 120$  V, (c)  $V = 140$  V, (d)  $V = 160$  V, and (e)  $V = 200$  V. The distance from the tip of the nanotube to the counterelectrode was  $\sim 4$   $\mu$ m. Reprinted with permission from [20], Z. L. Wang et al., *Appl. Phys. Lett.* 80, 856 (2002). © 2002, American Institute of Physics.

and the electrode drops slightly, resulting in the recovery of the nanotube shape and a larger distance from the electrode. The head shaking of the nanotube due to “ballistic” emission results in a variation in the distance of its tip from the electrode, thus leading to a fluctuation in the emission current. This may also account for the blinking of the emission current from carbon nanotubes. The ballistic emission is possible because the small size of a nanotube can only hold a small amount of electrons at its tip. A rough estimation indicates that losing one electron at the tip can change the tip potential by  $\sim 0.15$  V for a 20 nm diameter nanotube. The head shaking is a result of its large aspect ratio, which leads to body swing during field emission.

#### 4. ELECTRIC TRANSPORT OF CARBON NANOTUBES

Electrical transport in single-walled nanotubes (SWNTs) and multiwalled nanotubes (MWNTs) is of great importance for their applications in electronics. Measurements of nanotube conductance mainly use two techniques. Using lithographically made gold electrodes, a carbon nanotube is laid down across two electrodes, and the  $I$ - $V$  characteristic is measured [25]. The other technique takes advantage of using liquid mercury as a soft contacting electrode; a nanotube is inserted into the mercury, and the conductance is monitored as a function of the depth that the nanotube is inserted into the mercury [26]. The latter has been carried out *in-situ* in TEM. This chapter intends to review the progress in applying the second technique in the electrical property characterization of nanotubes. A comprehensive review of all of the existing literature and a comparison of data in electrical characterization can be found in [27].

##### 4.1. Ballistic Quantum Conductance at Room Temperature

Our original technique involved two contact measurements on free-standing MWNTs in air. An arc-produced fiber composed of MWNTs was attached to a conducting tip of a scanning probe microscope, and dipped into various liquid metals. The conductance was recorded as a function of the depth  $L$  that the nanotube penetrated into the liquid metal. Figure 13 shows a schematic diagram of the measurements in an atomic force microscope (AFM). This experiment has three main advantages: 1) the carbon nanotube is as-synthesized without contamination; 2) the soft metal contact reduces the contact resistance, allowing a sensitive measurement on the conductance of the nanotube; and 3) the length of the nanotube exposed outside the liquid metal surface is a variable that allows a direct measurement of the conductance of the nanotube as its length is being reduced.

If  $Z$  represents the depth of the nanotube into the mercury surface, the conductance traces revealed quantized conductance steps with step heights of about  $1 G_0$  (Fig. 14), with  $G_0 = 2e^2/h = 1/(12.9 \text{ k}\Omega)$ . For a single tube, the conductance is  $G_0$ , and the jump to  $2G_0$  occurs once the second nanotube touches the mercury. This effect appears only if the carbon nanotube is defect-free, which means that the tubes are produced by arc discharge rather than catalytic

Figure 13. Experimental setup for measuring the electrical conductance of a single MWNT using the soft contact method in an AFM apparatus.

growth. The conductance is quantized, and it is independent of the length of the carbon nanotube. No heat dissipation was observed in the nanotube. This is the result of ballistic conductance, and it is believed to be a result of single graphite layer conductance. A recent observation using a different technique has confirmed our result [28].

The quantized steps typically develop only after many dipping cycles: the initial dipping cycles do not show steps, but rather sequences of sloping structures. Despite a lack of sophistication, these measurements consistently produce the highest measured two-point conductances for closed MWNTs, which points to reproducible low-contact resistances. In about 80 fibers that we tested, we did not observe nanotubes with conductances (significantly) greater than  $1 G_0$ , although anomalous low ultimate conductances have been observed. In this work, we arrived at the following conclusions: 1) MWNTs are one-dimensional conductors; 2) the current in closed MWNTs flows on the outer surface; 3) MWNTs can sustain very large current densities; 4) transport in MWNTs is quantized with  $1 G_0$  at room temperature, suggesting ballistic conduction, but with half the expected value; and 5) the average current density carried out by the nanotube over its cross section can exceed  $10^7 \text{ A/cm}^2$ .

Figure 14. Conductance of a carbon nanotube as a function of the depth  $z$  the nanotube is inserted into the mercury surface, showing the quantum conductance of the nanotube. The flat plateau indicates that, within a certain length, the conductance of the nanotube is independent of its length.

## 4.2. In-Situ Measurement

The conductance measurement of individual carbon nanotubes has also been carried out using the *in-situ* technique introduced in Section 2.1. The same specimen holder used for the mechanical property measurements was used for the conductance measurement, except that the counterelectrode is replaced by a mercury droplet, which served as the soft contact for the measurement. Figure 15 shows the contact of a carbon nanotube with the mercury electrode, and a conductance of  $G_0$  was observed. It is also interesting to note that the contact area between the nanotube and the mercury surface is curved. This is likely due to the difference in surface work function between the nanotube and mercury; thus, electrostatic attraction could distort the mercury surface. This effect effectively reduces the contact resistance between the nanotube and the Hg electrode.

*In-situ* nanotube conductances are determined by applying a voltage difference of 100 mV between the Hg droplet and the nanotube fiber, and measuring the current. Three types of behavior are found. For type 1, more than half of the nanotubes that clearly contact the Hg surface (as seen from a slight bowing of the nanotube, as for example in Fig. 16a, or a distortion of the Hg surface) have resistances  $R$  that are out of our range, that is,  $>1$  M $\Omega$ . For type 2 tubes, the conductance is  $13$  k $\Omega$   $< R < 15$  k $\Omega$ . For the remainder,  $15$  k $\Omega$   $< R < 100$  k $\Omega$  (type 3). We have not observed nanotubes whose resistance is significantly less than  $13$  k $\Omega$  (i.e.,  $6.5$  k $\Omega$ , as expected for  $2 G_0$ ). This observation is consistent with the in-air experiments.

We previously measured currents up to  $1$  mA through the tubes before they are damaged, implying current densities at the outer layer of up to  $10^{10}$  A/cm $^2$  for a  $10$  nm diameter tube (assuming surface conduction). Higher currents ( $>1$  mA) damage the nanotubes. We observed that defective nanotubes tend to break at the defects (Fig. 17), while type 2 nanotubes invariably break near the Hg contact (Fig. 16b). In particular, type 2 nanotubes do not break halfway between the contacts, which is where the temperature would be the greatest for freely suspended nanotubes if the nanotubes were dissipative conductors. Hence, we

**Figure 15.** *In-situ* TEM image showing the conductance measurement through a single carbon nanotube. The inset is the contact area of the nanotube with the mercury surface.

**Figure 16.** *In-situ* observation of electric transport through a single carbon nanotube. (a) Applied voltage  $V = 0.1$  V, current  $I = 7.3$   $\mu$ A, resistance of the carbon  $R = 12.7$  k $\Omega$ , which corresponds to a conductance  $G = (12.7$  k $\Omega)^{-1} = 1.02 G_0$ . (b) After applying a  $4$  V voltage, the nanotube was broken, and the break occurred at the contact of the nanotube and the Hg. (c) The conductance of this carbon nanotube contaminated with graphitic particles is  $0.25 G_0$ .

conclude that the heat dissipation occurs primarily at the contacts, consistent with (but not conclusive evidence for) ballistic transport.

## 4.3. Top-Layer Conductance in MWNT

We now examine the origin of quantum conductance in MWNT at room temperature. Graphite has a unique layer structure, in which the conductivity parallel to the graphitic

**Figure 17.** Examples of nanotube failure modes. MWNTs (a) before and (b) after passing a large current, showing the breakpoints at the defect sites. (c), (d) An MWNT before and after passing a large current through it. In (d), the tip of the MWNT had been contacted to an Au surface, and current was passed through it. Only the outer layer, starting at the contact point, has been damaged, suggesting that the current flows over the surface.

**Figure 18.** (a) Atomic structure of graphitic sheets. (b) A carbon nanotube model with a closed end. (c) Top-layer conductance of a defect-free, closed-end MWNT.

plane ( $a$ - $b$  axis plane) is about 50 times higher than that along the  $c$  axis (Fig. 18a). If the applied voltage is small, so that the interlayer tunneling effect can be ignored, and the end of the nanotube is closed (Fig. 18b), the electric current mainly flows along the top surface layer, provided the tube is perfect and there is no defect. Since the layer thickness of  $\sim 0.34$  nm is comparable to the electron wavelength of 0.5 nm in the graphitic plane, quantum conductance is possible. The unique structure of the nanotube greatly reduces the phonon density of states; thus, the mean-free-path length of the electron is longer than  $10 \mu\text{m}$  [29], possibly resulting in a room-temperature quantum effect. This is possible for a structurally perfect nanotube with closed ends (Fig. 18c). If the applied voltage is large, interlayer tunneling among the nanotube walls is inevitable; the effective size of the object that carries the current is large, finally destroying the quantum conductance effect. On the other hand, if there is a defect, the density of phonons near the defect is different from the rest of the nanotube; a reduced mean-free-path length of the electron at the defect site results in the disappearance of the quantum effect as well. Therefore, nanotubes grown by the CVD process that contain a large density of defects are unlikely to exhibit quantum conductance.

Figure 7d shows an MWNT after passing a large current, which was brought into contact with an Au surface (which replaced the Hg droplet in this experiment). Due to the flow of the shock short-circuit current, the surface of the nanotube is disrupted starting at the contact point, while the interior layers are not visibly affected. This observation provides further evidence that the electronic current passes over the surface layers of the nanotube, for example, single-layer conductance. The observation of Aharonov-Bohm oscillations in carbon nanotubes also supports the top-layer conductance [30].

## 5. SUMMARY

This chapter has reviewed the experimental methods for *in-situ* nanomeasurements of carbon nanotubes based on transmission electron microscopy. The static and dynamic properties of the nanotubes can be obtained by applying

controllable static and alternating electric fields. Resonance of the carbon nanotubes can be induced by tuning the frequency of the applied voltage. The technique is powerful in such a way that it can directly correlate the atomic-scale microstructure of the carbon nanotube with its physical properties, providing a one-to-one correspondence in structure-property characterization. This is a new approach toward nanomechanics.

The work function at the tips of individual multiwalled carbon nanotubes has been measured by an *in-situ* transmission electron microscopy technique. The tip work function shows no significant dependence on the diameter of the nanotubes in the range of 14–55 nm. The majority of the nanotubes have a work function of 4.6–4.8 eV at the tips, which is 0.2–0.4 eV lower than that of carbon. Field emission of the individual carbon nanotubes was observed by *in-situ* transmission electron microscopy. A fluctuation in emission current was due to a variation in the distance between the nanotube tip and the counterelectrode owing to a “head-shaking” effect of the nanotube during field emission.

We also presented the conductance measurements of individual carbon nanotubes using the two-electrode contacting technique. We discovered that freely suspended MWNTs are 1-D conductors with quantum conductance at room temperature. A large current density is sustained, and the current is carried out by the outermost layer of the MWNT. Carbon nanotubes contaminated on the surface either by graphitic particles or during lithographical manipulation do not show quantum conductance. Defects can destroy quantum conductance, resulting in heat dissipation.

## GLOSSARY

**Ballistic transport** Elastic transport process during which an electron experiences no inelastic collision; thus, no heat is generated. This is possible if the length of the transport wire is shorter than the inelastic mean-free-path length of the electron in the material.

**Bending modulus** Elastic property of a tubular structure that describes its inherent stiffness. It is determined not only by the Young’s modulus of the materials that are made of the tubular structure, but also by the geometrical parameters of the tube.

**Field emission** Emission of electrons from a solid surface under an externally applied electric field.

**Quantum conductance** Electron wave elastic transmission through a solid wire without inelastic collision; the trace of the transmission coefficient derived from quantum scattering theory is defined to be the electric conductance  $G$ , which is a multiple of  $G_0 = 2e^2/h = 1/(12.9 \text{ k}\Omega)$ , depending on the number of conduction channels, but independent of the length of the wire, provided that the length of the transport wire is shorter than the inelastic mean-free-path length of the electron.

**Work function** Energy required to extract an electron from a semi-infinite solid surface to infinity.

**Young’s modulus** Elastic property of solids that describes the inherent stiffness of the material. It is the slope of the stress-strain curve in the elastic region.

## 1. INTRODUCTION

Tremendous progress has been made in the past four decades in miniaturizing and integrating transistors and capacitors for logic applications onto silicon. By comparison, passive components (resistors, capacitors, and inductors) at the circuit board level have made only incremental advances in size and density. Consequently, passive components occupy an increasingly larger area and mass fraction of electronic systems, and are a major hurdle to the miniaturization of many electronic systems. This is particularly true for analog and mixed-signal applications that use a larger number of passives than typical digital applications. The surface of cell phone boards can be over 50 percent occupied by passives.

Almost no through-hole axial-leaded resistors and disk capacitors are used anymore; they have been replaced with smaller rectangular surface-mount components with solder joints at both ends. The size of these modern discretes is described by a number such as 0603, which indicates a size of  $60 \times 30$  mils ( $1.5 \times 0.75$  mm). The 0402 ( $1.0 \times 0.5$  mm) size

is commonly used, and the smallest discrete passives today are 0201 ( $0.50 \times 0.25$  mm), which represents a considerable challenge in handling and attachment. About a trillion passive devices were placed in electronic systems in 2000, with the vast majority utilizing surface-mount technology. Today, each mounted passive costs about half a cent to purchase, and about 1.3 cents for conversion (assembly) for a total of 1.8 cents. Therefore, the present total market for passive devices is around \$18 billion annually [1–3].

If passive components could be integrated in somewhat the same manner as transistors have been on integrated circuits, they might enjoy the same economy of manufacture, functional density, and performance enhancements. For that reason it is an active area of research and development in the microelectronics systems industries. The “nano” aspect of this comes about because of the use of very thin films, under  $500 \text{ \AA}$  in many cases, to achieve passive integration into circuit boards.

### 1.1. Definitions

The concept of “integrated,” “integral,” “embedded,” “arrayed,” or “networked” passives involves manufacturing them as a group in or on a common substrate instead of in their own individual packages. The distinction with present technology is as follows:

Discrete passive component is a single passive element in its own leaded or surface mount technology (SMT) package. An example would be a single resistor, capacitor, or inductor in an 0402 package. This will typically have two contacts to be soldered to the board. Presently, the vast majority of passives are utilized in this manner and this is what passive integration seeks to eliminate. (Fig. 1.)

Integrated passive component (IP) is a general term for multiple passive components that share a substrate and packaging. They may be housed inside the layers of the primary interconnect substrate, which would give them the sub-designation of an “embedded passive component,” or they may be on the surface of a separate substrate that is then placed in an enclosure and surface mounted on the primary interconnect substrate, in which case they would be called “passive arrays” or “passive networks.” (Fig. 2.)

**Figure 1.** Cell phone RF section utilizing 0402 surface mount passives grouped around a single integrated circuit.

## 1.2. Types of Interconnect Substrates

There is a vast array of materials, processing methods, and configurations in use as interconnect substrates—from resin-impregnated paper with printed conductors on the low end to single-crystal silicon with photolithographic thin film build-up layers on the high end. In between there is FR4, ceramic, polymer film, and rigid inorganics, each of which can be composed of a multitude of specific materials and processed in dozens of ways. The number of possible interconnect substrates times the number of processes to achieve them times the number of materials and processes for integrated passives equals an impossible number to describe individually. In order to make this manageable, the types of substrates must be grouped.

The primary natural division is into organic and inorganic designations. “Organic” means that there is a polymer material, either thermoset or thermoplastic, in the board even if it makes up a small fraction by mass. This will limit the maximum temperature for any processing to around 200 °C–300 °C and possibly lower for some steps. Inorganic substrates, such as alumina, can withstand well over 700 °C–1,000 °C and are usually limited by the softening point of the metals. Integrated passives are highly developed in ceramic substrates, but these make up only a small fraction of the total boards sold, especially in consumer products. The major emphasis in integrated passive research

**Figure 2.** Integration of passive components into a system's substrate.

today is for organic-containing materials such as FR4, BT, and flex, which make up about 85 percent of the boards manufactured today and a larger fraction of boards in consumer products. Therefore, the necessity for low processing temperatures is an important consideration in integrated passive development.

## 1.3. Overview of Integrated Passive Fabrication

At present, neither the optimal materials nor methods for fabricating integrated passives on organic substrates have been established. This is a limiting factor in their use in the most common substrates. Due to the planar nature of integrated passives, the formation and patterning of films are central to this technology. There are three broad classes of films required: conductive, resistive, and dielectric. Conductive films are those that are needed for carrying current with a minimum of voltage loss, such as the top and bottom plates of capacitors and the spiral windings of a planar inductor. There is no advantage to having parasitic resistance in this type of film; that would only degrade the performance of the capacitor or inductor. Therefore, these would normally be metals or else very conductive metal-filled polymer thick films with resistances less than about 0.1  $\Omega$ /square. Narrow tolerance and repeatability is not a major issue as long as the overall resistance is low enough for the application. Of course, it would be desirable for integrated passives to utilize the same metal used as interconnect on the substrate. Resistive films would be used in making integrated resistors only, and would be specified on the basis of providing predictable, reproducible values of resistance in a sufficiently small footprint. A wide variety of materials could be used for this, ranging from resistive alloys (NiCr, CrSi, TaN<sub>x</sub>, TiN<sub>x</sub>O<sub>y</sub>) to ceramic-metal nanocomposites (cermets) to carbon-filled polymers. Resistivities of 100 to 10,000  $\Omega$ /square are required. Dielectric films would be used to form integrated capacitors, and a vast array of materials with a wide range of dielectric constants are feasible from simple unfilled polymers for small-valued capacitors ( $k = 2$ –5) to amorphous metal oxides ( $k = 9$ –50) to highly ordered mixed oxides for the highest possible dielectric constants ( $k > 1,000$ ). There are essentially no fabrication issues for inductors; they are simply shaped conductors made from the interconnect metallization already present in the boards.

These three types of films can be formed subtractively or additively by sputtering, CVD, evaporation, anodization, dry oxidation, sol-gel, spin-on, doctor blade coating, chemical conversion, and many others. Etching options include liquids and a variety of reactive and unreactive, directed or nondirected plasmas. Also, they can be modified by annealing. Integrated passives are not a new idea; they have been used for decades in ceramic substrates and on various substrates under the name “hybrids.” Thick-film pastes of conductors and dielectrics are used to form resistors, capacitor dielectrics, and spiral inductors that are fired simultaneously with the green tape of the insulating layers. However, the firing requirements mean that this technology is not transferable to heat-sensitive organic substrates. Glass has been used for integrated passive substrates by Intarsia, and silicon had a brief period of use as an MCM substrate; Bell

Labs and N-Chip utilized an integrated decoupling capacitor as part of the buildup over a silicon substrate for their MCM designs. Organic substrates make up the vast majority of interconnect boards due to their low cost, and it is here that integrated passive efforts are most important. Because organic boards cannot tolerate temperatures much above about 250 °C, many processing options are not possible including all involving fired ceramic thick films. Whatever methods and materials are chosen must be compatible with the board's conductors and insulation layers already in place, integrated passives already in place, and any fabrication following.

## 2. MOTIVATION AND CHALLENGES

Both technical and economic issues should be considered in order to determine the ultimate worth of changing technologies. Deciding which engineering option will provide a higher return on each dollar invested cannot be based solely on the goal of lowering the cost to make the same product; the implications are much more nebulous and include concepts such as increased functionality, added product value, higher consumer appeal, and the ability to make products that cannot be realized with the older technology. Some of these issues are difficult to quantify; for instance, what is the added dollar value to a cell phone that is made 20 percent smaller? There is a real worth to this type of improvement, but it is a function of consumer psychology, which is notoriously difficult to enumerate. The merely technical issues often can be quantified fairly accurately.

### 2.1. Reasons for Integrating Passives

For integrated passives, the reasons in favor of integration can be broken down into these motivations:

1. *Reduced system mass, volume, and footprint.* Individual packages are eliminated and passives can go underground leaving more room on the surface for ICs.
2. *Improved electrical performance.* Integrated passives can have lower parasitics, particularly much lower inductance in capacitors.
3. *Increased design flexibility.* The component's resistance, capacitance, or inductance can be sized to any desired value within the technology's range.
4. *Improved reliability.* Solder joints are eliminated.
5. *Reduced unit cost.* Integrated passives can be formed simultaneously and with very low incremental cost. Also, they are inherently lead-free.

Not all integrated passives have smaller footprints than the surface mount devices they might replace. In fact, the higher values of integrated capacitors and inductors would occupy a much larger area. For example, a 100 nF integrated capacitor formed by sputtering 3,000 Å of Al<sub>2</sub>O<sub>3</sub> onto a circuit board would require almost 4 cm<sup>2</sup> of area, compared to only 0.01 cm<sup>2</sup> for a 0402 surface mount capacitor plus its associated keep-away distance. Similarly, a 50 nH planar spiral inductor could be made from five turns of 5 mil conductor, but would have an outer diameter of 3.3 mm. Furthermore, this inductor would require a keep-away distance on all layers of the substrate—not just one like a

capacitor or a resistor—about equal to its radius to avoid interference from other metal with its electromagnetic field that would reduce its effective value. Its total area would be 0.34 cm<sup>2</sup> and would be effectively multiplied times the number of layers in the substrate that must be kept clear. Integrated resistors and small-valued capacitors are much closer to, or even smaller than, their surface mount size. The reduction in system form factor with integrated passive technology would come from the fact that integrated passives, regardless of their footprint, can be fabricated under the surface of the board, which frees up top-surface area that was formerly occupied by surface mount passives. Since many wireless and mixed-signal systems have something like half of the board surface occupied by passives, the footprint reduction can be significant. Additionally, system mass may be reduced by stripping an integrated resistor, capacitor, or inductor down to only its electrically active portions, leaving less than a milligram of metal and/or dielectric. The integrated passive would depend on the substrate for mechanical support and the layers above and below it for environmental protection, thus eliminating the mass and volume of the individual package.

The price paid for this integration is that additional board layers may be required to accommodate these passives in their integrated form, adding cost and complexity to the manufacturing process, which can offset some of the benefits of freeing up surface area and reducing volume or mass. This is an important tradeoff in passive integration and will be a major driving force in the economic viability of any integrated approach. It is not clear that more layers will always be required for integrated passives; savings in wiring and, especially, vias required to route all passive connections to the surface may be significant if the passives can be placed on any desired layer. As previously mentioned, active logic devices can be scaled down to nanometer scales, principally by improvements in processing technology, since they can operate with arbitrarily few electrical quanta. But passives may have to maintain values of resistance, capacitance, and inductance regardless of their size, and footprint reduction can come about only by improvements in materials to give higher specific values per unit area. This is particularly problematic for integrated capacitors.

Due to their simplified structure and lack of leads and contacts, integrated capacitors and resistors tend to have considerably less parasitic inductance than their surface mount counterparts. Also, short leads to the integrated capacitor or inductor can result in less parasitic resistance. As a result, integrated passives tend to be “purer” components with less undesired properties to be taken into account in the design phase. Lower parasitic inductance is particularly important for capacitors in high-frequency applications such as decoupling and RF filtering, since, above the self-resonance frequency, the inductive properties of the capacitor dominate the component's behavior, making it act completely like an inductor. Integrated capacitors can be fabricated that have far higher self-resonant frequencies and therefore a larger usable frequency range than is possible with any discrete capacitor, no matter how much the latter is optimized for low inductance. This is a major motivation for integrating capacitors, as will be discussed next.

An additional electrical advantage comes about because the value of integrated passives can be specified exactly. If an 18.2 nF capacitor, a 2,360  $\Omega$  resistor, and a 14.6 nH inductor are needed for a design, the integrated passives can be sized to give those values (within tolerance limits); it is not necessary to choose the next closest value from a catalog of discrete passives or to create the values by stringing together discretely in series and/or parallel. Using multiple discretely may take up a large amount of board space, require a large number of lead attach steps, and exacerbate problems associated with parasitics.

With regard to reliability, the use of integral passives does eliminate two solder joints per passive, which are major failure points for systems with discrete components. However, the use of new materials and fabrication methods necessary for integration may bring with them new failure modes that have not been fully revealed. There is much research to be done to validate the conjecture that integrated passives enhance system reliability. The standard environmental and thermal stress tests will still apply, but, while discrete components may be tested on their own to identify failure modes not associated with the solder joints, integrated passives must always be tested in the systems that they will occupy, since the interconnect substrate forms their packaging. Of particular concern is the result of mechanical stresses on large-area capacitors and long resistors brought about by CTE mismatch, layer-to-layer slippage during fabrication, and flexure.

Because integrated passives can be formed simultaneously, the incremental cost of producing just one more is nearly zero. This characteristic is attractive for systems that require dense placement of passives, the direction in which most systems are heading. A major issue in business models for integrated passives is whether all of them can be integrated or only some. If they can all be integrated, then there is no need for any pick-and-place equipment for surface mount passives, just for the ICs, and the cost model needs to consider only one technology set for passives: integration. However, if only most of them can be integrated, then it may be more difficult to be cost-competitive, since the manufacturing facility must support both technologies at once. Some passives, such as large-value capacitors and inductors, may be very challenging to integrate due to their large footprints, even in buried layers, and may be best left as surface mounts. On the plus side, integrated passives are inherently lead-free. At present, economic analysis to determine the feasibility of integrated passives is specific to both the application and the integrated passive technology.

## 2.2. Problems with Integrating Passive Devices

The problems with implementing integrated passives on organic boards are as well-understood as their potential benefits.

1. *Indecision on materials and processes.* Research continues on many resistor materials and capacitor dielectrics.
2. *Lack of design tools.* For both component sizing and system layout.

3. *Requires vertical integration.* The same company must manufacture both substrates and passives.
4. *Yield issues.* One bad component can scrap the entire board.
5. *Tolerance issues.* Integrated passives cannot be pre-sorted prior to inclusion on the board.
6. *Lack of standardization.* The various segments of the integrated passive industry aren't speaking the same language [4].
7. *Surface mount technology is improving.* Moving toward 01005.
8. *Lack of costing models.* It's not easy to tell when integrated passives might be more cost effective.

It's not that it cannot be done; scores of research projects have shown that the full required range of  $R$ ,  $C$ , and  $L$  values are achievable on just about any substrate. The problem is that the optimal materials and processes have not been identified, if they exist for a given substrate, and that the infrastructure does not yet exist in the industry for their design and manufacture. The physical integration of passive components into circuit boards necessitates the integration of the corresponding business units. For example, a manufacturer that previously made only boards but now expands into integrated passives finds itself in the business of making passive components instead of simply buying them out of a catalog. That means having to understand issues of passive performance, fabrication, sizing, tolerance, parasitics, and reliability, which were previously taken care of by a separate entity.

There are two main aspects to the design issue: designing the individual components and designing the components into a system. Taking the narrower one first, designing individual integrated resistors and capacitors is easy but dependent on the materials used, since this will influence the value density of the structure, such as the number of nF/cm<sup>2</sup> for an integrated capacitor. If the ohms/square of the resistor film or the nF/cm<sup>2</sup> of the dielectric film are known, then it is a simple matter to size the component for a required overall value. Therefore, the component's material and processing technology have to be established before components can be sized. For inductors, the design situation is much more complex. Accurate sizing of a spiral inductor from first principles requires solving Maxwell's equations for a spiral shape on a Cartesian geometry with various other conductors from the eventual system layout present to distort the magnetic field. Although there are some excellent approximate design tools for isolated spirals, the presence of other conductive materials nearby means that the design of the integrated inductor usually can't be done as a standalone component. Trial and error with physical prototypes sometimes will be required.

With regard to overall layout, only a few programs are capable of taking integrated passives into consideration by incorporating them from SPICE-like electrical models, autorouting around them, or optimizing their placement on and among layers. Doing all of these by hand is possible but can be quite tedious, and very few designers are experienced with integrated passives to the extent of knowing the pertinent layout issues necessary for taking advantage of their unique electrical and size characteristics. However, progress is being made in this area by design and layout software vendors, and there is no major technological hurdle to enabling

these programs to utilize integrated passives effectively and with the same ease of operation as they do for surface mount boards. Again, the processes must be established first.

On the assembly side, attachment of surface mount discretes is one of the last steps to be performed on a circuit board prior to its inclusion in the overall system. All of the layers and conductors are fully formed and tested before the passives go on. The only concession made by the board designers to the eventual presence of the surface mount passives, and ICs for that matter, is that proper attach metallurgy be available and that the board be able to withstand the temperatures associated with the attachment process. The attachment typically uses reflowed or wave solder, requiring about 250 °C for up to a few minutes, or else uses conductive epoxies, which usually have even milder thermal requirements. However, if integrated passives are utilized, they will be fabricated as part of the board's manufacturing flow, and the portions of the board already formed will have to be able to withstand not only the thermal stresses that a particular integrated passive technology requires, but also any chemical and mechanical exposures that are involved. Subsequent interconnect/insulator processing must not degrade any integrated passives that are already in place, and any integrated passive processing must not degrade the board layers already in place. Not only are the passives integrated into the board, but their processing requirements are mixed in as well.

The same yield problem exists for integrated passives as is well known for integrated circuits; one bad component out of many can force the entire board to be scrapped. The problem might not be apparent until the substrate is completed, so a considerable amount of fabrication may be wasted if the bad component is formed early on. Rework might be possible, but few procedures for this have been developed or reported in the literature. This same problem was identified and solved for active integration, enabling tens of millions of components to be formed on silicon with IC yields routinely over 75 percent. The same issue impacts tolerance; discrete passives may be presorted by value while the values for planar integrated passives will be ruled by sizing tolerances associated with film patterning or printing. In the case of integrated capacitors, because they are area-ruled, the resulting variation in value will be higher than the variation in one-dimensional sizing. Attempting to make smaller integrated passives will result in less exact values. Trimming technology for integrated passives requires further development. The use of singulated and embedded passives might help to alleviate these problems by enabling sorting for yield and tolerance.

Meanwhile, surface mount technology continues to improve. On the average, surface mount passives have gone down by about one case size every four years. Sizes as small as 0201 ( $0.50 \times 0.25$  mm) are in use and, although it is hard to imagine them becoming much smaller, there is work in progress for 01005 components. With a 10 mil keep-away distance, the theoretical density for 0402s is 107 components/cm<sup>2</sup> and for 0201 it is 270/cm<sup>2</sup>. However, in some instances, integrated passives may be the only way to make the product possible. This situation is rapidly approaching in the case of decoupling upcoming generations of microprocessors that will draw very high bursts of current

from the board's power and ground planes. Surface mount capacitors may exhibit too much inductance to do the job, and integrated capacitors may be the only way to enable these chips to function.

### 2.3. Cost Modeling

The greater the detail necessary to accurately model a system, the less general and more application-specific are the results. This is the situation with integrated passives on organic boards. Because the specific processes and materials have not yet been reduced to a manageable number, it is not currently possible to say when passive integration is and is not economically feasible. No generalized models exist to aid the manufacturer. This sounds like a chicken-and-egg problem, but it can be cracked by first assuming a specific and feasible material and process set for the existing manufacturing infrastructure and for the potential product, and then performing the costing based on that [5, 6].

What is the impact of passive integration on an existing board design that utilized surface mounts? Of primary importance is that the number of layers will probably increase due to the need to accommodate subsurface passives. Also, if reduced board form factor is desired, this will also add pressure to increase the number of layers simply to accommodate the interconnects. PWB cost goes about linearly with number of layers. Adding another signal layer to a controlled impedance board actually requires the addition of two layers, since a ground or power layer has to be added as well between the signal planes. The decrease in board area will result in a more compact product, but the benefit of this is harder to put into terms of dollars than is the cost. It does have the advantage of increasing throughput since there can be more boards per panel, but board yield will probably decrease, for the reasons discussed earlier in this section. There may be some decrease in wiring and, particularly, via density due to the reduced need to route to specific areas on the surface to accommodate surface mount units. Instead, it may be possible to put the passive in any given layer and position where it is needed. Overall, each design needs to be considered on a case by case basis, at least until much more experience with these designs has been accumulated.

## 3. APPLICATIONS FOR INTEGRATED PASSIVES

In principle, integrated passives can replace discretes in any application, but in what forms will they find widespread use? Except for decoupling, the circuit schematic will not generally change if integrated passives are used instead of discretes, though slightly fewer integrated passives may be used if exact component values can be made in one unit instead of having to string discretes together in series or parallel to achieve a specific value. Therefore, replacement of resistors and most capacitors will be at a ratio of one to one. This section will discuss some of the most likely initial applications and describe what factors will motivate the switch from surface mount to integration.

### 3.1. Replacing Surface Mount Discretes with Arrays and Networks

Individual surface mount discrete passives can be replaced with a smaller number of integrated passives formed, not inside the primary interconnect board, but on a separate substrate that is then mounted on the surface of the primary board. This integration approach is referred to as passive arrays or passive networks and can result in significant assembly cost savings with a minimum of design and process changes. Arrays will have the same number of total contacts but are achieved with fewer component placements. Passive networks contain internal connections that result in fewer mounted components and contacts. Not only are there fewer components to mount, but each one is bigger than the individual units it replaces, and therefore easier to handle, but it has a smaller total footprint on the board than the group it replaces. Since this brings almost all of the advantages of passive integration with few of the problems, both listed above, this trend is well underway and represents the majority of integrated passive usage today, especially for units mounted on organic boards. The reason this approach has gained rapid acceptance is that it maintains the separation between passive integration issues and substrate issues. The only concession for the board is that pads be moved to accommodate the layout of the integrated surface mount units. The board maker does not have to be in the passive manufacturing business and the integrated units can be pre-sorted and tested to avoid yield and tolerance problems.

Numerous configurations of  $R + C$  networks are available in quantity from reputable vendors, and custom arrangements are possible. Integrated inductors are also available. Off-the-shelf versions include filters, terminators, and low-inductance decouplers. With diodes and transistors added to silicon substrates, networks can include ESD protection, oscillators and amplifiers. RC termination is a popular application for passive networks, since densely packed groups of resistors and capacitors are required to terminate wide bus lines. Integrated RC termination networks can be formed in single packages with footprints to match the physical bus width on the board and will require only half the number of pads since there are internal R-C connections within the unit.

There is much more to be squeezed out of this approach as the passive networks become merged with active devices to form what NEMI refers to as “functional modules,” which could include, for instance, Bluetooth or GPS subsystems mounted as surface units on the primary interconnect board. There is tremendous potential flexibility with little downside. For example, a cell phone maker could include a GPS receiver in the form of a surface mount module that would include integrated passives and integrated antennas, as well as integrated transistors on one piece of silicon in a single chip scale package. The company would not have to worry about going into the business of manufacturing GPS systems and could also upgrade or switch vendors when required, possibly with the same surface pad layout. At this point, the distinction between which is the primary interconnect substrate and which is the add-on module becomes blurred. In the limit, the main board may have no passives at all and simply provide interconnection among various functional modules.

### 3.2. Decoupling

High-frequency operation of digital logic circuitry places severe demands on power distribution systems to supply stable, noise-free power during the clock-driven simultaneous switching of millions of transistor gates. Decoupling capacitors are necessary to supply these large current surges, ramping as fast as 500 A/ns, to high-power microprocessor and logic ICs during the switching portions of the clock cycles. The purpose of this is to ensure that unacceptable drops in logic voltage levels do not occur due to the high current demands on a power supply that may be located many inches away down narrow conductor paths. Between cycles of current demand, the power distribution system recharges these capacitors in preparation for the next switching cycle. It's not too simplistic to think of the capacitors as actually providing the power to run the chips with the power supply merely acting as a battery charger during low-demand periods. In other terms, the impedance of the power supply is too high to prevent voltage drop during high demand periods, so the capacitors must provide low impedance power to the chip [7, 8].

Sizable groups of surface mount decoupling capacitors can be seen surrounding the microprocessor on almost any circuit board. Even memory chips are starting to draw enough power to require decoupling capacitors. The two main requirements for these capacitors are that they provide sufficient charge to run the chip for one clock cycle and that they provide that power at low impedance to prevent excessive voltage drop during moments of high current draw by the chip. Of these two criteria, the low impedance issue is the more challenging to surface mount capacitors. The inherent parasitic inductance of surface mounts requires that many separate capacitors be arranged in parallel in order to lower the overall inductance, resulting in a large number of small caps instead of a few large-valued units. That means using more board area near the microprocessor, where space is at a premium anyway, and more solder joints. Also, the temperature extremes are higher near the chip, which can cause a variety of reliability problems, including failure of those solder joints.

The much lower parasitic inductance of integrated capacitors, the ability to bury them beneath the surface of the board, and the lack of solder joints makes them very attractive for replacing surface mount capacitors in decoupling. Because of their inherently low inductance, there is no need to use multiple capacitors in parallel; a single large integrated capacitor will suffice. The inductance is so low that, when using integrated capacitors, the designer must consider the inductance of the vias and interconnects from the power/ground planes to the capacitor, while these contributions are usually negligible compared to the inductance of surface mount capacitors. The major unknown in replacing surface mount decoupling capacitors is how much capacitance is needed. With surface mount, an excess of capacitance is usually present because of all the units placed in parallel to lower the total inductance, but, with integrated capacitors, probably much less will suffice. Exactly how much less is not fully understood and can only be determined with a combination of modeling and power/ground voltage measurements with a variety of integrated capacitor values.

### 3.3. DC/DC Conversion

One application for integrated capacitors, either on a substrate or on the ICs themselves, is as charge storage elements in DC-to-DC converters. For example, charging capacitors in series and discharging them in parallel achieves a step-down function. If the switching frequency is high enough, relatively small capacitors can be used for small (~1 W) converters. Localized power conversion of this type becomes more and more important as IC supply voltages decrease and large currents must be supplied.

### 3.4. Passive Replacement in FR4

Developing passive integration for commodity FR4 will open up a huge market. Because it is such a large target, there is a concerted effort to solve the problems associated with integration onto this platform. In October 1998, NIST funded the Advanced Embedded Passives Technology Consortium (AEPT) to develop the materials, design, and processing technology for embedding passive devices onto circuit board substrates. This combination of industrial partners and associations is tackling the parallel issues of processing, materials, design software, cost modeling, standardization, testing, and reliability for FR4. AEPT made this task manageable by selecting a small number of integration technologies (materials and processes) and building the modeling, reliability, and costing efforts around those. As the results and products come onto the market over the next few years, many of the obstacles will be solved or made manageable, enabling integration to penetrate this market.

### 3.5. Passive Replacement in HDI

The various forms of HDI interconnect will employ processing steps not common in the FR4 domain such as sputtering, buildup, spin on, dry etching, and more. A wider spectrum of metals and dielectrics will also be used. This provides the opportunity to employ a variety of possible integrated passive processes and materials into this maturing technology. If these are all developed in parallel, integrated passives will arrive as part of the infrastructure instead of as an add-on.

## 4. INTEGRATION OF RESISTORS

Integrated resistors are fabricated either by depositing and patterning a layer of resistive material or by printing resistive paste in series with an interconnect line on an insulating substrate. In keeping with the concept of a planar, stacked assembly, the resistor will be a film of material, probably between a few hundred angstroms and a few microns thick [9, 10].

Assuming that all of the resistance is in the resistor material and not in the interconnects, the resistance of the structure is

$$R = \frac{\rho L}{Wt}$$

where  $R$  = resistance,  $\Omega$ ,  $\rho$  = resistivity of the material,  $\Omega$ -cm,  $L$  = length of the strip, cm,  $W$  = width of the strip, cm and  $t$  = thickness of the strip, cm.

The resistivity of a material is an intrinsic property and is a function of composition and microstructure. For thin films, the resistivity can be somewhat different from that of bulk materials, and is generally higher.

Sheet resistance is defined by

$$R = \left(\frac{\rho}{t}\right)\left(\frac{L}{W}\right) = R_s N_s$$

where  $R_s = \rho/t$  = sheet resistance,  $\Omega$ /square,  $N_s = L/W$  = the number of squares, and  $L$  = length of the strip, cm.

The sheet resistance is the resistance of a square of material ( $L = W$ ) when the electrical contacts cover opposite edges completely. The size of the square is irrelevant as long as length equals width and the contacts completely cover two opposing sides. When long, narrow materials are used, the resistor is thought of as squares in series.

Resistors consisting of many squares are usually formed in a serpentine pattern to fit into an allocated substrate area with corner squares counted as somewhat less than a full square, 0.556 squares, since the current does not have to traverse the entire side-to-opposite-side distance. Thus, a material with a resistivity of 1 m $\Omega$ -cm, that is, 1  $\mu$ m thick would have a sheet resistance of 10  $\Omega$ /square, and this number, multiplied by the number of squares, would give the value of the resistor in Ohms. The benefit of expressing films of resistor materials in  $\Omega$ /square is that it does not matter what the resistivity or the thickness is as long as it gives the desired sheet resistance. For example, in sputtering TaN<sub>x</sub> resistors, the sputtering conditions such as vacuum level, temperature, power, gas composition, etc. may be varied to affect both the material's film thickness and resistivity. It may be impossible to change conditions so that only resistivity or film thickness is adjusted to desired values due to the inevitable cross-dependencies of processing conditions. However, if the sheet resistance is the target variable, processing conditions can be optimized to give the desired value of  $\Omega$ /square without having to measure or specify both the thickness and resistivity. Also, the sheet resistance is a quantity easily measured with standard four-point probes or from simple test structures, again without having to measure either of its two constituent variables.

Once a resistor material and process are selected, it is a simple matter to determine the length/width ratio to give any required value of resistance from the Ohms/square of the material. However, to separate these two measures out of the ratio and establish the actual footprint of the resistor, other factors must be considered such as the following:

- **Heat dissipation.** Integrated resistors must be designed so that the temperature rise during use will not heat them to the point that their value drifts significantly or that failure mechanisms are accelerated to the point of affecting their reliability. Large area resistors are favored regardless of their number of squares. For resistors integrated into circuit boards, three-dimensional thermal simulations are necessary to predict operating temperatures at all parts of the components and assembly.
- **Tolerance.** Tolerance and precision improves for larger areas.  $\pm 10\%$  value precision is considered acceptable for most resistors, but many applications require tolerances down to 1%.

- **Parasitic capacitance.** Long serpentine resistors will exhibit characteristics of capacitors at high frequencies due to coupling between adjacent strips, resulting in a drop in resistor impedance. Small numbers of squares and large strip spacing are favored to minimize this, regardless of the total area.

#### 4.1. Materials for Integrated Resistors

A resistor's performance is a direct function of its composition, microsegregation of composition, crystal structure, film thickness, temperature, and voltage, at least. These, in turn, are functions of processing conditions such as pressure, temperature, power, gas flow, etc. for sputtering, CVD, or evaporation of thin films and cure time and temperature for thick films. Subsequent anneals, which alter crystal structure and composition microsegregation, are often used to modify resistor properties. Some useful reviews of this topic are available [11].

The use of integrated resistors, and capacitors and inductors for that matter, requires that the design and process engineers work together to an extent that is not necessary when off-the-shelf discretely are used. The selection of an integrated resistor technology for a given application requires the simultaneous consideration of electrical performance issues (resistivity, temperature effects, stability) and compatibility with the materials and processing of other parts of the substrate/interconnect/passive assembly. No resistor material should be considered that cannot be deposited, cured, and/or patterned by techniques and chemicals that do not harm the pre-existing substrate, interconnects, and other passive components in place. For these reasons, the integrated passive engineer must understand the potential resistor film materials and processing methods, how those methods affect the composition and structure of

the films, and how the resulting composition and structure affect the electrical properties.

Resistor materials that can be processed at under about 250 °C can generally be used on polymer board materials or organic buildup layers. Of course, these same technologies could also be used on inorganic substrates such as glass, silicon, or ceramic since these are typically more thermally and chemically robust than polymer. There are two restrictions to transferring the technology to ceramic substrates: (1) The ceramic surface may be significantly rougher than organics, resulting in yield and tolerance problems with thin film devices, and (2) ceramic substrates are fired at temperatures usually exceeding 600 °C, which may not be tolerated by some resistor materials.

Most integrated passive resistor applications can be realized using two ranges of sheet resistance: about 100 Ω/square and about 10,000 Ω/square. The lower range can be obtained using any one of several materials, including TaN<sub>x</sub>, CrSi, NiCr, and TiN<sub>x</sub>, and the high end of the resistance range can be covered by cermet or, perhaps, TiN<sub>x</sub>O<sub>y</sub> and LaB<sub>6</sub>. Polymer thick film materials (PTF) can accommodate the entire range, but problems with value stability exist at this time. Elemental metals are generally too conductive to be used for anything but very low valued current sensing applications. Table 1 shows the status of these materials on organic substrates. It should be remembered that these films, formed by any method, cannot subsequently be annealed at high temperature on organic substrates for the purposes of modifying their structure and properties.

#### 5. INTEGRATION OF CAPACITORS

A very wide range of capacitor dielectric materials is potentially useful for integration; some of the most important are shown in Table 2. Ideally, this dielectric constant should

**Table 1.** Materials for integrated resistors.

Material	Resistivity range (μΩ-cm)	Film thickness	Sheet resistance (Ω/square)	TCR (ppm/°C)
Ag	1.6	2 μm	0.0080	4,100
Cu	1.7	2 μm	0.0085	4,330

be flat with regard to frequency, temperature, voltage, and time. The dielectric should be capable of being bent and stretched to a reasonable degree so that it will not suffer from the effects of CTE mismatch with other board materials during normal temperature excursions and so it can be used in applications with little packaging such as smart cards. It should be amendable to mass production at an economic cost using common materials and patterning techniques that do not harm other parts of the board or components already in place. Certainly, any material and process technology will compromise on some of these issues, which is why no one perfect integrated capacitor dielectric has yet been identified from the hundreds of journal and proceedings articles to date.

There are two broad classes of dielectrics: paraelectrics and ferroelectrics (Table 3). The distinguishing feature between the two is that ferroelectric materials do not lose their ionic polarization when the field is removed and paraelectrics do. Because of lattice hindrances in ferroelectrics, the electric field can pull the ions into configurations that do not relax back to the previous state once the field is removed. As a result, ferroelectrics, analogous to ferromagnetic materials, can possess a residual polarization after the field is removed. Furthermore, this

**Table 3.** Comparison of paraelectric and ferroelectric dielectrics.

<i>k</i>	Paraelectrics 2–50	Ferroelectrics up to 1,000s
<i>k</i> vs. <i>T</i>	little dependence, <500 ppm/°C	Can be highly dependent due to crystal phase transitions and ion mobility
<i>k</i> vs. frequency	little dependence	Decreases significantly, typically above a few GHz
<i>k</i> vs. film thickness	no dependence since amorphous	Highly dependent due to effects on crystal structure
<i>k</i> vs. bias dielectric fatigue	no dependence none	Decreases with DC bias <i>k</i> can decrease significantly with cycles and time
<i>k</i> vs. film structure cure requirements	little or no dependence none	Film must be crystalline May require up to 700 °C in O <sub>2</sub>

residual polarization can be oriented in one direction or the other depending on the direction of the last field. It is this trait that gives them utility in nonvolatile memories. Paraelectric materials are those which cannot be left with a residual polarization once the field is removed because they do not have a mobile charged atom with more than one stable lattice position. This residual polarizability defines ferroelectric and paraelectric materials, but this feature is irrelevant to any projected substrate-level integrated capacitor application. The important difference from the point of view of integrated passives is that ferroelectrics generally have much greater dielectric constants than do paraelectrics, sometimes by as much as three orders of magnitude, because of the mobile ionic charge. For example, the common ferroelectric barium titanate is a perovskite crystal with a Ti cation at the center that can shift back and forth within the confines of this crystal a distance larger than the ions can move in a typical paraelectric such as tantalum oxide. This motion creates a considerably larger dipole arm than is possible in Ta<sub>2</sub>O<sub>5</sub>, resulting in a much larger dielectric constant for BaTiO<sub>3</sub>. Incidentally, it is the fact that this Ti ion can remain shifted to one side or the other after the field is removed that gives BaTiO<sub>3</sub> its ferroelectric residual polarization behavior. However, to achieve this very high dielectric constant, ferroelectrics must be in an oriented, single-crystal form, which usually requires a curing temperature in oxygen far in excess of what can be tolerated by organic boards. Adapting ferroelectric dielectrics to organics is a major goal of capacitor integration development.

The fact that so many different dielectric materials have been evaluated in just the past few years for applications as integrated capacitors is indicative of the uncertainty in this area. Scores of dielectrics representing all classifications of these materials (oxides, polymers, ceramics, etc.) have been evaluated experimentally in order to identify the technical advantages and disadvantages with regard to fabrication, electrical performance, and reliability as an integrated component. In any new technology, this is a necessary procedure to both cull out the materials that are clearly impractical and to provide the information to establish the economical viability of those that are feasible. The list includes almost every material that has ever been used as a capacitor dielectric as

well as one class of material that was invented specifically for the purpose: ferroelectric nanopowders dispersed in curable epoxy. As it turns out, very few out of this multitude are completely impractical for use as in integrated capacitors, which means that there is a large number of choices that have passed the technical challenges and remain to be evaluated economically.

There is a tremendous amount of research currently underway on high specific capacitance materials and structures, not only for integrated passives, but also for gate dielectrics and memory cells for ICs. Many of the same goals are sought for all capacitor development programs: high specific capacitance, low leakage, high breakdown, and sufficient stability. However, what are considered good properties is very much a function of application. A gate dielectric with a leakage of a mA/cm<sup>2</sup> at 5 V may be considered a low-leakage material for that application, but this is a tremendous amount of leakage for an integrated passive capacitor used in, for instance, an A/D converter. Similarly, a capacitor that might be considered very stable against frequency for energy storage applications might be far too variable to be used as a filter element. There are several excellent overviews of dielectric materials, some written long before integrated passives were conceived [12].

Because integrated capacitors are planar and area-ruled, the best way to express their value is as capacitance per unit area or “specific capacitance.” The following equation uses convenient units:

$$\text{specific capacitance in } \frac{\text{nF}}{\text{cm}^2} = 0.885 \frac{\text{dielectric constant}}{\text{dielectric thickness in } \mu\text{m}}$$

One of these factors is a function of the dielectric material itself and the other depends on its form (film thickness). See Table 4.

Figure 3 shows the length required for the side of a square integrated capacitor to provide a given amount of capacitance for various dielectric materials. The *x*-axis is the total capacitance of the structure, not the specific capacitance, and the *y*-axis is the required length of one side of the square plate of dielectric material in mils. Since integrated capacitors are area-ruled, the lines have a slope of

**Table 4.** Specific capacitance achievable from integratable dielectrics.

Dielectric	Dielectric constant	Thickness (μm)	Specific capacitance (nF/cm <sup>2</sup> )	Energy density at 5 V (μJ/cm <sup>2</sup> )
BCB	2.7	2.0	1.2	0.015
SiO <sub>2</sub>	3.7	0.2	16	0.20
Ferroelectric nanopowders in an epoxy matrix	90	5.0	16	0.20

Al <sub>2</sub> O <sub>3</sub>	9	0.2	40	0.50
Ta <sub>2</sub> O <sub>5</sub>	24	0.2	110	1.40
TiO <sub>2</sub>	40	0.2	180	2.30
Barium titanate	~2000	1.0	1800	22

**Figure 3.** Square plate sizes required for various integrated capacitor technologies.

1/2 on log-log coordinates. A few representative dielectrics are shown for some practical thicknesses. Other dielectric materials of known dielectric constant and thickness may be interpolated into the diagram to show their required sizes. The four horizontal dashed lines represent the areas of common surface mount components along with a 10 mil keep-away distance. For comparison purposes, these surface mount components were converted to square areas so that the “square plate width” for these units is the average side length required. It is clear from this diagram that integrated capacitors do not necessarily have a smaller footprint than their surface mount counterparts. For instance, using 2,000 Å of a paraelectric such as Al<sub>2</sub>O<sub>3</sub> or Ta<sub>2</sub>O<sub>5</sub> would result in a smaller footprint only for capacitor values below a few nF. For micron thicknesses of BCB, polyimide, SiO<sub>2</sub>, or SiN, the crossover is around 10–100 pF. However, integrated passives are placed below the surface of the interconnect substrate so, no matter their footprint, they take up no surface area, enabling the system to either be smaller or to have more ICs.

## 6. INTEGRATION OF INDUCTORS

Integrated inductors are the easiest of the IPs to fabricate since they are usually spirals of the conductor material, but they are the most difficult to accurately model. Also, since inductors are magnetic devices, they pose an integration problem not shared by resistors and capacitors: They perform best when there is a sufficient volume of space to allow their magnetic fields to be unimpeded by other structures. As a result, a “keep-away” distance is required for inductors in order to avoid loss of inductance relative to an isolated structure and to prevent interference with nearby signal lines and ground planes from the inductor’s field. Inductors perform poorly over conductive substrates such as doped Si and over dense layers of interconnects due to the magnetic field’s interaction with conductive materials.

The easiest way to fabricate integrated inductors is to simply form a spiral out of the interconnect material, typically 1 to 8 turns with a total outer diameter of 0.2–2.0 mm,

which will provide an inductance of around 1–40 nH. Unfortunately, the prediction of the resulting inductance for integrated spirals, or other inductor shapes, is very complex due to the interaction of magnetic fields with the structure's width, spacing, number of turns, inner diameter, spacing to ground, and the presence of nearby conductors. There are several empirical and semi-empirical methods that can be used to approximate these parameters, most of which use the mutual and self-inductance of concentric rings to approximate a spiral form. A more direct but computationally intensive method involves solving Maxwell's equations with a finite element field solver, which takes into account the distortion of the inductor's fields due to nearby conductive structures.

There are several strategies for increasing the value of integrated inductors. Ferromagnetic alloys such as Fe/Ni can be plated around the windings in order to efficiently guide and focus the fields. However, this means increased cost because of considerably more processing and can also result in the addition of parasitic capacitance between the coil and the plated metal. Ideally, the conductors would be completely embedded within the ferromagnetic material, but almost any geometry of core material addition around the conductors is beneficial. Several other topologies, such as solenoids, toroids, and meanders, are also useful. Two-layer spirals yield approximately double the  $L$ , but with about double the resistance and additional capacitive coupling between the spirals. In addition to applications in signal filtering, these electromagnetic devices have applications in driving MEMS, power conversion, and magnetic sensing. These devices continue to be a focus of intense research.

## 7. STATUS OF PASSIVE INTEGRATION

Embedded passives in primary interconnect boards are not a new idea; they have been used in ceramic substrates for decades. Favored materials and processes for resistors, capacitors, and inductors in LTCC are well-characterized with regard to manufacturing requirements, performance, and economics, and there is a large infrastructure supporting them. A company wishing to use them on ceramics can find accurate and well-developed design tools, cost models, and performance information, and can then buy fully supported equipment and processes from vendors. The main drawback with embedded passives in ceramic is that tolerance is rarely better than around 10 percent due to printing variations, firing variations, shrinkage, and the inability to trim component values. Ceramic substrates, while growing in use with the rest of the industry, will never approach organic boards in sales volume.

Integrated passives are also widely available as surface mount arrays or networks, usually fabricated on Si, that can be mounted onto the surface of ceramic or organic boards using the same sort of infrastructure used for surface mount discretes. This technology is rapidly gaining market share due to the obvious economic advantages with a minimum of changes in board design or on the factory floor for implementation.

To date, integrated passives have not been utilized as embedded structures in organic substrates to a significant degree, particularly with FR4, which makes up the vast

majority of boards sold today. Penetration into this very large market is the driving force for R&D in the area. The problems with this implementation are well understood; both academia and industry are doing their parts in their own ways to solve these issues. Literature, conferences, and workshops for integrated passives on organic substrates began to appear in the mid-90s, and the typical journal article or conference presentation is a demonstration of a material or a process to make resistor, capacitor, or inductor test structures, or else to make a simple multicomponent device such as a filter or terminator. The striking characteristic about the literature is the vast array of materials and processes that have been investigated for integrated resistors or capacitor dielectrics. The list is very long and varied, including metals, ceramics, and polymers, as well as nano- and microcomposites of these materials that can be formed and patterned in dozens of candidate processes. It will take years for the set of candidate processes to be reduced for FR4 and flex. Also, there is very little in the way of design software that is capable of performing automated layout, although some is under development. It will ultimately be economics that determines which integrated passive technologies are suitable for implementation on a given substrate for a proposed application. Although the literature does contain many good papers on economic analysis, the large number of candidate processes and the application-specific nature of the problem make it difficult to give general conclusions. All of these issues must be solved at the same time to create a set of viable commercialized processes.

### 7.1. Issues for Implementation on Organic Substrates

A comprehensive economic evaluation of using an integrated passive technology versus a discrete passive technology must take into account the following:

1. *Electrical design issues.* Schematic differences due to differences in component characteristics.
2. *Board design issues.* Footprint, routing, number of layers.
3. *Fabrication issues.* Materials, processes, tolerances, yield.
4. *Manufacturing issues.* Implementation and scale up of fabrication technology to produce a volume process.
5. *Added value to the product.* Increased customer appeal resulting from smaller form factor and mass, performance.

A summary of the status of these issues and a brief description of the remaining challenges follows,

#### 7.1.1. Electrical Design Issues

Embedded passives in primary interconnect boards are not new; they have been used in ceramic substrates for decades. Favored materials and processes for resistors, capacitors, and inductors in LTCC are well-characterized with regard to manufacturing requirements, performance, and economics, and there is a large infrastructure supporting them. The main technical drawback with embedded passives in between

ceramic layers is that tolerance is rarely better than around 10 percent due to variations in printing, firing, and shrinkage, and to the inability to trim component values. If passives are formed on the surface of the ceramic substrate (“hybrids”), they can be trimmed after firing. Ceramic substrates, while growing in use with the rest of the industry, will never approach organic boards in sales volume, and, therefore, will continue to host only a small fraction of the overall passives produced, discrete or integrated.

Integrated passives are also widely available as arrays or networks, usually fabricated on IC-sized Si using basic front-end technologies, that can be surface mounted onto ceramic or organic boards using the same sort of infrastructure used to install discretely. This technology is rapidly gaining market share due to the obvious economic advantages with a minimum of changes in board design or on the factory floor for implementation.

To date, integrated passives have not been utilized as embedded structures in organic substrates to a significant degree, particularly with FR4, which makes up the vast majority of boards sold today. This potentially very large market is the driving force for R&D in the area. The problems with this implementation are well understood; both academia and industry are doing their parts in their own ways to solve these issues. Literature, conferences, and workshops for integrated passives on organic substrates began to appear in the mid-90s, and the typical journal article or conference presentation since then is a demonstration of a material or a process to make resistor, capacitor, or inductor test structures, or else to make a simple multicomponent device such as a filter or terminator. The striking characteristic about the technical literature is the vast array of materials and processes that have been investigated for integrated resistors and for capacitor dielectrics. The list is very long and diverse, including metals, ceramics, polymers as well as nano- and microcomposites of these materials that can be formed and patterned through many different processes. Methodology from the ceramic side is difficult to port to organics because these processes typically require much higher processing temperatures than can be tolerated by organic board materials and can only be applied if processed separately and laminated onto the board afterwards. A more manageable number of candidate processes, together with design software, costing models, and supply infrastructure, must be developed before embedded passives can move into organic boards.

### 7.1.2. Board Design Issues

The impact of passive integration on board design will be profound. The main effect will be to increase the number of layers since some considerable area must now be created to accommodate the planar integrated components. This is based on the assumption that integrated components will require more area per component than the discretely they replace, and this will be true for the most part. A secondary effect is the change in routing requirements since not all passives must be connected at the surface.

The size gap is largest for capacitors. At the time of this writing, an 0402 can be purchased with 2.2  $\mu\text{F}$  which, even with keep-away distance figured in, amounts to

230,000 nF/cm<sup>2</sup>. The highest values from the various processes becoming available for commercialization are much lower: up to about 1 nF/cm<sup>2</sup> for unfilled polymers, maybe 30 for ferroelectric-filled polymers, 50 for fired ferroelectric-coated foils for lamination, and the low hundreds for sputtered or anodized paraelectric. Ferroelectric thin films cured in place might reach over 1,000 nF/cm<sup>2</sup>, but that technology seems the farthest away. Only the smallest-valued capacitors can be replaced on a size-competitive basis with embedded components. Somewhere above that range, the remaining driving forces include economy of manufacture, replacement of solder joints, and very low inductance for decoupling. It may rarely make sense to attempt to integrate the largest capacitors on the board, those over about a micro-Farad that are generally used for energy storage. Larger capacitor areas not only occupy more layer space, but also pose a higher reliability risk.

Since a range of six decades or more of capacitance is required for many common systems, no one dielectric could provide the entire range with reasonable footprints regardless of its specific capacitance. Even if the lowest-valued capacitors can be fabricated, say, 10 mils across with acceptable tolerance, the highest-valued would then be unacceptably large at 10 inches. For this reason, it might be useful to employ the board’s interlayer dielectric for the low-valued components and a more exotic high-*k* material for the large values. The low-valued capacitors generally require paraelectric-type performance, matching most common board dielectrics. The other technology should have as high a specific capacitance as possible in order to embed the most components.

The size of integrated resistors is ruled by the number of squares and only indirectly by the specific resistance of the material. The lower limit of resistor linewidth is set by either thermal or tolerance issues. Large numbers of squares are to be avoided due to capacitive coupling between the meanders, resulting in a decrease in impedance at high frequencies. Resistor materials need to span between about 100 and 10,000  $\Omega$ /square to cover the entire range of values normally required in electronic systems. The available thin film processes such as TaN<sub>x</sub>, CrSi, and NiP are limited to only a few hundred  $\Omega$ /square at most. There is some promise of achieving 10,000  $\Omega$ /square with metal-deficient compounds or sputtered cermets, but more development is needed. Fired thick film materials on foil, borrowed from LTCC technology, and polymer thick films can cover the entire range with no more than a few squares. If the fundamental problems of reliability and value drift can be solved, PTF will be hard to beat as a flexible, economical process.

The number of extra board layers required for an embedded passive approach can be estimated. The total area requirements of proposed integrated passives from a schematic can be calculated for given set of integratable *R*, *C*, and *L* technologies. This can greatly exceed the interconnect area on the board in some applications. Dividing the total required area by the desired circuit board footprint will give a good estimate of the number of layers needed. Layout optimization may alter this number a bit, but this alone may indicate the worth of embedding for a specific application.

### 7.1.3. Fabrication and Manufacturing Issues

Materials and their processes are inextricably connected in passive integration, so choosing a material usually sets the processing method, while choosing a processing method usually restricts the number of materials. For instance, if  $TaN_x$  is desired as the resistor material, about the only way to deposit it is by sputtering. Conversely, if plating is desired, the number of resistor materials is reduced to only a few candidates. It is possible to categorize these groups as follows.

**Processes Requiring Vacuum** Sputtering and CVD are necessary for most thin film processes. These tend to be subtractive techniques requiring photolithography, and they are capable of excellent tolerance. An extensive range of component values is enabled by this, particularly with thin film dielectrics that make possible specific capacitances over the limit of about 20 nF/cm<sup>2</sup>, that is, available with thick film methods and as high as several hundred nF/cm<sup>2</sup>. Many tried-and-true materials are possible for resistors, but most are under a couple of hundred  $\Omega$ /square; considerable work remains to be done to achieve values over 1,000  $\Omega$ /square, which are needed for the high end of resistor values. Inductor materials up to a few microns can be deposited in this way, but they may be too thin to achieve high  $Q$  at high inductance values. Complete integrated and interconnected  $R$ ,  $C$ , and  $L$  systems have been demonstrated using thin film methods, and they are well suited to HDI and buildup technologies. However, they are relatively expensive and it may not make economic sense to include vacuum processes solely for the purpose of creating integrated passives, especially on low-cost commodity boards.

**Polymer Thick Film** These are additive processes using screenprinted preformulated inks. For resistors, a very wide range of  $\Omega$ /square is available, enabling almost any practical resistor value to be fabricated with no more than 10 squares. For capacitors, the maximum may be in the low tens of nF/cm<sup>2</sup> with ferroelectric characteristics using high  $k$  nanopowders dispersed in curable polymers. Tolerances are no better than about 10 percent for either, and resistor inks tend to have unstable values with regard to humidity, temperature, and time; extensive research is underway to improve this. The attractive feature of PTF is the low cost of capital equipment, inks, and processing. If value drift problems of PTF resistors can be solved, they will find widespread use for integration on almost any platform. Trimming has already been demonstrated to improve tolerance. PTF capacitor inks should be useful for decoupling, especially if specific capacitance can approach 100 nF/cm<sup>2</sup>, since tolerance and stability are not so important in this application.

**Integrated passives Formed Before Inclusion in the Board** Separating the processing of capacitor dielectrics and resistor materials from the board enables the use of a host of materials that have been long used on ceramic substrates such as  $BaTiO_3$  dielectrics and  $RuO_2$  and  $LaB_6$  resistors. Commercialized processes are soon to be released

from DuPont that involve printing resistors and capacitors that are fired onto Cu foil and provided for lamination into FR4 or flex film stacks. The metal is then photodefined to create the separated passive components. Ohmega-Ply® has provided plated NiP resistors on Cu foil for some years, and has seen some commercial use. Costs are probably intermediate between PTF and vacuum processes.

Table 5 is taken, for the most part, from p. 6 of the Passives chapter of the 2000 *NEMI* roadmap, with some updates by the author of this article.

## 8. THE FUTURE OF INTEGRATED PASSIVES

The implementation of integrated passives will be an evolution, not a revolution. Passive arrays and networks will continue to increase their market share as they replace terminators, filters, and other natural groups of passives. This should top out at some fraction of total passives, probably less than a quarter. The use of embedded capacitors for decoupling is a certainty since their parasitic inductance is lower than can be achieved with any surface mount components. Upcoming high-current and high-speed microprocessors cannot be decoupled any other way. Penetration into commodity boards is an important goal that will be realized gradually as the interrelated issues are resolved. Once cost savings are demonstrated, market share should increase steadily.

How far can this concept go? Figure 4 shows a hypothetical system with passives, chips, and other subsystems integrated together. In this format, all individual component packaging is discarded, and the layers of the “board” become the mechanical and environmental protection for each part so that there is very little mass that does not have electrical function. The chips are thinned to fit within one layer of the stack, and the surface is left only for those components that require access to the outside world. The system could hardly be smaller or have shorter interconnects. On our way to this ideal, integrating passive components is essential.

Between the current rapid development of integrated passive component technology and the increasing requirements of future electronic systems, significant commercial

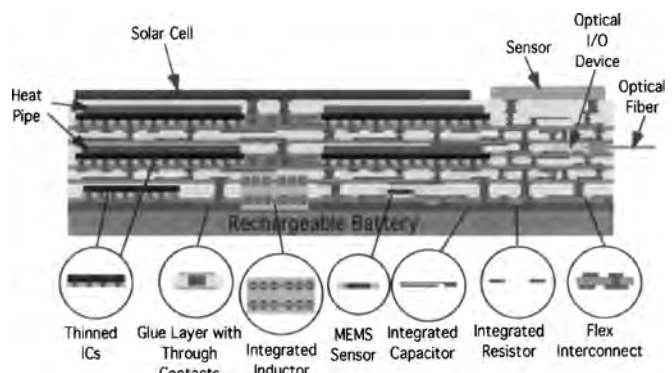

Figure 4. The complete integration of an electronic system.

**Table 5.** Implementation issues for integrated passives.

	Discretes	Integrated arrays and networks	Integrated passives
Cost	Good—the benchmark for all other technologies	Better when local densities have 4–8 devices close together	Better when the average component density is above 3/cm <sup>2</sup> , cost is panel-size dependent, number of layers is increased by integration. Pb-free technology
Size	Good—board area required for each and every device	Better—50% and greater board area savings over discretes	Best—no surface board area required since the devices are buried, but more total area required
Frequency range	Good, but self resonates at low frequencies	Better—higher self resonant frequency	Best—very high self resonant frequencies due mainly to decreased lead length and avoidance of inductive current loops
Reliability	Good—heavy use of solder joints	Better—reduces the number of solder joints	Best—eliminates solder joints
Flexibility	Best—most flexible for both design and manufacturing	Better than integrated, not quite as good as discretes	Good, but requires modeling and simulation up front, cannot be reworked
Time to market	Best—flexibility allows quick turns	Better—simple networks and arrays can be quickly designed and manufactured	Fair—most board shops require 5–7 days to build an integrated passive board
Value range	Best—all values available at commodity prices	Good—more work needed on high sheet resistance and high specific capacitance processes	Good—more work needed on high sheet resistance and high specific capacitance processes
Tolerances	Best—tight tolerances available at commodity prices	Better—can be presorted like discretes, with slightly more loss of parts	Good—10% achievable as formed, and trimming possible

use appears assured, but when? For those of us “in the business,” this never happens fast enough. There is always a gap between what can be done technically and what is economically viable at a given time, which is a challenge when drawing up roadmaps. For passive integration, this gap is especially large because of the vast number of materials and processes that have been demonstrated. Now, the infrastructure needs of design tools, costing models, and supply chains must be established, and this will happen as a few tentative processes are commercialized in the coming years. Once at least some technologies are available for OEMs to consider, the first pieces of their associated infrastructure will provide nucleation for the simultaneous solution of the interrelated issues of passive integration.

What year will more than half of passives be integrated? The microelectronics industry is full of cautionary tales; many of us remember other questions such as “What year will more than half of ICs be made from GaAs instead of Si?” or “What year will more than half of chip connections be TAB instead of wirebond?” But some technologies prove their economic viability and become industry standards, such as surface mounting. Is passive integration economically viable? Certainly for decoupling it is and, in fact, may be the only way to handle the future generations of high-power, high-frequency microprocessors. For discrete replacement in general, the best processes and materials are still being identified, and this is the most important task now. If we find suitable technologies, then passive integration will probably show a long, steady climb to dominance in a manner similar to surface mount as the

infrastructure, supply chain, and industry acceptance grow simultaneously.

## GLOSSARY

**Cermet** A nanocomposite of ceramic and metal used as a resistor material.

**Decoupling** Installing a capacitor between a power supply and an integrated circuit chip so that the capacitor actually powers the chip and the power supply simply recharges the capacitor.

**Ferroelectric** A dielectric material that can hold polarization after the electric field is removed and that typically exhibits a very high dielectric constant, up to thousands.

**FR4** A polymer-based circuit board material commonly used in consumer electronics.

**Integrated passive** A resistor, capacitor, or inductor fabricated directly into the printed wiring board instead of mounted on top as a separate component.

**Nanocomposite dielectric** A capacitor dielectric made from a nanodispersion of high-*k* ceramic in a low-*k* matrix.

**National Electronic Manufacturing Initiative (NEMI)** An industry consortium to identify major manufacturing issues in the field of electronics.

**Paraelectric** A dielectric material that cannot hold polarization after the electric field is removed and that typically exhibits a dielectric constant of 2–50.

**PTF** Polymer thick film.

## 1. INTRODUCTION

Over the last decade, nanoscience and nanotechnology [1–4] have emerged as two of the pillars of the research that will lead us to the next industrial revolution [5] and, together with molecular biology and information technology, will map the course of scientific and technological developments in the 21st century. This progress has been largely due to the development of sophisticated theoretical and experimental techniques, and practical tools, for understanding, characterizing, and manipulating nanoscale structures, processes, and systems. On the experimental front, the most significant developments were brought about by the invention of the scanning tunneling microscope (STM) in 1982 [6], followed by the atomic force microscope (AFM) [7] in 1986. These are tip-based devices which allow for a nanoscale manipulation of the morphology of the condensed phases and the determination of their electronic structures. These probe-based techniques have been extended further and are now collectively referred to as scanning probe microscopy (SPM). The SPM-based techniques have been improved considerably, providing new tools in research in such fields of nanotechnology as nanomechanics, nanoelectronics, nanomagnetism, and nanooptics [8].

The fundamental entities of interest to nanoscience and nanotechnology are the isolated individual nanostructures and their assemblies. Nanostructures are constructed from

a countable (limited) number of atoms or molecules. Their sizes are larger than individual molecules and smaller than microstructures. Nanoscale is a magical point on the dimensional scale: Structures in nanoscale (called *nanostuctures*) are considered at the borderline of the smallest of human-made devices and the largest molecules of living systems. One of their characteristic features is their high surface-to-volume ratio. Their electronic and magnetic properties are often distinguished by quantum mechanical behavior, while their mechanical and thermal properties can be understood within the framework of classical statistical mechanics. Nanostructures can appear in all forms of condensed matter, be it soft or hard, organic or inorganic, and/or biological. They form the building blocks of nanotechnology, and the formation of their assemblies requires a deep understanding of the interactions between individual atoms and molecules forming the nanostructures. Accordingly, nanotechnology has been specialized into three broad areas, namely, wet, dry, and computational nanotechnology.

Wet nanotechnology is mainly concerned with the study of nanostructures and nanoprocesses in biological and organic systems that exist in an aqueous environment. An important aspect of research in wet nanotechnology is the design of smart drugs for targeted delivery using such nanostructures as nanotubes and self-assembling materials [9, 10] as platforms. Dry nanotechnology, on the other hand, addresses the electronic and mechanical properties of metals, ceramics, focusing on fabrication of structures in carbon (e.g., fullerenes and nanotubes), silicon, and other inorganic materials.

Computational nanotechnology is based on the fields of mathematical modeling and computer-based simulation [11], which allow for computation and prediction of the underlying dynamics of nanostructures and processes in condensed matter physics, chemistry, materials science, biology, and genetics. Computational nanotechnology, therefore, covers

the other domains of nanofields by employing concepts from both classical and quantum mechanical many-body theories. It can provide deep insight into the formation, evolution, and properties of nanostructures and mechanisms of nanoprocesses. This is achieved by performing precise atom-by-atom numerical experiments (modeling and simulation) on many aspects of various condensed phases. The precision of such calculations depends on the accuracy of the interatomic and intermolecular potential energy functions at hand.

At the nanoscale, the implementation of the computational science leads to the study of the evolution of physical, chemical, and biophysical systems on significantly reduced length, time, and energy scales. Computer simulations at this scale form the basis of computational nanoscience. These simulations could allow for an understanding of the atomic and molecular scale structures, energetics, dynamics, and mechanisms underlying the physical and chemical processes that can unfold in isolated nanostructures, and their assemblies, under different ambient conditions.

This review is concerned with one of the most important elements of the computational approach to the properties of, and processes involving, nanoscale structures, namely, the phenomenological interatomic and intermolecular potentials. The mathematical expressions for the phenomenological forces and potential energies between atoms and molecules necessary for prediction of bulk (macroscopic) fluid and solid properties are rather well understood [12–14]. There are sufficient, effective phenomenological intermolecular potential energy functions available for the statistical mechanics prediction of macroscopic systems [13–17]. Parameters of phenomenological interaction energies between atoms and simple molecules can be calculated through such measurements as X-ray crystallography, light scattering, nuclear magnetic resonance spectroscopy, gas viscosity, thermal conductivity, diffusivity, and the virial coefficients data [18]. Most of the present phenomenological models for interparticle forces are tuned specifically for statistical mechanical treatment of macroscopic systems. However, such information may not be sufficiently accurate in the treatment of nanosystems where the number of particles are finite and the statistical averaging techniques fail.

Nanostructures consist of many-body systems, and a rigorous modeling of their properties has to be placed within the quantum mechanical domain, taking into account the electronic degrees of freedom. For simple atoms and molecules, the quantum mechanical *ab initio* calculation methods [19] have been successful in producing accurate intermolecular potential functions. While *ab initio* calculations may be satisfactory for simple molecules, for complex molecules and macromolecules they may not be able to produce the accurate needed information. However, even with today's enhanced computational platforms and sophisticated quantum mechanical techniques [20], the nanostructures that can be studied from a quantum mechanical, or *ab initio*, basis are those composed of at most a few hundred atoms. Consequently, the use of phenomenological interatomic and intermolecular potentials in simulations is still necessary. This allows modeling of nanostructures consisting of several mil-

lions of atoms, and recently simulations involving more than  $10^9$  atoms have been performed.

To motivate the use of interatomic and intermolecular potentials and show how they enter into nanoscale modeling, we consider, in Section 2, two of the widely used methods for numerical modeling at the nanoscale. This is followed, in Section 3, by a description of several types of state-of-the-art interatomic potentials that are in current use for modeling the energetics and dynamics of several classes of materials, including metals, semimetals, and semiconductors. We will then briefly review the applications of these potentials in specific computational modeling studies.

## 2. COMPUTER-BASED SIMULATION METHODS

Computer simulations applied in nanoscience consist of computational “experimentations” conducted on an assembly of a countable number of molecules with the assumption of predefined intermolecular interaction models. Computer simulations can direct an experimental procedure and have the potential of replacing an experiment if accurate intermolecular potentials are used in their development.

Computer simulation modeling of the physics and chemistry of nanostructures composed of several millions to several hundreds of millions of atoms can be performed by employing several distinct approaches. The most widely used approaches include (1) Monte Carlo simulation and (2) molecular dynamics simulation.

The cell in which the simulation is performed is replicated in all spatial dimensions, generating its own periodic images containing the periodic images of the original  $N$  atoms. This is the periodic boundary condition, and is introduced to remove the undesirable effects of the artificial surfaces associated with the finite size of the simulated system. The forces experienced by the atoms and molecules are obtained from prescribed two-body or many-body interatomic and intermolecular potentials,  $H_I(r_{ij})$ , according to

$$F_i = - \sum_{j>i} \nabla_{r_i} H_I(r_{ij}) \quad (1)$$

where  $r_{ij}$  is the separation distance between two particles  $i$  and  $j$ .

### 2.1. Monte Carlo Simulation Methods

The Metropolis Monte Carlo (MC) simulation methods can be used in nanoscience to simulate various complex physical phenomena, including prediction of phase transitions, thermally averaged structures, and charge distributions, just to name a few [21]. A variety of MC simulations are used depending on the nanosystem under consideration and the kind of computational results in mind. They include, but are not limited to, classical MC, quantum MC, and volumetric MC. In classical MC, the classical Boltzmann distribution is used as the starting point to perform various property calculations. Through the use of quantum MC, one can compute quantum mechanical energies, wave functions, and electronic structure using Schrödinger's equation. The volumetric MC is used to calculate molecular volumes and sample molecular phase space surfaces [22].

## 2.2. Molecular Dynamics Simulation Methods

In the molecular dynamics (MD) simulation methods [23–25], the emphasis is on the motion of individual atoms within an assembly of  $N$  atoms, or molecules, that make up the nanostructure under study. The dynamical theory employed to derive the equations of motion is either the Newtonian deterministic dynamics or the Langevin-type stochastic dynamics. The initial data required are the initial position coordinates and velocities of the particles, in either a crystalline or an amorphous state, located in a primary computational cell of volume  $V$ .

To save computational time, the simplifying assumption is made that each particle interacts with its nearest neighbors, located in its own cell as well as in the image cells, that are within a specified cutoff radius. The  $3N$  coupled differential equations of motion can then be solved by a variety of numerical finite-difference techniques, one of which is the velocity Verlet algorithm [23], according to which the positions,  $r_i$ , and velocities,  $v_i$ , of the particles of mass,  $m_i$ , are updated at each time step,  $dt$ , by

$$\begin{aligned} r_i(t + dt) &= r_i(t) + v_i(t) dt + \frac{1}{2} dt^2 \frac{F_i(t)}{m_i} \\ v_i\left(t + \frac{dt}{2}\right) &= v_i(t) + \frac{1}{2} dt \frac{F_i(t)}{m_i} \\ v_i(t + dt) &= v_i\left(t + \frac{dt}{2}\right) + \frac{1}{2} dt \frac{F_i(t + dt)}{m_i} \end{aligned} \quad (2)$$

The dynamical history of a particular microstate of the system, constructed initially, is followed by computing the space–time trajectories through the phase space via (2). At each instant of the simulation time, the exact instantaneous values of the observables, such as pressure, temperature, and thermodynamics response function, are also obtained, leading to time-average values at the conclusion of the simulation.

### 2.2.1. Constant-Temperature Molecular Dynamics Simulation: Nosé–Hoover Dynamics

For a large class of problems in the physics and chemistry of nanostructures, the type of system that is considered is a closed one. This is a system with a fixed volume,  $V$ , a fixed number of particles,  $N$ , maintained at a constant temperature,  $T$ . Within statistical mechanics, such a system is represented by a constant ( $NVT$ ), or canonical, ensemble [26], where the temperature acts as a control parameter.

A constant-temperature MD simulation can be realized in a variety of ways. A method that generates the canonical ensemble distribution in both the configuration space and the momentum space parts of the phase space was proposed by Nosé [27–29] and Hoover [30] and is referred to as the extended-system method. According to this method, the simulated system and a heat bath couple to form a composite system. This coupling breaks the energy conservation that otherwise restricts the behavior of the simulated system and leads to the generation of a canonical ensemble. The conservation of energy still holds in the composite system,

but the total energy of the simulated system is allowed to fluctuate.

The mathematical formulation of the method is based on the extension of the space of dynamical variables of the system beyond that of the coordinates and momenta of the real particles to include one additional *phantom coordinate*,  $s$ , and its conjugate momentum,  $p_s$  [31]. This extra degree of freedom acts as a heat bath for the real particles. There are, therefore, four systems to consider, namely, the real  $(r_i, p_i)$  system, the virtual  $(\tilde{r}_i, \tilde{p}_i)$  system, the real extended  $(r_i, p_i, s, p_s)$  system, and the virtual extended  $(\tilde{r}_i, \tilde{p}_i, s, p_s)$  system. The aim of Nosé’s approach is to show that there is a method for selecting the Hamiltonian of the extended system and, simultaneously, to relate the variables of the real system to those of the virtual system, such that the micro-canonical partition function of the extended virtual system is proportional to the canonical partition function of the real system [31].

The Hamiltonian of the virtual extended system is

$$H^* = \sum_{i \rightarrow N} \frac{\tilde{p}_i^2}{2ms^2} + H_I(\tilde{r}_{ij}) + \frac{p_s^2}{2Q} + gk_B T \ln s \quad (3)$$

where  $g$  is the number of degrees of freedom,  $k_B$  is the Boltzmann constant,  $Q$  is a parameter that behaves like a “mass” associated with the motion of the coordinate  $s$ , and  $r_i, p_i$  and  $\tilde{r}_i, \tilde{p}_i$  are the canonical position and momentum coordinates of all the particles in the real and virtual systems, respectively. The virtual coordinates, and the time, are related to the corresponding real coordinates via the transformations

$$\begin{aligned} r_i &= \tilde{r}_i \\ p_i &= \frac{1}{s} \tilde{p}_i \\ dt &= \frac{1}{s} d\tilde{t} \end{aligned} \quad (4)$$

Since  $H_I$  in (3) is the potential energy for both the real and the virtual systems, the first two terms on the right-hand side of (3) represent the kinetic and potential energies of the real system, respectively, and the last two terms correspond to the kinetic and potential energies, respectively, associated with the extra degree of freedom.

From this Hamiltonian, the equations of motion of the real system are

$$\begin{aligned} \frac{dr_i}{dt} &= \frac{p_i}{m_i} \\ \frac{dp_i}{dt} &= F_i - \eta p_i \\ \frac{d\eta}{dt} &= \frac{1}{Q} \sum_i \frac{p_i^2}{m_i} - gk_B T \end{aligned} \quad (5)$$

where  $\eta$  is called the friction coefficient of the bath. This coefficient is not a constant and can take on both positive and negative values. This gives rise to what is called a negative-feedback mechanism. The last equation in (5) controls the functioning of the heat bath. From this equation, we observe that if the total kinetic energy is greater than

$gk_B T/2$ , then  $d\eta/dt$ , and hence  $\eta$ , is positive. This prompts a friction inside the bath and, correspondingly, the motion of the atoms is decelerated to lower their kinetic energy to that of the bath. On the other hand, if the kinetic energy is lower than  $gk_B T/2$ , then  $d\eta/dt$  will be negative, the bath will heat up, and the motion of the atoms will be accelerated. Equations (5) are collectively referred to as the Nosé–Hoover thermostat.

### 2.2.2. Equations of Motion

The implementation of the Nosé–Hoover dynamics substantially modifies (2), the equations of motion. A velocity Verlet version of this dynamics formulation can be given by the following expressions [32]:

$$\begin{aligned} r_i(t+dt) &= r_i(t) + v_i(t)dt + \frac{1}{2}dt^2 \left[ \frac{F_i(t)}{m_i} - \eta(t)v_i(t) \right] \\ v_i\left(t + \frac{dt}{2}\right) &= v_i(t) + \frac{dt}{2} \left[ \frac{F_i(t)}{m_i} - \eta(t)v_i(t) \right] \\ \eta\left(t + \frac{dt}{2}\right) &= \eta(t) + \frac{dt}{2Q} \left[ \sum_{i \rightarrow N} m_i v_i^2(t) - gk_B T \right] \\ \eta(t+dt) &= \eta\left(t + \frac{dt}{2}\right) \\ &\quad + \frac{dt}{2Q} \left[ \sum_{i \rightarrow N} m_i v_i^2\left(t + \frac{dt}{2}\right) - gk_B T \right] \\ v_i(t+dt) &= 2 \frac{[v_i(t + \frac{dt}{2}) + dt F_i(t+dt)/(2m_i)]}{[2 + \eta(t+dt)dt]} \end{aligned} \quad (6)$$

A particular parameterization of  $Q$  is given by

$$Q = gk_B T \tau^2 \quad (7)$$

where  $\tau$  is the relaxation time of the heat bath, normally of the same order of magnitude as the simulation time step,  $dt$ . It controls the speed with which the bath damps down the fluctuations in the temperature. The number of degrees of freedom is given by  $g = 3(N - 1)$ .

## 3. INTERATOMIC POTENTIALS

To study nanostructures composed of several hundred to several million atoms or molecules, the computationally most efficient method is the use of phenomenological interatomic and intermolecular potentials. This is because the existing quantum mechanical techniques are able to deal with at most a few hundred atoms.

The phenomenological potentials are obtained by using phenomenological approaches of selecting a mathematical function and fitting its unknown parameters to various, experimentally determined, properties of the system, such as its lattice constant.

Interatomic and intermolecular potentials must be able to model the energetics and dynamics of nanostructures, and this fact lies at the very foundation of computer-based modeling and simulations. Potentials describe the physics of the model systems, and the significance of much of the modeling and simulation results, their accuracy, and the extent

to which they represent the real behavior of nanostructures, and their transitions, under varied conditions, depends in a critical manner on the accuracy of the interatomic and intermolecular potentials employed.

A great deal of effort has been expended over the years to develop phenomenological intermolecular potentials to model the bonding in various classes of materials, such as metallic, semimetallic, semiconducting, and organic atoms and molecules. For a review, see [11, 33, 34].

Basically, intermolecular potential energies include pairwise additive energies, as well as many-body interactions. The interparticle interaction potential energy between atoms and molecules is generally denoted by  $H(r) = H_{\text{rep}} + H_{\text{att}}$ , where  $r$  is the intermolecular distance,  $H_{\text{rep}}$  is the repulsive interaction energy, and  $H_{\text{att}}$  is the attractive interaction energy; see Figure 1. From the equation above, the interaction force is

$$\mathbf{F} = -\nabla H(\mathbf{r}) = \mathbf{F}_{\text{rep}} + \mathbf{F}_{\text{att}}$$

For neutral and spherically symmetric molecules when the separation ( $r$ ) is very small, an exponential repulsive term,  $H_{\text{rep}} = \alpha \exp(-\beta r)$ , dominates, and the potential is strongly positive. Hence, the  $H_{\text{rep}} = \alpha \exp(-\beta r)$  term describes the short-range repulsive potential due to the distortion of the electron clouds at small separations. For neutral and spherically symmetric molecules when the separation ( $r$ ) is large, the London dispersion forces dominate.

Among pairwise additive energies, one can mention the repulsive potentials, van der Waals energies, interactions involving polar and polarization of molecules, interactions involving hydrogen bonding, and strong intermolecular energies, including covalent and Coulomb interactions [35, 36]. Among many-body interactions, one can name the Axilrod–Teller triple–dipole interactions [37–39].

To be effective for computational nanotechnology, interatomic and intermolecular potentials must possess the following properties [40, 41]:

- Flexibility.* A potential energy function must be sufficiently flexible that it could accommodate as wide a range as possible of fitting data. For solid systems, these data might include lattice constants, cohesive energies, elastic properties, vacancy formation energies, and surface energies.
- Accuracy.* A potential function should be able to accurately reproduce an appropriate fitting database.
- Transferability.* A potential function should be able to describe at least qualitatively, if not with quantitative accuracy, structures not included in a fitting database.

Figure 1. Pair interaction energy.

- (d) *Computational efficiency.* Evaluation of the function should be relatively efficient depending on quantities such as system sizes and time scales of interest, as well as available computing resources.

In this section, we shall describe some of the potential functions that meet these criteria and are widely used in computational nanoscience.

### 3.1. Interatomic Potentials for Metallic Systems

Bonding in metallic systems operates over the range of 0.2 to 0.5 nm [42]. At large interatomic distances, the predominant forces arise from van der Waals interactions, which are responsible for long-range cohesion. Metallic bonding, like covalent bonding, arises from the sharing of electrons, and hence its proper description requires the consideration of the many-body effects. Two-body potentials are incapable of describing this bonding [43, 44] since:

- For most cubic metals, the ratio of the elastic constants,  $C_{12}$  to  $C_{44}$ , is far from unity, whereas a pairwise potential leads to the Cauchy relation, that is,  $C_{12} = C_{44}$ .
- The prediction of the unrelaxed vacancy formation energy gives values around the cohesive energy, which is completely incorrect for metals. The relaxation energy for metals is quite small, and the experimental data suggest that the vacancy formation energy for metals is about one-third of the cohesive energy.
- The interatomic distance between the first and second atomic layers within an unreconstructed surface structure (bulk cross section) is predicted to be expanded by pairwise potentials. This is in contrast with the experimental data, which suggest a contraction of the open-surface lattice spacing; that is, pair potentials fail to predict an inward relaxation of the metallic surfaces.
- Pairwise potentials overestimate the melting point by up to 20% of the experimental value.
- Potentials with a functional form having only one optimum at the diatomic equilibrium distance cannot be fitted properly to the phonon frequencies.

Two approaches have been proposed for going beyond pair potentials and incorporating many-body effects into two-body potentials.

The first approach is to add a term, which is a functional of the local electronic density of a given atom, to the pairwise term. This method has itself led to several alternative potentials that mimic the many-body effects. These many-body potentials are known as the embedded-atom model (EAM) potentials [45–47], which have been employed in several studies involving elemental metals and their alloys [48–53], the glue model potentials [54], the Finnis–Sinclair potentials for the body-centered cubic (bcc) elemental metals [55], which have also been developed for the noble metals [56], the Sutton–Chen (SC) potentials [57] for the 10 face-centered cubic (fcc) elemental metals, and the Rafii-Tabar–Sutton potentials [58] for the fcc random binary alloys, which have also been used in several modeling studies [11, 59–61].

The second approach is to go from pair potentials to cluster potentials by the addition of higher order interactions, for example, three-body and four-body terms, with appropriate functional forms and symmetries. This has led to potentials, such as the Murrell–Mottram cluster potentials [44]. Inclusion of higher order terms provides a more accurate modeling of the energetics of the phenomena than is given by pair potentials alone. In the following sections, we consider the potentials pertinent to each approach.

#### 3.1.1. Many-Body Embedded-Atom Model Potentials

The many-body EAM potentials were proposed [45–47] to model the bonding in metallic clusters. They were the first alternatives to the traditional pair potential models. Their construction is based on the use of density functional theory (DFT), according to which the energy of a collection of atoms can be expressed exactly by a functional of its electronic density [62]. Similarly, the energy change associated with embedding an atom into a host background of atoms is a functional of the electronic density of the host before the new atom is embedded [63, 64]. If we can find a good approximation to the embedding functional, then an approximate expression for the energy of an atom in a metal can be constructed.

The total electron density of the host atoms is approximated as a linear superposition of the electron densities (charge distributions) of individual host atoms. To zeroth order, the embedding energy can be equated to the energy of embedding an atom in a homogeneous electron gas, whose density,  $\rho_{h,i}$ , matches the host density at the position of the embedded atom, augmented by the classical electrostatic interaction with the atoms in the host system [65]. The embedding energy for the homogeneous electron gas can be calculated from an *ab initio* basis. Computation of  $\rho_{h,i}$  from a weighted average of the host density over the spatial extent of the embedded atom improves the description by accounting for the local inhomogeneity of the host density. The classical electrostatic interaction reduces to a pairwise sum if a frozen atomic charge density is assumed for each host atom [65]. This approach, called the quasi-atom method [63], or the effective-medium theory [64], provides the theoretical basis of the EAM and similar methods.

In the EAM, the total energy of an elemental system is, therefore, written as

$$H_I^{\text{EAM}} = \sum_i F_i[\rho_{h,i}] + \frac{1}{2} \sum_i \sum_{j \neq i} \phi_{ij}(r_{ij}) \quad (8)$$

where  $\rho_{h,i}$  is the electron density of the host at the site of atom  $i$ ;  $F_i[\rho]$  is the embedding functional, that is, the energy to embed atom  $i$  into the background electron density,  $\rho$ ; and  $\phi_{ij}$  is a pairwise central potential between atoms  $i$  and  $j$ , separated by a distance  $r_{ij}$ , and represents the repulsive core–core electrostatic interaction. The host electron density is a linear superposition of the individual contributions and is given by

$$\rho_{h,i} = \sum_{j \neq i} \rho_j^*(r_{ij}) \quad (9)$$

where  $\rho_j^*$ , another pairwise term, is the electron density of atom  $j$  as a function of interatomic separation. It is important to note that the embedding functional,  $F_i[\rho]$ , is a universal functional that does not depend on the source of the background electron density. This implies that the same functional can be employed to compute the energy of an atom in an alloy as that employed for the same atom in a pure elemental metal [48]. Indeed, this is one of the attractive features of these potentials. For a solid at equilibrium, the force to expand, or contract, due to the embedding function is exactly balanced by the force to contract, or expand, due to the pairwise interactions. At a defect, this balance is disrupted, leading to the displacements as atoms move to find a new balance [65]. The positive curvature of  $F$  plays a key role in this process, by defining the optimum tradeoff between the number of bonds and the length of those bonds.

The expression for the Cauchy pressure for a cubic crystal can be found from (8) and is seen to depend directly on the curvature of the function  $F$  as described in [46]:

$$C_{11}-C_{44} = \frac{1}{\Omega} \frac{d^2 F}{d\rho_{h,i}^2} \left[ \sum_j \frac{d\rho}{dr_{ij}} \frac{x_{ij}^2}{r_{ij}} \right]^2 \quad (10)$$

where  $\Omega$  is the atomic volume and  $x_{ij}$  is the  $x$  component of the  $r_{ij}$ .

To apply these potentials, the input parameters required are the equilibrium atomic volume, the cohesive energy, the bulk modulus, the lattice structure, as well as the repulsive pair potentials and the electron density function [50]. Among the extensive applications of these potentials, we can list their parameterization and use in the computation of the surface energy and relaxation of various crystal surfaces of Ni and Pd and the migration of hydrogen impurity in the bulk Ni and Pd [46], the computation of the formation energy, migration energy of vacancies and surface energies of a variety of fcc metals [48], the calculation of the surface composition of the Ni–Cu alloys [66], the computation of the elastic constants and vibrational modes of the Ni<sub>3</sub>Al alloy [49], the self-diffusion and impurity diffusion of the fcc metals [51], the computation of the heats of solution for alloys of a set of fcc metals [52], and the computation of the phase stability of fcc alloys [53]. There has also been an application of these potentials to covalent materials such as Si [67].

In a recent application [68], the second-order elastic moduli ( $C_{11}$ ,  $C_{12}$ ,  $C_{44}$ ) and the third-order elastic moduli ( $C_{111}$ ,  $C_{112}$ ,  $C_{123}$ ,  $C_{144}$ ,  $C_{166}$ ,  $C_{456}$ ), as well as the cohesive energies and lattice constants, of a set of 12 cubic metals with fcc and bcc structures were used as input to obtain the corresponding potential parameters for these metals [69]. The resulting potentials were then used to compute the pressure–volume ( $P$ – $V$ ) curves, the phase stabilities, and the phonon frequency spectra, with excellent agreement obtained for the  $P$ – $V$  curves with the experimental data, and a reasonable agreement obtained for the frequency curves.

The EAM potentials can also be written for ordered binary alloys [65]. We can write

$$H_{\text{alloy}}^{\text{EAM}} = \sum_i F_i[\rho_{h,i}] + \frac{1}{2} \sum_i \sum_{j \neq i} \phi_{t_i, t_j}(r_{ij}) \quad (11)$$

where  $\phi$  now depends on the type of atom  $t_i$  and atom  $t_j$ . The host electron density is now given by

$$\rho_{h,i} = \sum_{j \neq i} \rho_{t_j}^*(r_{ij}) \quad (12)$$

where the terms in the sum each depend on the type of neighbor atom  $j$ . Therefore, for a binary alloy with atom types A and B, the EAM energy requires definitions for  $\phi_{AA}(r)$ ,  $\phi_{BB}(r)$ ,  $\phi_{AB}(r)$ ,  $\rho_A(r)$ ,  $\rho_B(r)$ ,  $F_A(\rho)$ , and  $F_B(\rho)$ .

### 3.1.2. Many-Body Finnis–Sinclair Potentials

The Finnis–Sinclair (FS) potentials [55] were initially constructed to model the energetics of the transition metals. They avoid the problems associated with using pair potentials to model metals, for example, the appearance of the Cauchy relation between the elastic constants  $C_{12} = C_{44}$  which is not satisfied by cubic crystals. They also offer a better description of the surface relaxation in metals.

In the FS model, the total energy of an  $N$ -atom system is written as

$$H_I^{\text{FS}} = \frac{1}{2} \sum_{i \rightarrow N} \sum_{j \neq i} V(r_{ij}) - c \sum_i (\rho_i)^{1/2} \quad (13)$$

where

$$\rho_i = \sum_{j \neq i} \phi(r_{ij}) \quad (14)$$

The function  $V(r_{ij})$  is a pairwise repulsive interaction between atoms  $i$  and  $j$ , separated by a distance  $r_{ij}$ ,  $\phi(r_{ij})$  are two-body cohesive pair potentials, and  $c$  is a positive constant. The second term in (13) represents the cohesive many-body contribution to the energy. The square root form of this term was motivated by an analogy with the second-moment approximation to the tight-binding model [70]. To see this, we start with the tight-binding approach [71] in which the total electronic band energy, that is, the total bonding energy, which is given as the sum of the energies of the occupied one-electron states, is expressed by

$$E_{\text{tot}} = 2 \int_{-\infty}^{E_f} E n(E) dE \quad (15)$$

where  $n(E)$  is the electron density of states,  $E_f$  is the Fermi level energy, and the factor 2 refers to spin degeneracy.  $E_{\text{tot}}$  is an attractive contribution to the configurational energy, which is dominated by the broadening of the partly filled valence shells of the atoms into bands when the solid is formed [72]. It is convenient to divide  $E_{\text{tot}}$  into contributions from individual atoms

$$E_{\text{tot}} = \sum_i E_i = 2 \sum_i \int_{-\infty}^{E_f} E n_i(E) dE \quad (16)$$

where

$$n_i(E) = \sum_v |\langle \Psi_v | i \rangle|^2 \delta(E - E_v) \quad (17)$$

is the projected density of states on site  $i$  and  $|\Psi_v\rangle$  are the eigenfunctions of the one-electron Hamiltonian. As has

been discussed in [72], to obtain  $n_i(E)$  exactly, it is, in principle, necessary to know the positions of all the atoms in the crystal. Furthermore,  $n_i(E)$  is a very complicated functional of these positions. However, it is not necessary to calculate the detailed structure of  $n_i(E)$ . To obtain an approximate value of quantities such as  $E_i$ , which involves integrals over  $n_i(E)$ , we need only information about its width and gross features of its shape. This information is conveniently summarized in the moments of  $n_i(E)$ , defined by

$$\mu_n^i = \int_{-\infty}^{\infty} E^n n_i(E) dE \quad (18)$$

The important observation, which allows a simple description comparable to that of interatomic potentials, is that these moments are rigorously determined by the local environment. The exact relations are [72]:

$$\begin{aligned} \mu_2^i &= \sum_j h_{ij}^2 \\ \mu_3^i &= \sum_{jk} h_{ij} h_{jk} h_{ki} \\ \mu_4^i &= \sum_{jkl} h_{ij} h_{jk} h_{kl} h_{li} \end{aligned} \quad (19)$$

where

$$h_{ij} = \langle \chi_i | H | \chi_j \rangle \quad (20)$$

$\chi_i$  is the localized orbital centered on atom  $i$ , and  $H$  is the one-electron Hamiltonian. Therefore, if we have an approximate expression for the  $E_i$  in terms of the first few  $\mu_n^i$ , the electronic band energy can be calculated with essentially the same machinery used to evaluate the interatomic potentials. Now, the exact evaluation of  $E_i$  requires the values of all the moments on site  $i$ . However, a great deal of information can be gained from a description based only on the second moment,  $\mu_2^i$ . This moment provides a measure of the squared valence band width and thus sets a basic energy scale for the problem. Therefore, a description using only  $\mu_2^i$  assumes that the effects of the structure of  $n_i(E)$  can be safely ignored, since the higher moments describe the band shape. Since  $E_i$  has units of energy and  $\mu_2^i$  has units of (energy)<sup>2</sup>, we have

$$E_i = E_i(\mu_2^i) = -A\sqrt{(\mu_2^i)} = -A\sqrt{\sum_j h_{ij}^2} \quad (21)$$

where  $A$  is a positive constant that depends on the chosen density of states shape and the fractional electron occupation [65].

The functions  $\phi(r_{ij})$  in (14) can be interpreted as the sum of squares of hopping (overlapping) integrals. The function  $\rho_i$  can be interpreted as the local electronic charge density [45] constructed by a rigid superposition of the atomic charge densities  $\phi(r_{ij})$ . In this interpretation, the energy of an atom at site  $i$  is assumed to be identical to its energy within a uniform electron gas of that density. Alternatively,  $\rho_i$  can be interpreted [55] as a measure of the local density of atomic sites, in which case (13) can be considered as a

sum consisting of a part that is a function of the local volume, represented by the second term, and a pairwise interaction part, represented by the first term. The FS potentials, Equation (13), are similar in form to the EAM potentials in (8). However, their interpretations are quite different. The FS potentials, as has been shown above, were derived on the basis of the tight-binding model and this is the reason their many-body parts, which correspond to the  $F_i[\rho_{n,i}]$  functionals in the EAM potentials, are in the form of square root terms. Furthermore, the FS potentials are less convenient than the EAM potentials for a conversion from the pure metals to their alloys. Notwithstanding this difficulty, FS potentials have been constructed for several alloy systems, such as the alloys of the noble metals (Au, Ag, Cu) [56].

### 3.1.3. Many-Body Sutton–Chen Long-Range Potentials

The Sutton–Chen (SC) potentials [57] describe the energetics of 10 fcc elemental metals. They are of the FS type and therefore similar in form to the EAM potentials. They were specifically designed for use in computer simulations of nanostructures involving a large number of atoms.

In the SC potentials, the total energy, written in analogy with (13), is given by

$$H_I^{\text{SC}} = \varepsilon \left[ \frac{1}{2} \sum_i \sum_{j \neq i} V(r_{ij}) - c \sum_i (\rho_i)^{1/2} \right] \quad (22)$$

where

$$V(r_{ij}) = \left( \frac{a}{r_{ij}} \right)^n \quad (23)$$

and

$$\rho_i = \sum_{j \neq i} \left( \frac{a}{r_{ij}} \right)^m \quad (24)$$

where  $\varepsilon$  is a parameter with the dimensions of energy,  $a$  is a parameter with the dimensions of length and is normally taken to be the equilibrium lattice constant, and  $m$  and  $n$  are positive integers with  $n > m$ . The power law form of the potential terms was adopted so as to construct a unified model that can combine the short-range interactions, afforded by the  $N$ -body second term in (22) and useful for the description of surface relaxation phenomena, with a van der Waals tail that gives a better description of the long-range interactions. For a particular fcc elemental metal, the potential in (22) is completely specified by the values of  $m$  and  $n$ , since the equilibrium lattice condition fixes the value of  $c$ . The values of the potential parameters, computed for a cutoff radius of 10 lattice constants, are listed in Table 1. These parameters were obtained by fitting the experimental cohesive energies and lattice parameters exactly. The indices  $m$  and  $n$  were restricted to integer values, such that the product  $m \times n$  was the nearest integer to  $18\Omega^f B^f / E^f$ , Equation (9) in [57], where  $\Omega^f$  is the fcc atomic volume,  $B^f$  is the computed bulk modulus, and  $E^f$  is the fitted cohesive energy.

The SC potentials have been applied to the computation of the elastic constants, bulk moduli, and cohesive energies

**Table 1.** Parameters of the Sutton–Chen potentials.

Element	$m$	$n$	$\varepsilon$ (eV)	$c$
Ni	6	9	$1.5707 \times 10^{-2}$	39.432
Cu	6	9	$1.2382 \times 10^{-2}$	39.432
Rh	6	12	$4.9371 \times 10^{-3}$	144.41
Pd	7	12	$4.1790 \times 10^{-3}$	108.27
Ag	6	12	$2.5415 \times 10^{-3}$	144.41
Ir	6	14	$2.4489 \times 10^{-3}$	334.94
Pt	8	10	$1.9833 \times 10^{-2}$	34.408
Au	8	10	$1.2793 \times 10^{-2}$	34.408
Pb	7	10	$5.5765 \times 10^{-3}$	45.778
Al	6	7	$3.3147 \times 10^{-2}$	16.399

of the fcc metals, and the prediction of the relative stabilities of the fcc, bcc, and hexagonal close-packed (hcp) structures [57]. The results show reasonable agreement with the experimental values. These potentials have also been used in modeling the structural properties of metallic clusters in the size range of 13 to 309 atoms [73].

### 3.1.4. Many-Body Murrell–Mottram Potentials

The Murrell–Mottram (MM) potentials are an example of cluster-type potentials and consist of sums of effective two- and three-body interactions [44, 74, 75]:

$$U_{\text{tot}} = \sum_i \sum_{j>i} U_{ij}^{(2)} + \sum_i \sum_{j>i} \sum_{k>j} U_{ijk}^{(3)} \quad (25)$$

The pair interaction term is modeled by a Rydberg function, which has been used for simple diatomic potentials. In the units of reduced energy and distance, it takes the form

$$\frac{U_{ij}^{(2)}}{D} = -(1 + a_2 \rho_{ij}) \exp(-a_2 \rho_{ij}) \quad (26)$$

where

$$\rho_{ij} = \frac{r_{ij} - r_e}{r_e} \quad (27)$$

$D$  is the depth of the potential minimum, corresponding to the diatomic dissociation energy at  $\rho_{ij} = 0$ , that is, for  $r_{ij} = r_e$ , with  $r_e$  the diatomic equilibrium distance.  $D$  and  $r_e$  are fitted to the experimental cohesive energy and lattice parameter, respectively. The only parameter involved in the optimization of the potential is  $a_2$ , which is related to the curvature (force constant) of the potential at its minimum [44, 74, 75]. The three-body term must be symmetric with respect to the permutation of the three atom's indices,  $i$ ,  $j$ , and  $k$ . The most convenient way to achieve this is to create functional forms that are combinations of interatomic coordinates,  $Q_1$ ,  $Q_2$ , and  $Q_3$ , which are irreducible representations of the  $S_3$  permutation group [76]. If we construct a given triangle with atoms  $(i, j, k)$ , then the coordinates  $Q_i$  are given by

$$\begin{bmatrix} Q_1 \\ Q_2 \\ Q_3 \end{bmatrix} = \begin{bmatrix} \sqrt{1/3} & \sqrt{1/3} & \sqrt{1/3} \\ 0 & \sqrt{1/2} & -\sqrt{1/2} \\ \sqrt{2/3} & -\sqrt{1/6} & -\sqrt{1/6} \end{bmatrix} \begin{bmatrix} \rho_{ij} \\ \rho_{jk} \\ \rho_{ki} \end{bmatrix} \quad (28)$$

where

$$\rho_{\alpha\beta} = \frac{r_{\alpha\beta} - r_e}{r_e} \quad (29)$$

and  $r_{\alpha\beta}$  represents one of the three triangle edges ( $r_{ij}$ ,  $r_{jk}$ ,  $r_{ki}$ ). These interatomic coordinates have specific geometrical meanings.  $Q_1$  represents the perimeter of the triangle in reduced units;  $Q_2$  and  $Q_3$  measure the distortions from an equilateral geometry [44]. All polynomial forms that are totally symmetric in  $\rho_{\alpha\beta}$  can be expressed as sums of products of the so-called integrity basis [44], defined as

$$Q_1, \quad Q_2^2 + Q_3^2, \quad Q_3^3 - 3Q_3Q_2^2 \quad (30)$$

A further condition that must be imposed on the three-body term is that it must go to 0 if any one of the three atoms goes to  $\infty$ . The following general family of functions can be chosen for the three-body part to conform to the functional form adopted for the two-body part:

$$\frac{U_{ijk}^{(3)}}{D} = P(Q_1, Q_2, Q_3) F(a_3, Q_1) \quad (31)$$

where  $P(Q_1, Q_2, Q_3)$  is a polynomial in the  $Q$  coordinates and  $F$  is a damping function, containing a single parameter,  $a_3$ , which determines the range of the three-body potential. Three different kinds of damping functions can be adopted:

$$\begin{aligned} F(a_3, Q_1) &= \exp(-a_3 Q_1) && \text{exponential} \\ F(a_3, Q_1) &= \frac{1}{2} \left[ 1 - \tanh\left(\frac{a_3 Q_1}{2}\right) \right] && \tanh \\ F(a_3, Q_1) &= \text{sech}(a_3 Q_1) && \text{sech} \end{aligned} \quad (32)$$

The use of the exponential damping function can lead to a problem; namely, for large negative  $Q_1$  values (i.e., for triangles for which  $r_{ij} + r_{jk} + r_{ki} \ll 3r_e$ ), the function  $F$  may be large so that the three-body contribution swamps the total two-body contribution. This may lead to the collapse of the lattice. To overcome this problem, it may be necessary, in some cases, to add a hard wall function to the repulsive part of the two-body term.

The polynomial,  $P$ , is normally taken to be

$$\begin{aligned} P(Q_1, Q_2, Q_3) &= c_0 + c_1 Q_1 + c_2 Q_1^2 + c_3 (Q_2^2 + Q_3^2) \\ &\quad + c_4 Q_1^3 + c_5 Q_1 (Q_2^2 + Q_3^2) \\ &\quad + c_6 (Q_3^3 - 3Q_3 Q_2^2) \end{aligned} \quad (33)$$

This implies that there are seven parameters to be determined. For systems where simultaneous fitting is made to data for two different solid phases, the following quartic terms can be added:

$$C_7 Q_1^4 + C_8 Q_1^2 (Q_2^2 + Q_3^2) + C_9 (Q_2^2 + Q_3^2)^2 + C_{10} Q_1 (Q_3^3 - 3Q_3 Q_2^2) \quad (34)$$

The potential parameters for a set of elements are given in Table 2.

**Table 2.** Parameters of the Murrell–Mottram potentials.

### 3.1.5. Many-Body Rafii-Tabar–Sutton Long-Range Alloy Potentials

We now consider the case of many-body interatomic potentials that describe the energetics of metallic alloys, in particular, the fcc metallic alloys. The interatomic potential that models the energetics and dynamics of a binary, A–B, alloy is normally constructed from the potentials that separately describe the A–A and the B–B interactions, where A and B are the elemental metals. To proceed with this scheme, a combining rule is normally proposed. Such a rule would allow for the computation of the A–B interaction parameters from those of the A–A and B–B parameters. The combining rule reflects the different averaging procedures that can be adopted, such as arithmetic or geometric averaging. The criterion for choosing any one particular combining rule is the closeness of the results obtained, when computing with the proposed A–B potential obtained with that rule, with the corresponding experimental values where they exist.

The RTS potentials [11, 58] are a generalization of the SC potentials and model the energetics of the metallic fcc random binary alloys. They have the advantage that all the parameters for the alloys are obtained from those for the elemental metals without the introduction of any new parameters. The basic form of the potential is given by

$$\begin{aligned}
 U^{\text{RTS}} = & \frac{1}{2} \sum_i \sum_{j \neq i} \hat{p}_i \hat{p}_j V^{\text{AA}}(r_{ij}) + (1 - \hat{p}_i)(1 - \hat{p}_j) V^{\text{BB}}(r_{ij}) \\
 & + [\hat{p}_i(1 - \hat{p}_j) + \hat{p}_j(1 - \hat{p}_i)] V^{\text{AB}}(r_{ij}) \\
 & - d^{\text{AA}} \sum_i \hat{p}_i \left[ \sum_{j \neq i} \hat{p}_j \Phi^{\text{AA}}(r_{ij}) + (1 - \hat{p}_j) \Phi^{\text{AB}}(r_{ij}) \right]^{1/2} \\
 & - d^{\text{BB}} \sum_i (1 - \hat{p}_i) \left[ \sum_{j \neq i} (1 - \hat{p}_j) \Phi^{\text{BB}}(r_{ij}) + \hat{p}_j \Phi^{\text{AB}}(r_{ij}) \right]^{1/2}
 \end{aligned} \quad (35)$$

The operator  $\hat{p}_i$  is the site occupancy operator and is defined as

$$\begin{aligned}
 \hat{p}_i &= 1 & \text{if site } i \text{ is occupied by an A atom} \\
 \hat{p}_i &= 0 & \text{if site } i \text{ is occupied by a B atom}
 \end{aligned} \quad (36)$$

The functions  $V^{\alpha\beta}$  and  $\Phi^{\alpha\beta}$  are defined as

$$\begin{aligned}
 V^{\alpha\beta}(r) &= \varepsilon^{\alpha\beta} \left[ \frac{a^{\alpha\beta}}{r} \right]^{n_{\alpha\beta}} \\
 \Phi^{\alpha\beta}(r) &= \left[ \frac{a^{\alpha\beta}}{r} \right]^{m_{\alpha\beta}}
 \end{aligned} \quad (37)$$

where  $\varepsilon$  and  $\beta$  are both A and B. The parameters  $\varepsilon^{\text{AA}}$ ,  $c^{\text{AA}}$ ,  $a^{\text{AA}}$ ,  $m^{\text{AA}}$ , and  $n^{\text{AA}}$  are for the pure element A, and  $\varepsilon^{\text{BB}}$ ,  $c^{\text{BB}}$ ,  $a^{\text{BB}}$ ,  $m^{\text{BB}}$ , and  $n^{\text{BB}}$  are for the pure element B, given in Table 1.

$$\begin{aligned}
 d^{\text{AA}} &= \varepsilon^{\text{AA}} c^{\text{AA}} \\
 d^{\text{BB}} &= \varepsilon^{\text{BB}} c^{\text{BB}}
 \end{aligned} \quad (38)$$

The mixed, or alloy, states are obtained from the pure states by assuming the combining rules:

$$V^{\text{AB}} = (V^{\text{AA}} V^{\text{BB}})^{1/2} \quad (39)$$

$$\Phi^{\text{AB}} = (\Phi^{\text{AA}} \Phi^{\text{BB}})^{1/2} \quad (40)$$

These combining rules, based on purely empirical grounds, give the alloy parameters as

$$\begin{aligned}
 m^{\text{AB}} &= \frac{1}{2} (m^{\text{AA}} + m^{\text{BB}}) \\
 n^{\text{AB}} &= \frac{1}{2} (n^{\text{AA}} + n^{\text{BB}}) \\
 a^{\text{AB}} &= (a^{\text{AA}} a^{\text{BB}})^{1/2} \\
 \varepsilon^{\text{AB}} &= (\varepsilon^{\text{AA}} \varepsilon^{\text{BB}})^{1/2}
 \end{aligned} \quad (41)$$

These potentials were used to compute the elastic constants and heat of formation of a set of fcc metallic alloys [58], as well as to model the formation of ultrathin Pd films on a Cu(100) surface [59]. They form the basis of a large class of MD simulations [11, 33].

### 3.1.6. Angular-Dependent Potentials

Transition metals form three rather long rows in the periodic table, beginning with Ti, Zr, and Hf and terminating with Ni, Pd, and Pt. These rows correspond to the filling of 3d, 4d, and 5d orbital shells, respectively. Consequently, the d-band interactions play an important role in the energetics of these metals [77], giving rise to angular-dependent forces that contribute significantly to the structural and vibrational characteristics of these elements. Pseudopotential models are commonly used to represent the intermolecular interaction in such metals [78, 79]. Recently, an *ab initio* generalized pseudopotential theory [80] was employed to construct an analytic angular-dependent potential for the description of the element Mo [81], a bcc transition metal. According to this prescription, the total cohesive energy is expressed as

$$\begin{aligned}
 H_I^{\text{Mo}} = & H_{\text{vol}}(\Omega) + \frac{1}{2N} \sum_i \sum_{j \neq i} V_{2(ij)} \\
 & + \frac{1}{6N} \sum_i \sum_{j \neq i} \sum_{k \neq i, j} V_{3(ijk)} \\
 & + \frac{1}{24N} \sum_i \sum_{j \neq i} \sum_{k \neq i, j} \sum_{l \neq i, j, k} V_{4(ijkl)} \quad (42)
 \end{aligned}$$

where  $\Omega$  is the atomic volume,  $N$  is the number of ions,  $V_3$  and  $V_4$  are, respectively, the angular-dependent three- and four-ion potentials, and  $H_{\text{vol}}$  includes all one-ion intratomic contributions to the cohesive energy. The interatomic potentials,  $V_{2(ij)}$ ,  $V_{3(ijk)}$ , and  $V_{4(ijkl)}$ , denote

$$\begin{aligned}
 V_{2(ij)} &\equiv V_2(r_{ij}; \Omega) \\
 V_{3(ijk)} &\equiv V_3(r_{ij}, r_{jk}, r_{ki}; \Omega) \\
 V_{4(ijkl)} &\equiv V_4(r_{ij}, r_{jk}, r_{kl}, r_{li}, r_{ki}, r_{lj}; \Omega) \quad (43)
 \end{aligned}$$

where  $r_{ij}$ , for example, is the ion-ion separation distance between ions  $i$  and  $j$ . These potentials are expressible in terms of weak pseudopotential and d-state tight-binding and hybridization matrix elements that couple different sites. Analytic expressions for these functions are provided [80, 81] in terms of distances and angles subtended by these distances.

The potential expressed by (42) was employed to compute the values of a set of physical properties of Mo, including the elastic constants, the phonon frequencies, and the vacancy formation energy [81]. These results clearly show that the inclusion of the angular-dependent potentials greatly improves the computed values of these properties as compared with the results obtained exclusively from an effective two-body interaction potential,  $V_2^{\text{eff}}$ . Furthermore, the potential was employed in an MD simulation of the melting transition of Mo, the details of which can be found in [81].

## 3.2. Interatomic Potentials for Covalently Bonding Systems

### 3.2.1. Tersoff Many-Body C–C, Si–Si, and C–Si Potentials

The construction of Tersoff many-body potentials is based on the formalism of an analytic bond order potential, initially suggested by Abell [82]. According to Abell's

prescription, the binding energy of an atomic many-body system can be computed in terms of pairwise nearest neighbor interactions that are, however, modified by the local atomic environment. Tersoff employed this prescription to obtain the binding energy in Si [83–85], C [86], Si–C [85, 87], Ge, and Si–Ge [87] solid-state structures.

In Tersoff's model, the total binding energy is expressed as

$$H_I^{\text{TR}} = \sum_i E_i = \frac{1}{2} \sum_i \sum_{j \neq i} V(r_{ij}) \quad (44)$$

where  $E_i$  is the energy of site  $i$  and  $V(r_{ij})$  is the interaction energy between atoms  $i$  and  $j$ , given by

$$V(r_{ij}) = f_c(r_{ij})[V^{\text{R}}(r_{ij}) + b_{ij}V^{\text{A}}(r_{ij})] \quad (45)$$

The function  $V^{\text{R}}(r_{ij})$  represents the repulsive pairwise potential, such as the core–core interactions, and the function  $V^{\text{A}}(r_{ij})$  represents the attractive bonding due to the valence electrons. The many-body feature of the potential is represented by the term  $b_{ij}$ , which acts as the bond order term and which depends on the local atomic environment in which a particular bond is located. The analytic forms of these potentials are given by

$$\begin{aligned}
 V^{\text{R}}(r_{ij}) &= A_{ij} \exp(-\lambda_{ij} r_{ij}) \\
 V^{\text{A}}(r_{ij}) &= -B_{ij} \exp(-\mu_{ij} r_{ij}),
 \end{aligned}$$

$$f_c(r_{ij}) = \begin{cases} 1 & \text{for } r_{ij} < R_{ij}^{(1)} \\ \frac{1}{2} + \frac{1}{2} \cos \left[ \frac{\pi(r_{ij} - R_{ij}^{(1)})}{R_{ij}^{(2)} - R_{ij}^{(1)}} \right] & \text{for } R_{ij}^{(1)} < r_{ij} < R_{ij}^{(2)} \\ 0 & \text{for } r_{ij} > R_{ij}^{(2)} \end{cases}$$

$$\begin{aligned}
 b_{ij} &= \chi_{ij} [1 + (\beta_i \zeta_{ij})^{n_i}]^{-0.5n_i} \\
 \zeta_{ij} &= \sum_{k \neq i, j} f_c(r_{ik}) \omega_{ik} g(\theta_{ijk}) \quad (46)
 \end{aligned}$$

$$g(\theta_{ijk}) = 1 + \frac{c_i^2}{d_i^2} - \frac{c_i^2}{d_i^2 + (h_i - \cos \theta_{ijk})^2}$$

$$\lambda_{ij} = \frac{\lambda_i + \lambda_j}{2} \quad \mu_{ij} = \frac{\mu_i + \mu_j}{2}$$

$$\omega_{ik} = \exp[\mu_{ik}(r_{ij} - r_{ik})]^3$$

$$A_{ij} = \sqrt{A_i A_j} \quad B_{ij} = \sqrt{B_i B_j}$$

$$R_{ij}^{(1)} = \sqrt{R_i^{(1)} R_j^{(1)}} \quad R_{ij}^{(2)} = \sqrt{R_i^{(2)} R_j^{(2)}}$$

where the labels  $i$ ,  $j$ , and  $k$  refer to the atoms in the  $ijk$  bonds and  $r_{ij}$  and  $r_{ik}$  refer to the lengths of the  $ij$  and  $ik$  bonds whose angle is  $\theta_{ijk}$ . Singly subscripted parameters, such as  $\lambda_i$  and  $n_i$ , depend only on one type of atom, for example, C or Si. The parameters for the C–C, Si–Si, and Si–C potentials are listed in Table 3. For C, the parameters

**Table 3.** Parameters of the Tersoff potentials for C and Si.

Parameter	C	Si
$A$ (eV)	$1.3936 \times 10^3$	$1.8308 \times 10^3$
$B$ (eV)	$3.467 \times 10^2$	$4.7118 \times 10^2$
$\lambda$ (nm <sup>-1</sup> )	34.879	24.799
$\mu$ (nm <sup>-1</sup> )	22.119	17.322
$\beta$	$1.5724 \times 10^{-7}$	$1.1000 \times 10^{-6}$
$\eta$	$7.2751 \times 10^{-1}$	$7.8734 \times 10^{-1}$
$c$	$3.8049 \times 10^4$	$1.0039 \times 10^5$
$d$	4.384	16.217
$h$	-0.57058	-0.59825
$R^{(1)}$ (nm)	0.18	0.27
$R^{(2)}$ (nm)	0.21	0.30
$\chi$	1	1
$\chi_{C-Si}$	0.9776	

were obtained by fitting the cohesive energies of carbon polytypes, along with the lattice constant and bulk modulus of diamond. For Si, the parameters were obtained by fitting to a database consisting of cohesive energies of real and hypothetical bulk polytypes of Si, along with the bulk modulus and bond length in the diamond structure. Furthermore, these potential parameters were required to reproduce all three elastic constants of Si to within 20%.

### 3.2.2. Brenner–Tersoff-Type First-Generation Hydrocarbon Potentials

The Tersoff potentials correctly model the dynamics of a variety of solid-state structures, such as the surface reconstruction in Silicon [83, 84] or the formation of interstitial defects in carbon [86]. However, while these potentials can give a realistic description of the C–C single-, double-, and triple-bond lengths and energies in hydrocarbons, solid graphite, and diamond, they lead to nonphysical results for bonding situations intermediate between the single and double bonds, such as the bonding in the Kekulé construction for graphite where, due to bond conjugation, each bond is considered to be approximately one-third double bond and two-thirds single bond in character. To correct for this, and similar problems in hydrocarbons, as well as to correct for the nonphysical overbinding of radicals, Brenner [88] developed a Tersoff-type potential for hydrocarbons that can model the bonding in a variety of small hydrocarbon molecules as well as in diamond and graphite. In this potential, (44) and (45) are rewritten as

$$H_i^{\text{Br}} = \frac{1}{2} \sum_i \sum_{i \neq j} V(r_{ij}) \quad (47)$$

and

$$V(r_{ij}) = f_c(r_{ij}) [V^{\text{R}}(r_{ij}) + \bar{b}_{ij} V^{\text{A}}(r_{ij})] \quad (48)$$

where

$$\begin{aligned} V^{\text{R}}(r_{ij}) &= \frac{D_{ij}}{S_{ij} - 1} \exp\left[-\sqrt{2S_{ij}}\beta_{ij}(r_{ij} - R_{ij}^{\text{c}})\right] \\ V^{\text{A}}(r_{ij}) &= \frac{-D_{ij}S_{ij}}{S_{ij} - 1} \exp\left[-\sqrt{(2/S_{ij})}\beta_{ij}(r_{ij} - R_{ij}^{\text{c}})\right] \\ \bar{b}_{ij} &= \frac{b_{ij} + b_{ji}}{2} + F_{ij}(N_i^{(\text{t})}, N_j^{(\text{t})}, N_{ij}^{\text{conj}}) \\ b_{ij} &= [1 + G_{ij} + H_{ij}(N_i^{(\text{H})}, N_i^{(\text{C})})]^{-\delta_i} \\ G_{ij} &= \sum_{k \neq i, j} f_c(r_{ik}) G_i(\theta_{ijk}) \\ &\quad \times \exp[\alpha_{ijk}\{(r_{ij} - R_{ij}^{\text{c}}) - (r_{ik} - R_{ik}^{\text{c}})\}] \\ G_c(\theta) &= a_0 \left[1 + \frac{c_0^2}{d_0^2} - \frac{c_0^2}{d_0^2 + (1 + \cos \theta)^2}\right] \end{aligned} \quad (49)$$

The quantities  $N_i^{(\text{C})}$  and  $N_i^{(\text{H})}$  represent the number of C and H atoms bonded to atom  $i$ ,  $N_i^{(\text{t})} = (N_i^{(\text{C})} + N_i^{(\text{H})})$  is the total number of neighbors of atom  $i$ , and its values, for neighbors of the two carbon atoms involved in a bond, can be used to determine if the bond is part of a conjugated system. For example, if  $N_i^{(\text{t})} < 4$ , then the carbon atom forms a conjugated bond with its carbon neighbors.  $N_{ij}^{\text{conj}}$  depends on whether an  $ij$  carbon bond is part of a conjugated system. These quantities are given by

$$\begin{aligned} N_i^{(\text{H})} &= \sum_{l \neq i, j}^{\text{hydrogen atoms}} f_c(r_{il}) \\ N_i^{(\text{C})} &= \sum_{k \neq i, j}^{\text{carbon atoms}} f_c(r_{ik}) \\ N_{ij}^{\text{conj}} &= 1 + \sum_{k \neq i, j}^{\text{carbon atoms}} f_c(r_{ik}) F(x_{ik}) \\ &\quad + \sum_{l \neq i, j}^{\text{carbon atoms}} f_c(r_{jl}) F(x_{jl}) \\ F(x_{ik}) &= \begin{cases} 1 & \text{for } x_{ik} \leq 2 \\ \frac{1}{2} + \frac{1}{2} \cos[\pi(x_{ik} - 2)] & \text{for } 2 < x_{ik} < 3 \\ 0 & \text{for } x_{ik} \geq 3 \end{cases} \\ x_{ik} &= N_k^{(\text{t})} - f_c(r_{ik}) \end{aligned} \quad (50)$$

The expression for  $N_{ij}^{\text{conj}}$  yields a continuous value as the bonds break and form, and as the second-neighbor coordinations change. For  $N_{ij}^{\text{conj}} = 1$ , the bond between a pair of carbon atoms  $i$  and  $j$  is not part of a conjugated system, whereas for  $N_{ij}^{\text{conj}} \geq 2$  the bond is part of a conjugated system.

The functions  $H_{ij}$  and  $F_{ij}$  are parameterized by two- and three-dimensional cubic splines, respectively, and the potential parameters in (47)–(50) were determined by first fitting to systems composed of carbon and hydrogen atoms only, and then the parameters were chosen for the mixed hydrocarbon systems. Two sets of parameters, consisting of 63

and 64 entries, are listed in [88]. These parameters were obtained by fitting a variety of hydrocarbon data sets, such as the binding energies and lattice constants of graphite, diamond, simple cubic and fcc structures, and the vacancy formation energies. The complete fitting sets are given in Tables I, II, and III in [88].

### 3.2.3. Brenner–Tersoff-Type Second-Generation Hydrocarbon Potentials

The potential function, expressed by (47)–(50) and referred to as the first-generation hydrocarbon potential, was recently further refined [41, 89] by including improved analytic functions for the intramolecular interactions and by an extended fitting database, resulting in a significantly better description of bond lengths, energies, and force constants for hydrocarbon molecules, as well as elastic properties, interstitial defect energies, and surface energies for diamond. In this improved version, the terms in (48) are redefined as

$$\begin{aligned}
 V^R(r_{ij}) &= f_c(r_{ij}) \left[ 1 + \frac{Q_{ij}}{r_{ij}} \right] A_{ij} \exp(\alpha_{ij} r_{ij}) \\
 V^A(r_{ij}) &= -f_c(r_{ij}) \sum_{(n=1,3)} B_{ijn} \exp(\beta_{ijn} r_{ij}) \\
 \bar{b}_{ij} &= \frac{p_{ij}^{\sigma\pi} + p_{ji}^{\sigma\pi}}{2} + p_{ij}^{\pi} \\
 p_{ij}^{\pi} &= \pi_{ij}^{\text{rc}} + \pi_{ij}^{\text{dh}} \\
 p_{ij}^{\sigma\pi} &= [1 + G_{ij} + P_{ij}(N_i^{(\text{H})}, N_i^{(\text{C})})^{-1/2}] \\
 G_{ij} &= \sum_{k \neq i, j} f_c(r_{ik}) G_i[\cos(\theta_{jik})] \exp[\lambda_{ijk}(r_{ij} - r_{ik})] \\
 \pi_{ij}^{\text{rc}} &= F_{ij}(N_i^{(\text{t})}, N_j^{(\text{t})}, N_{ij}^{\text{conj}}) \\
 N_{ij}^{\text{conj}} &= 1 + \left[ \sum_{k \neq i, j}^{\text{carbon atoms}} f_c(r_{ik}) F(x_{ik}) \right]^2 \\
 &\quad + \left[ \sum_{l \neq i, j}^{\text{carbon atoms}} f_c(r_{jl}) F(x_{jl}) \right]^2 \\
 \pi_{ij}^{\text{dh}} &= T_{ij}(N_i^{(\text{t})}, N_j^{(\text{t})}, N_{ij}^{\text{conj}}) \\
 &\quad \times \left[ \sum_{k \neq i, j} \sum_{l \neq i, j} (1 - \cos^2 \omega_{ijkl}) f_c(r_{ik}) f_c(r_{jl}) \right] \\
 \cos \omega_{ijkl} &= e_{ijk} e_{ijl}
 \end{aligned} \tag{51}$$

$Q_{ij}$  is the screened Coulomb potential, which goes to  $\infty$  as the interatomic distances approach 0. The term  $\pi_{ij}^{\text{rc}}$  represents the influence of radical energetics and  $\pi$ -bond conjugation on the bond energies, and its value depends on whether a bond between atoms  $i$  and  $j$  has a radical character and is part of a conjugated system. The value of  $\pi_{ij}^{\text{dh}}$  depends on the dihedral angle for the C–C double bonds.  $P_{ij}$  represents a bicubic spline, and  $F_{ij}$  and  $T_{ij}$  are tricubic spline functions. In the dihedral term,  $\pi_{ij}^{\text{dh}}$ , the functions  $e_{jik}$  and  $e_{ijl}$  are unit vectors in the direction of the cross products  $\mathbf{R}_j \times \mathbf{R}_k$  and  $\mathbf{R}_j \times \mathbf{R}_l$ , respectively, where the  $\mathbf{R}$ 's

are the interatomic vectors. The function  $G_c[\cos(\theta_{jik})]$  modulates the contribution that each nearest-neighbor makes to  $\bar{b}_{ij}$ . This function was determined in the following way. It was computed for the selected values of  $\theta = 109.47^\circ$  and  $\theta = 120^\circ$ , corresponding to the bond angles in diamond and graphitic sheets, and for  $\theta = 90^\circ$  and  $\theta = 180^\circ$ , corresponding to the bond angles among the nearest neighbors in a simple cube lattice. The fcc lattice contains angles of  $60^\circ$ ,  $90^\circ$ ,  $120^\circ$ , and  $180^\circ$ . A value of  $G_c[\cos(\theta = 60^\circ)]$  was also computed from the above values. To complete an analytic function for the  $G_c[\cos(\theta)]$ , sixth-order polynomial splines in  $\cos(\theta)$  were used to obtain its values for  $\theta$  between  $109.47^\circ$  and  $120^\circ$ . For  $\theta$  between  $0^\circ$  and  $109^\circ$ , for a carbon atom  $i$ , the angular function

$$g_c = G_c[\cos(\theta)] + Q(N_i^{(\text{t})})[\gamma_c \cos(\theta) - G_c\{\cos(\theta)\}] \tag{52}$$

is employed, where  $\gamma_c \cos(\theta)$  is a second spline function, determined for angles less than  $109.47^\circ$ . The function  $Q(N_i^{(\text{t})})$  is defined by

$$Q(N_i^{(\text{t})}) = \begin{cases} 1 & \text{for } N_i^{(\text{t})} \leq 3.2 \\ \frac{1}{2} + \frac{1}{2} \cos \left[ \frac{\pi(N_i^{(\text{t})} - 3.2)}{3.7 - 3.2} \right] & \text{for } 3.2 < N_i^{(\text{t})} < 3.7 \\ 0 & \text{for } N_i^{(\text{t})} \geq 3.7 \end{cases} \tag{53}$$

The large database of the numerical data on parameters and spline functions was obtained by fitting the elastic constants, vacancy formation energies, and formation energies for interstitial defects for diamond.

## 3.3. Interatomic Potential for C–C Nonbonding Systems

The nonbonding interactions between carbon atoms are required in many of the simulation studies in computational nanoscience and nanotechnology. These can be modeled according to various types of potentials. The Lennard-Jones and Kihara potentials can be employed to describe the van der Waals intermolecular interactions between carbon clusters, such as  $C_{60}$  molecules, and between the basal planes in a graphite lattice. Other useful potentials are the exp-6 potential [90], which also describes the  $C_{60}$ – $C_{60}$  interactions, and the Ruoff–Hickman potential [91], which models the  $C_{60}$ –graphite interactions.

### 3.3.1. Lennard-Jones and Kihara Potentials

The total interaction potential between the carbon atoms in two  $C_{60}$  molecules, or between those in two graphite basal planes, could be represented by the Lennard-Jones potential [92]:

$$H_I^{IJ}(r_{ij}^{IJ}) = 4\epsilon \sum_i \sum_{j>i} \left[ \left( \frac{\sigma}{r_{ij}^{IJ}} \right)^{12} - \left( \frac{\sigma}{r_{ij}^{IJ}} \right)^6 \right] \tag{54a}$$

where  $I$  and  $J$  denote the two molecules (planes) and  $r_{ij}$  is the distance between atom  $i$  in molecule (plane)  $I$  and atom

$j$  in molecule (plane)  $J$ . The parameters of this potential ( $\varepsilon = 0.24127 \times 10^{-2}$  eV,  $\sigma = 0.34$  nm) were taken from a study of graphite [93]. The Kihara potential is similar to the Lennard-Jones potential except that a third parameter,  $d$ , is added to correspond to the hard-core diameter, that is,

$$H_I^{LJ}(r_{ij}^{JJ}) = \begin{cases} 4\varepsilon \sum_i \sum_{j>i} \left[ \left\{ \frac{\sigma - d}{r_{ij}^{JJ} - d} \right\}^{12} - \left\{ \frac{\sigma - d}{r_{ij}^{JJ} - d} \right\}^6 \right] & \text{for } r > d \\ \infty & \text{for } r \leq d \end{cases} \quad (54b)$$

### 3.3.2. exp-6 Potential

This is another potential that describes the interaction between the carbon atoms in two  $C_{60}$  molecules

$$H_I^{\text{EXP6}}(r_{ij}^{JJ}) = \sum_i \sum_{j>i} \left[ A \exp(-\alpha r_{ij}^{JJ}) - B/(r_{ij}^{JJ})^6 \right] \quad (55)$$

Two sets of parameter values are provided, and these are listed in Table 4. These parameters have been obtained from the gas phase data of a large number of organic compounds, without any adjustment. The measured value of the  $C_{60}$  solid lattice constant is  $a = 1.404$  nm at  $T = 11$  K. The calculated value using set 1 was  $a = 1.301$  nm and using set 2 was  $a = 1.403$  nm. The experimentally estimated heat of sublimation is equal to  $-45$  kcal/mol (extrapolated from the measured value of  $-40.1 \pm 1.3$  kcal/mol at  $T = 707$  K). The computed value using set 1 was  $-41.5$  kcal/mol and using the set 2 was  $-58.7$  kcal/mol. We see that whereas set 2 produces a lattice constant nearer the experimental value, the thermal properties are better described by set 1.

### 3.3.3. Ruoff–Hickman Potential

This potential, based on the model adopted by Girifalco [94], describes the interaction of a  $C_{60}$  molecule with a graphite substrate by approximating these two systems as continuum surfaces on which the carbon atoms are “smeared out” with a uniform density. The sums over the pair interactions are then replaced by integrals that can be evaluated analytically. The  $C_{60}$  is modeled as a hollow sphere having a radius  $b = 0.355$  nm, and the C–C pair interaction takes on a Lennard-Jones form

$$H_I(r_{ij}) = c_{12}r^{-12} - c_6r^{-6} \quad (56)$$

with  $c_6 = 1.997 \times 10^{-5}$  [eV · (nm)<sup>6</sup>] and  $c_{12} = 3.4812 \times 10^{-8}$  [eV · (nm)<sup>12</sup>] [94]. The interaction potential between the hollow  $C_{60}$  and a single carbon atom of a graphite substrate, located at a distance  $z > b$  from the center of the

sphere, is then evaluated as

$$V(z) = V_{12}(z) - V_6(z) \quad (57)$$

where

$$V_n(z) = [c_n/2(n-2)][N/(bz)] \times [1/(z-b)^{n-2} - 1/(z+b)^{n-2}] \quad (58)$$

where  $N$  is the number of atoms on the sphere ( $N = 60$  in this case) and  $n = 12, 6$ . The total interaction energy between the  $C_{60}$  and the graphite plane is then obtained by integrating  $V(z)$  over all the atoms in the plane, giving

$$H_I(R) = E_{12}(R) - E_6(R) \quad (59)$$

where

$$E_n(R) = \{c_n/[4(n-2)(n-3)]\}(N^2/b^3) \times [1/(R-b)^{n-3} - 1/(R+b)^{n-3}] \quad (60)$$

and  $R$  is the vertical distance of the center of the sphere from the plane.

## 3.4. Interatomic Potential for Metal–Carbon System

In modeling the growth of metallic films on semimetallic substrates, such as graphite, a significant role is played by the interface metal–carbon potential since it controls the initial wetting of the substrate by the impinging atoms and also determines the subsequent diffusion and the final alignments of these atoms. This potential has not been available, and we have used an approximate scheme, based on a combining rule, to derive its general analytic form [95]. To construct a mixed potential to describe the interaction of an fcc metallic atom (M) with C, we assumed a generalized Morse-like potential energy function

$$H_I^{\text{MC}}(r_{ij}) = \sum_i \sum_{j>i} E_{\text{MC}} \left[ \exp\{-N\alpha(r_{ij} - r_w)\} - N \exp\{-\alpha(r_{ij} - r_w)\} \right] \quad (61)$$

and to obtain its parameters, we employed a known Morse potential function

$$H_I^{\text{CC}}(r_{ij}) = \sum_i \sum_{j>i} E_{\text{C}} \left[ \exp\{-2\alpha_1(r_{ij} - r_d)\} - 2 \exp\{-\alpha_1(r_{ij} - r_d)\} \right] \quad (62)$$

that describes the C–C interactions [96] and a generalized Morse-like potential function

$$H_I^{\text{MM}}(r_{ij}) = \sum_i \sum_{j>i} E_{\text{M}} \left[ \exp\{-m\alpha_2(r_{ij} - r_0)\} - m \exp\{-\alpha_2(r_{ij} - r_0)\} \right] \quad (63)$$

**Table 4.** Parameters of the exp-6 potential for C.

	A (kcal/mol)	B [kcal/mol × (nm) <sup>6</sup> ]	$\alpha$ (nm) <sup>-1</sup>
Set 1	42,000	$3.58 \times 10^8$	35.8
Set 2	83,630	$5.68 \times 10^8$	36.0

that describes the M–M interactions [97]. Several combining rules were then tried. The rule giving the satisfactory simulation results led to

$$\begin{aligned} E_{\text{MC}} &= \sqrt{E_{\text{C}}E_{\text{M}}} \\ r_{\text{w}} &= \sqrt{r_{\text{d}}r_0} \\ \alpha &= \sqrt{\alpha_1\alpha_2} \\ N &= \sqrt{2m} \end{aligned} \quad (64)$$

Since a cutoff is normally applied to an interaction potential, the 0 of this potential at a cutoff,  $r_{\text{c}}$ , was obtained according to the prescription in [96], leading to

$$\begin{aligned} H_i^{\text{MC}}(r_{ij}) &= \sum_{i>j} \sum E_{\text{MC}}[\exp\{-N\alpha(r_{ij}-r_{\text{w}})\} \\ &\quad - N \exp\{-\alpha(r_{ij}-r_{\text{w}})\}] \\ &\quad - E_{\text{MC}}[\exp\{-N\alpha(r_{\text{c}}-r_{\text{w}})\} \\ &\quad - N \exp\{-\alpha(r_{\text{c}}-r_{\text{w}})\}] \\ &\quad - E_{\text{MC}}N\alpha/\eta[1 - \exp\eta(r_{ij}-r_{\text{c}})] \\ &\quad \times [\exp(-N\alpha(r_{\text{c}}-r_{\text{w}})) - \exp(-\alpha(r_{\text{c}}-r_{\text{w}}))] \end{aligned} \quad (65)$$

where  $\eta$  is a constant whose value was chosen to be  $\eta = 20$ . This was a sufficiently large value so that the potential (65) was only modified near the cutoff distance. The parameters pertinent to the case when the metal atoms were silver, that is,  $M = \text{Ag}$ , are listed in Table 5. The parameters for (62) were obtained by fitting the experimental cohesive energy and the interplanar spacing,  $c/2$ , of the graphite exactly, and the parameters for (63) were obtained by fitting the experimental values of the stress-free lattice parameter and elastic constants  $C_{11}$  and  $C_{12}$  of the metal.

### 3.5. Atomic-Site Stress Field

In many modeling studies involving the mechanical behavior of nanostructures, such as the simulation of the dynamics of crack propagation in an atomic lattice, it is necessary to compute a map of the stress distribution over the individual atomic sites in a system composed of  $N$  atoms.

The concept of atomic level stress field was developed by Born and Huang [98] using the method of small homogeneous deformations. Applying small displacements to a pair of atoms  $i$  and  $j$ , with an initial separation of  $r_{ij}$ , it can be shown that [99] the Cartesian components of the stress tensor at site  $i$  are given by

$$\sigma_{\alpha\beta}(i) = \frac{1}{2\Omega_i} \sum_{j>i} \frac{\partial \Phi(r_{ij})}{\partial r_{ij}} \frac{r_{ij}^{\alpha} r_{ij}^{\beta}}{r_{ij}} \quad (66)$$

**Table 5.** Parameters of the Ag–C potential.

$\alpha_1$	$49.519 \text{ (nm)}^{-1}$
$\alpha_2$	$3.7152 \text{ (nm)}^{-1}$
$E_{\text{C}}$	3.1 eV
$E_{\text{Ag}}$	0.0284875 eV
$m$	6.00
$r_0$	0.444476 nm
$r_{\text{d}}$	0.12419 nm

where  $\alpha, \beta = x, y, z$ ,  $\Phi(r_{ij})$  is the two-body central potential, and  $\Omega_i$  is the local atomic volume, which can be identified with the volume of the Voronoi polyhedron associated with the atom  $i$  [100].

For the many-body potential energy given by (35), the stress tensor is given by

$$\begin{aligned} \sigma_{\alpha\beta}^{\text{RTS}}(i) &= \frac{1}{2\Omega_i} \left[ \sum_{j \neq i} \frac{\partial V(r_{ij})}{\partial r_{ij}} - \frac{1}{2} d^{\text{AA}} \hat{p}_i \right. \\ &\quad \times \sum_{j \neq i} \left( \frac{1}{\sqrt{\rho_i^{\text{A}}}} + \frac{1}{\sqrt{\rho_j^{\text{A}}}} \right) \frac{\partial \Phi^{\text{A}}(r_{ij})}{\partial r_{ij}} - \frac{1}{2} d^{\text{BB}} (1 - \hat{p}_i) \\ &\quad \times \sum_{j \neq i} \left( \frac{1}{\sqrt{\rho_i^{\text{B}}}} + \frac{1}{\sqrt{\rho_j^{\text{B}}}} \right) \frac{\partial \Phi^{\text{B}}(r_{ij})}{\partial r_{ij}} \left. \right] \frac{r_{ij}^{\alpha} r_{ij}^{\beta}}{r_{ij}} \end{aligned} \quad (67)$$

which for an elemental lattice with the two-body potentials given in [37] reduces to (see also [101])

$$\begin{aligned} \sigma_{\alpha\beta}^{\text{RTS}}(i) &= \frac{\varepsilon}{a^2} \frac{1}{2\Omega_i} \left[ \sum_{j \neq i} -n \left( \frac{a}{r_{ij}} \right)^{n+2} + cm \left( \frac{1}{\sqrt{\rho_i}} + \frac{1}{\sqrt{\rho_j}} \right) \right. \\ &\quad \times \left. \left( \frac{a}{r_{ij}} \right)^{m+2} \right] \frac{r_{ij}^{\alpha} r_{ij}^{\beta}}{r_{ij}} \end{aligned} \quad (68)$$

where only the contribution of the virial component to the stress field has been included and the contribution of the kinetic energy part (momentum flux) has been ignored as we are only interested in the low-temperature stress distributions. The volumes associated with individual atoms,  $\Omega_i$ , can be obtained by computing numerically their corresponding Voronoi polyhedra according to the prescription given in [23].

### 3.6. Direct Measurement of Interparticle Forces by Atomic Force Microscopy

The invention of the atomic force microscope (AFM) [7] in 1986 and its modification to optical detection [102] has opened new perspectives for various micro- and nanoscale surface imaging in science and industry. The use of AFM not only allows for nanoscale manipulation of the morphology of various condensed phases and the determination of their electronic structures, it can be also used for direct determination of interatomic and intermolecular forces.

However, its use for measurement of interparticle interaction energies as a function of distance is getting more attention for various reasons. For atoms and molecules consisting of up to 10 atoms, quantum mechanical *ab initio* computations are successful in producing rather exact force-distance results for interparticle potential energy. For complex molecules and macromolecules, one may produce the needed intermolecular potential energy functions directly only through the use of atomic force microscopy (AFM). For example, atomic force microscopy data are often used to develop accurate potential models to describe the intermolecular interactions in the condensed phases of such molecules as  $\text{C}_{60}$  [103].

The atomic force microscope is a unique tool for direct study of intermolecular forces. Unlike traditional microscopes, AFM does not use optical lenses, and therefore it provides very high resolution range of various sample properties [7, 104, 105]. It operates by scanning a very sharp tip across a sample, which “feels” the contours of the surface in a manner similar to the stylus tracing across the grooves of a record. In this way, it can follow the contours of the surface and so create a topographic image, often with subnanometer resolution.

This instrument also allows researchers to obtain information about the specific forces between and within molecules on the surface. The AFM, by its very nature, is extremely sensitive to intermolecular forces and has the ability to measure force as a function of distance. In fact, measurement of interactions as small as a single hydrogen bond have been reported [106–110]. Noncontact AFM will be used for attractive interaction force measurement. Contact AFM will be used for repulsive force measurement. Intermittent-contact AFM is more effective than noncontact AFM for imaging larger scan sizes.

In principle, to perform such a measurement and study with AFM, it is necessary to specially design the tip for this purpose [102, 111, 112]. Sarid [8] has proposed force–distance relationships when the tip is made of a molecule, a sphere, and a cylinder assuming van der Waals dispersion attractive forces. Various other investigators have developed the methodologies for force–distance relationships for other tip geometric shapes, including cylinder, paraboloid, cone, pyramid, a conical part covered by the spherical cap, and so on [105, 111, 113–119]. For example, Zanette et al. [111] present a theoretical and experimental investigation of the force–distance relationship in the case of a pyramidal tip. Data analysis of interaction forces measured with the atomic force microscope is quite important [120]. Experimental recordings of direct tip–sample interaction can be obtained as described in [121], and recordings using flexible cross-linkers can be obtained as described in [122, 123]. The noise in the typical force–distance cycles can be assumed to be, for example, Gaussian.

Recent progress in AFM technology will allow the force–distance relationship measurement of inter- and intramolecular forces at the level of individual molecules of almost any size.

Because of the possibility to use the AFM in liquid environments [109, 124], it has become possible to image organic micelles, colloids, biological surfaces such as cells and protein layers, and generally organic nanostructures [4] at nanometer resolution under physiological conditions. One important precaution to be considered in the force measurement is how to fix micelles, colloids, and biological cells on a substrate and a probe securely enough for measuring force but flexible enough to keep the organic nanostructure intact and, in the case of biological cells, keep it biologically active [124]. A variety of techniques for this purpose has been proposed, including the use of chemical cross-linkers, flexible spacer molecules [125], inactive proteins as cushions in the case of biological systems [126], and self-assembled monolayers [127]. An important issue to consider in liquid state force–distance measurements is the effect of pushing the organic nanostructures on to the substrate and AFM probe.

As the AFM probe is pushed onto the nanostructure, there is a possibility of damaging it or adsorbing it to the probe physically.

Also making microelectrophoretic measurements of the zeta potential will allow us to calculate the total interparticle energies indirectly. From the combined AFM and microelectrophoretic measurements, accurate force–distance data can be obtained. From the relationship between force and distance, an interparticle force vs. distance curve can be created. Then, with the use of the phenomenological potential functions presented in this review, the produced data can be readily fitted to a potential energy function for application in various nanotechnology and nanoscience computational schemes.

### 3.7. Conclusions

In this chapter, we have presented a set of state-of-the-art phenomenological interatomic and intermolecular potential energy functions that are widely used in computational modeling at the nanoscale. We have also presented a review of direct measurement of the interparticle force–distance relationship from which intermolecular potential energy functions data can be generated. There is still a great deal of work to be done in order to develop a thorough database for interatomic and intermolecular potential energy functions to be sufficient for applications in nanoscience and nanotechnology. This is because, to control the matter atom by atom, molecule by molecule, and/or at the macromolecular level, which is the aim of nanotechnology, it is necessary to know the exact intermolecular forces between the particles under consideration. In the development of intermolecular force models applicable for the study of nanostructures, which are at the confluence of the smallest of human-made devices and the largest molecules of living systems, it is necessary to reexamine the existing techniques and come up with more appropriate intermolecular force models.

It is understood that formidable challenges remain in the fundamental understanding of various phenomena on the nanoscale before the potential of nanotechnology becomes a reality. With the knowledge of better and more exact intermolecular interactions between atoms and molecules, it will become possible to increase our fundamental understanding of nanostructures. This will allow development of more controllable processes in nanotechnology and optimization of production and design of more appropriate nanostructures, such as nanotubes [128], and their interactions with other nanosystems.

## GLOSSARY

**Atomic force microscope (AFM)** An instrument for analyzing the material surface all the way down to the atoms and molecules level. A combination of mechanical and electronic probe is used in AFM to magnify surfaces up to 100,000,000 times to produce 3-D images of them.

**Body-centered cubic crystalline (BCC) structure** A structure in which the simplest repeating unit consists of nine equivalent lattice points, eight of which are at the corners of a cube and the ninth of which is in the center of the body of the cube.

**Embedded-atom model (EAM)** This is a type of interatomic potential, first suggested by Friedel, which describes the bonding of an atom in terms of the local electronic density.

**Face-centered cubic crystalline (FCC) structure** A structure in which the simplest repeating unit consists of fourteen equivalent lattice points, eight of which are at the corners of a cube and another six in the centers of the faces of the cube. Found in cubic closest-packed structures.

**Hexagonal close pack (HCP) crystalline structure** HCP structure is a special case of a hexagonal structure with alternating layers shifted so its atoms are aligned to the gaps of the preceding layer, and with  $c/a = \sqrt{8/3} = 1.633\dots$ . With this ratio, the atomic separation within a layer (on the x-y plane) is the same as the separation between layers.

**Molecular dynamics (MD)** This consist of the study of intramolecular conformations and molecular motions, using computational simulations taking into account the.

**Monte Carlo (MC) method of computation** This is a stochastic technique of computation/simulation which uses random numbers.

**Scanning tunneling microscope (STM)** This is an instrument able to image conducting surfaces to atomic accuracy; has been used to pin molecules to a surface. This is a more powerful device than AFM.

## 1. INTRODUCTION

Nanostructured materials exhibit outstanding physical, mechanical, and chemical properties opening a range of new applications in high technologies; see, for example, [1–7]. These outstanding properties of nanostructured materials are due to the interface and nanoscale effects. In particular, interfaces—grain and interphase boundaries—play the crucial role in physical and chemical processes occurring in nanocrystalline bulk materials and films where the volume fraction of the interfacial phase ranges from 10 to 50%. At the same time, the structure and the properties of interfaces in nanostructured materials are strongly influenced by technological parameters of their fabrication. In these circumstances, in order to technologically control, design, and

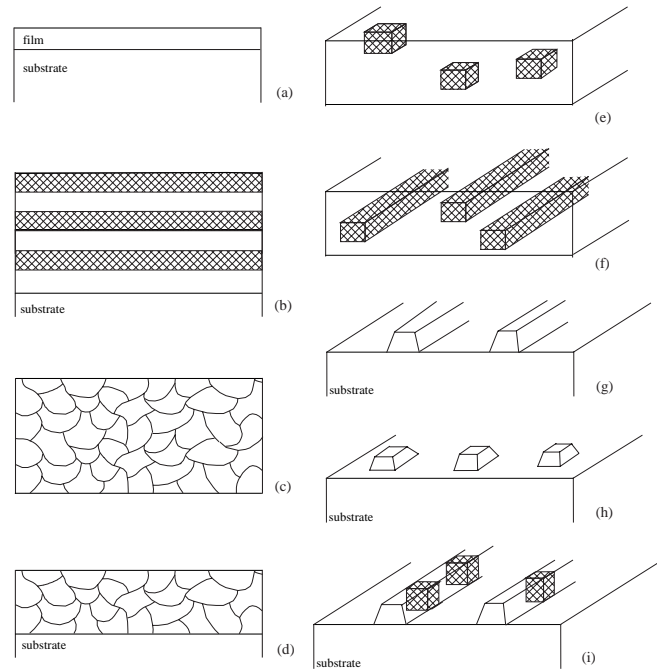

enhance functional characteristics of nanostructured materials, it is very important to understand the behavior of interfaces in them.

In description of the effects of interfaces on the properties of nanostructured materials, of special interest are theoretical models of interfaces. Such models represent a very essential constituent in a description of the relationship between fabrication technologies, structure, and functional properties of nanomaterials. Models of interfaces include, in particular, computer, geometric, and continuum models. Computer models commonly concentrate on simulations of the atomic structure of interfaces. Geometric models of solid/solid interfaces are concerned with their translational and rotational symmetries, in which case interfacial defects are treated as local violations of these symmetries. Continuum models use results of geometric and/or computer models in description of interfaces and interfacial defects as sources of internal stress fields, contributing to structural stability, mechanical, transport, and other properties of nanomaterials. Continuum models, in fact, provide a link between descriptions of the structure of interfaces and their properties. In this chapter we give a review of geometric and continuum models describing the specific structural and behavioral peculiarities of interfaces in nanostructured materials, with focuses placed on interfacial defects. In doing so, we will consider classification of interfaces in nanostructured materials (Section 2), specific features of interfaces and interfacial defects in nanostructured bulk materials and films (Sections 2 and 3), interfacial defects playing the role as misfit defects (causing relaxation of residual stresses) in nanocrystalline films and coatings (Sections 4 and 5), partial misfit dislocations at interphase boundaries in nanoscale films (Section 6), and grain boundary defects and their effects on diffusion and plastic deformation processes in nanocrystalline bulk materials (Sections 7 and 8). Finally, we will discuss the notion of nanodefects in nanostructures, extending the notion of defects to the case of assembled nanostructures, and we will summarize results of a theoretical description of interfacial defects in diverse nanostructured materials (Sections 9 and 10).

## 2. CLASSIFICATION OF INTERFACES IN NANOSTRUCTURED MATERIALS

Following Gleiter [3, 8], nanostructured materials can be divided into the following three basic categories, depending on both their structure and the shape of the crystallites: materials in the form of (isolated, substrate-supported, or embedded) nanometer-sized particles, thin wires, and films; materials in which the nanometer-sized microstructure is limited to a thin (nanometer-sized) surface region of a bulk solid; and bulk materials with a nanometer-sized microstructure. These categories are rather general, in which case nanostructured materials belonging to one category contain interfaces with very different structures and properties. In this context, for aims of this review focused on defects at solid/solid interfaces in nanostructured materials, we suggest classification of such interfaces, which takes into account their structural geometry as well as crystalline structure and phase content of solids adjacent to interfaces. In doing so, internal (solid/solid) interfaces in nanostructured materials can be divided into the following basic categories: (i) plane interphase boundaries between single crystalline nanoscale films and single crystalline substrates (Fig. 1a), and between single crystalline nanolayers in multilayered coatings (Fig. 1b); (ii) short and curved grain boundaries in nanocrystalline bulk materials (Fig. 1c), thin films (Fig. 1d), and thick coatings; (iii) plane and short interphase boundaries between grains of nanocrystalline films and single crystalline substrate (Fig. 1d); (iv) short and curved interphase boundaries in nanocomposites consisting of equaxed nanoparticles (Fig. 1e); (v) curved interphase boundaries in nanocomposites consisting of nanowires embedded into a matrix (Fig. 1f); (vi) striplike interphase boundaries between freestanding nanowires and single crystalline substrates (Fig. 1g); (vii) squarelike interphase boundaries between freestanding nanoislands (quantum dots) and substrate (Fig. 1h); (viii) short and curved interphase boundaries surrounding quantum dots embedded into nanowires (Fig. 1i).

Crystalline structure and phase content of adjacent solids cause the existence of geometrically necessary or, in other terms, intrinsic defects at solid/solid interfaces. In particular, these intrinsic defects are associated with misorientation inherent to grain boundaries, and provide a partial relaxation of misfit stresses occurring due to geometric mismatch between different crystalline lattices of different phases matched at interphase boundaries. The intrinsic defects exist also at solid/solid interfaces in conventional materials (with micrometer-sized structure), where interfaces are tentatively plane and have large dimensions. Interfaces in conventional materials are commonly modeled as plane interfaces of infinite extent. In doing so, ensembles of intrinsic interfacial defects are modeled as infinite, periodically arranged structures. However, these theoretical representations of interfaces and interfacial defects are oversimplified in the case of the nanostructured materials, in which most interfaces are curved and short (see Fig. 1). Owing to curved geometry of interfaces in nanostructured materials, high-density ensembles of their junctions, first of all, triple junctions of grain and interphase boundaries, exist in such materials. They have both the structure and properties different from

**Figure 1.** Interfaces in nanostructured materials: (a) plane interphase boundaries between single crystalline nanoscale film and single crystalline substrate; (b) plane interphase boundaries between single crystalline nanolayers in multilayered coatings; (c) short and curved grain boundaries in nanocrystalline (nanograined) bulk materials; (d) short and curved grain boundaries in nanocrystalline (nanograined) film as well as plane and short interphase boundaries between grains of nanocrystalline film and single crystalline substrate; (e) short and curved interphase boundaries in nanocomposite consisting of equaxed nanoparticles embedded into a matrix; (f) curved interphase boundaries in nanocomposite consisting of nanowires embedded into a matrix; (g) striplike interphase boundaries between freestanding nanowires and single crystalline substrate; (h) squarelike interphase boundaries between freestanding nanoislands (quantum dots) and substrate; (i) interphase boundaries surrounding quantum dots embedded into nanowires.

those of interfaces that they adjoin; see, for example, [9]. As a result, triple junctions treated as interfacial defects of the special type are capable of strongly influencing functional properties of nanostructured materials. In addition, interfaces in diverse nanostructured materials are short, in which case their length is of the same order as periods of arrangements of intrinsic defects at interfaces in conventional materials. With finite extent of interfaces and influence of triple junctions, arrangement of intrinsic interfacial defects is different from conventionally modeled periodic arrangement (see, e.g., [9–13]), causing these defects to exhibit behavior different from that of interfacial defects at interfaces in conventional materials.

In the case of plane interphase boundaries between nanoscale films and single crystalline substrates (Fig. 1a) or between nanoscale layers in multilayered coatings (Fig. 1b), geometry of interphase boundaries is similar to that in conventional films. Nevertheless, nanoscale effects come into play in this case, causing the formation of specific interfacial structures such as partial misfit dislocations associated with

V-shaped stacking faults in films of nanoscale thickness (see Section 6) and amorphization of interphase boundaries (see experimental data [14] and a theoretical model [15]).

Parallel with structural geometry and phase content, conditions of fabrications of nanostructured materials strongly affect interfacial defect structure of interfaces. More precisely, nanostructured materials are commonly fabricated by highly nonequilibrium methods causing the formation of so-called extrinsic interfacial defects, that is, defects which are not geometrically necessary at interfaces. Grain boundaries with high densities of extrinsic defects are called nonequilibrium boundaries and exhibit specific properties different from those of equilibrium grain boundaries containing intrinsic defects only [16–22]. It is believed that the nonequilibrium grain boundaries are responsible for the very unusual mechanical properties of nanostructured materials produced by severe plastic deformation [20, 21]. By analogy with the notion of nonequilibrium grain boundaries [16–22], it is natural to define nonequilibrium interphase boundaries as those containing high-density ensembles of extrinsic defects. Such nonequilibrium interphase boundaries are expected to exist in nanocomposites fabricated at highly nonequilibrium conditions.

In this chapter we will consider theoretical models of intrinsic and extrinsic defects and their ensembles at interfaces in nanostructured materials. Focuses are placed on defects in nanocrystalline bulk materials, films, and coatings, because the theory of such defects is well developed. Theoretical representations of such defects can serve as a basis for a theoretical description of interfacial defects in nanocomposite systems.

### 3. SPECIFIC FEATURES OF INTERFACES AND INTERFACIAL DEFECTS IN NANOCRYSTALLINE (NANOGRAINED) FILMS AND COATINGS

Nanocrystalline thin films (thick coatings) (Fig. 1a) can be treated as polycrystalline films (coatings) in the limiting case, where the grain size is on the order of a few nanometers. As a corollary, nanocrystalline films have the “conventional” structural and behavioral features that are inherent to both nanocrystalline and polycrystalline films as well as the “specific” structural and behavioral features associated with their nanoscale structure.

The existence of both grain boundaries and interphase (film/substrate) boundaries causes the “conventional” features of nanocrystalline and polycrystalline films, which are as follows: (a) There is a strong elastic interaction between grain boundaries in a nanocrystalline (or polycrystalline) film and the film/substrate interface which is a source of misfit stresses. (b) Film/substrate interfaces are complicately arranged; each interface consists of fragments with various structures and properties, bounded by junctions of grain boundaries and the film/substrate interface. Due to the features (a) and (b), grain boundaries and film/substrate interfaces strongly affect both the structure and the properties of each other in nanocrystalline and polycrystalline films.

In addition, interfaces in nanocrystalline films (Fig. 1d) have the following “specific” features related to their nanoscale structure:

- (1) The volume fraction of the interfacial phase is extremely high in nanocrystalline films.
- (2) Grain boundaries are short and curved.
- (3) There is a strong elastic interaction between neighboring interfaces, because (extremely short) distances between them are close to the characteristic scales of their stress fields.
- (4) In nanocrystalline films there is a strong effect of triple junctions and nanograins on interfaces and vice versa, because the volume fraction of triple junctions is extremely high in nanocrystalline solids and because nanograins commonly are more distorted than conventional grains in polycrystalline films.
- (5) Formation of nanocrystalline films frequently occurs at highly nonequilibrium conditions that essentially influence the interfacial structures.<sup>1</sup>

The points under discussion should be definitely taken into account in a theoretical description of interfaces and interfacial defects in nanocrystalline films, which, in most cases, can not be unambiguously identified with the help of contemporary experimental methods. With these points, let us consider interphase boundaries between nanocrystalline films and (single crystalline) substrates (Fig. 1d). To do so, first let us discuss structural geometry of interphase boundaries between single crystalline films and single crystalline substrates. In general, such interphase boundaries can be coherent, incoherent, or semicoherent, depending on the structural and chemical features of the matched phases as well as on external factors such as temperature and the geometric sizes (e.g., thickness) of the matched crystalline samples. In doing so, according to a qualitative description of the coherent, incoherent, and semicoherent states of interfaces given by Möbus et al. [23], the key classifying factor for these states is supposed to be the way in which the mismatch (geometric misfit) between the adjacent crystalline lattices (Fig. 2a) is accommodated.

- (1) For a coherent interface between a thin film and a thick substrate, the mismatch is accommodated completely by straining the lattice of the adjacent film (Fig. 2b). In this event, misfit stresses (stresses occurring due to the mismatch at interface) are characterized by the spatial scale being the film thickness.
- (2) For a semicoherent interface, localized misfit dislocations (misfit dislocations) provide at least partial compensation of long-range misfit stresses (Fig. 2c) (for more details, see reviews [24–29]).
- (3) A completely incoherent interface can be treated as resulted from a rigid contact of two crystalline lattices distorted only at the contact regions (Fig. 2d).

Incoherent interfaces do not induce long-range strains; there are only short-range distortions occurring due to faults in

<sup>1</sup>The same features are inherent also to bulk nanocrystalline materials.

**Figure 2.** Interphase boundaries between single crystalline films and substrates. (a) Origin of dilatation misfit stresses is the geometric mismatch between crystal lattice parameters,  $a_1$  and  $a_2$ , of film and substrate. (b) Coherent boundary. (c) Semicoherent boundary. (d) Incoherent interphase boundary.

chemical binding at the interface. Such distortions are characterized by a spatial scale close to interatomic distances in the adjacent phases.

Now let us turn to a consideration of structural geometry of interphase boundaries between nanocrystalline films and single crystalline substrates. As it has been noted in Section 2, any nanocrystalline film/substrate interface consists of many fragments bounded by junctions of grain boundaries and the interface. Grains of the film that are adjacent to the film/substrate interface are misoriented relative to each other and, generally speaking, relative to the substrate. As a corollary, fragments of the film/substrate boundary are characterized by the misorientation and the dilatation misfit between the crystalline lattices of the film grains and the substrate. Each fragment of the film/substrate interface is either coherent, incoherent, or semicoherent, depending on its misfit and misorientation parameters and the structural and chemical features of the matched grain and the substrate, as well as on external factors such as temperature and the film thickness. Thus, in general, the nanocrystalline film/substrate interface is partly coherent, semicoherent, and incoherent; it consists of coherent, semicoherent, and incoherent fragments (Fig. 3). In this situation, the film/substrate interface contains defects of the two types: dilatation misfit defects (responsible for partial compensation of dilatation misfit stresses generated due to mismatch between the crystal lattice parameters of the film and the substrate) and misorientation defects (that provide misorientation between the adjacent grains of the film and the single crystalline substrate). More than that, misfit defects can be generated not only at film/substrate interfaces, but also at grain boundaries of the film. In Sections 4 and 5 we will consider geometric and continuum models of interfacial defects in nanocrystalline films with focuses placed on misfit defects at grain boundaries in these films.

**Figure 3.** Partly coherent, semicoherent, and incoherent interphase boundary between nanocrystalline film and single crystalline substrate.

#### 4. GRAIN BOUNDARY DISLOCATIONS AS MISFIT DEFECTS IN NANOCRYSTALLINE FILMS AND COATINGS

Misfit stresses occur in crystalline films due to the geometric mismatch at interphase boundaries between crystalline lattices of films and substrates. In most cases a partial relaxation of misfit stresses in single crystalline films is realized via generation of misfit dislocations that form dislocation rows in interphase boundary plane (Fig. 2c) or more complicatedly arranged configurations; see, for example, experimental and theoretical works [23–41]. Generally speaking, the formation of misfit dislocation rows at interphase boundaries is either desirable or disappointing, from an applications viewpoint, depending on the roles of films and interphase boundaries in applications of film/substrate composite solids. So, if the properties of a film are exploited, the formation of misfit dislocation rows commonly is desirable as it results in a (partial) compensation of misfit stresses in the film. If the properties of an interphase boundary are exploited, the formation of misfit dislocation rows commonly is undesirable, since the formed misfit dislocation cores violate the pre-existent ideal (coherent) structure of the interphase boundary.

The structure and the properties of nanocrystalline films are different from those of single crystalline films. Therefore, relaxation of misfit stresses in nanocrystalline films, in general, can occur via micromechanisms that are different from the standard micromechanism, the formation of rows of perfect misfit dislocations (Fig. 2c). In particular, we think that, due to the existence of grain boundaries in nanocrystalline films, an effective alternative to the standard physical micromechanism for relaxation of misfit stresses in such films is the formation of grain boundary dislocations as misfit defects. These grain boundary dislocations (with Burgers vectors being displacement-shift-complete lattice vectors which characterize grain boundary translation symmetries) induce stress fields that compensate for, in part, misfit stresses and are located at grain boundaries and triple junctions of interphase and grain boundaries (Fig. 4). The formation of grain boundary dislocations as misfit defects does not induce any extra violations of coherent fragments of interphase boundaries and, therefore, does not lead to degradation of their functional properties used in applications. In this section we, following [29], will discuss the behavioral peculiarities of nanocrystalline and

**Figure 4.** Grain boundary dislocations as misfit defects in nanocrystalline film.

polycrystalline films with grain boundary dislocations as misfit defects.

First, let us discuss a scenario for the formation of grain boundary dislocations as misfit defects. Nanocrystalline films are often synthesized at highly nonequilibrium conditions, in which case grain boundaries in these films are highly distorted and are characterized by misorientation parameters which, in general, vary along grain boundary planes. Each distorted boundary contains both the so-called “equilibrium” or, in other terms, intrinsic grain boundary dislocations (which provide the mean misorientation characterizing the boundary) and “nonequilibrium” or extrinsic grain boundary dislocations (which provide local deviations of the distorted boundary misorientation from its mean value) (Fig. 5) [16–19]. Nonequilibrium dislocations in a grain boundary, after some relaxation time interval, disappear via entrance to a free surface of a sample and/or via annihilation of dislocations with opposite Burgers vectors (Fig. 5a). As a result of the relaxation processes discussed, a distorted grain boundary commonly transforms into its equilibrium state with the misorientation being (tentatively) constant along the boundary plane.

**Figure 5.** “Equilibrium” and “nonequilibrium” dislocations (shown as open and solid dislocation signs, respectively) in distorted and low-energy grain boundaries. (a) “Nonequilibrium” dislocations completely disappear after relaxation. (b) Some “nonequilibrium” dislocations keep existing as misfit defects (compensating for misfit stresses generated at interphase boundary shown as dotted line) after relaxation.

However, the relaxation processes result in complete disappearance of nonequilibrium grain boundary dislocations in materials with initially distorted grain boundaries, only if there are not sources of long-range stresses affecting evolution of defects in the grain boundary phase (Fig. 5a). In nanocrystalline films with initially distorted grain boundaries, the misfit stresses (generated at film/substrate interfaces) influence evolution of nonequilibrium dislocations. More precisely, we expect that the low-energy (equilibrium) state of a nanocrystalline film corresponds to the existence of not only equilibrium grain boundary dislocations, but also some residual nonequilibrium grain boundary dislocations that play the role of misfit defects (Figs. 4 and 5b) compensating for misfit stresses in the film. In other words, in the framework of the scenario discussed, fabrication of nanocrystalline films at nonequilibrium conditions produces high-density ensembles of nonequilibrium grain boundary dislocations, while misfit stresses generated at interphase (film/substrate) boundaries cause some nonequilibrium grain boundary dislocations to keep existing, even after relaxation, as misfit defects compensating for these misfit stresses (Fig. 5b).

In general, the most spatially homogeneous distribution of misfit dislocations is characterized by the minimal elastic energy density and, therefore, is most stable. Grain boundary dislocations commonly are characterized by Burgers vectors being essentially lower than those of perfect misfit dislocations being crystal lattice dislocations. This specific feature allows grain boundary dislocations to be more homogeneously distributed along an interphase boundary as compared with perfect misfit dislocations, if the sum Burgers vectors of ensembles of misfit, grain boundary and perfect, dislocations are the same per unit of the boundary plane area. As a corollary, the existence of grain boundary dislocations as misfit dislocations often is more energetically favorable than that of perfect misfit dislocations [19]. This statement is supported by data of experiments dealing with measurements of residual stresses in nanocrystalline films and coatings. So, as it has been noted in [42], residual stresses are low in nanocrystalline cermet coatings (fabricated by thermal spray methods at highly nonequilibrium conditions), resulting in a capability for producing very thick coatings. So, nanocrystalline coatings were fabricated up to 0.65 cm thick and could probably be made with arbitrary thickness [42]. At the same time, in a conventional polycrystalline cermet coating, stress buildup limits coating thickness to typically 500–800  $\mu\text{m}$ . This is naturally explained as caused by a misfit stress relaxation micromechanism (in the situation discussed, the formation of grain boundary misfit dislocations) which comes into play in nanocrystalline films and coatings, and is different from and more effective than the standard micromechanism, the formation of perfect misfit dislocations.

In general, as with ensembles of dislocations with identical Burgers vectors (Fig. 4), complicately arranged configurations of grain boundary dislocations with various Burgers vectors are capable of effectively contributing to accommodation of misfit stresses in nanocrystalline solids. In particular, following a theoretical model [43], dislocation dipoles at grain boundaries can play the role of misfit defect configurations. This statement is indirectly supported by the

experimentally detected fact that misfit dislocation dipoles exist in a single crystalline GaInP film deposited onto a GaAs substrate [44].

## 5. MISFIT DISCLINATIONS AT GRAIN BOUNDARIES IN NANOCRYSTALLINE FILMS AND COATINGS

Parallel with nonequilibrium dislocations and their configurations, the so-called grain boundary disclinations (rotational defects) are generated in nanocrystalline materials fabricated at highly nonequilibrium conditions [18, 45]. Such disclinations, after some relaxation time interval, annihilate in the absence of sources of long-range stresses affecting the grain boundary phase evolution. In nanocrystalline films containing grain boundary disclinations, the misfit stresses (generated at film/substrate interfaces) influence evolution of disclinations. More precisely, in the general situation, the low-energy (equilibrium) state of a nanocrystalline film is expected to correspond to the existence of not only some residual nonequilibrium dislocations, but also some residual grain boundary disclinations that play the role of misfit defects (Fig. 6). In this section we, following theoretical models [29, 46], will briefly discuss the behavioral peculiarities of nanocrystalline films with grain boundary disclinations as misfit defects.

So, relaxation of misfit stresses through the formation of misfit disclinations (defects of the rotational type) (Fig. 6) [29, 46] is an alternative to the formation of misfit dislocation rows (Fig. 2b). The effective action of the disclination micromechanism for stress relaxation has been experimentally detected in semiconducting polycrystalline films [47–49]. Also, the disclination relaxation micromechanism is capable of effectively contributing to relaxation of residual stresses in crystalline films deposited on amorphous substrates (see a theoretical model [50]) as well as diverse nanocrystalline and polycrystalline films [51–55]. Owing to the presence of the grain boundary phase in nanocrystalline films, disclinations at grain boundaries play the role as misfit disclinations in such films (Fig. 6). The specific feature of the disclination micromechanism for relaxation of misfit stresses in nanocrystalline films is that cores of grain boundary disclinations playing the role as misfit defects are located at existent grain boundaries (either at boundaries in film interior or at junctions of interphase and grain boundaries) and, therefore, do not induce any extra violations of the interphase boundary structure. The disclination micromechanism for relaxation of misfit stresses is of particular importance in nanocrystalline films, because of the fact that grain

**Figure 6.** Grain boundary dislocations and disclinations as misfit defects in nanocrystalline film.

boundary disclinations are intensively generated in nanocrystalline materials synthesized at highly nonequilibrium conditions (see, e.g., [45]) and because of extremely high volume fraction of the grain boundary phase in nanocrystalline films.

Following [46], let us consider a model composite system consisting of a thin nanocrystalline film of thickness  $h$  deposited onto a semifinite substrate (Fig. 7). The film and substrate are assumed to be isotropic solids having the same values of the shear modulus  $G$  and the same values of the Poisson ratio  $\nu$ . Interphase (film/substrate) boundary is a semicoherent interface which induces misfit stresses and contains misfit disclinations at junctions of grain boundaries and the interface. For simplicity, misfit disclinations are assumed to be arranged periodically (Fig. 7) and to be characterized by identical value,  $\omega$ , of the disclination strength.

In the framework of the model discussed, Kolesnikova et al. [46] have calculated the basic characteristics (stored elastic energy density, equilibrium residual strain, critical values of film thickness) of a film with misfit disclinations. According to these calculations, the difference,  $\Delta E = E_{discl} - E_{coher}$ , between the energy densities of the interphase boundary with misfit disclinations and the coherent interphase boundary is as follows:

$$\Delta E = \frac{G}{4\pi(1-\nu)} \omega^2 l \Phi \left( \frac{h}{l} \right) - \frac{G}{(1-\nu)} \omega f \frac{h^2}{l} \quad (1)$$

where  $h$  denotes the film thickness,  $l$  the distance between neighboring disclinations (or, in other words, period of the misfit disclination array),  $G$  the shear modulus,  $\nu$  the Poisson ratio,  $f$  the misfit parameter (defined as  $f = 2(a_2 - a_1)/(a_1 + a_2)$ , with  $a_1$  and  $a_2$  being the crystal lattice parameters of the substrate and the film, respectively),

$$\begin{aligned} \Phi = \int_{-\tilde{h}}^0 \left[ \frac{1}{2} \ln \frac{\cosh 2\pi(\tilde{x} + \tilde{h}) - 1}{\cosh 2\pi(\tilde{x} - \tilde{h}) - 1} \right. \\ + \pi(\tilde{x} + \tilde{h}) \frac{\sinh 2\pi(\tilde{x} + \tilde{h})}{\cosh 2\pi(\tilde{x} + \tilde{h}) - 1} \\ - \pi(\tilde{x} + 3\tilde{h}) \frac{\sinh 2\pi(\tilde{x} - \tilde{h})}{\cosh 2\pi(\tilde{x} - \tilde{h}) - 1} \\ \left. - 4\pi^2 \tilde{x} \tilde{h} \frac{1}{\cosh 2\pi(\tilde{x} - \tilde{h}) - 1} \right] (\tilde{x} + \tilde{h}) d\tilde{x} \quad (2) \end{aligned}$$

If  $\Delta E < 0$  ( $> 0$ , respectively), the formation of misfit disclinations at the interphase boundary (Fig. 7) is energetically favorable (unfavorable respectively).

From Eq. (1) it follows that the characteristic energy of difference  $\Delta E$  depends on four parameters of the film with misfit disclinations at the interphase boundary: disclination strength  $\omega$ , the misfit parameter  $f$ , the film thickness  $h$ ,

**Figure 7.** Model of interphase boundary with misfit disclinations.

and the distance  $l$  between neighboring disclinations. Analysis [46] of the relationships (given by Eqs. (1) and (2)) between  $\Delta E$ ,  $\omega$ ,  $f$ ,  $h$ , and  $l$  shows the following. The critical thickness for generation of misfit disclinations in nanocrystalline (and polycrystalline) films is 0, if disclination strength ranges from 0 to some value  $\omega_0$  denoted as the optimum disclination strength. More precisely, the formation of misfit disclinations is more energetically favorable ( $\Delta E < 0$ ) than the coherent state of the interphase boundary at any value of the film thickness, below some value  $h_0$  denoted as the optimum thickness. (It is contrasted to the situation with “conventional” misfit dislocations (see, e.g., [24–27]) whose formation in a thin film is energetically favorable compared to the coherent state, only if the film thickness exceeds some critical value.) As a corollary, the discussed micromechanism for relaxation of misfit stresses—generation of misfit disclinations at grain boundaries (Fig. 6)—serves as an effective alternative to the standard micromechanism—generation of misfit dislocations (Fig. 2b)—in nanocrystalline films characterized by low values of film thickness, in particular, in films with nanoscaled thickness. The effective action of the disclination micromechanism for relaxation of misfit stresses in nanocrystalline films can be responsible for the experimentally observed fact that residual stresses are low in nanocrystalline cermet coatings synthesized by thermal spray methods (see discussion in [42] and Section 4).

## 6. PARTIAL MISFIT DISLOCATIONS IN NANOSCALE FILMS

Now let us turn to a discussion of interfacial defects at plane interphase boundaries between nanoscale single crystalline films and substrates (Fig. 1a). One of the structural features of nanoscale films is the experimentally observed [56–60] enhanced formation of partial misfit dislocations (associated with stacking faults) at film/substrate boundaries. In this section we, following [41, 61], consider a model describing generation and evolution of configurations of partial misfit dislocations associated with V-shaped stacking faults in nanolayer/substrate composites.

In general, misfit dislocations formed at film/substrate interfaces are either perfect (Fig. 2b) or partial (Fig. 8). Perfect misfit dislocations are characterized by Burgers vectors being crystal lattice vectors and just locally, at dislocation line cores, violate the ideal crystalline structure; see, for example, [23–29] (Fig. 2b). Partial misfit dislocations are characterized by Burgers vectors that commonly are lower than crystal lattice vectors and have line cores which bound plane stacking faults, in which case the ideal crystalline structure is violated at both line cores and plane stacking faults; see, for example, [56–60] (Fig. 8). In most situations the formation of perfect misfit dislocations is more energetically favorable compared to partial misfit dislocations. Therefore, the perfect misfit dislocations are the traditional subject of theoretical and experimental studies. However, there are also film/substrate systems in which the enhanced formation of partial misfit dislocations is experimentally detected [56–60]. Following theoretical analysis [41, 61], the formation of partial misfit dislocations associated with V-shaped stacking faults is energetically favorable in

**Figure 8.** Configurations of partial misfit dislocations in nanolayer/substrate composites: (a) single partial misfit dislocations associated with V-shaped stacking faults; and (b) complicatedly arranged configurations of partial misfit dislocations.

film/substrate systems characterized by low (nanoscale) values of film thickness and large misfit between crystal lattice parameters of the film and substrate. This statement (directly supported by experimental data [60]) is highly interesting due to rapidly growing industrial needs in technologies exploiting nanofilm/substrate systems characterized by large misfit parameters.

Let us consider both generation and evolution of complicatedly arranged configurations of partial misfit dislocations, namely the experimentally observed [60] configurations each consisting of three partial misfit dislocations located at respectively the top line and the two edge lines that bound a V-shaped stacking fault in a film (Fig. 8b). In the limiting case where the partial misfit dislocations located at the edge lines of the stacking fault reach the film free surface, the complicatedly arranged configuration (Fig. 8b) transforms into a simple configuration consisting of one partial misfit dislocation at top of the V-shaped stacking fault, that connects the film free surface and the film/substrate boundary (Fig. 8a). Such simple configurations of partial misfit dislocations have been observed in experiments [59].

Let us consider characteristics of complicatedly arranged configurations of partial misfit dislocations (Fig. 8b) in heteroepitaxial (nanofilm/substrate) systems (for details, see [61]). In doing so, for definiteness, we will focus our consideration on partial misfit dislocations in heteroepitaxial systems GaAs/Si (001) that are interesting for applications. One of the important characteristics of a thin solid film is its critical thickness, defined as the thickness at which the formation of misfit dislocations in film/substrate system becomes energetically favorable; see, for example, [24–27]. In the situation discussed (Fig. 8b), the critical thickness  $h_c$  of a film is defined as the thickness at which the formation of one complicatedly arranged configuration of partial misfit dislocations is energetically favorable in the film.

Let us consider a model heteroepitaxial system consisting of an elastically isotropic semi-infinite crystalline substrate and an elastically isotropic thin film with thickness  $h$ . The shear modulus  $G$  and the Poisson ratio  $\nu$  are assumed to

be identical for the substrate and the film. For definiteness, hereinafter we confine our examination to the situation with one-dimensional misfit  $f = 2(a_2 - a_1)/(a_1 + a_2) > 0$ , where  $a_1$  and  $a_2$  are the crystal lattice parameters of the substrate and the film, respectively. In the initial state with a coherent interphase boundary, owing to the geometric mismatch between the crystalline lattices of the film and the substrate, the film is elastically uniformly distorted. It is characterized by the elastic strain  $\varepsilon = -f < 0$ .

Now let us turn to a consideration of the model heteroepitaxial system with a complicatedly arranged configuration of partial misfit dislocations (Fig. 8b). Let the “top” partial misfit dislocation be located at line  $(h, 0)$  which bounds the top of V-shaped stacking fault, and the partial misfit dislocations of the  $90^\circ$  type be located at lines  $(d, \pm s)$  that bound the edges of V-shaped stacking fault. Let the top misfit dislocation be characterized by Burgers vector  $\mathbf{b}$ , and the “lateral” misfit dislocations be characterized by Burgers vectors  $\mathbf{b}_{p1} = -\mathbf{b}_x - \mathbf{b}_y$  and  $\mathbf{b}_{p2} = \mathbf{b}_x - \mathbf{b}_y$ , respectively. For our further consideration, the lateral misfit dislocation at line  $(d, s)$  (line  $(d, -s)$ , respectively) can be effectively represented as the superposition of two edge dislocations with Burgers vectors  $\mathbf{b}_y$  and  $\mathbf{b}_x$  ( $-\mathbf{b}_x$ , respectively); see Figure 8b. The V-shaped stacking fault bounded by the top and lateral misfit dislocations (Fig. 8b) is characterized by top angle  $2\alpha$ .

According to calculations [61], the critical film thickness  $h_c$  at which the formation of a complicatedly arranged configuration of misfit dislocations (Fig. 8b) in a film becomes energetically favorable can be found from the following transcendental equation:

$$\begin{aligned}
& 2b_p^2 - 8\pi f(1 + \nu)(bh + 2b_y d) + \frac{8\pi\gamma(1 - \nu)(h - d)}{G \cos \alpha} \\
& + b^2 \left( 1 - \ln \frac{b}{2h - b} - \frac{2h(h - b)}{(2h - b)^2} \right) \\
& - 2bb_y \left( \ln \frac{(h - d)^2 + s^2}{(h + d)^2 + s^2} - \frac{2s^2}{(h - d)^2 + s^2} \right. \\
& \quad \left. + \frac{2(s^2 + 2dh)}{(h + d)^2 + s^2} - \frac{8dhs^2}{[(h + d)^2 + s^2]^2} \right) \\
& + 2bb_x s \left( \frac{2(h - d)}{(h - d)^2 + s^2} - \frac{2(h - d)}{(h + d)^2 + s^2} \right. \\
& \quad \left. - \frac{8dh(h + d)}{[(h + d)^2 + s^2]^2} \right) - \frac{4b_x b_y s d^3}{(d^2 + s^2)^2} \\
& - b_y^2 \left( \ln \frac{b_y^2 s^2}{(d^2 + s^2)(2d - b_y)^2} + \frac{4d(d - b_y)}{(2d - b_y)^2} \right. \\
& \quad \left. - \frac{d^2(d^2 + 3s^2)}{(d^2 + s^2)^2} \right) \\
& - b_x^2 \left( \ln \frac{b_x^2(d^2 + s^2)}{s^2(2d - b_x)^2} + \frac{4d(d - b_x)}{(2d - b_x)^2} \right. \\
& \quad \left. - \frac{d^2(3d^2 + s^2)}{(d^2 + s^2)^2} \right) = 0 \tag{3}
\end{aligned}$$

where  $\gamma$  is the stacking fault energy density (per unit area). Equation (3) allows one to analyze relationships between characteristics (critical thickness, misfit parameter)

of nanofilm/substrate composites with perfect misfit dislocations (Fig. 2b), single partial misfit dislocations associated with V-shaped stacking faults (Fig. 8a), and complicatedly arranged configuration of partial misfit dislocations (Fig. 8b).

In particular, theoretical analysis [61] based on Eq. (3) shows the following. The formation of perfect misfit dislocations is energetically favorable in composites with comparatively small values of misfit parameter ( $f < 0.1$ ). At the same time, during growth of the films (nanolayers) with comparatively large values of misfit parameter (tentatively  $f > 0.01$ ), the formation of single partial misfit dislocations is energetically favorable, if the film thickness  $h$  is in the range  $h_c < h < h'_c$ . In the situation discussed, when the film thickness  $h$  exceeds the critical value  $h'_c$  (which commonly is in the range of a few nanometers and decreases with increase of misfit parameter  $f$ ), single partial misfit dislocations associated with V-shaped stacking faults (Fig. 8a) transform into complicatedly arranged configurations of partial misfit dislocations (Fig. 8b). Further growth of the film thickness leads to the merging of the three partial misfit dislocations (elements of a complicatedly arranged configuration) into a perfect misfit dislocation at the interphase (film/substrate) boundary, in which case the stacking fault disappears.

The statement that partial misfit dislocations transform into perfect misfit dislocations during growth of films, resulted from theoretical analysis [61], is in agreement with experimental data [60]. These data are indicative of the fact that the density of perfect misfit dislocations increases and the density of partial misfit dislocations decreases with increase of film thickness.

It should be noted that, according to theoretical analysis [34], the generation of partial misfit dislocations effectively competes with that of conventional perfect dislocations also in germanium pyramid-like quantum dots (nanoisland films) on silicon substrate. In doing so, different partial dislocation structures are energetically preferred in different regions of the interface. Single partial dislocation is generated near lateral free surface of a nanoisland. Then, during its motion towards the nanoisland base center, the second partial dislocation is generated [34].

## 7. GRAIN BOUNDARY DISLOCATIONS AND ENHANCED DIFFUSION IN NANOCRYSTALLINE BULK MATERIALS

Let us turn to a discussion of interfacial defects and their effects on physical processes occurring in bulk nanocrystalline materials. In this section, we consider grain boundary defects and their role in diffusion processes in bulk nanocrystalline materials. Diffusion properties of bulk nanocrystalline materials, in general, are different from those of conventional coarse-grained polycrystals. Thus, following [62–66], bulk nanocrystalline materials exhibit the anomalously enhanced diffusion. For instance, the boundary diffusion coefficients in bulk nanocrystalline materials fabricated by high-pressure compaction and severe plastic deformation methods are several orders of magnitude larger than those in conventional polycrystalline materials with the

same chemical composition [62–66]. With these experimental data, the anomalously fast diffusion is treated as the phenomenon inherent to only nanocrystalline materials and is attributed to their specific structural and behavioral peculiarities [8, 62]. At the same time, however, there are experimental data indicating that the boundary diffusion coefficients in dense bulk nanocrystalline materials are lower than those measured in [62, 64–66] and similar to the boundary diffusion coefficients in conventional coarse-grained polycrystals or a little higher [67–71]. These data form a basis for the viewpoint that the atomic diffusion in nanocrystalline materials is similar to that in conventional coarse-grained polycrystals. In doing so, the difference in the diffusivities between nanocrystalline and coarse-grained materials is treated to be related to only the difference in the volume fraction of the grain boundary phase.

Thus, in general, there are controversial experimental data and theoretical representations of diffusion processes in nanocrystalline materials. Nevertheless, mechanically synthesized nanocrystalline bulk materials are definitely recognized to exhibit enhanced diffusion properties compared to those of nanocrystalline materials fabricated by nonmechanical (more equilibrium than mechanical) methods and those of coarse-grained polycrystals; see [64–66]. The experimentally documented phenomenon in question can be naturally explained as that occurring due to the deformation-induced nonequilibrium state of grain boundaries, in which case the grain boundary diffusivity highly increases. In this section we will consider theoretical models of diffusion processes in nanocrystalline materials with special attention being paid to the role of extrinsic defects at nonequilibrium grain boundaries in the diffusion enhancement occurring in mechanically synthesized nanocrystalline bulk materials.

Theoretical models of diffusion in nanocrystalline materials can be divided into the three following basic categories: (1) Models that describe grain boundary diffusion in conventional coarse-grained polycrystals and are directly extended to the situation with nanocrystalline materials, with nanoscale effects neglected. (2) Models focused on the specific features of diffusion in nanocrystalline materials in the general situation, taking into account the nanoscale effects, but neglecting the influence of preparation technologies on the structure and the diffusion properties of nanocrystalline materials. In short, such models deal with the “nanostructure-diffusion” relationship. (3) Models focused on the structural and behavioral peculiarities of grain boundaries in nanocrystalline materials, taking into account the peculiarities of their fabrication. In short, such models are concerned with the “preparation-nanostructure-diffusion” relationship.

Theoretical models of the first type and their applications to a description of diffusion in nanocrystalline materials have been reviewed in detail by Larikov [72]. Such models are, in particular, those [73–77] describing spatial distributions of diffusion species within and near grain boundaries in polycrystals, models [78–86] focused on macroscopic mechanisms of grain boundary diffusion, and models [87–94] dealing with diffusion-assisted processes (diffusional creep, diffusion-induced grain boundary migration, transformations of grain boundary dislocations and disclinations, etc.) in polycrystals. Now let us turn to a brief discussion of models

describing the enhanced diffusion in nanocrystalline materials in the general situation, with the specific features of their preparation being neglected. In [95, 96] it has been demonstrated that nanocrystalline materials exhibit much larger variety of possible kinetic diffusion regimes compared to coarse-grained polycrystals. In particular, together with conventional A-, B-, and C-regimes occurring in polycrystals [77], the additional diffusion kinetic regimes have been distinguished, depending on the grain size, diffusion temperature and time, the grain boundary segregation level in the case of impurity diffusion, and other parameters [96].

Gleiter [62] considered the anomalously fast diffusion in nanocrystalline materials as the phenomenon related to the three following factors: (i) The diffusion in nanocrystalline materials is essentially enhanced due to the existence of high-density network of grain boundary junction tubes which commonly are characterized by more increased diffusion rate than grain boundaries themselves. (The highly enhanced diffusivity of triple junctions of grain boundaries is experimentally identified in polycrystals; see [97–102] and discussion in review article [9] concerning grain boundary junctions.) (ii) Rigid body relaxation of grain boundaries that occurs via relative translational displacements of their adjacent crystallites and reduces the boundary free volume is hampered in nanocrystalline materials. This is related to the fact that rigid body relaxations of the various boundaries surrounding every nanocrystallite require its different displacements due to their different atomic structure. (iii) In grain boundaries of nanocrystalline materials, the concentration of impurities that often reduce boundary diffusivity is lower than that in grain boundaries in conventional polycrystals.

Let us discuss factors (i)–(iii) in terms of Arrhenius formula for diffusivity in solids. The coefficient  $D$  of self-diffusion occurring via transfer of vacancies<sup>2</sup> is given by the following Arrhenius relationship (e.g., [86])

$$D = D_0 \exp[-(\varepsilon_f + \varepsilon_m)/kT] \quad (4)$$

where  $D_0$  denotes the constant dependent on parameters of the ideal crystalline lattice,  $k$  the Boltzmann's constant,  $T$  the absolute temperature,  $\varepsilon_f$  and  $\varepsilon_m$  the energies of respectively formation and migration of vacancies. In nanocrystalline materials (characterized by extremely high volume fraction of the grain boundary phase), self-diffusion processes occur mostly via transfer of grain boundary vacancies. In these circumstances, all the factors (i)–(iii) discussed by Gleiter [62] induce the characteristic boundary free volume to be increased and, as a corollary, both formation and migration of boundary vacancies to be facilitated in nanocrystalline materials as compared to those in conventional polycrystals. In terms of Arrhenius formula (4), the diffusion coefficient  $D$  is increased in nanocrystalline materials, because their characteristic energies,  $\varepsilon_f$  and  $\varepsilon_m$ , are decreased due to factors (i)–(iii) discussed in [62].

Now let us discuss theoretical models describing the enhanced diffusion in nanocrystalline materials fabricated

<sup>2</sup> In general, diffusion processes in crystals occur via transfer of point defects of different types. However, self-diffusion occurring via transfer of vacancies is most effective; it is characterized by the largest coefficient of diffusion, e.g., [86, 103].

at highly nonequilibrium conditions (say, by severe plastic deformation methods). Following [104–107], together with factors (i)–(iii) discussed by Gleiter [62], the existence and transformations of ensembles of grain boundary dislocations and disclinations strongly enhance diffusion processes in nanocrystalline materials fabricated at highly nonequilibrium conditions. The effects of such defects on diffusion are briefly as follows [106, 107]:

(a) Disorderedly distributed grain boundary dislocations and disclinations are formed in nanocrystalline materials fabricated at highly nonequilibrium conditions. Such dislocations and disclinations rearrange to annihilate or to form more ordered, low-energy configurations, in which case they move to new positions. Climb of (grain boundary) dislocations is accompanied by generation of new point defects [103, 108]—vacancies and interstitial atoms—serving as new carriers of diffusion. In this situation, generation of new vacancies at grain boundaries occurs under the action of the driving force related to a release of the elastic energy of “nonequilibrium” or, in other words, extrinsic grain boundary dislocations during their transformations. The action of the driving force in question facilitates diffusion processes in nanocrystalline materials. The effect discussed is quantitatively described by Eq. (4) with the sum  $\varepsilon_f + \varepsilon_m$  being replaced by  $\varepsilon_f - W_v + \varepsilon_m$ , where  $W_v (>0)$  is the energy release due to the climb of a grain boundary dislocation, per one vacancy emitted by the dislocation.

(b) Cores of grain boundary dislocations and disclinations are characterized by excess free volume, in which case their presence in grain boundaries increases the total free volume that characterizes the grain boundary phase in nanocrystalline materials. This decreases values of  $\varepsilon_f$  and  $\varepsilon_m$  and, therefore, enhances diffusion processes occurring by vacancy mechanism.

(c) Dilatation stress fields of grain boundary dislocations and disclinations influence migration of vacancies. More precisely, in spirit of the theory of diffusion in stressed solids [109], the elastic interaction between vacancies and grain boundary dislocations and disclinations is characterized by the energy

$$\varepsilon_{int} = -\sigma_{ii}\Delta V/3 \quad (5)$$

where  $\sigma_{ii}$  denotes the sum of dilatation components (say, components  $\sigma_{xx}$ ,  $\sigma_{yy}$ , and  $\sigma_{zz}$  written in  $(x, y, z)$ -coordinates) of stress fields created by grain boundary defects, and  $\Delta V$  the excess free volume associated with a vacancy. To minimize  $\varepsilon_{int}$ , vacancies migrate to regions where compressive stresses exist. This vacancy migration contributes to the enhanced diffusion in nanocrystalline materials. The effect discussed is quantitatively described by Eq. (4) with the sum  $\varepsilon_f + \varepsilon_m$  being replaced by the sum  $\varepsilon_f + \varepsilon_m + \varepsilon_{int}$ .

Thus, the factor (a) gives rise to the diffusion enhancement owing to the influence of grain boundary dislocations on the generation of vacancies. The factors (b) and (c) facilitate the vacancy migration and therefore, cause the diffusion enhancement in nanocrystalline materials. According to the theoretical analysis [106], the most essential contribution to the diffusion enhancement is due to the dislocation climb in grain boundaries (see factor (a)). With this taken into

account, below we will consider the effects of grain boundary dislocations on diffusion in nanocrystalline materials, with focuses placed on the climb of grain boundary dislocations composing dipole configurations.

Nanocrystalline materials are effectively fabricated by mechanical methods at highly nonequilibrium conditions (see, e.g., [19–22, 110]), in which case “nonequilibrium” or, in other words, extrinsic defect structures are formed at grain boundaries (Fig. 5a). During some relaxation time interval after mechanical synthesis of a nanocrystalline sample, extrinsic grain boundary dislocations with opposite Burgers vectors move (climb and glide) to each other and annihilate, and the geometrically necessary dislocations move (climb and glide) to their equilibrium positions (Fig. 5a).

The climb of grain boundary dislocations during the relaxation time interval is accompanied by both emission and absorption of point defects: vacancies and interstitial atoms. In these circumstances, emission of vacancies (“take-off” of vacancies from dislocation cores and their consequent displacement into the surrounding grain boundary phase) is more intensive than that of interstitial atoms, because vacancies are essentially more mobile compared to interstitial atoms [103]. Also, it should be noted that absorption of vacancies, which accompanies the climb of grain boundary dislocations, needs vacancies to permanently move to dislocation cores from a surrounding material, while emission of vacancies is not related to such a restrictive condition. As a corollary, emission of vacancies occurs more intensively than absorption of vacancies and absorption of slow interstitial atoms. With the aforesaid taken into account, in the following we will focus our consideration on the effects of only those processes of grain boundary dislocation climb that are accompanied by emission of vacancies.

The largest contribution to energy of “nonequilibrium” defect structures at grain boundaries commonly is related to the existence of extrinsic grain boundary dislocations. Therefore, climb and annihilation of such dislocations, which are accompanied by emission of vacancies, are characteristic processes of relaxation of grain boundaries in nanocrystalline materials.

Let us discuss the effect of dislocation-climb-induced emission of vacancies on diffusion in nanocrystalline materials. The coefficient of diffusion occurring via vacancy mechanism (which commonly is most effective) in the absence of extrinsic grain boundary defects is given by Eq. (4), where factor  $\exp(-\varepsilon_f/kT)$  characterizes equilibrium concentration of vacancies (when dislocation climb and dilatation stresses do not influence vacancy formation). The vacancy concentration in vicinity of the climbing dislocations (Fig. 9) is higher than the equilibrium concentration, because vacancy formation is facilitated due to the climb of dislocations. The effect in question is quantitatively described by the following change of the vacancy formation energy:  $\varepsilon_f \rightarrow \tilde{\varepsilon}_f = \varepsilon_f - W_v$  and by the corresponding local change of diffusion coefficient:  $D \rightarrow D^*$ . Here  $W_v(\lambda)$  is the decrease of the dislocation dipole energy  $W$  due to emission of one vacancy, related to the climb of the dislocations composing the dipole, and  $D^*$  in vicinity of the climbing dislocations (Fig. 9) is given as

$$D^* = D \exp\left(\frac{W_v}{kT}\right) \quad (6)$$

**Figure 9.** Climb and annihilation of grain boundary dislocations composing dipole configuration.

Following [106, 107], the energy decrease  $W_v(\lambda)$  is

$$W_v(\lambda) = \frac{a}{d} \Delta W(\lambda) = \frac{a}{d} (W(\lambda) - W(\lambda - a)) \quad (7)$$

for  $\lambda > 2a$ , and

$$W_v(\lambda) = \frac{Gb^2 a (\ln 2 + Z)}{4\pi(1 - \nu)} \quad (8)$$

for  $\lambda \leq 2a$ . With the dependence  $W_v(\lambda)$  given by Eqs. (7) and (8), for  $G = 50$  GPa,  $a \approx 0.3$  nm,  $b \approx a/3$ ,  $Z \approx 1$ , and  $\nu \approx 1/3$ , let us estimate the diffusion coefficient in vicinity of the climbing dislocations. In doing so, with factor  $\exp(W_v/kT)$  averaged on  $\lambda$  (ranging from 0 to  $10a$ ), we find that  $D^* \approx 300D$ .

In nanocrystalline materials during relaxation time interval (after synthesis at highly nonequilibrium conditions, say, after fabrication by severe plastic deformation method), almost all grain boundaries contain nonequilibrium defect structures, in particular, extrinsic dislocations whose annihilation enhances diffusion. In this situation,  $D^*$  plays the role of grain boundary diffusion coefficient in nanocrystalline materials fabricated at highly nonequilibrium conditions. To summarize, estimations [106, 107] allow us to conclude that the climb of grain boundary dislocations (Fig. 9) essentially enhances diffusion processes in nanocrystalline materials (in particular, nanocrystalline materials fabricated by severe plastic deformation), causing increase of the grain boundary diffusion coefficient by about two orders. Thus, the climb of grain boundary dislocations is capable of strongly contributing to the experimentally observed (see [63–66]) anomalously fast diffusion in nanocrystalline materials during some relaxation time interval after their synthesis at highly nonequilibrium conditions.

Following [104–107], the elastic interactions between the diffusing species and grain boundary dislocations and disclinations (see point (c)) facilitate migration of vacancies and impurities, causing the diffusion enhancement in vicinities of grain boundaries. In this situation, the diffusion rate is increased by factor  $M \sim 1 \div 5$  in vicinities of grain boundaries. The effect discussed is small compared to that related to the climb of grain boundary dislocations.

Thus, there are controversial experimental data and theoretical representations on diffusion processes in nanocrystalline materials. At the same time, diffusion in mechanically synthesized bulk nanocrystalline materials is definitely recognized as the strongly enhanced diffusion compared to

that in coarse-grained polycrystals and nanocrystalline materials fabricated by nonmechanical (more equilibrium than mechanical) methods. This experimentally documented phenomenon is naturally explained as that occurring due to the deformation-induced nonequilibrium state of grain boundaries, in which case extrinsic grain boundary dislocations strongly enhance the boundary diffusivity.

## 8. INTERFACIAL DEFECTS AND DEFORMATION MECHANISMS IN NANOCRYSTALLINE BULK MATERIALS

Nanocrystalline materials exhibit the unique mechanical behavior due to nanoscale and interface effects; see, for example, [111–113]. High-density ensembles of grain boundaries in nanocrystalline materials serve as effective obstacles for lattice dislocation slip which dominates in coarse-grained polycrystals. In addition, the image forces acting in nanometer-sized grains cause the difficulty in forming lattice dislocations in such nanograins [114, 115]. In these circumstances, the grain refinement hampers the lattice dislocation slip. At the same time, grain boundaries provide the effective action of alternative deformation mechanisms occurring via motion of grain boundary defects. As a corollary, the grain refinement leads to the competition between the lattice dislocation slip and deformation mechanisms associated with the active role of grain boundaries. It is believed that nanocrystalline matter represents the arena for the discussed competition which causes unique mechanical properties of nanocrystalline materials [116–125]. In this context, identification of effective deformation mechanisms and their contributions to plastic flow is very important for understanding the fundamentals of the mechanical behavior of nanocrystalline materials as well as development of technologies based on plastic forming of nanostructures.

The deformation mechanisms in nanocrystalline materials, in many cases, cannot be unambiguously identified with the help of contemporary experimental methods, because of high precision demands on experiments at the nanoscale. Therefore, theoretical modeling of defects and plastic deformation processes is a very important constituent of both fundamental and applied research of nanostructured materials. In this section, we briefly review theoretical models of deformation mechanisms and grain boundary defects being carriers of plastic flow in nanocrystalline materials with focuses placed on new deformation modes.

Let us consider plastic deformation mechanisms in nanocrystalline materials. The specific deformation behavior of nanocrystalline materials, in particular, is exhibited in the so-called abnormal Hall–Petch effect which manifests itself as the softening of a material with reduction of the grain size  $d$  [111–113]. The most theoretical models relate the abnormal Hall–Petch dependence to the competition between deformation mechanisms in nanocrystalline materials; for example, [116–125]. In the framework of this approach, deformation mechanisms associated with the active role of grain boundaries dominate over conventional lattice dislocation motion in nanocrystalline materials, in which case the grain refinement leads to a softening of a material. In doing so, generally speaking, standard and new deformation

mechanisms associated with the active role of grain boundaries can contribute to plastic flow in nanocrystalline materials. The standard deformation mechanisms are the grain boundary sliding and Coble creep related to enhanced diffusional mass transfer along grain boundary planes [116–123]. This idea is originated, in fact, from the classical theory of creep and superplasticity of microcrystalline materials where these mechanisms play the essential role; see, for example, [126, 127]. We think that, together with these two standard deformation mechanisms associated with the active role of grain boundaries, nonconventional (new) deformation mechanisms are capable of effectively contributing to plastic flow in nanocrystalline bulk materials and coatings. In particular, such specific deformation mechanisms are creep associated with enhanced diffusion along triple junctions of grain boundaries [124] and rotational deformation mode [128, 129].

First, let us consider the triple junction diffusional creep. In general, in recent years, triple junctions of grain boundaries have been recognized as defects with the structure and properties being essentially different from those of grain boundaries that they adjoin [9]. For instance, from experimental data and theoretical models it follows that triple junctions play the role of enhanced diffusion tubes [97–99, 102], nuclei of the enhanced segregation of the second phase [100, 130], strengthening elements and sources of lattice dislocations [114–116, 131–133] during plastic deformation, and drag centers of grain boundary migration during recrystallization processes [134, 135]. Also, as it has been shown in experiments [98], creep associated with enhanced diffusion along triple junctions contributes to plastic flow of coarse-grained polycrystalline aluminum. Actually, since triple junction diffusion coefficient  $D_{ij}$  highly exceeds grain boundary diffusion coefficient  $D_{gb}$  [97–99, 102], enhanced diffusional mass transfer along triple junction tubes occurs under mechanical stresses and contributes to plastic forming of a mechanically loaded material. The contribution in question is characterized by a rather specific dependence of plastic strain rate on grain size  $d$ . More precisely, grain size exponent is  $-4$  in this case [98], in contrast to grain boundary diffusional creep (Coble creep) and bulk diffusional creep characterized by grain size exponents  $-3$  and  $-2$ , respectively:

$$\dot{\epsilon}_{ij} \propto D_{ij} \cdot d^{-4} \quad (9)$$

$$\dot{\epsilon}_{gb} \propto D_{gb} \cdot d^{-3} \quad (10)$$

$$\dot{\epsilon}_{bulk} \propto D_{bulk} \cdot d^{-2} \quad (11)$$

Here  $\dot{\epsilon}_{ij}$ ,  $\dot{\epsilon}_{gb}$ , and  $\dot{\epsilon}_{bulk}$  are plastic strain rates that correspond to triple junction diffusional creep, grain boundary diffusional creep, and bulk diffusional creep, respectively.  $D_{bulk}$  denotes the bulk self-diffusion coefficient.

Fedorov et al. [124] suggested a theoretical model describing the yield stress dependence on grain size in fine-grained materials, based upon competition between conventional dislocation slip, grain boundary diffusional creep, and triple junction diffusional creep. It has been shown that the contribution of triple junction diffusional creep increases with

reduction of grain size, causing a negative slope of the Hall–Petch dependence in the range of small grains. The results of model [124] are compared with experimental data [136–140] from copper and shown to be in rather good agreement.

Now let us turn to a discussion of a rotational deformation mechanism in nanocrystalline materials. The primary carriers of the rotational plastic deformation in solids are believed to be dipoles of grain boundary disclinations [141]. A grain boundary disclination represents a line defect that separates two grain boundary fragments with different misorientation parameters (Fig. 10). That is, grain boundary misorientation exhibits a jump at disclination line. A disclination dipole consists of two grain boundary disclinations of opposite signs. Motion of a disclination dipole causes plastic deformation accompanied by crystal lattice rotation (Fig. 10). It is called the rotational deformation

**Figure 10.** Rotational deformation occurs through movement of a dipole of grain boundary disclinations. Grain boundary fragments separated by disclination of strength  $\omega$  are characterized by misorientation parameters  $\theta_2$  and  $\theta_1$ , where  $\omega = \theta_2 - \theta_1$ .

mode. Conventional electron microscopy experiments are indicative of the essential role of the rotational plastic flow in coarse-grained materials under high-strain deformation (for a review, see [142, 143]). It is supported also by experimental observation of grain rotations in superplastically deformed microcrystalline materials [127, 144].

The rotational deformation is capable of being very intensive in nanocrystalline materials [128]. Actually, the volume fraction of grain boundaries is extremely high in nanocrystalline materials, in which case grain boundary disclinations can be formed, roughly speaking, in every point of a mechanically loaded sample. In addition, the elastic energy of a disclination dipole rapidly diverges with increasing distance between disclinations [141]. Therefore, such dipoles are energetically permitted mostly for grain boundary disclinations that are close to each other. It is the case of nanocrystalline materials where the interspacings between neighboring grain boundaries are extremely small. Finally, nanocrystalline materials contain high-density ensembles of triple junctions where the crossover from the conventional grain boundary sliding to the rotational deformation effectively occurs. Murayama et al.'s atomic-level observation of disclination dipoles in deformed nanocrystalline materials [145] supports the theoretical statement [128] on the rotational deformation in nanostructures.

Thus, owing to interface and nanoscale effects in nanocrystalline materials, the set of deformation mechanisms in these materials is richer than that in conventional coarse-grained polycrystals. In particular, triple junction diffusional creep and the rotational deformation mode (Fig. 10) are capable of essentially contributing to plastic flow of nanocrystalline bulk materials and coatings. These deformation mechanisms should be definitely taken into account in further research of plastic flow processes in nanocrystalline materials, including the phenomenon of high-strain-rate superplasticity [146, 147].

## 9. NANODEFFECTS IN NANOSTRUCTURES

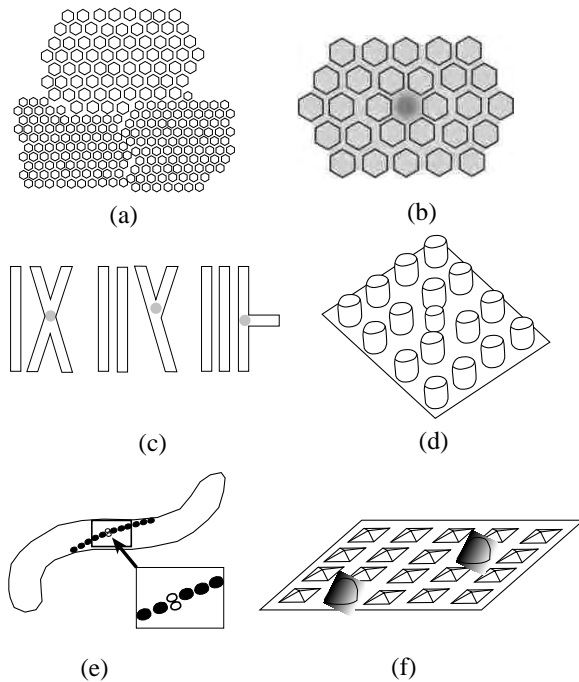

In this section, we will discuss the notion of nanodefects in ordered nanostructures, which extends the conventional notion of interfacial defects in solids. New physical, chemical, and biological properties are exhibited by ordered nanostructures that represent assemblies of crystallites with at least one characteristic size being on the order of a few nanometers [1–7]. Examples of such nanostructures are self-assembled ordered arrays of semiconductor quantum dots and wires [148–152], self-assembled ordered arrays of carbon nanotubes [153, 154], and nanoparticles embedded into organic matter [1–7, 155]. Their unique properties are due to the combined nanoscale, interface, and interaction effects. The nanoscale effect occurs because many fundamental processes in solids are associated with particular length scales being on the order of a few nanometers. The interface effect comes into play because a large fraction of atoms (up to 50%) of each nanosized crystallite are located at interfaces where their behavior is different from that in the bulk. The interaction between assembled nanosized crystallites causes

their unique collective properties which are more than just a sum of properties of individual crystallites.

Spatial arrangement of nanocrystallites and uniformity in their size and shape are among the most important issues for the combined nanoscale, interface, and interaction effects crucially affecting the functional properties of ordered nanostructures. In the first approximation self-assembled ordered nanostructures are commonly treated as regular, periodically ordered arrays of identical nanocrystallites, in which case a theoretical description of their properties is simplified. However, real self-assembled nanostructures, as it is well documented experimentally, are not regular. There are deviations of spatial positions, sizes, and shapes of their structural units from ideal ones. In addition, there are topological defects which violate nanoscale translational order inherent to self-assembled periodic nanostructures, similar to topological defects in conventional crystal lattices [155–160]. That is, symmetry of a periodically ordered nanostructure relative to translation by a period (being commonly on the order of nanometers) is locally violated by topological defects. Examples of such topological defects are interphase-boundary-like defects in ordered assemblies of two different sizes of CdSe nanoparticles [155] (Fig. 11a), vacancy-like defects in self-assembled superlattice films of FePt nanoparticles with partial chemical ordering [157] (Fig. 11b), carbon nanohorns [158], X-, Y-, and T-like junctions of carbon nanotubes [159] (Fig. 11c), interstitial-like defect in lithographically synthesized supramolecular pillar arrays in a thin polymer melt [160] (Fig. 11d), impurity-like defect (double crystal) in a chain of nanoparticles in magnetostatic bacteria [156] (Fig. 11e), impurity-like defects (dome nanoislands) in ordered arrays of pyramid quantum dots [148, 149] (Fig. 11f). With their generic definition as topological defects of nanoscale translational order inherent to nanostructures, we will call such defects nanodefects.

Nanodefects are formed during fabrication and processing of nanostructures at highly nonequilibrium conditions. In some cases, they are capable of strongly influencing the behavior of ordered nanostructures. For instance, the formation of impurity-like defects (dome nanoislands) in ordered arrays of pyramid quantum dots dramatically breaks uniformity of quantum dots in size and shape, giving rise to degradation of their functional characteristics highly desired for applications [148, 149]. In general, new properties of nanostructures may arise due to the presence of nanodefects. For instance, carbon nanotubes with such nanodefects as Y- and T-like junctions could act as multiterminal electronic devices [161].

Thus, the definition of nanodefects in ordered nanostructures as topological defects violating nanoscale periodic translational order inherent to nanostructures is generic for diverse nanostructures. Analysis of data in the literature shows that nanodefects are experimentally found in diverse periodically ordered nanostructures where they are capable of strongly influencing functional properties. Use of the notion of nanodefects may allow researchers involved in science and engineering of different nanostructures to share views and develop interdisciplinary ideas.

**Figure 11.** Nanodefects in ordered nanostructures (schematically). (a) Interphase-boundary-like defects in ordered assemblies of two different sizes of CdSe nanoparticles. (b) Vacancy-like defects in self-assembled superlattice films of FePt nanoparticles with partial chemical ordering. (c) X-, Y-, and T-like junctions of carbon nanotubes. (d) Interstitial-like defect in lithographically synthesized supramolecular pillar arrays in a thin polymer melt. (e) Impurity-like defect (double crystal) in a chain of nanoparticles in magnetostatic bacteria. (f) Impurity-like defects (dome nanoislands) in ordered arrays of pyramid quantum.

## 10. CONCLUDING REMARKS

Thus interfaces in nanostructured materials are characterized by the specific structural and behavioral features associated with generation and evolution of interfacial defects in these materials (see Sections 2 and 3). In particular, the elastic interaction between grain boundary defects and interphase boundaries in nanocrystalline film/substrate composites causes extrinsic grain boundary defects—dislocations and disclinations (Figs. 4–6)—to serve as misfit defects compensating for misfit stresses. The effective contribution of grain boundary defects to relaxation of misfit stresses in nanocrystalline films explains the experimentally documented (see discussion in [42]) fact that residual stresses are low in nanocrystalline coatings synthesized by thermal spray methods, compared to their coarse-grained counterparts.

One of the behavioral structural features of nanoscale single crystalline films (Fig. 1a) is the experimentally observed [56–60] enhanced formation of partial misfit dislocations associated with stacking faults. Partial misfit dislocations at interphase (film/substrate) boundaries (Fig. 8) transform into perfect misfit dislocations with increase of film thickness. This statement, resulted from theoretical analysis [61] (see also Section 6), is in agreement with experimental data [60] which are indicative of the fact that density of perfect

misfit dislocations increases and density of partial misfit dislocations decreases with increase of film thickness.

Diffusion in mechanically synthesized bulk nanocrystalline materials is definitely recognized as the strongly enhanced diffusion compared to that in coarse-grained polycrystals and nanocrystalline materials fabricated by nonmechanical (more equilibrium than mechanical) methods [64–66]. This experimentally documented phenomenon is naturally explained as that occurring due to the deformation-induced nonequilibrium state of grain boundaries, in which case transformations of extrinsic grain boundary dislocations strongly enhance the boundary diffusivity (see Section 7).

Owing to interface and nanoscale effects in nanocrystalline materials, the set of deformation mechanisms in these materials is richer than that in conventional coarse-grained polycrystals. In particular, triple junction diffusional creep and the rotational deformation mode (Fig. 10) are capable of essentially contributing to plastic flow of nanocrystalline bulk materials and coatings (see Section 8).

To summarize, the effects of interfacial defects should be definitely taken into account in experimental research and theoretical description of the structure and behavior of advanced nanostructured bulk materials and films. Identification and systematic study of these effects in nanostructures are important for both understanding the fundamentals of the combined nanoscale, interface, and interaction effects and development of current and novel technologies exploiting nanostructures.

## GLOSSARY

**Grain boundary disclinations** Disclinations—defects of rotational type—located at grain boundaries.

**Grain boundary dislocations** Dislocations located at grain boundaries.

**Misfit defects** Defects creating stresses that compensate for, in part, misfit stresses in films.

**Misfit stresses** Stresses occurring due to geometric mismatch at interphase boundaries between crystalline lattices of adjacent films and substrates.

**Nanodefects** Topological defects locally violating nanoscale translational order inherent to assembled periodic nanostructures.

**Rotational deformation mode** Plastic deformation accompanied by crystal lattice rotation in grain interiors.

## 1. INTRODUCTION

Nanostructured materials were first introduced as interfacial materials over two decades ago by Gleiter [1]. The main characteristic of these materials is the enhanced volume fraction of their interface component, namely, grain boundaries and triple junctions (*i.e.*, an intersection line of three or more grain boundaries), compared with their conventional polycrystalline counterparts. A three-dimensional study by Palumbo, Thorpe, and Aust [2], assuming a grain boundary thickness of 1 nm and a tetrakaidecahedron as the grain shape (and later generalized to any grain shape [3]), has shown that the grain boundary volume fraction increases rapidly from a few percent at a grain size of 100 nm to about 45% at a grain size of 3 nm, for example, Figure 1. For grain sizes below 20 nm, the triple junction volume fraction reaches significant values and exhibits greater grain size dependence than does the grain boundary volume fraction. Over the range of reasonable grain boundary thickness values, that is, 0.5 to 1.5 nm, the relative grain boundary and triple junction contributions to the volume fraction are

not significantly changed [4]. Several of the unusual properties observed for nanocrystalline materials, to be discussed herein, are directly associated with grain boundaries and/or triple junctions.

Another type of interfacial structural element is the quadruple node, that is, the intersection of (usually four) triple lines [3]. The contribution of quadruple nodes to the volume fraction of the intercrystalline component can be significant for grain sizes below about 5 nm, and may be important in the transition from the nanocrystalline state to the amorphous or noncrystalline state [3]. The quadruple node will not be considered in detail herein, since very few investigations have been conducted with nanomaterials having grain sizes below 5 nm and, consequently, little is known concerning its contribution to the properties of nanomaterials.

## 2. INTERFACIAL STRUCTURE

### 2.1. Grain Boundaries

Gleiter [1] first recognized that the intercrystalline component of a material will form a distinct microstructural constituent when processing the material to have a nanocrystalline structure. Initially, according to Gleiter [5], the interfacial component of a nanocrystalline material was considered as a structure, exhibiting no short-range order. This did not imply that grain boundaries are disordered: every boundary was assumed to have a two-dimensionally ordered structure, the periodicity and interatomic spacings of which are different from boundary to boundary.

Several studies have suggested that grain boundaries in nanocrystalline materials are more disordered than those in conventional polycrystalline materials. One study suggested a gas-like disorder at the grain boundaries [6]. In another

study, Wunderlich, Ishida, and Maurer [7], using high-resolution electron microscopy (HREM), concluded that grain boundaries in nanocrystalline Pd have an “extended” structure not typically observed in conventional systems. In addition, it was concluded from simulation studies that materials with very small grain sizes, generally  $<10$  nm, show “amorphous” grain boundaries [8–10], at least for highly idealized microstructures with randomly oriented grains and mainly high-energy grain boundaries. As was pointed out in [10], “it would be interesting to know the degree to which grain misorientations in actual nano materials are truly random and the degree to which agglomeration, sintering, and grain growth lead to the formation of lower-energy and hence crystalline grain boundaries.” It would be expected that maximum energy grain boundaries are highly disordered and thus appear to have an “amorphous-like” structure. However, how many such grain boundaries occur in nanomaterials may well depend on the method of synthesis of the material.

In contrast to the above studies, there are several studies that appear to indicate that the structure of grain boundaries is the same in both nanocrystalline and coarse-grained materials. For example, Thomas, Siegel, and Eastman [11], using HREM, observed that the interfacial structure of nano Pd is consistent with that typically observed in coarse-grained materials. It was also concluded from comparisons of diffraction data from nanocrystalline and coarse-grained Pd samples that grain boundaries in nano Pd are reasonably ordered [12, 13]. In addition, lattice parameter measurements indicated no significant grain boundary excess volume in nano Pd; therefore, the reduced density typically observed in nano Pd samples must be due to porosity associated with

the specific processing method, that is, vapor condensation and compaction. In agreement with this latter conclusion, a maximum porosity of only  $0.3 \pm 0.1\%$  was measured in nano Ni produced by electrodeposition and the intercrystalline density of this material was only about 2% less than the density of single crystal nickel [14]. High-resolution electron microscopy has revealed that the grain boundary structure in electrodeposited nanocrystalline nickel is similar to the structure found in conventional polycrystalline materials [15]. Twinning and low angle boundaries with misfit dislocations similar to what is found in materials with large grain size were also observed [15]. As will be seen in the subsequent discussion of interfacial effects on properties, many property studies of nanocrystalline materials support the view of ordered grain boundary structures.

## 2.2. Triple Junctions

A microstructural element, which has been largely overlooked in the interpretation of nanocrystal properties, is the triple junction. Theoretical and experimental studies have demonstrated that triple junctions can be considered distinct structural defects, capable of possessing a unique line energy [16–18].

Several complementary models for the structure of triple junctions have been advanced. Bollmann [19–21] has shown that the application of the O-lattice model for grain boundaries intersecting at a triple line leads to two distinct classes of triple junctions: (1) those for which the adjoining grain boundary dislocation arrays (as calculated through the nearest neighbor relationships) form nodes where the Burgers vectors balance to zero (I-lines), and (2) those for which the crystallographic arrangement precludes such a nodal balance (U-lines). In the latter case, the triple line can be considered a crystalline defect with distinct physical characteristics [19–21]. Support for Bollmann’s treatment has been obtained in electron microscopy studies [22, 23] and in experimental studies of corrosion [24] and superplasticity [25].

Doni and Bleris [26] evaluated the geometric characteristics of triple junctions composed of low  $\Sigma$  coincidence site lattice (CSL) grain boundaries, and have shown that these “special” triple junctions can be structurally characterized through the symmetry of the CSL, that is, CSL displacement shift complete (DSC) relaxations. Palumbo and Aust [27] have shown that a one-dimensional periodicity along the triple junction, arising through low-index planar continuity, can be achieved when the sequence of crystallographic rotations describing the junction can be represented about a low-index axis. This coincident axial direction (CAD) approach to the structural characterization of triple junctions is analogous to plane matching [28] and CAD [29] models of interface structure. However, the one-dimensional periodicity associated with the CAD model may be of greater significance to linear triple junctions than to planar grain boundaries. The CAD approach is considered the one-dimensional limit to Bollmann’s three-dimensional disclination treatment of triple lines and is applicable when nodal balancing of adjoining grain boundary dislocation arrays cannot occur (U-lines).

Cahn and Kalonji [30] have derived a triple-junction classification scheme that is independent of the character of the adjoining interfaces, and based solely upon crystallographic symmetry restrictions arising from the presence of adjoining junctions. Such a treatment may be of particular significance to nanostructured materials where the mean distance between adjacent triple junctions becomes very small.

In all models considered, it should be noted that increasing randomness in global and local crystallographic texture of the material would lead to an enhanced frequency of occurrence of triple junctions possessing “defect” character [31, 32]. Commonly applied nanocrystalline processing methods (*e.g.*, mechanical attrition, vapor condensation and compaction, high current density pulse electroplating) would be expected to yield such highly random distributions of crystals.

### 2.3. Impurity Segregation

The problem of harmful impurity segregation to the nanocrystalline interfaces is not thought to be a factor in their properties, due to the impurity dilution associated with typically about  $10^{19}$  boundaries per  $\text{cm}^3$  [5]. For example, by applying an equation developed for the intercrystalline volume fraction (*i.e.*, cumulative volume fraction of grain boundaries and triple junctions) (*e.g.* Fig. 1) [2], and assuming complete segregation of bulk impurities, the maximum grain boundary concentration attainable for a given average grain size is depicted in Figure 2 [33]. It is evident that even with conventional material of high purity, for example, 10 ppm total bulk impurities with  $10\ \mu\text{m}$  average grain size, grain boundary solute concentrations can be greater than 3 at %; decreasing the grain size of this material to  $<30\ \text{nm}$  results in a maximum grain boundary solute concentration of  $<0.01$  at % [33]. However, it was concluded

**Figure 2.** Solute dilution at grain boundaries from extreme reduction in grain size. Reprinted with permission from [33], G. Plumbo and U. Erb, *MRS Bulletin* 24, 27 (1999). © 1999, Materials Research Society.

that uncontaminated samples are required before definitive information can be obtained regarding the nature of the grain boundary structure in nanocrystalline materials such as Cr [13]. Klement et al. [34] using energy dispersive X-ray (EDX) measurements in a scanning transmission electron microscope (STEM) determined the presence of S segregation at intercrystalline defects in annealed nano Ni containing 0.16 wt % S produced by electrodeposition [35]. Figure 3 shows the S concentration along and normal to a grain boundary of initially 10 nm Ni annealed for 30 min at 493 K. After this anneal, a dual-sized grain structure was present: 10–20 nm grain size matrix and grains produced by abnormal grain growth with a size from 50 to 130 nm. Along the grain boundary of the larger grains, the S content fluctuates (Fig. 3(a)), which may suggest a dependency on the local grain boundary structure. Triple junctions are known for their special properties compared with grain boundaries and bulk materials [36], for example, preferred sites (sinks) for solutes. This is evident at position “0” in Figure 3(a), which was at a triple junction, showing higher S content than at the grain boundary. Normal to the grain boundary, Figure 3(b), a large difference in the S content within the grains and directly at the grain boundary was detected. The observed solute (S) segregation at grain boundaries and triple lines may play a significant role in the properties of nano materials, at least in the annealed condition.

## 3. INTERCRYSTALLINE DEFECTS AND PROPERTIES OF NANOCRYSTALLINE MATERIALS

### 3.1. General

In recent years, wide ranges of novel property measurements have been attributed to the large interfacial volume fraction in nanocrystalline materials. However, a number of these novel properties were not strictly due to the increased intercrystalline volume fraction associated with the ultrafine grain size, but rather to other secondary defects that were introduced during synthesis. It is instructive, therefore, to consider a nanostructured material as having two types of defect structures. The first is the primary defect structure, which is the set of grain boundaries, triple lines, and quadruple nodes that form the ultra-fine interfacial network. The other is a secondary defect structure, which may be composed of

**Figure 3.** EDX measurements showing the S concentration (a) along and (b) normal to a grain boundary in nanocrystalline Ni after annealing at 493 K for 30 min [34].

entrained porosity, residual amorphous regions, lattice dislocations, and extrinsic grain boundary dislocations.

The nature of the secondary defect structure is strongly dependent on the synthesis method used to obtain the ultrafine intercrystalline network. For example, nanocrystalline materials produced in powder form (through inert gas condensation, ball milling, etc.) followed by consolidation, can have entrained porosity that significantly affects certain materials properties [37]. While crystallization of amorphous precursors, recrystallization following severe plastic deformation, and electrodeposition, can all produce fully dense nanostructures, the first two can also introduce relatively extensive secondary defect structures. For example, amorphous grain boundary structures [38, 39] and residual amorphous regions [40] have been reported in nanocrystalline materials produced from melt-spun precursors. For nanocrystalline materials produced by severe plastic deformation, substantial extrinsic grain boundary dislocations and a subgrain boundary network have been observed [41]. In contrast, high resolution transmission electron microscopy of electrodeposited nanocrystalline Ni and Ni-1.2 wt % P showed very low densities of lattice dislocations, and the grain boundary structures were found to be qualitatively the same as those in conventional polycrystalline materials [15]. Electrodeposition can produce nanostructured materials, which are relatively unencumbered by such secondary defect structures. This presents an opportunity to study material properties that fundamentally scale with the dimensions of the intercrystalline network.

In the present section, only those observations on properties of nanocrystalline materials will be discussed in relation to their primary defect structures. In considering the intercrystalline region to consist of distinct grain boundary and triple junction defects, the influence of these defects on the bulk properties of nanocrystalline materials will depend upon their relative volume fraction contributions (e.g., Fig. 1) and on their specific structural and chemical character (Section 2). Several material properties are significantly affected by changes in the scale of the interfacial network, while others remain essentially unchanged [42]. Properties that depend strongly on the interactions of grain boundaries with other microstructural defect structures (e.g., dislocations, vacancies, solute, second-phase particles, domain walls, etc.) are greatly influenced by the decrease in grain size. Examples include hardness, yield and tensile strength, and ductility [43]. In contrast, those material properties that depend predominantly on the local bond structure are relatively insensitive to changes in grain size down to 10 nm. Examples include saturation magnetization, heat capacity, thermal expansion, and Young's modulus [43].

## 3.2. Thermal Stability and Grain Growth in Nanocrystalline Materials

### 3.2.1. General

One of the most significant effects of the large volume fraction of intercrystalline interfaces is the strong thermodynamic potential for microstructural transformation through grain growth. While there have been numerous studies, grain growth in nanostructured materials is not well understood

at present. In part, this is due to the intrinsic difficulties of studying nm-scale microstructural evolution. It is also due to the complexities introduced by the interaction of migrating grain boundaries and the secondary defect structures that were introduced during synthesis of the nm-scale intercrystalline network. It is difficult, therefore, to draw meaningful comparisons between grain growth observations of nanocrystalline materials produced by different synthesis methods [37].

Perhaps the most significant differences in secondary defect structures are between those methods that produce nanostructured powders requiring further consolidation and those methods that produce fully dense nanostructures in one processing step. For instance, entrained porosity has been observed to have a considerable effect on the rate of grain growth. Nanostructured TiO<sub>2</sub> samples having similar starting grain sizes, but different entrained porosity (~25% and ~10%), were studied [44]. After comparable annealing treatments, the sample with the larger porosity had an annealed grain size of ~30 nm, while the sample with ~10% porosity had an annealed grain size of ~500 nm. Significant differences have also been observed between nanostructures that are both fully dense and fully crystalline, but are produced by different synthesis methods. For example, it was found [45] that the grain boundary diffusivity of nanostructured nickel produced by severe plastic deformation was several orders of magnitude higher than the diffusivity of nanostructured nickel produced by electrodeposition. The difference was attributed to the presence of extrinsic grain boundary dislocations that were formed during severe plastic deformation.

It is relatively difficult, therefore, to directly compare grain growth studies of nanostructured materials produced by different synthesis methods because of the intrinsic differences in the effects of the secondary defect structures on grain boundary migration. By contrast, the class of electrodeposited nanocrystalline materials is relatively unencumbered by secondary defect structures such as porosity, residual amorphous regions, and extrinsic grain boundary dislocations and is, therefore, a good system to study the thermodynamic effects of large volume fractions of internal intercrystalline interfaces.

### 3.2.2. Thermal Stability

The thermal stability of nanostructured electrodeposits has been most frequently studied by calorimetry. The enthalpy release during grain growth is typically measured as a function of annealing temperature at a constant scan rate. In the calorimetric (enthalpic) transformation signals for 20-nm starting grain size nanocrystalline Ni [46] and Co [47], there is a broad, low-energy exotherm followed by a main heat release peak in both cases. This type of curve has been reported in several studies of Ni [34, 46, 48–50], Ni-Fe alloys [49], and Ni-1.9 wt % P [51]. A qualitatively similar transformation signal has also been obtained using *in-situ* electrical resistivity measurements of electrodeposited nanocrystalline Co, Ni, and Ni-Fe alloys during annealing [52].

Integrating the area under the thermal signals provides the enthalpy released during grain growth. For the thermal signals of Figure 4, this yields 15.8 J/g for Ni and 17.1 J/g

**Figure 4.** Thermal signal of grain growth obtained by modulated differential scanning calorimetry for 20 nm electrodeposits of Ni [46] and Co [47]. Reprinted with permission from [64], G. Hibbard et al., *Mat. Sci. Forum* 386–388, 387 (2002). © 2002, Trans. Tech.

for Co. If this enthalpy release is related to the reduction in intercrystalline volume fraction during growth (requiring a model of intercrystalline volume fraction as a function of grain size *e.g.*, [2]), then an average interfacial enthalpy can be estimated. Using the heat releases reported in previous studies of electrodeposited nickel [34, 46, 48, 49], values in the range of 0.6 to 1.2 J/m<sup>2</sup> are obtained. The excess interfacial enthalpy of nanostructured Co was found to be similar—1.1 J/m<sup>2</sup> [47]. The values for nickel correspond well with the extrapolated value for grain boundary energy (1.0 J/m<sup>2</sup>) determined from conventional polycrystalline nickel [53], and are not enhanced such as the 2.8 J/m<sup>2</sup> value reported for 12-nm nanocrystalline Ni produced by mechanical attrition [54].

The peak temperature,  $T_p$ , of the thermal signal has been used both as a relative measure of stability and to obtain the effective activation energy for grain growth,  $Q$ . Physically, the peak temperature indicates the point of maximal heat release from the sample during the scan. From the change in peak temperature with scanning rate, an activation energy can be obtained. Figure 5 shows a modified Kissinger plot [55] for representative examples of Ni [46], Ni-1.2 wt % P [15], Ni-20 wt % Fe [49], and Co [47]. In general terms, those systems exhibiting higher peak temperatures during calorimetry are further to the left in Figure 5, while those with higher activation energies have steeper slopes. The activation energy for nanostructured nickel electrodeposits has been obtained in several studies with values ranging from 1.20 eV to 1.46 eV. For polycrystalline Ni, the activation energies for lattice and grain boundary self-diffusion have been reported as 2.9 eV and 1.2 eV, respectively [56]. This has led several studies to suggest that grain growth in nanostructured nickel electrodeposits is controlled by grain boundary self-diffusion [48, 49, 57].

**Figure 5.** Modified Kissinger analysis for calorimetric studies of Ni [46], Ni-1.2 wt % P [15], Ni-20 wt % Fe, [49] and Co [47]. Reprinted with permission from [64], G. Hibbard et al., *Mat. Sci. Forum* 386–388, 387 (2002). © 2002, Trans. Tech.

A substantial increase in thermal stability can be obtained by alloying nanostructured Ni electrodeposits with P. The activation energy increases from ~1.2–1.4 eV for nickel electrodeposits to 2.25 eV [15] with 1.2 wt % P addition and 2.63 eV [51] with 1.9 wt % P addition. In addition, the peak temperatures increase from ~538–573 K for Ni to over 673 K with P additions. A similar increase in thermal stability can be obtained by alloying nanostructured Ni electrodeposits with Fe. The activation energy increases to 1.61 eV [52] for Ni-10 wt % Fe and to 2.43 eV [52] or 2.53 eV [49] for Ni-20 wt % Fe electrodeposits. Based on X-ray diffraction (XRD) of annealed structures, this trend of increasing thermal stability with increasing Fe content was also seen for nanostructured Pd-Fe electrodeposits [58, 59]. For Co electrodeposits, the activation energies and peak temperatures of grain growth were higher than for Ni electrodeposits. This suggests the possibility that alloying nanostructured Co electrodeposits with Fe or P may yield nanostructures with even greater thermal stability than that obtained thus far with Ni-Fe or Ni-P electrodeposits.

### 3.2.3. Grain Growth

A review of the suggested transformation mechanisms for grain growth in nano materials reveals substantially less agreement between studies than among the calorimetric observations. Several methods have been used to study the grain growth transformation mechanisms in nanostructured electrodeposits. The most frequently used method has been a decoupled annealing/characterization approach in which growth mechanisms are inferred from quenched-in transformed microstructures. A range of characterization techniques, including transmission electron microscopy (TEM) [15, 34, 46–48, 52, 57, 60–64], XRD [50, 51, 58, 59, 65],

scanning electron microscopy (SEM) [52, 66], atom probe field ion microscopy (APFIM) [51], and 3-dimensional atom probe (3DAP) [67, 68] have been used. Transformation mechanisms have also been inferred from *in-situ* annealing experiments (*i.e.*, coupled characterization and annealing) using TEM [15, 60, 62], XRD [50], and electrical resistivity measurements [52].

The most extensive observations of annealed microstructures have come from the nanocrystalline Ni system [34, 46, 48, 50, 52, 60, 61, 64, 66]. Direct TEM observation of annealed Ni has shown a wide range of annealed microstructures and it is instructive to consider this range in some detail. The first type was obtained during *in-situ* TEM annealing at 573 K and resulted in a  $\sim 30$ -nm stabilized (through 20.5 h) nanostructure [60]. For isothermal annealing at temperatures below 573 K, a second type of annealed structure with a nonuniform grain structure having grains in the size range of  $\sim 100$  to  $\sim 1000$  nm embedded in a nanocrystalline matrix, was obtained [34, 52]. For isothermal annealing in the temperature range of 573 K to 693 K, a third type was obtained, which had a uniform grain structure with mean grain size on the order of  $\sim 500$  nm [34, 57]. A fourth type, obtained by annealing at 773 K for 1 h, had a nonuniform grain structure with 12- to  $50\text{-}\mu\text{m}$  sized grains having planar interfaces surrounded by submicron-sized matrix grains [66]. A fifth type was obtained during annealing at still higher temperatures (*e.g.*, 873 K for 3 h) and showed a uniform grain structure with grains in the size range of  $\sim 50$  to  $100\ \mu\text{m}$  [52].

Taken individually, these disparate annealing structures have implied distinct growth mechanisms, which may become active over different temperature ranges. Indeed, the following mechanisms have been suggested. A-Sherik et al. [60] reported uniform growth followed by a stabilization. It was also suggested that abnormal growth occurred at lower annealing temperatures (less than 593 K) and that normal growth occurred at higher annealing temperatures [34]. A transition from abnormal growth to normal growth with increasing scanning temperature was noted [48]. It was also claimed that growth changed from normal to abnormal with increasing annealing time at a constant temperature [50]. Other work [52, 69] suggested that there was concurrent abnormal and normal grain growth.

A recent comprehensive study [64, 70] examined the structural evolution of nanocrystalline Ni at 493 K, 593 K, and 693 K over a period of annealing times ranging from  $\sim 1$  s to 432 ks (120 h). It has shown that the microstructural evolution during annealing of nanocrystalline Ni occurs sequentially, through at least four distinct stages of growth, and that these individual stages can explain the previously observed annealed nanocrystalline nickel structures. An example of this multistaged grain growth is shown in Figure 6, in which low magnification, bright-field TEM images are shown of nanocrystalline Ni after annealing for  $\sim 1$  s, 3.6 ks (1 h), 39.6 ks (11 h), and 432 ks (120 h) at 693 K. Four distinct microstructures can be seen: a nonuniform annealed microstructure with 100 to 700 nm grains in a nanocrystalline matrix (Fig. 6a); a uniform microstructure with  $\sim 500$  nm grain size (Fig. 6b); a nonuniform microstructure with large grains of size  $\sim 5$  to  $50\ \mu\text{m}$  with planar growth

**Figure 6.** Bright-field TEM images of 20 nm Ni after the following annealing times at 693 K:  $\sim 1$  s (a), 3.6 ks (1 h) (b), 39.6 ks (11 h) (c), and 432 ks (120 h) (d) [70]. Reprinted with permission from [64], G. Hibbard et al., *Mat. Sci. Forum* 386–388, 387 (2002). © 2002, Trans Tech.

interfaces (Fig. 6c); and a uniform microstructure with a grain size of  $\sim 50\ \mu\text{m}$  (Fig. 6d).

Of the five types of annealed structures listed in the previous section, only the stabilized nanostructure (*i.e.*, type 1) was not observed during the microstructural evolution at 693 K. Indeed, there was no evidence of a stabilized nanostructure at either of the other two annealing temperatures (493 K and 593 K) through 120 h of annealing [70]. The previous observations of a stabilized nanostructure [60] were likely due to grain boundary pinning by the free surfaces during *in-situ* TEM annealing.

During the first stage of growth, the nanocrystalline matrix is consumed by a small fraction of the grains growing abnormally into the nanocrystalline matrix. There are several dragging forces to consider in rationalizing this type of growth behavior. First, nanostructured nickel electrodeposits typically have sulfur impurities in the range of 100 to 1000 ppm due to bath additives [71]. However, sulfur may not be the major dragging force at the outset of growth, because of solute dilution from the large intercrystalline volume fraction [33]. In fact, 3DAP of nanostructured Ni in the as-deposited condition has shown sulfur impurities to be evenly distributed through the electrodeposit [67]. Other dragging mechanisms may be of more significance at the start of abnormal growth. In particular, it has been suggested that triple line drag [*e.g.*, 72, 73] and vacancy drag [*e.g.*, 74] may become increasingly important as the grain size is reduced. Once growth has begun, however, it is expected that solute pinning effects will increase in importance as the abnormal growth front consumes the matrix,

collecting sulfur as it migrates. Indeed, significant sulfur enrichment was observed at the interface between large abnormally growing grains and the nanocrystalline matrix in nanostructured nickel annealed for 30 min at 493 K using HREM (e.g., see Fig. 3b [34]).

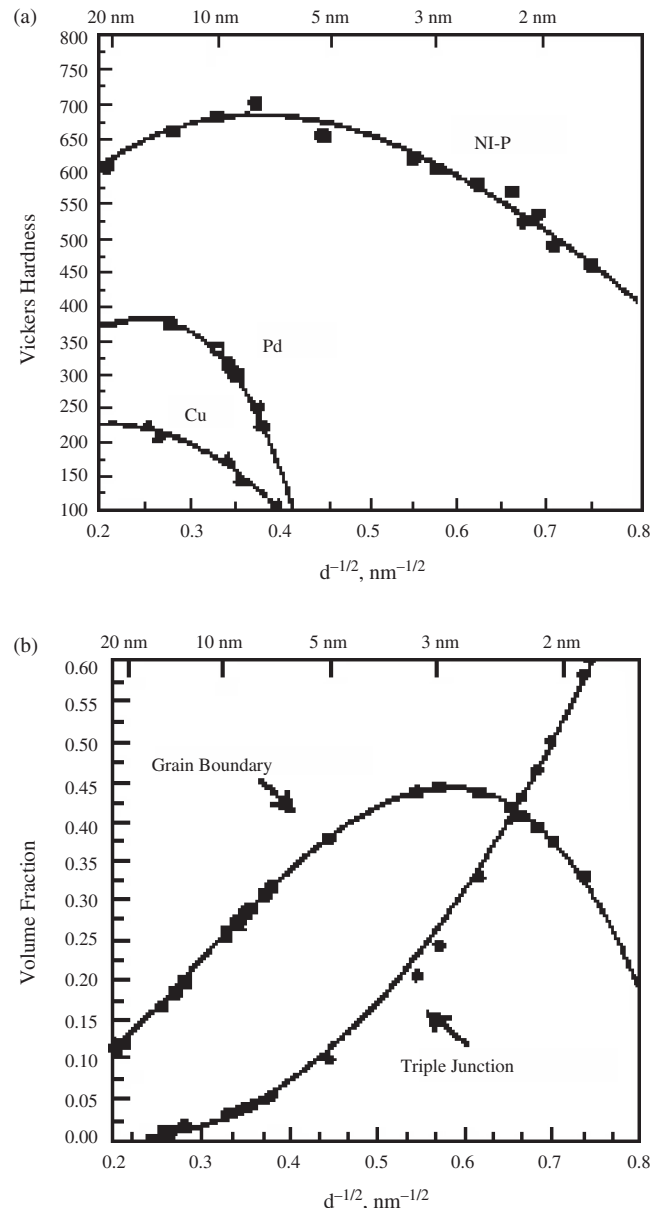

Perhaps one of the most dramatic effects of sulfur segregation in a nanocrystalline material can be seen in Figure 7. The characteristic feature of this late-stage abnormal grain growth is the migration of planar interfaces into a submicron, grain-sized matrix. EDX and STEM of the planar interface region showed sulfur-rich, second-phase precipitates that appeared to wet the interface [70, 75]. Initiation of this second stage of abnormal grain growth is likely linked to a redistribution of sulfur during the prolonged period of uniform (second stage) growth (Fig. 6b), during which the system approaches thermodynamic equilibrium with respect to nickel-sulfide precipitation and grain boundary, structure-dependent segregation [70, 75].

### 3.3. Mechanical Properties

As expected, the plastic deformation behavior of nanocrystalline materials is strongly dependent upon the interfacial volume fraction. Much of the early work was concerned with room temperature micro-hardness measurements (e.g., Fig. 8). This figure shows the results obtained for room temperature Vickers hardness measurements of Ni-P electrodeposits [76]. Also shown are the results on nanocrystalline Pd and Cu produced by the inert gas condensation technique [77]. Initial increases, followed by significant decreases in hardness, are noted with decreasing grain size ( $d$ ) in the nanocrystal range of  $d \leq 20$  nm. The observed decreases in hardness are contrary to the Hall-Petch behavior [78, 79] and consistent with results reported elsewhere [80, 81] for nanocrystalline materials. Others have only reported a reduction in the Hall-Petch slope in the nanometer range (e.g., [82]). Results of hardness and compressive yield stress measurements on nanocrystalline Cu, made by inert gas condensation and compaction with grain sizes from about 20 nm to 16 nm, suggest a deviation from linearity at the smallest grain sizes measured [83]. However, Erb et al. [84, 85], in

an extensive study of electrodeposited Ni, found a strong deviation from linearity below about 25 nm grain size and a negative Hall-Petch slope between 11 nm and 6 nm, as depicted in Figure 9.

Chokshi et al. [77] interpreted their results for Pd and Cu seen in Figure 8 in terms of room temperature Coble creep, arising from the disorder associated with large intercrystalline fractions. However, in one study [86], it appeared that grain boundary diffusional creep is not an appreciable factor in determining the room temperature mechanical behavior of nanocrystalline Cu and Pd. Modified dislocation pile-up theories involving small numbers of dislocations [87, 88] can be used to explain the deviation behavior of the Hall-Petch

**Figure 9.** Hardness of nanocrystalline Ni as a function of grain size [84, 85].

relationship but not the negative slopes shown in Figures 8 and 9. A significant reduction in the Hall–Petch slope was predicted to occur for the extreme case of only one dislocation loop being expanded against the grain boundary obstacle stress [89]. Scattergood and Koch [90] concluded from their model that a continued drop in dislocation line tension with decreasing grain size leads to a negative Hall–Petch slope. Wang et al. [91] concluded that the dislocation pile-up mechanism no longer applies to nanocrystalline materials below a critical grain size, for example, about 10 nm for FCC metals. In agreement with the latter conclusion, computer simulation results [92, 93] indicate that no dislocation activity occurs below a critical grain size (of the order of 10 nm for metals) and that plastic deformation then occurs entirely by grain boundary sliding.

Using a two-component model of grain boundaries and grains, Carsley et al. [94] calculated the hardness of nanocrystalline metals as a function of grain size. They assumed Hall–Petch behavior for the grains down to the finest grain sizes, while the hardness of the assumed amorphous grain boundaries was estimated from a relation between hardness and shear modulus in the glassy state. The shear modulus of the amorphous state is assumed to be about one-half of the crystalline value. Using a simple rule of mixtures to obtain the hardness of the two combined phases, their Hall–Petch plot [94] agreed with some data for Ni [84, 95].

A composite model based upon geometric considerations, in terms of the volume fraction of crystalline and intercrystalline components, was proposed by Wang et al. [91, 96] to evaluate the strength of nanocrystalline materials. It was shown that this model can be used for interpreting the various observations involving deviation from the Hall–Petch relationship and a negative Hall–Petch slope. In addition to grain boundaries and triple junctions, this analysis also included quadruple nodes where triple lines (usually four) are linked up [3]. The strength contributions

for grain boundaries ( $\sigma_{gb}$ ), triple lines ( $\sigma_{tl}$ ), and quadruple nodes ( $\sigma_{qn}$ ) was shown to have the following sequence [96]:  $\sigma_{gb} > \sigma_{tl} > \sigma_{qn}$ . The result of comparing the measured yield strength of nanocrystalline Ni electrodeposits to the composite model incorporating strength contributions from grain boundaries, triple junctions, and quadruple nodes is shown in Figure 10. The experimental yield strength data not only fit the composite model reasonably well but also show a behavior consistent with that of the hardness studies of bulk nano Ni electrodeposits (e.g., Fig. 9).

It should be noted that the onset of decreasing strength, that is, deviation from Hall–Petch behavior, in these systems (Figs. 8, 9, and 10) occurs at grain sizes where triple lines begin to comprise a significant fraction of the bulk specimen volume (Fig. 8b). The observed phenomena are in general agreement with the triple-line softening effects first reported by Rabukhin [97], who investigated the effect of triple junctions on the room-temperature tensile properties of conventional polycrystalline wires (Al, Cu, W) having various grain sizes. By electrochemical thinning of the wires to a diameter less than the average grain size, triple junctions could be eliminated from the microstructure. In all cases, an increase in strength and decrease in ductility was noted on such a transition from an equiaxed (with triple lines) to bamboo grain structure (no triple lines). The grain size dependence of the proof stress was found to obey the Hall–Petch relationship; however, at constant grain size, low values of proof stress were always obtained with the equiaxed geometry. Using a similar approach, Lehockey et al. [98] confirmed triple-line softening effects in Ni.

**Figure 10.** The result of fitting the yield strength of nanocrystalline nickel electrodeposits to a composite model incorporating strength contributions from grain boundaries ( $\sigma_{gb}$ ), triple lines ( $\sigma_{tl}$ ), and quadruple nodes ( $\sigma_{qn}$ ). Wang et al. [96] also derived an analytical expression for assessing the creep rate of nanocrystalline materials by a diffusion mechanism, including triple line diffusion. The overall creep rate is the sum of the creep rate due to lattice diffusion, grain boundary diffusion, and triple line diffusion. It was predicted that the creep rate due to triple line diffusion will exhibit a stronger grain size dependence than that due to grain boundary diffusion. For example, the contribution of triple line diffusion to steady-state creep rate appears to be the inverse of  $d^4$  ( $d$  = grain size), which is one order of magnitude higher than grain boundary diffusion and two orders higher than lattice diffusion in terms of grain size dependence. In addition, the secondary creep rate is still linearly proportional to the applied tensile stress, compared to the dislocation mechanism in which the exponent of the applied stress is usually greater than three.

It is evident from the work of Wang et al. [91, 96] that at high stress levels, grain boundary sliding is the major room temperature deformation mechanism in nanocrystalline Ni electrodeposits. However, the contribution from creep mechanisms through intercrystalline regions can be significant for smaller grain size. A negative Hall–Petch slope was observed when the grain size was below about 10 nm. It was suggested [96] that the deviation from the Hall–Petch relationship can be attributed to a dynamic creep process due to intercrystalline diffusion mechanisms.

Contrary to earlier measurements on nanocrystalline materials prepared by consolidation of precursor powder particles, [5, 86, 99] nanocrystalline nickel electrodeposits showed little grain size dependence of Young's modulus, at least for grain sizes larger than about 10 nm [100]. This result provides further support for the findings of Krstic et al. [101] and Zugic et al. [102], which demonstrated that the previously reported large reductions in modulus with nanoprocessing were likely the result of high residual porosity. Subsequent measurements [83, 103] on compacted nanocrystalline metals with lower residual porosity confirmed that the initially reported large reductions in Young's modulus were indeed mainly the result of residual porosity.

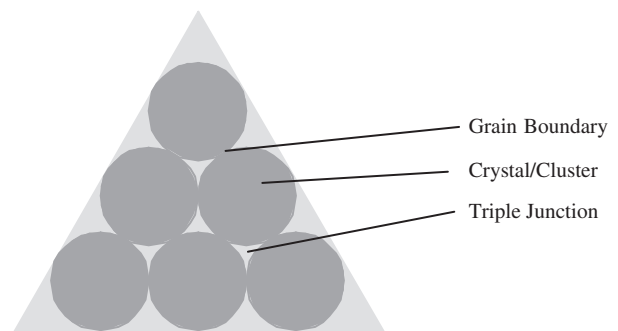

Zhou et al. [104] recently measured Young's modulus as a function of grain size for grain sizes ranging from about 30 nm to less than 5 nm in nano Ni-P samples having fully dense structure and constant P content (2 wt %). As shown in the comparison between Young's modulus and the interfacial volume fraction of Figure 11, a continuous decrease in Young's modulus at grain sizes below 30 nm was observed, which is considered to be the result of all interface contributions. The large drop in Young's modulus at a grain size of 4 nm is mainly due to the sharp increase of triple junction volume fraction indicated in Figure 11. Using a simple composite model, the Young's moduli of the grain boundary and triple junction components were determined to be 184 GPa and 143 GPa, respectively [104]. In this same study [104], nanoindentation measurements revealed a transition from regular to an inverse Hall–Petch relationship with decreasing grain size; this was explained in terms of triple junction contributions.

With respect to the hardness curve for Ni-P shown in Figure 8a, it should be noted that the grain size for the smallest grain sizes (<3 nm) was derived from X-ray line broadening measurements. However, the XRD scans for

**Figure 11.** A comparison between the measured Young's modulus for nanocrystalline Ni-P and the calculated interfacial volume fraction, as a function of grain size. Reprinted with permission from [104], Y. Zhou et al., *Scripta Mater.* 48, 825 (2003). © 2003, Elsevier Science.

these particular samples resembled those typically obtained for amorphous structures. These electrodeposits contained increasing P content with decreasing grain size and it has been previously shown [105, 106] that there is a smooth, but not fully characterized, transition from the nanocrystalline to the amorphous structure. The smooth decrease in hardness through the nanocrystalline to the amorphous transition in Figure 8a indicates that a common structural element may be responsible for ductilization in both the nanocrystalline and amorphous states. This transition coincides with the region following the plateau in the grain boundary volume fraction at a grain size of  $\sim 3$  nm (Fig. 8b) below which the triple junction volume fractions assume relatively large values. Figure 12 schematically illustrates a limiting case for this phenomenon [107]. When the mean grain size becomes very small, individual atoms can be better represented as spherical clusters of atoms. Under these conditions, the grain boundary is shown by the point of contact between adjacent spherical clusters, while the triple junction region assumes a relatively large volume. Thus, the transition to the non-nanocrystalline state is defined as the crystal (cluster) size, where the ratio of triple junction to grain boundary volume fraction begins to approach infinite values [107]. It was

**Figure 12.** Schematic representation of a postulated limiting grain size for crystallinity, where the triple junction to grain boundary volume fraction ratio approaches infinite values [107].

suggested that the common structural element, which could be responsible for the ductilization, is the disclination [76].

### 3.4. Physical Properties

#### 3.4.1. Magnetic Properties

Many of the earlier studies on nanocrystalline materials have reported that there is a large reduction in saturation magnetization ( $M_s$ ) with increasing interfacial volume fraction (*i.e.*, decreasing grain size) [5, 108–111]. For example, a 40% decrease in saturation magnetization for nano Fe (6 nm grain size) was found compared to bulk  $\alpha$ -Fe [5]. It was also reported [112] that the spontaneous magnetization of nano Gd samples was about 75% of the value for polycrystalline Gd. All of these previous nano materials were produced using the gas condensation method, which yields materials with high internal porosity that can provide large surface areas for oxide formation after exposing the samples to air. In contrast, Aus et al. [113] reported that the saturation magnetization of nanocrystalline Ni was not strongly dependent on the grain size. In this study, the grain sizes of Ni varied from 100  $\mu\text{m}$  to 10 nm; for the Ni with the smallest grain size, the observed saturation magnetization was only 10% less than conventional polycrystalline Ni. These results were obtained on bulk nanocrystalline Ni produced by electrodeposition and were explained in terms of the negligible porosity/oxide formation in this material. Other studies [114–117] have generally confirmed the initial results of Aus et al. [114]. Kisker et al. [118] presented results for gas-condensed Ni, which showed the saturation magnetization to be independent of grain size as long as the material was not exposed to air. However, after exposure to air,  $M_s$  decreased to about 80% of its original value.

Studies were conducted on the effect of structural disorder introduced by grain boundaries, on the magnetic properties of nanocrystalline metals [119–121]. Grain boundary configurations representing various degrees of disorder were generated using molecular dynamics simulations with embedded atom potentials. These boundary configurations ranged from  $\Sigma 3$  boundaries with minimum structural disorder through  $\Sigma 5$  and  $\Sigma 13$  special grain boundaries of intermediate structural disorder to random amorphous grain boundaries with maximum disorder. Electronic structure calculations were performed using the tight-binding linear muffin-tin orbital atomic-sphere-approximation method. These calculations have shown that the magnetic moment is rather insensitive to the degree of structural disorder associated with grain boundaries. Even when all the material was amorphous, the average moment was found to be reduced by only 15%. It was concluded that, for the case of nanocrystalline Ni with a grain size of 10 nm at which the grain boundary atoms comprise about 30% of the volume, the overall effect of structural disorder on the average moment is very small, in good agreement with the experimental data reported by Aus et al. [113] for electrodeposited nickel.

Further experimental evidence and detailed calculations for nanocrystalline Ni-Fe, Ni-P, Co, and Co-W [122, 123] also indicate that the structural disorder introduced by grain boundaries and triple junctions has an insignificant effect

on saturation magnetization compared with chemical disorder introduced by alloying additions. In addition, Tamimoto et al. [124] have shown that the magnetization of fully dense and highly pure nanocrystalline Fe (density increased by explosive compaction) is almost the same as that of polycrystalline Fe. The grain boundaries in the high-density nano metals are not so disordered as the “gas-like” state originally proposed in the early days of nano materials [5, 6], and their magnetic behavior is quite similar to that of conventional grain boundaries in polycrystalline metals [124].

#### 3.4.2. Electrical Properties

Grain boundaries have long been recognized to affect the electrical properties of metals [125]. Conventional polycrystalline metals (grain size  $>1 \mu\text{m}$ ) contain a relatively low volume fraction of grain boundaries, and therefore their influence on the electrical resistivity is only significant at low temperatures [126–129]. For nanocrystalline materials (grain size  $<100 \text{ nm}$ ), however, the grain boundary volume fraction can increase to levels that are comparable to that of the crystalline component (*e.g.*, Fig. 1) and thus the effects of the grain boundaries quickly become a significant factor. Consequently, an increase in the electrical resistivity of various nanocrystalline materials has been reported even at room temperature [5, 116, 130–132].

A comparison of results of electrical property measurements performed on nanostructured materials produced by different synthesis routes (*e.g.*, gas condensation [5], electrodeposition [116, 130, 132]) show very similar trends. In most cases, the electrical resistivity was observed to increase with decreasing grain size. For example, the room temperature resistivity for Ni was increased from about  $6 \mu\Omega \text{ cm}$  at 100  $\mu\text{m}$  grain size in fully annealed material, to about  $22 \mu\Omega \text{ cm}$  at 11-nm grain size in electrodeposited material [130]. This can be attributed to electron scattering at defects, such as grain boundaries and triple junctions. In fact, a linear relationship between excess resistivity—defined as the total resistivity of the nanocrystalline material minus the resistivity of conventional polycrystalline material (100  $\mu\text{m}$  grain size) with negligible intercrystalline volume fraction—was observed for nanocrystalline Ni of varying grain size [130].

A more comprehensive study [52, 133] has recently shown that the contribution to the electrical resistivity from the grain boundaries in nano Ni, Co, and Ni-Fe alloy varies linearly with the grain boundary area. It was also shown that the grain boundary contribution can be quantified in terms of a specific electrical resistivity. The specific grain boundary resistivity (SGBR) for electrodeposited pure Ni and Co at 295 K was found to be  $2.82 \times 10^{-6} \mu\Omega \text{ cm}^2$  and  $3.26 \times 10^{-6} \mu\Omega \text{ cm}^2$ , respectively. The SGBR values for electrodeposited Ni with 16%, 31%, and 34% Fe were 3.01, 3.09, and  $2.99 \times 10^{-6} \mu\Omega \text{ cm}^2$ , respectively [52]. These SGBR values for electrodeposited Ni, Co, and Ni-Fe alloy were determined to be independent of temperature. The SGBR values determined from measurements on nano materials were similar to those previously determined for polycrystalline Cu, Al, and Al bicrystals [52, 133]. This indicates that the structure of grain boundaries in nano materials is similar to that in polycrystalline materials at least with respect to electron scattering effects.

### 3.5. Corrosion Properties

The corrosion behavior of nanocrystalline materials produced by crystallization of amorphous precursor materials has shown both beneficial and detrimental effects (e.g., [134–139]). The conflicting results may largely be due to the difficulty of correlating the complex microstructures and chemical compositions of the crystallized-amorphous materials to the corrosion resistance. However, nanostructured materials produced by electrodeposition have shown considerable advances in the understanding of the role of primary defect structures on the corrosion properties [140–145].

The corrosion behavior of nanocrystalline Ni has been extensively studied using potentiostatic and potentiodynamic polarizations in various corrosion environments: 2 N H<sub>2</sub>SO<sub>4</sub> solution (pH = 0), 30 wt % KOH solution (pH = 13), and 3 wt % Na Cl solution (pH = 7) [140–143]. While the overall corrosion rate in the passive region was somewhat higher for nanocrystalline than polycrystalline Ni, localized corrosion at grain boundaries and triple junction was found to disappear with decreasing grain size [140, 141]. X-ray photoelectron spectroscopy of the specimens polarized in the passive region showed that the passive film formed on the nanostructured specimen is more defective than that formed on the polycrystalline specimen, while the thickness of the passive layer was the same on both specimens [146]. This higher defective film on the nanocrystalline specimen allows for a more uniform breakdown of the passive film, which in turn leads to a more uniform corrosion. In contrast, as shown previously [24, 147], in coarse-grained Ni the breakdown of the passive film occurs first at the triple junctions and grain boundaries rather than the crystal surface, leading to a preferential attack at these defects.

Similar observations were made for the corrosion behavior in HCl of nanocrystalline 304 stainless steel (grain size 25 nm) produced by sputtering [148]. The reduced susceptibility to localized corrosion was attributed to the fine-grained microstructure, which allowed for a uniform distribution of Cl<sup>-</sup> ions. Further tests, (American Society for Testing and Materials (ASTM) G28-susceptibility to intergranular attack; ASTM G35, G36, and G44-susceptibility to stress corrosion cracking) have shown that nanostructured Ni is intrinsically resistant to intergranular attack and intercrystalline stress corrosion cracking [144]. The material was also found to be resistant to pitting attack and only slightly susceptible to crevice corrosion (ASTM G 48) [144].

Potentiodynamic polarization in conjunction with energy dispersive X-ray spectroscopy was used to investigate the role of sulfur on the passivation behavior of nanocrystalline Ni with an average grain size of about 30 nm and a sulphur content of about 1080 ppm [149]. Several of the as-deposited nano Ni samples were annealed at 1223 K for 15 min in order to obtain polycrystalline Ni through grain growth with the same overall sulfur content as in nano Ni. In addition to extensive grain growth, this anneal also resulted in sulfur segregation to grain boundaries and subsequent formation of grain boundary precipitates. In 0.25 M Na<sub>2</sub>SO<sub>4</sub> solution (pH = 6.5), the presence of 1080 ppm sulfur reduced the passivity of both as-plated and annealed nano Ni, as compared to polycrystalline Ni 200 (<100 ppm S). However, even at such a high concentration of sulfur, as-plated nano Ni is highly resistant to localized corrosion while the

annealed polycrystalline counterpart with the same sulfur content resulted in highly localized attack with grain dropping. This is demonstrated in Figure 13. For the annealed nanocrystalline Ni, the localized grain boundary corrosion penetrated as deep as 130 μm into the sample, which resulted in “grain dropping” in some areas. However, in the case of nanocrystalline Ni, the corrosion attack due to uniformly distributed surface pitting is very shallow, usually less than 2 μm in depth. At higher pH (pH = 11.5, 1 vol% NH<sub>4</sub>OH solution), both as-plated and annealed nanocrystalline Ni with 1080 ppm sulfur displayed passive behavior comparable to that of conventional polycrystalline Ni 200. However, the passive current density for the annealed nano Ni was approximately one order of magnitude higher and localized grain boundary/triple junction attack on Ni sulfide precipitates was observed.

Uniform surface dissolution was observed in electrodeposited nanocrystalline Co, grain size 12 nm, (containing 440 ppm S and 290 ppm C) after potentiodynamic polarization in a deaerated 0.25 M Na<sub>2</sub>SO<sub>4</sub> solution at pH of 6.5 [150]. Uniform metal dissolution can be expected when it is assumed that the S impurities are evenly dispersed throughout the nanocrystalline structure, similar to what has been observed in a 3-D atom probe study by Warren et al. [67] in electrodeposited nanocrystalline Ni containing 550 ppm (by weight) of S. However, the surface of annealed nanocrystalline Co, (average grain size 10 μm) and containing the same total amount of impurities as the electrodeposited nanocrystalline Co, showed considerable preferential attack along the grain boundaries [150], where segregation of S would be expected after the anneal (15 min at 1223 K) [34]. The results of these studies [149, 150] support the previous considerations (Fig. 2 [33]) that solute dilution by nano processing can be used as an effective method to improve the overall intergranular degradation resistance.

### 3.6. Hydrogen Diffusion and Activity

The dependence of diffusion or local atomic jumps of hydrogen on the hydrogen concentration may be used as a local probe to obtain information on the spectra of available trapping sites in interfaces. The spectrum of hydrogen sites in

**Figure 13.** Surface (top) and cross-sectional (bottom) corrosion morphologies of nickel containing 1080 ppm sulfur. Left-annealed nanocrystalline Ni (1223 K for 15 min); right-as-plated nanocrystalline Ni [149].

the interfaces of nano Pd, prepared by gas condensation and compaction, appears to differ from that in amorphous alloys, for example, amorphous  $\text{Pd}_{83}\text{Si}_{17}$  [151]. For example, the energy distribution of the hydrogen sites, as deduced from the variation of hydrogen diffusivity with concentration, is enhanced by about 30% compared to amorphous  $\text{Pd}_{83}\text{Si}_{17}$ . However, the hydrogen diffusivity in nano Pd at low hydrogen concentrations with respect to that in the crystalline state is more greatly reduced than in amorphous  $\text{Pd}_{83}\text{Si}_{17}$  [151]. This indicates that the interfacial traps in the nano Pd have higher binding energies than in amorphous alloys. As was concluded in [152], this behavior is in contrast to that observed in nanocrystalline alloys prepared by crystallization from the amorphous state, and fits the different interface structures found for cluster-compacted nano metals and crystallized alloys by means of positron lifetime spectroscopy [153, 154]. It should be noted in this regard that a study [124] using explosion densified nanocrystalline Fe (density >95% of theoretical value) indicated that the self-diffusivity was close to that for conventional polycrystalline grain boundary diffusion expected from the extrapolation of high temperature data. It was concluded that the grain boundary structure of high-density nano metals is similar to that of conventional grain boundaries in coarse-grained metals [124]. In another study [155], a misorientation dependence of grain boundary diffusion of Ni in nanocrystalline thin films of nickel silicide (grain size 40–60 nm) was observed. Again, it was concluded that “the grain boundaries in our samples are well structured and do not consist of an amorphous phase” [155].

The transport behavior of hydrogen in electrodeposited nanocrystalline Ni foil (average grain size of 17 nm) at 293 K was determined using an electrochemical double cell [156]. Figure 14 shows a typical hydrogen permeation curve, where the anodic exit current density is plotted as a function of cathodic charging time. Three distinct breakthrough events are evident, as indicated by the arrows in Figure 14. On the basis of determined diffusivities, permeation flux values, and area (volume) fraction considerations [156], these breakthrough events were considered to be due to hydrogen transport through distinct triple junction, grain boundary,

**Figure 14.** Anodic exit current density as a function of cathodic charging time at  $0.1 \text{ mA/cm}^2$  for nanocrystalline Ni (17-nm grain size) foil of 0.17-mm thickness. Reprinted with permission from [156], G. Palumbo et al., *Scripta Met. Mater.*, 25, 679 (1991). © 1991, Elsevier Science.

and lattice paths, respectively. The triple junction diffusivity was determined to be approximately three times faster than grain boundary diffusivity and 70 times faster than lattice diffusion. Other studies [157] have also shown that diffusive transport occurs at a considerably faster rate through the triple junctions than along the adjoining grain boundaries. These results provide support for the defect character of triple junctions. Furthermore, the existence of a “measurable” triple junction diffusivity in nanocrystalline Ni indicates the importance of triple junction defects in the bulk properties of nanocrystalline materials.

Nanocrystalline Ni electrodeposits having an average grain size of 20 nm are also observed to display higher electrocatalytic behavior when compared to cold worked, fine grained, and fully annealed reference structures, with regard to the hydrogen evolution reaction (HER) for alkaline water electrolysis at room temperature [158]. The enhanced HER kinetics are considered to be the direct result of the high area fraction of grain boundaries, and to some extent, triple junctions which intersect the free surface of the electrode. It has been also shown [159] that the HER kinetics can be further enhanced by alloying nanocrystalline Ni with molybdenum.

An additional study [158] into the transport behavior of hydrogen in nickel as determined by an electrolytic-charging technique revealed that substantial increases in hydrogen diffusivity and capacity are obtained when Ni is in nanocrystalline form. Figure 15 illustrates three representative permeation transients corresponding to hydrogen transport through nanocrystalline (20 nm), fine-grained (1  $\mu\text{m}$ ), and single-crystal Ni foils of 140- $\mu\text{m}$  thickness. Detection of permeated hydrogen in the Ni bielectrodes of identical thickness is observed in the following order: (1) nanocrystalline, (2) fine grained, and (3) single crystal structures. In addition,

**Figure 15.** Hydrogen permeation transient showing anodic exit current density (flux) versus time for nanocrystalline, fine-grained, and single-crystal Ni foils (0.14-mm thickness). Reprinted with permission from [158], D. M. Doyle et al., *Acta Met. Mater.* 43, 3027 (1995). © 1995, Elsevier Science.

the apparent concentration of hydrogen in the 20-nm grain size sample is found to be about 60 times greater than that of the single crystal structure with regard to the permeation transients shown in Figure 15. The increased hydrogen diffusivity and capacity are attributed to the high intercrystalline content, which provides: (1) a high density of short circuit diffusion paths, and (2) large free volumes to which increased segregation of hydrogen can occur.

Permeation experiments were also conducted in a double chamber, ultra-high vacuum system separated by a test nickel specimen [160]. Hydrogen permeabilities and diffusivities through microcrystalline and nanocrystalline Ni were measured in the temperature range of 303 K to 473 K. Steady-state permeability measurements indicate that nanocrystalline Ni (average grain size of 78 nm) displays enhanced permeability below 323 K (*e.g.*, a factor of six at 303 K), as compared to the microcrystalline Ni (average grain size of 3  $\mu\text{m}$ ). Also, diffusivity measurements in combination with hydrogen trapping site density measurements suggest that there are more intercrystalline hydrogen trapping sites in the nanocrystalline Ni.

#### 4. GRAIN BOUNDARY ENGINEERED NANOSTRUCTURES

Grain boundary engineering involves the deliberate control of both the (1) density and (2) types of grain boundaries in a polycrystalline aggregate in a effort to improve the overall mechanical, physical, and chemical properties of materials. In recent years, grain boundary engineering has emerged as an effective method which can alleviate intergranular degradation concerns in many polycrystalline metals, alloys, and metal matrix composites [161, 162]. As discussed in Section 3, the primary grain boundary engineering concept as applied to nanocrystals was the consideration of the grain and triple junction volume fraction enhancement by grain size reduction. In addition to these geometric considerations, solute segregation to grain boundaries must also be considered a major cause of cracking and corrosion susceptibility in many materials. Despite attempts at “cleaner” melting, casting, and fabrication processes, even small residual impurity contents (*i.e.*, ppm range) can represent large grain boundary concentrations owing to large enrichment factors [36]. Structurally ordered “special” low  $\Sigma$  boundaries are less prone to solute segregation and their increased population in materials can provide significant resistance to solute segregation. However, even more substantive improvements may be attainable by using nanocrystalline materials. As was discussed in Section 2 and depicted in Figure 2, nano processing may be applied to allow for greater tolerance of prevalent impurity levels [33]. In addition, the grain boundaries in these ultra-fine grained materials likely represent the “cleanest” grain boundaries ever produced, thus providing large potential for significantly enhanced intergranular degradation resistance. This subject is discussed in more detail in [163].

The structure-property relationships presented in Section 3 were mainly for nanostructures with little consideration of the second concept of grain boundary engineering—the types or structures of grain boundaries,

**Figure 16.** CSL frequency as a function of average grain size for Ni-15% Fe. Values in parentheses indicate annealing times. Reprinted with permission from [165], G. Palumbo and K. T. Aust, in “Grain Growth in Polycrystalline Materials III,” p. 311, 1998. © 1998, The Minerals, Metal, and Materials Society.

that is, the grain boundary character distribution. For conventional polycrystalline materials, the optimization of boundary character distribution to achieve a high population of low  $\Sigma$  CSL boundaries has recently emerged as a technically viable and cost-effective means of achieving significant performance improvements (*e.g.*, enhanced ductility, creep resistance, fracture resistance, corrosion resistance) in practical engineering materials [164]. For polycrystalline materials, it has been shown that mobility differences between low  $\Sigma$  and general grain boundaries during grain growth can be used to optimize conventional metallurgical thermomechanical processes in order to achieve significant increases in the population of low  $\Sigma$  CSL boundaries [165]. In order to assess the possibility to achieve high frequencies of special boundaries in nanocrystalline materials by annealing, a series of experiments have been conducted on nanocrystalline Ni-15 wt % Fe having an initial average grain size of 30 nm. Specimens were annealed at 873 K for annealing times in the range of 5 s to 900 s and subsequently analyzed by electron backscatter diffraction [165]. Initial results from this analysis as shown in Figure 16 are encouraging. The low  $\Sigma$  CSL population is found to increase with increasing grain size in the range of 150 nm to 300 nm and then subsequently decrease with increasing grain size in the range 300 nm to 7  $\mu\text{m}$ . These measurements must be extended to grain sizes below 100 nm and with other nanocrystalline materials to evaluate the effect of optimized grain boundary character distribution in nanocrystals on the materials performance. Post-deposition annealing of nanostructured electrodeposits has been proposed [162] as a means of optimizing grain boundary character distributions, which could result in further property improvements of these materials.

#### 5. SUMMARY

Experimental results are discussed concerning the influence of primary intercrystalline defects, that is, grain boundaries and triple junctions, on the properties of nanocrystalline materials. The properties considered are largely based on nanostructured materials relatively free of secondary

defects introduced during synthesis, such as porosity, residual amorphous regions, lattice dislocations, and extrinsic grain boundary dislocations. These property studies include thermal stability and grain growth, mechanical, physical, corrosion, hydrogen diffusion, and activity.

For nanocrystalline materials having grain sizes above about 10–20 nm, grain boundaries play a dominant role, for example, increased strength and electrical resistivity, resistance to intergranular degradation, enhanced hydrogen diffusivity, and enhanced electrocatalytic behavior. At smaller grain sizes, triple junctions appear to exert a stronger influence, as in softening effects observed in measurements of hardness, yield strength, and Young's modulus.

In addition to some high-resolution electron microscopy and diffraction studies, property measurements such as grain boundary energy and diffusivity, grain growth, magnetic behavior, and specific grain boundary resistivity support the view of ordered grain boundary structures in nanocrystalline materials, similar to those in polycrystalline materials. The presence of low angle ( $\Sigma 1$ ) and twin ( $\Sigma 3$ ) boundaries has been observed in materials having <100 nm grain size and  $\Sigma \leq 29$  boundaries found for larger grain sizes. Further enhancement of the properties of nanostructured materials is, therefore, possible by optimization of the grain boundary character distribution.

## GLOSSARY

**Abnormal grain growth** Movement of grain boundaries by diffusion in which a bimodal grain size distribution usually emerges as some grains became very large at the expense of small grains.

**Activation energy** The energy required to cause a specific reaction to occur. In diffusion-related processes, the activation energy is related to the energy required to move an atom from one lattice site to another.

**Amorphous materials** Materials that have no regular repetitive arrangement of atoms in a solid which extends over a very large distance.

**Creep rate** The rate at which a material deforms when a stress is applied usually at a high temperature.

**Grain boundaries** Regions between grains or crystals of a polycrystalline or nanocrystalline material. The grain has a different orientation on either side of the grain boundary.

**Hall–petch behavior** A specific relationship between yield strength or hardness and grain size in a metallic material.

**Impurity segregation** Increased concentration of elements at structural defects in the material, such as at grain boundaries and triple junctions. The impurities often originate from processing or raw materials and usually have a deleterious effect on the properties or processing of a material.

**Interfacial effects** Influence of grain boundaries and triple junctions (i.e. intersection of three or more grain boundaries) on properties such as mechanical, physical, and chemical.

**Intergranular corrosion** Corrosion at grain boundaries due to local galvanic cells produced by grain boundary energy, segregation, or precipitation.

**Nanostructure** Structure of a material at a nano-scale, i.e. length-scale 1–100 nm.

**Saturation magnetization** All the magnetic moments have been aligned by the magnetic field producing the maximum magnetization.

**Twin boundary** A surface defect across which there is a mirror image misorientation of the crystal structure.

**Young's modulus** The slope of the linear part of a stress-strain curve in the elastic region.

## 1. INTRODUCTION

Ion implantation can trace its roots back to the Manhattan project of the 1940's and the development of the world's first atomic bombs. At the heart of the ion implanter is the mass analyzer, which was developed during the Manhattan project as a means of separating the different uranium isotopes.

Ion implantation involves the formation of a plasma using either a gaseous, solid, or occasionally liquid source containing the isotope which is to be implanted. Ions (usually positively charged) are then extracted from the plasma and accelerated to the desired energy (from several hundred eV to MeVs). The mass analyzer then selects the desired isotope, which is then implanted into a target. The beam is either electrostatically scanned over a single target, or a number of targets are mechanically scanned in front of the ion beam. Ion implantation is used in a number of applications, namely,

- semiconductor doping,
- synthesis of compound layers,
- materials modification,
- understanding the effects of radiation on living tissue.

This chapter deals primarily with nanostructures formed in semiconductor and semiconductor-related structures using ion implantation. It then proceeds to examine emerging fields of research where materials as diverse as superconductors and living cells are beginning to be probed and modified using ion implantation techniques.

## 2. ION IMPLANTATION IN SEMICONDUCTORS

### 2.1. Introduction

Different regions of semiconductor devices conduct via electrons or positive holes, with the dominant conducting species being termed the majority carrier and the lesser the minority carrier. In order to make a region of a semiconductor electron or hole rich, impurity atoms have to be introduced into the semiconductor lattice. These impurities can either donate electrons (e.g., arsenic (As), phosphorous (P), or antimony (Sb) in silicon (Si)) or accept electrons and thereby create positive holes (e.g., boron (B) in silicon (Si)). These impurity atoms are called dopants.

At least two ion implantation steps are used in the manufacture of over 99% of silicon chips and many semiconductor fabrication processes use more implantation steps. Ion implantation is used because of the controllability and precision it affords in placing the desired dopant at the required location within the semiconductor device.

The depth at which an implanted dopant comes to rest beneath the surface of the semiconductor is dependent on:

- mass of the dopant ion,
- energy of dopant ion,
- mass of the target atoms,
- implantation angle,
- orientation of the target,
- implantation temperature.

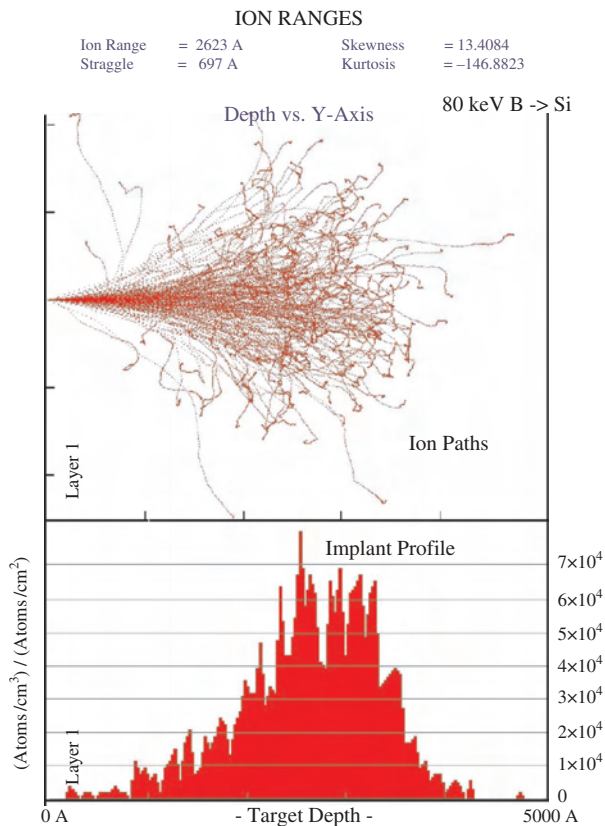

The processes responsible for slowing down the incoming dopant atom within the target are termed electronic and nuclear stopping.

Electronic stopping occurs via the excitation of the target electrons by the incoming dopant atom. It is an inelastic process and can be likened to the viscous drag experienced by a ball bearing when dropped into a jar of syrup.

Nuclear stopping, as the name suggests, is the slowing down of the incoming atom through elastic "collisions" between the incoming dopant atom and the target nuclei. These collisions can be described by classical Newtonian mechanics and can be likened to the collisions experienced by snooker balls.

The peak in the nuclear stopping occurs when the energy of the ion in keV is approximately equal to the atomic mass of the ion, so for boron (B), this is  $\sim 11$  keV, for arsenic (As)  $\sim 75$  keV, and for phosphorous (P)  $\sim 31$  keV. Electronic stopping becomes the predominant mechanism at about twice this value, with the peak in electronic stopping occurring when the energy in MeV is approximately equal to the mass of the ion, that is,  $\sim 11$  MeV for boron,  $\sim 75$  MeV for arsenic (As), and  $\sim 31$  MeV for phosphorous (P). Obviously, where each atom comes to rest, is a statistical process with some atoms coming to rest close to the surface while others come to rest at depth [1] (Fig. 1).

During the nuclear stopping process, target atoms can be given sufficient energy (10–20 eV) to displace them from their lattice sites and they in turn can displace other target atoms. Thus, in the region where nuclear stopping predominates the track of the incoming dopant atom is surrounded by the tracks of recoiling target atoms—termed the collision cascade (Fig. 2). For heavy ions (e.g., As, Sb) in a target such as silicon, the collision cascade is dense and starts close to the surface (Figs. 2c and 2d). For lighter ions (e.g., B Fig. 2a and P Fig. 2b), the collision cascade contains far fewer recoils, occurs close to the end of range, and is fairly diffuse. The damage produced during implantation is in the form of vacancies and interstitials, which can form defect clusters, dislocation clusters, and even extended defects as the implant progresses. When adjacent collision cascades overlap, the local energy within the system can be sufficient

**Figure 1.** Simulation of 80 keV B implantation into silicon, showing individual ion paths and depth distribution of implanted B atoms.

**Figure 2.** Simulated collision cascades from different elements implanted into silicon: (a) B; (b) P; (c) As; and (d) Sb.

to facilitate a local crystalline  $\rightarrow$  amorphous phase transformation and if the dose is increased still further, an amorphous layer can be produced.

Annealing subsequent to implantation is used to activate the implanted dopant atoms by placing them on substitutional lattice sites. Annealing is also used to remove, as far as is possible, the residual radiation damage resulting from implantation and to regrow regions that have been amorphized.

Doping, as mentioned previously, is used to modify the electrical properties of a semiconductor. However, by increasing the dose of implanted ions, it is possible to synthesize another compound within the target substrate. This often occurs at temperatures well below those required for conventional equilibrium growth. This phenomenon is thought to occur because some of the bonds within the target lattice have been broken by the incoming ion, and as the energetic reactants are intimately mixed the reaction can proceed immediately. Subsequent to implantation, the structure is normally annealed to remove as much of the implantation-induced damage as possible and to redistribute the implanted species. The process of ion beam synthesis (IBS) is shown schematically in Figure 3.

The size of the synthesized precipitates fabricated by IBS depends on:

- the implanted dose
- the implanted energy
- the number of nucleation sites available
- the implantation temperature
- annealing temperature and time

Before going on to look at the formation of ion-implanted nanostructures, it is pertinent to consider the mechanisms by which they nucleate and grow.

## 2.2. Precipitate Nucleation and Growth

The nucleation of ion beam synthesized phases depends on the implanted ion and the substrate material. The first step in the nucleation of the synthesized phase is

**Figure 3.** Schematic showing the process of ion beam synthesis.

thought to be via the occupation of interstitial sites by the implanted atom [2]. Extended X-ray absorption fine structure (EXAFS) studies [3] on the early stages of  $\text{CoSi}_2$  synthesis indicates the presence of  $\text{CoSi}_3$  cores, which subsequently grow into  $\text{CoSi}_2$  precipitates with the eightfold coordination of the nuclei reflected in the  $\text{CaF}_2$  structure of the  $\text{CoSi}_2$  phase.

The growth of the precipitates during implantation and the subsequent annealing phase is governed by thermally induced precipitate coarsening (Oswald ripening), the local concentration of the implanted atoms, and diffusion. Consider a system in which the concentration of solute (implanted atoms) remains constant. Then at a given temperature,  $T$ , if the solute concentration exceeds the solid solubility limit of the matrix, discrete precipitates of either a pure solute phase or a solute-matrix compound will form. If  $T_E$  is defined as the equilibrium temperature at which all the solute is in solid solution with the matrix, then providing the solid solubility decreases with temperature, when  $T < T_E$  precipitates will form. The degree of solute supersaturation is proportional to  $T_E - T$ . If  $r_c$  is the critical radius of a precipitate at an annealing temperature  $T_A$ , then precipitates with radii equal or greater than  $r_c$  will be stable at  $T_A$ , whereas those with smaller radii will be unstable and will dissolve. As  $T_A$  increases,  $r_c$  increases and the solute atoms released by the dissolution of the smaller unstable precipitates migrate to larger stable precipitates. As an implant profile roughly corresponds to a gaussian, the largest precipitates are found at the peak and the smallest in the wings. Thus, during annealing, as the temperature rises, the larger precipitates at the peak appear to suck in solute atoms from the wings. This is shown schematically in Figure 4.

The following sections examine specific examples of ion-beam synthesized nanostructures for a number of applications.

### 2.3. Light Emission from Silicon

The development of silicon-based, integrated circuit technology has more or less followed Moore's law for the past three decades. Moore's law was developed by Gordon Moore, one of the cofounders of Intel in 1965, states that "the number of transistors that can be placed on the same area of a microprocessor doubles every eighteen months." As silicon chips have

As temperature increases the critical radius of a precipitate increases

**Figure 4.** Schematic showing how the critical radius of the ion beam synthesized precipitates increases with increasing anneal temperature.

become smaller and faster, the feature size has decreased such that device technology nodes are now measured in nm. In 2002, Intel demonstrated fully functional chips using 90-nm node technology with 330 million transistors incorporated onto a single chip. It is true to say that ion-implanted nanostructures are already part of our everyday life.

The point is now being reached, however, where the delay time in the devices and interconnects, means that further miniaturization and increases in packing density are posing severe technological problems and are not yielding the increases in circuit speed required for the next generation of integrated circuits. One route to further improvements would be to utilize light rather than electrons for on-chip data transfer. Significant research into silicon-based optoelectronics has, therefore, been undertaken over the past 10–15 years to see whether conventional silicon circuit components can be integrated with optical components on a single chip. This research interest is not surprising given the potential impact such a technology would have on the computer and communications industries—especially if it were compatible with ultra large scale integration (ULSI) processing and integrated with optical fibers. With respect to the latter, the 1.5  $\mu\text{m}$  wavelength is of particular interest, as this corresponds to the wavelength window preferred for optical communication systems. However, the indirect nature of the bandgap in silicon would at first sight appear to preclude this as a possibility. Thus, the search has been to find a method of achieving optical emitters, waveguides, and detectors in silicon. Several alternatives have been tried; at present, some of the most promising utilize ion-implanted nanostructures.

### 2.4. Ion Beam Synthesis in Silicon

Before going on to look at light-emitting, silicon nanostructures, it is important to look at the development of ion beam synthesis. During the 1980's, it had been shown [4, 5] that when high doses (typically  $1.8 \times 10^{18} \text{ O}^+ \text{ cm}^{-2}$ ) of energetic (typically 200 eV) oxygen ions were implanted into silicon at elevated temperatures ( $\sim 600^\circ\text{C}$ ), a buried dielectric layer some 3000  $\text{\AA}$  thick was formed beneath a single crystal silicon overlayer (2000  $\text{\AA}$  thick). These structures termed separation by implanted oxygen (SIMOX) [6]

could be processed like conventional silicon but had the additional advantages that devices fabricated on them were much more tolerant to ionizing radiation and much less prone to parasitic transistor action between adjacent devices (latch-up). Early device characteristics were, however, inferior to those in conventional silicon because of residual defects and SiO<sub>2</sub> precipitates in the silicon overlayer (Fig. 5). The breakthrough came in 1986 [7, 8] when higher annealing temperatures were used. Before this the maximum annealing temperature had been 1200 °C, but by increasing this annealing temperature to 1300 °C for 6 h or 1405 °C for 30 min, the SiO<sub>2</sub> precipitates and the defects in the silicon overlayer were almost entirely removed (Fig. 6). The evolution of the SIMOX structure with annealing temperature is a good illustration of thermally induced precipitate growth and dissolution. By 1300 °C, the buried oxide layer is the only stable precipitate and all of the implanted oxygen tends to segregate towards it. Device characteristics from SIMOX structures annealed at  $\geq 1300$  °C showed significant improvements over those annealed at lower temperatures and by the late 1980's commercial implanters [9] had been produced for the fabrication of SIMOX wafers. More recently, SIMOX and other silicon on insulator (SOI) substrates have been used to enable further reductions in the feature size of complementary metal oxide semiconductor (CMOS) devices, enabling higher speeds and lower power consumption to be realized.

The success of SIMOX technology encouraged research in other types of ion beam synthesis, particularly in silicon. In 1987, White et al. [10] at AT&T Bell Laboratories reported the successful fabrication of hetero-epitaxial CoSi<sub>2</sub> in silicon. The ion beam synthesized CoSi<sub>2</sub> was found to have a very low resistivity [11] (12  $\mu\Omega$  cm) and was seen as having applications in novel hot electron devices, vertical devices, and high-speed interconnects. Discrete wires [12], dots, and buried structures [13] have all been fabricated using IBS CoSi<sub>2</sub>. Other metallic silicides were also synthesized using ion beams. These included NiSi<sub>2</sub> [14], CrSi<sub>2</sub> [15], YSi<sub>2</sub> [16], ErSi [17, 18], HfSi<sub>2</sub> [19] and WSi<sub>2</sub> [20]. Apart from the conducting silicides, semiconducting materials such as SiC [21] were also investigated. In the early 1990's, interest turned to IBS of semiconducting  $\beta$ FeSi<sub>2</sub>.

**Figure 5.** SIMOX structure implanted at  $1.8 \times 10^{18}$  O cm<sup>-2</sup> 200 keV and annealed at 1150 °C 2 h.

**Figure 6.** SIMOX structure implanted at  $1.7 \times 10^{18}$  O cm<sup>-2</sup> 200 keV and annealed at 1300 °C 2 h.

## 2.5. Light-Emitting $\beta$ FeSi<sub>2</sub>

$\beta$ FeSi<sub>2</sub> was of interest as it is a semiconductor with a bandgap of 0.87 eV. If it has a direct bandgap, then it has the potential to emit light at 1.5  $\mu$ m, which would make it compatible with optical fiber technology and facilitate the integration of electronic and optoelectronic components on a single chip. The potential impact of such a technology on the computer and communications industries would be enormous and thus significant research has been devoted to investigating the materials—optical and electronic properties of  $\beta$ FeSi<sub>2</sub>—over the past 10 years.

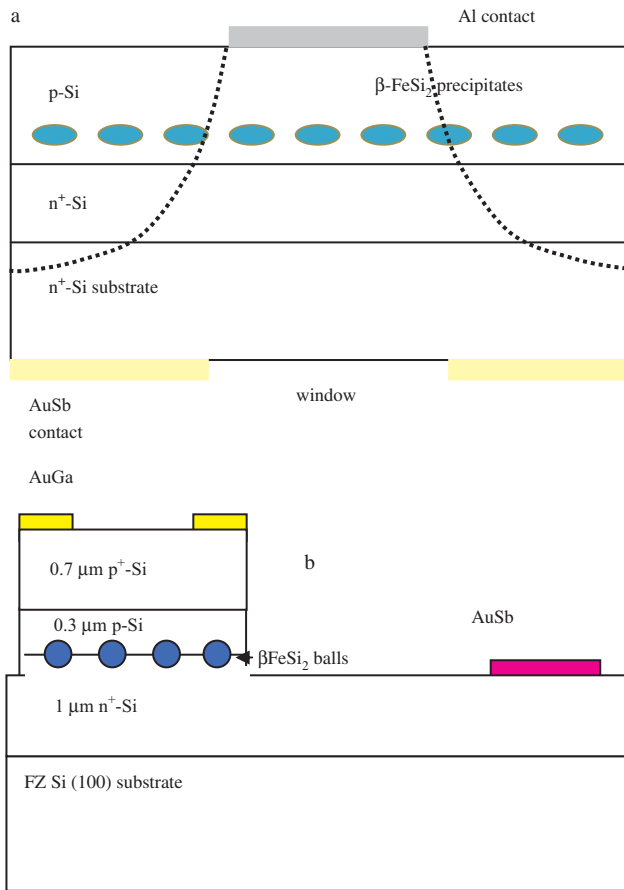

There has been some debate in the literature about the nature of the bandgap in  $\beta$ FeSi<sub>2</sub>. Band structure calculations [22, 23] predicted a direct energy gap of approximately 0.85 eV and an indirect energy gap at slightly lower energies. Some experimental observations [24–27] had concluded that the bandgap was indirect, while other experimental results [28–33] indicated a direct bandgap of 0.87–0.89 eV. The reason for this apparent discrepancy was attributed by some to the presence of defects in the surrounding silicon, in particular the D1 dislocation related line (0.81 eV) [34]. It was claimed the observed photoluminescence originated from these defects rather than from the  $\beta$ FeSi<sub>2</sub> itself. Obviously, if  $\beta$ FeSi<sub>2</sub> was to be seriously considered as a good candidate for optoelectronic devices, this particular controversy had to be resolved.

In 1997, Leong et al. [33] published results on an electroluminescent device operating at 1.5  $\mu$ m, in which a layer of  $\beta$ FeSi<sub>2</sub> precipitates had been fabricated by IBS above a silicon p-n junction. More recent theoretical studies by Miglio and Merregalli [35, 36] have concluded that the extreme sensitivity of the electronic bands to lattice deformation and the strong electron phonon coupling may account for the different experimental observations. They concluded that the growth conditions may be critical in determining whether the  $\beta$ FeSi<sub>2</sub> has a direct or an indirect bandgap.

To date, two methods [33, 37, 38] have been successfully employed to achieve room temperature electroluminescence (albeit rather weak) from silicon-based structures incorporating nano-precipitates of  $\beta$ FeSi<sub>2</sub>. These are:

### 2.5.1. Ion Beam Synthesis

Ion beam synthesis uses high dose Fe<sup>+</sup> implantation, at elevated temperatures, (500°–600 °C) into a silicon p-n junction, followed by a 900 °C, 18-h anneal in a nitrogen ambient [33, 37]. A schematic of this structure is shown in Figure 7a. The

**Figure 7.** (a) Schematic of the  $\beta\text{FeSi}_2/\text{Si}$  light emitting device fabricated by IBS; (b) Schematic of the  $\beta\text{FeSi}_2/\text{Si}$  LED fabricated by RDE.

optimum results to date were found for samples implanted with a dose of  $1.5 \times 10^{16}$  Fe  $\text{cm}^{-2}$ . It has also been found that the best results are obtained when the  $\beta\text{FeSi}_2$  precipitates are buried well below the silicon surface. This is thought to be because this allows carrier injection and direct recombination to occur in relatively undamaged silicon, whereas for the samples implanted at lower energies, this region is much thinner and contains a higher number of defects. The quenching of the EL signal for the IBS samples, is found to depend on the doping density of the p-type layer, and hence the proximity of the  $\beta\text{FeSi}_2$  precipitates to the depletion region. The best results were achieved for the highest p-type doping density ( $1 \times 10^{18}$  B  $\text{cm}^{-3}$ ).

### 2.5.2. Reaction Deposition Epitaxy

Using the reaction deposition epitaxy (RDE) technique, Suemasu et al. [38] deposited a thin ( $\sim 10$  nm), continuous layer of epitaxial  $\beta\text{FeSi}_2$  on a pregrown p-n junction. After which, the sample was annealed in ultra-high vacuum at  $850^\circ\text{C}$  for 1 h and then  $0.3 \mu\text{m}$  of p-type silicon was deposited, at  $500^\circ\text{C}$  by molecular beam epitaxy (MBE). The structure was then annealed in an argon ambient at  $900^\circ\text{C}$  for 14 h. A schematic of this structure is shown in Figure 7b. Using this technique, the  $\beta\text{FeSi}_2$  nano-balls are fabricated across the p-n junction. The room temperature electroluminescence (EL) increased superlinearly with injected current

density and a reasonable EL signal was observed at room temperature for injection currents above  $10 \text{ A cm}^{-2}$ .

The weak room temperature electroluminescence observed from  $\beta\text{FeSi}_2$  means that although this material is an interesting candidate for silicon-based optoelectronics, unless significant improvements are made in the intensity of the emitted light, it is not a serious candidate for commercial devices.

## 2.6. Ion-Implanted LEDs in Silicon-Dislocation Engineering

In 2001, Ng et al. [39] reported room temperature electroluminescence from a boron-implanted device, which the authors attribute to “Dislocation Engineering.” In this study, they implanted B to a dose of  $1 \times 10^{15}$  B  $\text{cm}^{-2}$  at an energy of 30 keV into an n-type silicon substrate (CZ  $2\text{--}4 \Omega \text{ cm}$ ). The sample was then annealed at  $1000^\circ\text{C}$  in a nitrogen ambient for 20 min. The implantation of B meant that a p-n junction was produced; the B implantation also produced small dislocation loops  $80\text{--}100$  nm in diameter located  $\sim 100$  nm below the junction. The authors claim that the strain field associated with these dislocation loops leads to an increase in the local bandgap of  $0.35\text{--}0.7$  eV, causing a blocking potential barrier that confines the carriers within the junction region and allows room temperature electroluminescence to be achieved. The main peak of the room temperature electroluminescence spectrum is found at  $1.16 \mu\text{m}$ . The authors claim an external quantum efficiency of  $2 \pm 0.1 \times 10^{-4}$  for this device, making it a promising candidate for silicon-based optoelectronics (for comparison, commercial GaAs infrared LED have external quantum efficiencies of typically  $\times 10^{-2}$ ).

In order to see whether this dislocation engineering approach could be used to fabricate devices operating at different wavelengths, Lourenco et al. [40] incorporated it with known radiative centers (such as  $\beta\text{FeSi}_2$  precipitates and Er). Nonradiative defect centers in the bulk and at the surface are thought to be responsible for the thermal quenching observed in  $\beta\text{FeSi}_2$  precipitate structures and those incorporating Er. The authors claim that the provision of a barrier between the surface and the bulk, in the dislocation engineered samples enables the recapture of blocked carriers, enhancing the radiative routes and significantly reducing the thermal quenching. The results presented [40] appear to support this supposition, although apart from wavelength tuning, the authors do not appear to have significantly improved on the efficiency of their original device.

In parallel to work on light emission from nanostructures in silicon, work has also been progressing on nanostructures in silicon dioxide both for light emission and novel device applications. These will be discussed in the following two sections.

## 2.7. Light Emission from Silicon Nanocrystals in Silicon Dioxide

Over the past decade, there has been significant interest in silicon nanocrystals fabricated in silicon dioxide layers on silicon. These materials are of interest for applications in optoelectronics and their potential uses in volatile memory devices [41, 42]. The nanocrystals are either produced by the implantation of silicon ions into silicon dioxide [43–47]

or by the annealing of sub-stoichiometric  $\text{SiO}_x$  layers (Si  $\sim$  46 at %) on silicon [48] fabricated using plasma-enhanced, chemical vapor deposition (PECVD). The implantation of silicon is seen as a particularly attractive route for the formation of these nanocrystals, since it is fully compatible with silicon process technology and enables precise amounts of atoms to be placed at controlled depths. It also allows the samples to be masked so that nanocrystals can be placed in discrete regions of a device.

Silicon nanocrystals formed by implantation are fabricated using high doses (typically  $1 \times 10^{15}$ – $1 \times 10^{17}$  ions  $\text{cm}^{-2}$ ) of silicon implanted into silicon dioxide at energies of 25–200 keV, such that the peak concentration of the implanted ions ranges from 0.3 to 46 Si at %. The samples are normally implanted at room temperature. Subsequent to implantation, the samples are annealed in an inert ambient at temperatures  $>950$  °C for times ranging from 1–20 h. Most of the experiments have been undertaken on thermally grown silicon dioxide layers on  $\langle 100 \rangle$  silicon wafers. The oxide layers are typically 100–600 nm thick, although Linros et al. [49] used films of 10–100 nm thick. The oxidation temperature is typically around 1100 °C and both wet and dry oxidation methods have been used. For thin layers of silicon dioxide, a single energy implant is normally used for which the projected range of the implanted ions is approximately one-third the oxide thickness. For thicker oxide layers, multiple energy implants are used to give an approximately constant concentration of implanted ions over a depth range commensurate with the oxide thickness (typically 100–400 nm).

After implantation, most of the implanted atoms exist as small, elemental, crystalline, nanoprecipitates with a smaller amount of the implanted species in a solid solution with the silicon dioxide. Silicon nanocrystals have been shown to be responsible for the strong red PL which is found at  $\sim 1.7$  eV [43, 44, 46, 50, 51]. It is now generally recognized that there is a strong correlation between the wavelength of the emitted light and the size of the silicon nanocrystals. More recently Lopez et al. [45] have shown that the photoluminescence (PL) intensity follows the volume fraction of precipitates. Figure 8 shows the results for silicon nanocrystals fabricated by both implantation and PECVD for a range of annealing temperatures and times. The nanocrystals fabricated by PECVD are generally smaller than those formed by implantation and appear to have a more uniform size distribution. Lopez et al. [45] have described two regimes with respect to the density of silicon nanocrystals. The first is when the concentration of silicon in the silicon dioxide layer falls below a certain critical value (Lopez et al. [45] suggest  $\leq 10\%$  at % Si, but other authors [46] think the value is lower). In this regime, the system should be treated as dilute, that is, each silicon nanocrystal can be treated as a discrete entity which is unaffected by other silicon nanocrystals since these are so far away from it that their influence is negligible. This is especially valid given the low diffusion coefficient of silicon in silicon dioxide, which is thought to be between  $5 \times 10^{-18}$  and  $1 \times 10^{-16}$   $\text{cm}^2 \text{s}^{-1}$  [52, 53]. For higher doses, Lopez et al. [45] suggest that this regime can no longer be treated as a dilute system and that the interaction between nanocrystals must also be taken into account.

Most reports on silicon-implanted nanostructures report a PL peak at around 1.7 eV (728 nm). However, Rebohle

**Figure 8.** Variation in precipitate diameter with Si concentration and annealing time for Si nanocrystals in  $\text{SiO}_2$ . Adapted with permission from [45], M. Lopez et al., *Nucl. Instrum. Meth. B* 178, 89 (2001). © 2001, Elsevier Science; [46], T. S. Iwayama et al., *Surf. Coatings Technology* 158–159, 712 (2002). © 2002, Elsevier Science; [47], C. Bonafos et al., *Nucl. Instrum. et al. [54] report blue-violet PL (2.7 eV) in silicon-implanted samples, while [54–56] report PL at 3.2 eV for Ge-implanted samples and [54] report intense PL at 3.1 eV for Sn-implanted samples. The PL in the blue appears to come from an oxygen deficiency center rather than the nanocrystals themselves.

Considering the luminescence at around 1.7 eV, most authors agree the exact position of this peak appears to be dependent on the implanted dose of silicon [45, 46, 57, 58], with a red shift in PL peak position generally being observed with an increasing dose. Most agree that this red shift only occurs after a certain critical dose [45, 46, 59], although the magnitude of this dose appears to be influenced by the experimental conditions. Electron paramagnetic resonance (EPR) results [43, 45] show the presence of an  $E'$  center. After this paramagnetic center is associated with oxygen vacancy related defects [60, 61] the paramagnetic center associated with dangling bonds at the Si/SiO<sub>2</sub> interface is also observed ( $P_b$  center). During annealing, the  $E'$  centers are quickly annealed out and the intensity of the  $P_b$  signal at first decreases and then saturates.

The highest PL peak intensity is reported [45, 46] for samples containing  $\sim 10$  at % Si. For samples containing  $\leq 10$  at %, the PL intensity is found to initially increase with annealing time, after which it saturates [47]. Lopez et al. [45] suggest that during the initial stages of annealing, the silicon nanocrystals grow and some kind of surface passivation takes place (to account for the observed reduction in the EPR signal due to  $P_b$  centers). The nanocrystals then reach the critical radius for that annealing temperature and their size stabilizes, as does the number of dangling bonds at the

silicon/silicon dioxide interface. Interestingly, Cheylan and Elliman [62] have found that using a second stage anneal at 500 °C in forming gas (95% N<sub>2</sub>, 5% H<sub>2</sub>) results in an increase in PL intensity and a red shift in the emission peak. They have concluded that this increase in PL intensity may be a consequence of the passivation of nonradiative defects (e.g., silicon-dangling bonds).

There is some debate in the research about the mechanisms responsible for the luminescence at 1.7 eV. Some investigations have concluded that the observed PL is a result of quantum confinement (direct recombination of electrons and holes confined within the silicon nanocrystal), while others have concluded that it results from surface states in the interfacial layer between the silicon nanocrystal and the surrounding silicon dioxide. At first sight, the red shift observed in the PL peak position with increasing silicon dose [45, 46, 63], would appear to support the quantum confinement supposition. However, at lower doses, although the precipitates increase in size with annealing temperature (Fig. 8), the PL peak position does not change. Moreover, for samples annealed in forming gas [62] the precipitate size remains approximately constant and a red shift in the peak intensity is observed, which tends to suggest that the interface states at the silicon dioxide interface are also involved in the light emission.

The model that is most widely accepted for the observed light emission from silicon nanocrystals [46, 64–66] is that the light comes from the recombination of a quantum-confined exciton which is self-trapped [59, 60] in a size-dependent Si = O level [67] at the silicon-crystal/silicon dioxide interface. These interface states appear to be critically dependent on both the surface configuration [47] and the density of the silicon nanocrystals [48].

## 2.8. Er-Implanted Silicon Nanocrystals

Very recently, Pacifici et al. [66] has shown that if Er is implanted into a structure containing silicon nanostructures fabricated by PECVD, intense room temperature electroluminescence at 1.54 μm is observed. The silicon nanocrystals were ~1 nm in diameter and Er was implanted to a dose of  $7 \times 10^{14}$  Er cm<sup>-2</sup>, at an energy to place its peak in the center of the silicon dioxide layer where the nanocrystals are located. When an LED incorporating this structure is forward biased, the EL is quite intense even at room temperature. The authors suggest that strong coupling between the silicon nanocrystals and the implanted Er atoms effectively enables the nanocrystals to pump the Er, that is, each silicon nanocrystal absorbs energy that is preferentially transferred to the Er atom. This is observed in the strong increase of the excitation cross-section of the Er atom in the presence of silicon nanocrystals when compared to Er in the pure oxide host. Quoted quantum efficiencies larger than 1% have been claimed for this type of device [68]. Moreover, Er-doped silicon nanocrystals could, in principle, form the basis of a silicon laser as they combine the advantages of silicon (efficient excitation) and SiO<sub>2</sub> (negligible thermal quenching of luminescence), while avoiding their disadvantages (low excitation efficiency of SiO<sub>2</sub> and strong nonradiative processes in bulk Si). In contrast, the dislocation engineered structures

are unlikely to prove suitable for the fabrication of a silicon laser, since they are likely to still suffer from the two main problems encountered in bulk silicon which prevent population inversion, for example, Auger recombination and free-carrier absorption [68].

## 2.9. Combined Si and C Implants into Silicon Dioxide

González-Verona et al. [69] implanted both C and Si into SiO<sub>2</sub> layers. They implanted Si first at two energies in order to obtain a rectangular implant profile, buried 100 nm–300 nm from the surface, with a silicon excess of ~30%. They then implanted C so that the peak of the implant lay at the center of the implanted silicon distribution, with the peak C concentration  $2 \times 10^{22}$  C cm<sup>-3</sup> being approximately equal to that of Si in this region. Subsequent to implantation, the samples were annealed at 1100 °C for 4 h. Samples implanted with just silicon showed a strong red luminescence from silicon nanostructures, whereas those that had also been implanted with carbon showed a strong white emission. Photoluminescence analysis of this white emission shows three distinct peaks at 1.45 eV (854 nm), 2.1 eV (590 nm), and 2.8 eV (442 nm). These are thought to correspond to silicon nanocrystals (~4 nm in diameter), carbon rich amorphous clusters, and 6H-SiC nanocrystals (~7 nm in diameter), respectively. These results demonstrate the versatility of IBS and a potential method of tuning the emitted light.

## 2.10. Blue Emission from Group IV Implanted Silicon Dioxide

Germanium-doped silica glasses are known to exhibit a strong absorption band at 5 eV. More recently, blue EL has been observed from silicon implanted layers [54, 70, 71], violet EL from Ge-implanted layers [54–56, 72, 73], and blue-violet EL from Sn-implanted SiO<sub>2</sub> layers [51]. It is thought that the light emission in these structures arises from an oxygen deficiency center rather than the nanocrystals themselves. However, a power efficiency of 0.5% has been achieved for Ge-implanted silicon dioxide layers and the first successfully integrated optocoupler has been demonstrated [74].

## 2.11. Other Implants into Silicon Dioxide

Apart from the work mentioned above, a wide variety of other compounds have been synthesized in silicon dioxide. These include GaAs [75], ZnS [76], and ZnTe [77].

## 2.12. Smart Cut

High-dose ion implantation does not always lead to the formation of compound layers or discrete elemental nanocrystals. This section describes how high doses of inert ions can be used as atomic scalpels to allow thin layers of crystalline material to be placed on any kind of substrate (dielectric, glass, plastic, quartz, amorphous silicon, crystalline semiconductor, etc.). The Smart Cut™ process developed in the LETI Laboratories, Grenoble, France,

in 1991 involves the implantation of  $H^+$  ions into a target substrate (usually silicon). These hydrogen atoms then form small bubbles and microcavities, the size and density of which is dependent on the implantation parameters. These structures grow during implantation in a manner that again depends on the implanted dose, implantation energy, dose rate, implant temperature, and thermal history of the implanted wafer. When the distance between cavities falls below a certain threshold value, intercavity fractures occur that propagate through a percolation-type process [78]. This leads to a structure where all the microcavities are joined and expressed on the surface of the wafer by the formation of a blister. The driving force behind the formation of this blister is the gas pressure in the microcavities and stresses within the layer. By bonding another substrate to the implanted wafer, blister formation is suppressed and instead, a homogeneous force exists throughout the surface layer, enabling the surface layer to be split away from the underlying material with relative ease. After this, the sample undergoes a high temperature anneal and surface polish. Figure 9 shows a schematic of the Smart Cut™ process.

Smart Cut™ can be used in any material where microcavities can be produced by hydrogen or inert gas implantation. The fact that it uses implantation allows the thickness of the Smart Cut™ layer to be tailored for each specific application. Smart Cut™ silicon on insulator substrates

have been in commercial production since 1996, where along with SIMOX they provide a route for the realization of high speed, low-power consumption CMOS ICs. Recently [79], Smart Cut™ has been used in crystalline SiC structures which have enabled it to be bonded onto silicon substrate. The process has been used successfully in GaAs and InP [79–81].

### 3. OTHER APPLICATIONS OF ION BEAM SYNTHESIS

#### 3.1. Superconducting Nanocrystals Synthesized by IBS

Another very recent application of ion beam synthesis is in the fabrication of superconducting  $MgB_2$  nanocrystals. Although superconductors based on the YBaCuO system have been found with high superconducting transition temperatures ( $T_c$ ), they cannot be readily deposited as thin films. The superconductor that can readily be deposited as a thin film is Nb, but this has a very low  $T_c$  of 5 K. The recent discovery of a superconducting phase transition with a high  $T_c$  value of 39 K in ceramic  $MgB_2$ , has stimulated a new wave of worldwide research into the superconducting properties of this material and other related  $AlB_2$ -type compounds [82, 83], since these have the potential of being grown as thin films.

So far, various thin film preparation methods have been explored for the fabrication of  $MgB_2$  in many different laboratories with different substrates [84–87]. It is worth noting here that the most important factor influencing the  $T_c$  value appears to be related to the deposition method rather than the substrate materials used. A survey of the available literature reveals a number of major technical problems, which stand in the way of realizing high  $T_c$   $MgB_2$  thin films using conventional growth techniques. These include possible MgO contamination, poor stoichiometry control, and the need for a high temperature post-deposition anneal. The annealing temperature normally employed for producing the high  $T_c$  superconducting thin films is generally between 600° and 1000 °C, suggesting that these growth methods involve Mg diffusion into the solid B. As Mg starts to melt and  $MgB_2$  starts to dissociate at temperatures around 620 °C [88, 89], such a high annealing temperature are obviously undesirable for superconductor fabrication.

In order to avoid the unwanted high temperature step while still maintaining favorable  $MgB_2$  formation conditions, IBS has been used [90]. This involved the implantation of  $^{11}B$  into a solid Mg target. Peng et al. [80] have shown that  $MgB_2$  thin films can be successfully fabricated by high dose  $^{11}B$  implantation into commercial Mg ribbon followed by a relatively low temperature anneal at 500 °C. Figure 10 shows a XTEM image of a Mg sample implanted with  $1 \times 10^{18} \text{ cm}^{-2}$   $^{11}B$  at 80 keV and annealed at 500 °C for 15 min in flowing Ar gas. Figure 10 shows a buried layer containing small nano-precipitates of  $MgB_2$ . Magnetic susceptibility measurements on these samples reveal both the low temperature superconducting transition at 15 K and the high temperature transition at 36 K. Preliminary studies on these structures also indicate that the size of the  $MgB_2$  nano-precipitates play

Figure 9. Schematic of Smart Cut™ process.

**Figure 10.** XTEM image of IBS MgB<sub>2</sub>.

a crucial role in determining the magnitude of the higher temperature transition temperature.

All of the work discussed thus far uses relatively high doses of ions to form discrete nanostructures. The work discussed in the final section considers much lower doses and looks at their impact in a wide diversity of areas.

### 3.2. Medical and Future Applications of Ion Implantation

The smallest structures that can be envisaged are those where only a single ion is implanted. This technique is already being employed to target living cells in order to better understand the way in which ionizing radiation interacts with biological material [91]. Such research has important implications both for the development of radiation treatment strategies for cancer [92, 93] and for identifying potential risks from low-level radiation. By targeting cells individually, using submicron ion beams that deliver a precise number of ions to each cell (usually 1), it is possible to address a number of important radiobiological questions not easily studied by other methods. There are three areas where this technique excels:

- the ability to irradiate selected targets within individual cells;
- the ability to selectively target one or more cells within a population of cells;
- the ability to deliver exact low doses of particles to one or more cells, or to a whole population of cells.

The recent application of microbeam techniques to radiobiology is already yielding important information regarding the effect of ionizing radiations on cells and tissues, particularly at low doses relevant to risk. The microbeam provides an elegant method for accurately delivering single particles to cellular and subcellular targets *in vitro*, which experimentally mimics what happens with

environmental exposure to  $\alpha$ -particle emitting radionuclides (i.e., from radon, which represents the largest single contribution to our overall background dose). Microbeams will also be an important tool in the development of improved radiotherapy treatment strategies. The unique ability of a microbeam to probe effects at the individual cell and subcellular level will ultimately lead to a better understanding of both the mechanisms involved in tumor cell killing by radiations and those involved in cancer induction to nearby healthy tissue from low doses outside the treatment field.

Of relevance to both clinical and risk related studies, is the role of so-called “nontargeted” effects where cells respond indirectly to energy deposited by radiations. One such effect is the occurrence of damage arising from radiation-induced cell signaling, both intracellular (i.e., from the cytoplasm to the nucleus) and intercellular (from cell to cell and referred to as the “bystander effect”). In fact, recent discoveries have revealed a number of radiobiological effects that are known to cause significant deviations from the assumed dose-effect relationship, particularly at low doses. Such effects include the bystander effect, genomic instability (where damage is revealed in cells several generations after the initial exposure), and low-dose hypersensitivity. The ability of a microbeam to selectively irradiate subcellular targets and individual cells, and give the ultimate low dose of particles (i.e., just a single particle), make it ideal for the study of these effects. As the understanding develops of the responses of subcellular targets to irradiation, so potential targets for new drug development may emerge.

In addition to their applications in radiobiology, ion microbeams and the new generation of nanobeams are likely to play an increasingly important role in the future where potential applications include:

- study of single event upsets in digital electronic devices;
- study of selective radiation damage and strain fields in ultra-large scale integrated circuits;
- nano-lithography in polymers using precisely defined single-ion tracks;
- surface modification of catalysts for improved chemical reaction yields and selectivity;
- nano-implantation into semiconductors for direct writing of quantum dots and wires;
- quantum computing using the implantation of single ions.

## 4. CONCLUSIONS

In this chapter, the history of the technique of ion beam synthesis has been reviewed from the development of atomic weapons to cancer therapy. It has been shown that IBS structures have enabled high-speed, radiation-tolerant integrated circuits to be developed and that this technology will provide an important route for the realization of even smaller devices for future generations of integrated circuits. Ion implanted nanostructures may also play a key role in the development of silicon-based optoelectronics, as they provide routes for the fabrication of both laser and light-emitting devices (LED) structures. In addition, IBS superconducting films are just beginning to be developed; these may allow the full potential of commercial superconductivity

to be realized and exploited. In the future, the development of nano-beams offers a huge diversity of opportunities from quantum computing to cancer therapy.

## GLOSSARY

**Å** Angstrom =  $10^{-10}$  m.

**Amorphous** Random arrangement of atoms.

**CaF<sub>2</sub> structure** Cubic structure type with Ca coordination number 8 and fluorine coordination number 4.

**Complementary metal oxide semiconductor (CMOS)** Basic building block of computer memory chips. Contains two transistors of opposing polarities, when one is off the other is on.

**CZ** Silicon grown by the Czochralski technique which involves dipping a seed crystal into a crucible of molten silicon and drawing out a single crystal silicon ingot.

**Doping** Introduction of impurities into a semiconductor lattice to modify electrical conduction.

**Electroluminescence** Light is emitted in response to an applied electric current.

**Electron paramagnetic resonance (EPR)** Technique which involves flipping the spin of an electron associated with a paramagnetic centre in a magnetic field.

**eV** Electron volt =  $1.60218 \times 10^{-19}$  J = 23.053 kcal/mol.

**Exciton** Electron hole pair found in semiconductors and insulators in an excited state. The hole behaves as a positive charge and the electron is attracted to it, to form an exotic atom state similar to a hydrogen atom.

**Extended X-ray absorption fine structure (EXAFS)** Technique for probing the local structure around almost any element in the periodic table (except the lightest). Gives information about near neighbours and average interatomic distances.

**Interstitials** Sites between crystal lattice planes where an impurity or host atom can be located. These atoms are not bonded to the crystal lattice.

**Ion beam synthesis** Synthesis of a compound layer within a target substrate using ion implantation.

**MeV** Mega electron volt = 1 million eV.

**Phonon** Quantum of lattice vibration.

**Photoluminescence light (PL)** Directed onto a sample where it is absorbed, and imparts excess energy to the material via a process of photon excitation. One mechanism by which this excess energy can be liberated is via the emission of light (luminescence) if this process involves photoexcitation the emitted light is termed photoluminescence.

**Superconductivity** is the ability for a material to conduct electricity with practically zero resistance.

**Ultra large scale integration (ULSI)** Refers to how many circuit elements can be placed on a single chip. Where very large scale integration (VLSI) stops and ULSI starts is unclear but it is generally thought that above 1 million circuit elements on a chip is ULSI.

**Vacancies** Sites in a crystal lattice where an atom is missing.

**Waveguide** A material medial that guides and confines a propagating electromagnetic wave.

## 1. INTRODUCTION

In this chapter, we review the recent results on the modification of surfaces (especially metal surfaces) induced by ion sputtering. The method is very common in so-called surface science since it provides a simple tool which can be used for many different purposes, such as material deposition and chemical analysis. Ion sputtering, which will be presented in greater detail in the next paragraph, consists of the bombardment of a target by ions (generally of noble gases like argon, neon, and xenon) accelerated by an electric field, in order to get typical kinetic energies in the range 0.1–10 keV ( $1 \text{ eV} = 1.6 \cdot 10^{-19} \text{ J}$ ). Roughly speaking, when the ion hits the target, it can penetrate for many nanometers in the solid, causing the displacement of many thousands of atoms from their original position and the ejection of few (typically less than ten) other atoms in the vacuum.

In many cases, one may be interested to collect the ejected atoms, for example, by inducing their deposition onto a substrate: if so, we speak about “sputter deposition,” which represents a convenient tool to produce thin films also on a large scale. On the other hand, performing an analysis of the ejected atoms (for example, by means of a mass spectrometer, like in the SIMS) one can obtain the composition of the target.

In many instances, one can use ion sputtering only to clean a surface, removing the first layers, and then exposing a fresh surface for other analysis or material deposition.

Within our scope, we are interested in the surface damage induced by ion sputtering. We will show that this damage can be “driven” to obtain morphologies characterized by a long-range order and a characteristic size on the nanometer scale. These nanopatterns can be used as substrates for subsequent depositions, or to modify the chemical properties of the target, or to produce electronic devices.

On these topics, many recent reviews have been published in specialized scientific journals [1–3].

## 2. ION SPUTTERING

The process of ion sputtering may remind one of sandblasting, the erosion of materials with a stream of abrasive particles: a projectile is accelerated in order to transfer its kinetic energy to the atoms of the target. As a consequence of the impact, atoms are removed from the target. In both methods, the erosion rate depends on the angle of incidence, but the physical processes involved are quite different since the average kinetic energy per atom in sandblasting (a few millielectron volts) is much lower than that in sputtering (electronvolts to several kiloelectronvolts). Unlike the abrasive particles, ions can penetrate deep into the target, and energy and momentum transfer occur on a different scale. An important experimental observation is that ion erosion occurs even in the limit of a small flux, and the sputter yield is independent of the flux. In other words, even a single ion can remove target atoms.

The first explanation of the sputtering process came from Stark [4]: ion bombardment leads to heating of the target, and subsequent boiling of atoms from the surface region. Actually, molecular dynamics simulations have shown that thermal spikes do occur [5]. When crystalline materials are bombarded with kiloelectronvolt ions, part of the material in the path of the ions has the radial distribution function of a liquid, consistent with local heating of the target. However, the sputter yield from such heating is low due to the short-lived nature of the spikes, typically a few picoseconds. There just is not enough time for atoms to boil off from the target.

A better description has been developed by Sigmund [4, 6, 7] and Thompson [8] (transport theory): the incident ion loses its energy to the target atoms through a series of collisions, as schematically shown in Figure 1. The target atoms

**Figure 1.** Schematic drawing of the collision cascade induced in a crystal by an energetic ion.

involved in these collisions, in turn, undergo further collisions, thereby setting up collision cascades. Some atoms near the surface receive a sufficient kick in these cascades to leave the target. In order to understand what happens when an ion impinges on a surface, we have to consider the way in which an energetic ion loses its energy through collisions. Two mechanisms must be considered: scattering with the nuclei and with the electrons. This view is so correct that the penetration range of the ions can be determined to a good approximation by treating the nuclear stopping and the electronic stopping independently. For all except the light ions (such as  $H^+$ ,  $He^+$ ), the nuclear energy loss dominates at low (kiloelectronvolt) energies. The nuclear energy loss can be calculated by modeling the interaction of the ion and the target nucleus with a (repulsive) screened Coulomb potential. Lindhard, Scharff, and Schafer wrote a universal expression for the nuclear stopping cross section (nuclear energy loss per unit path length per unit atomic density), now called the LSS expression, for any ion–target combination [9]. The transport theory incorporates the ideas of the stopping theory of Lindhard and co-workers. Being a continuum theory, it applies best to amorphous and polycrystalline targets.

While the mathematical treatment of the ion transport is sophisticated, the results take a simple form. The sputter yield  $Y$  (i.e., the number of target atoms ejected per incident ion) has the expression  $Y \approx \alpha NS(E)/E_b$ , where  $N$  is the atom density of the target,  $S(E)$  is the stopping power (a function of the incident energy  $E$ ),  $E_b$  is the binding energy for a surface atom in the target, and  $\alpha$  contains material and geometric parameters.

The consequences of the transport theory have been verified with great accuracy in the past since it was a crucial model for the development of the ion-implantation technique which is now commonly used in semiconductor technology. All of the results showed that this theory describes the ion sputtering quite well.

Before concluding this paragraph, we want to remark that the simulation of a collision cascade in a solid represented in past years a challenge for the development of fast computer codes and molecular dynamics techniques. Today, various PC programs are very popular among researchers in the field (the most famous is the TRIM code).

### 3. MORPHOLOGICAL MODIFICATIONS INDUCED BY ION SPUTTERING ON METALS

In the previous paragraph, we saw that, when an energetic ion hits the target, it dissipates its kinetic energy by multiple collisions with the atoms. As computer simulations show, the dissipative process occurs in a few picoseconds ( $1 \text{ ps} = 10^{-12} \text{ s}$ ). The final result is that many thousands of atoms are moved from their original position, and a few are ejected into vacuum. Of course, this atomic arrangement is out of equilibrium, and then the system tends to recover an energetically stable configuration. When the target is a metal, the main mechanism by which the atoms try to find their equilibrium is surface diffusion. From these simple considerations, we can deduce some general rules about the effect of ion sputtering on metals.

1. While the dissipation of the kinetic energy can be considered temperature independent, the mechanism for the equilibrium recovery is strongly temperature dependent since it depends on surface diffusion. Surface diffusion is a thermally activated process; generally speaking, an adatom (i.e., an atom on the surface) can move in different ways, and each way has an energy cost  $E$ . The rate  $v$  at which an adatom tries to follow a particular diffusion path can be written

$$v = v_0 \exp(-E/kT) \quad (1)$$

where  $v_0$  is on the order of  $10^{13} \text{ s}^{-1}$ ,  $k$  is the Boltzmann constant, and  $T$  is the surface temperature.

From 1, it is clear that, at high enough temperatures, the adatoms can follow many different paths to gain an equilibrium position, and so the damage recovery is very effective and fast. But lowering the temperature, the contrary happens, and the damage recovery is slow.

In conclusion, the surface morphology is due to a competition between the induced damage and the recovery by surface diffusion.

2. The surface morphology must depend on the rate at which the ions arrive on the surface [ion flux  $\Phi$ , expressed in ions/(cm<sup>2</sup> · s)]. In fact, since the damage happens in a few picoseconds, if the ion flux is low, the target has a sufficient time to recover, and the next ion again sees a surface in equilibrium. With the typical ion flux used in the laboratory, some milliseconds can pass between two hits in the same area.
3. Also, the total number of ions hitting the surface (ion dose  $D$ , expressed in ions/cm<sup>2</sup>) is a crucial parameter to determine the surface morphology. In fact, if the time delay between two ion hits is not long enough, the damage cumulates, and the final morphology is determined by the history of the ion sputtering process.

In light of these preliminary considerations, we can start to examine the experimental evidence. The recent studies on the present topic have been done with essentially three methods.

1. Surface microscopy: Since the typical spatial range of the structures present on an ion-bombarded surface is the nanometer, electron microscopy (SEM) and scanning probe microscopy (STM, AFM) have been extensively used. These techniques allow us to directly visualize the effect of the ion sputtering, but generally, they are applied in a nonreal-time mode: the sample is first processed, and then imaged with the microscope. Often, the time delay between the two stages is so long that it is not guaranteed that the surface morphology visualized by the microscope is really the same produced at the end of the ion sputtering since the smoothing mechanisms continue to act. Further, if one is interested in the statistical properties of the ion-bombarded surface (we will show that a statistical approach can be very convenient to analyze the data), many tens of images must be acquired, and the method can become very time consuming
2. Electron diffractive methods: LEED and SPA-LEED overcome some limitation of the previous techniques, in particular, they allow us to analyze a relatively large region of the sample, so it is an easy task to measure the statistical properties of the surface. However, rarely have these techniques been applied to real-time studies since the technical difficulties are relevant.
3. X-ray diffractive methods: In the last few years, diffraction techniques based on the scattering of X-rays have been successfully applied. The most interesting experiments have been carried out at synchrotron radiation facilities since the X-ray beam is characterized by high brilliance and monochromaticity. By means of these methods, it is possible to follow the evolution of the surface morphology in real time, during the ion sputtering.

### 3.1. Single Impacts

We begin our presentation of experimental results with the direct observations done on the surface damage induced by a single ion on a metallic surface. To perform this kind of study, the ion flux is reduced to very low rates,

and the sputtering time is so short that it is possible to image (with an appropriate microscopy, especially STM in an ultrahigh-vacuum environment) the effect of a single impact.

Figure 2 reports the result on an Ag(100) surface. Ar<sup>+</sup> ions, with an energy of 1 keV, are directed against the surface. Each dark spot represents a vacancy island corresponding to a single ion impact (the number of these holes corresponds very well with the ion dose). Around the hole, few islands are present (the bright spots in the figure). The interpretation of this image is straightforward. An ion impinging on the surface causes two kinds of defects: a vacancy island and some adatom clusters around it. The hole has a depth of one layer, and also the adatom clusters generally have a thickness of one layer. Quite similar results have been obtained by analyzing the single impacts on Pt(111) [10] and Al(111) [11]. By means of a detailed analysis of many images, and following the evolution of the surface morphology with increasing temperature, the authors showed that the adatom clusters come out from an inner layer, a few atoms are ejected from the surface, and many vacancies are frozen in subsurface layers.

From these results, we can deduce that such a mechanism is quite general for metals, and it is different from what happens in semiconductors, where a single ion impact causes only the ejection of a few atoms and the creation of a vacancy island, but not of adatom clusters (see Section 4).

This is the starting point for the interpretation of the experiments shown in the next paragraph: increasing the ion flux and dose, we induce many of these islands that interact between them to form the final surface morphology. In this sense, ion sputtering seems to be quite similar to the deposition of adatom and vacancy clusters at the same time.

**Figure 2.** Top: typical surface morphology after single ion impact experiment in Ag(100) at  $T = 115$  K (scan area  $40 \times 23$  nm<sup>2</sup>).

### 3.2. Submonolayer Regime

Increasing the ion dose, the surface defects created by a single impact (adatoms and vacancies) begin to self-organize on the surface. By carefully controlling the dose, it is possible to observe how this self-organization happens. Figure 3 shows the morphology of an Ag(110) surface bombarded with an ion dose of about 0.2 ML (here and in the following, we will use the monolayer (ML) as a unit, that is, a number of ions or atoms per  $\text{cm}^2$  equal to the surface density of the target). An array of holes, one layer deep, is visible. These holes are oriented along the (1–10) direction, where the diffusion of surface defects created by a single ion impact can diffuse easily (for more details, see Section 3.4). No adatoms are present on the surface, indicating that they diffuse faster than vacancies, then attaching to atomic steps or falling into the vacancy clusters. Of course, this particular morphology can be created only in a restricted temperature range: at lower temperatures, adatom clusters are also present, while at higher temperatures, the surface has sufficient energy to completely recover the damage.

Starting from a similar situation, it is possible to study the diffusion mechanism of adatom and vacancy clusters, as reported, for example, in [12–15]. In all of these experiments, ion sputtering is used to form on a metal surface a well-controlled distribution of holes, and then their time evolution is followed by collecting STM images on the same surface area. By the analysis of images, energetic barriers for the movement of surface defects can be inferred.

### 3.3. Isotropic Surfaces

In this paragraph, we will analyze the results obtained on isotropic surfaces. By this term, we mean metal surfaces in which free adatoms and vacancies diffuse in all of the allowed directions with the same probability. For example,

**Figure 3.** STM topography of Ag(110) surface after ion bombardment at a dose of about 0.2 ML ( $T = 130$  K, scan area  $120 \times 120$  nm<sup>2</sup>).

in a (111) surface of an fcc crystal, there are three equivalent directions, due to threefold surface symmetry, while in the (100) surface of an fcc crystal, the equivalent directions are four. Of course, the diffusion probability is not the same when the adatoms or vacancies are moving along a step since the bonds between atoms are different.

The surface morphology induced by ion sputtering on Pt(111) has been extensively studied in the past [16–19]. In Figure 4, we present a collection of typical images taken after different ion doses. They used Xe ions with an energy of 1 keV and an ion density current of  $0.3 \mu\text{A}/\text{cm}^2$ . This flux corresponds to an ion flux of 0.0013 ML/s. The temperature was fixed at 600 K. In the first panel, the ion dose was 0.093 ML, which corresponds to an eroded amount of 0.26 ML. This value is equal to the ion flux times the sputtering yield, which has been measured to be 2.8 in this experimental condition. Many vacancy islands, but no adatom clusters are present. With respect to the situation reproduced in Figure 2, this means that the surface temperature is high enough that adatom clusters are broken, and their atoms are moved around until they are incorporated

**Figure 4.** STM topographies of Pt(111) after ion erosion at 600 K. Scan area is  $81 \times 81$  nm<sup>2</sup> for (a)–(c) images and  $156 \times 156$  nm<sup>2</sup> for (d)–(f) images. Inset in (a): higher magnification gray-scale topography. Inset in (f): line scan through pit. Reprinted with permission from [16], M. Kalff et al., *Surf. Sci.* 486, 103 (2001). © 2001, Elsevier Science.

at steps or in the vacancy islands. These vacancy islands are more or less equally spaced. Increasing the amount of removed material, the holes become more and more deep, but it is more important to observe that these holes have the tendency to self-organize. After the removal of 333 ML, the self-organization is well evident: the shape of the holes reflects the surface symmetry, while the slope of each valley is quite regular and fixed.

Also, sputtering on Ag(100) produces very similar results [20]. Of course, now the holes are square since the symmetry of the surface is fourfold. In Figure 5, a series of images is shown, taken after the same ion dose, but at different temperatures. At low temperature, the surface appears rough, without any evidence of self-organization. Increasing  $T$ , holes and mounds appear, which become more and more pronounced and well organized. At high temperature, the surface is again flat.

From these images, we can calculate the average roughness of the surface. Plotting this quantity versus temperature, we obtain a characteristic bell-shaped behavior, reported in Figure 6. This curve presents a marked maximum and a rapid decrease of the roughness at low and

**Figure 5.** STM topographies of Ag(100) after ion erosion at different temperatures: (a)  $T = 180$  K, (b)  $T = 240$  K, (c)  $T = 300$  K, (d)  $T = 380$  K, and (e)  $T = 440$  K. For all images, ion energy 1 keV, ion flux 0.02 ML/s, and ion dose 36 ML. The bar corresponds to a length of 50 nm for images (a)–(b) and to 100 nm for images (c)–(e). **Figure 6.** Surface roughness  $W$  as a function of the sputtering temperature  $T_s$  in the case of Ag(100). Reprinted with permission from [20], G. Costantini et al., *Surf. Sci.* 416, 245 (1998). © 1998, Elsevier Science.

high temperature. A similar behavior has been reported for other isotropic surfaces, like Cu(100) [21, 22].

From the experimental results presented in this section, we can deduce several consequences.

1. The surface morphology modifications induced by ion sputtering are not due to a random process, contrary to what one would think at first sight: after a sufficiently high dose, the surface self-organizes in structures of typical dimensions of some nanometers. The shape of these structures reflects the surface symmetry, suggesting that the surface diffusion of adatoms and vacancies must have a crucial role in the determination of the final morphology.
2. Lowering the temperature, surface diffusion decreases, and as a consequence, the recovery of the damage and its reorganization are less effective; on the contrary, at high temperature, diffusion is so fast that the surface can recover the damage in a short time, and the surface is also flat after high doses. When the balance between the two processes (damage and diffusion) is correct, the roughness increases, and large holes and mounds appear.
3. As in growth experiments, increasing the ion flux has the same effect as lowering the temperature since the system has less time to recover the damage.
4. The average distance between holes or mounds increases with dose. This means that ion sputtering induces a relevant coarsening on the surface: small islands coalesce to form large ones. Mass transport is important both in-layer and intralayer.
5. The morphology depends weakly on the angle at which the ions impinge on the surface, at least in some range close to normal incidence, which depends on temperature. This point will be developed later in greater detail.
6. The morphology depends on the ion used since the damage depends on the ratio between the masses of the projectile and target. Also, ion energy can change some details of the surface morphology, but not the general trend.

### 3.4. Anisotropic Surfaces

A typical example of an anisotropic surface is represented by the (110) surface of an fcc crystal. In this surface, the atoms are arranged in channel: they are more compact along the  $\langle 1-10 \rangle$  direction (the neighbor distance is  $a/\sqrt{2}$ , where  $a$  is the lattice constant). Along this direction, often called the “in-channel” direction as opposed to the “cross channel,” the adatom and vacancy diffusion is faster, so the mass transport is strongly asymmetric.

The first systematic study of the morphology induced by ion sputtering on such surfaces was done in 1997 by Rusponi et al. [23]. The main result is reported in Figure 7, where the morphology after the same dose, but at different temperatures is reported. The experimental conditions were:  $\text{Ar}^+$  ions, ion flux 0.03 ML/s, ion dose 27 ML, ion energy 1 keV.

The general behavior is quite similar to that reported in Figure 5: at low  $T$ , the surface is rough, while at high  $T$ , the surface is flat. However, in the intermediate temperature range, the situation is much more complicated. At 230 K, a clear organization along the  $\langle 100 \rangle$  is visible: we recall that, along this direction, surface diffusion is slow. At 270 K,

rectangular mounds are present on the surface, while at 290 and 320 K, well-developed ripples are now present, but aligned along the “in-channel” direction. The ripple structure rotates by  $90^\circ$  passing from 230 to 320 K: this rotation is characteristic of anisotropic surfaces since the two principal directions are inequivalent for surface diffusion. We observed a similar behavior on other anisotropic surfaces like Cu(110) [24] and Rh(110), thus concluding that ripple formation and rotation with temperature are general behavior for these surfaces.

In order to explain this effect in terms of surface diffusion, we need to introduce a more complicated model with respect to the isotropic case. In fact, we could expect ripples aligned along  $\langle 1-10 \rangle$  since, in this direction, the atoms can rearrange easily, but the observation of ripples along  $\langle 100 \rangle$  at 230 K seems to require a pronounced mass transport along this direction. To solve this question, a more accurate analysis of the surface diffusion barriers is required.

Up to now, we considered only the possibility for an adatom (or vacancy) to move freely along one direction on a large terrace; but in a real surface, the adatom can do many other movements: for example, it can move along a step, or detach from it, or try to descend a step. All of these processes have the appropriate energetic barrier, and then at a fixed temperature, the rate for each process can be more or less high. It is the competition among all of these processes which determines the shape and orientation of the nanostructures induced by ion sputtering. In particular, kinetic Monte Carlo simulations and other considerations suggest that an important role is played by the so-called Ehrlich–Schwoebel (ES) process: when an adatom tries to descend from a step, it must overcome an extra barrier due to the repulsion that the step takes against the atom. In other words, the adatom must have more energy to descend the step than to move on a terrace. In this way, the mass transport between different layers is frustrated, at least until the temperature is high enough to give sufficient energy to the moving adatom to overcome the ES barrier. It is clear that, if an adatom cannot descend from a step, it can continue to move on a terrace, and when it hits another adatom on the same terrace, a new condensation cluster is formed. In this way, material is continuously accumulated in the upper layers, and the mass transport is unbalanced: the growth of mounds and ripples is favored.

Obviously, this scenario is also valid for isotropic surfaces, but we present it in this section because it is most important in the case of anisotropic surfaces.

In this light, we can sketch a model for the results presented in Figure 7.

1. At low temperature, the diffusion of adatoms and vacancies is inhibited. The damage caused by an ion cannot be recovered, and the morphology is only due to the accumulation of the damage.
2. At 230 K, diffusion is fast enough along the in-channel direction, favoring the motion of adatoms; a nonzero probability exists that two adatoms running along two neighboring channels stick together, forming an island elongated in the cross-channel direction. These islands form the condensation nuclei for the growing ripples: when further material reaches the islands, it

**Figure 7.** Six STM topographies taken after normal sputtering of Ag(110) by means of 1 keV  $\text{Ar}^+$ ; ion flux  $F = 0.03$  ML/s, ion dose 27 ML. The sputtering temperatures are, respectively, (a) 160 K, (b) 230 K, (c) 270 K, (d) 290 K, (e) 320 K, (f) 350 K. The scan size is  $175 \times 175$  nm<sup>2</sup> for image (a) and  $350 \times 350$  nm<sup>2</sup> for images (b)–(f).

accumulates as the ES barrier along the in-channel direction cannot be surpassed. Thus, the ripples grow along the cross-channel direction. We call this phase low-temperature ripple (LTR).

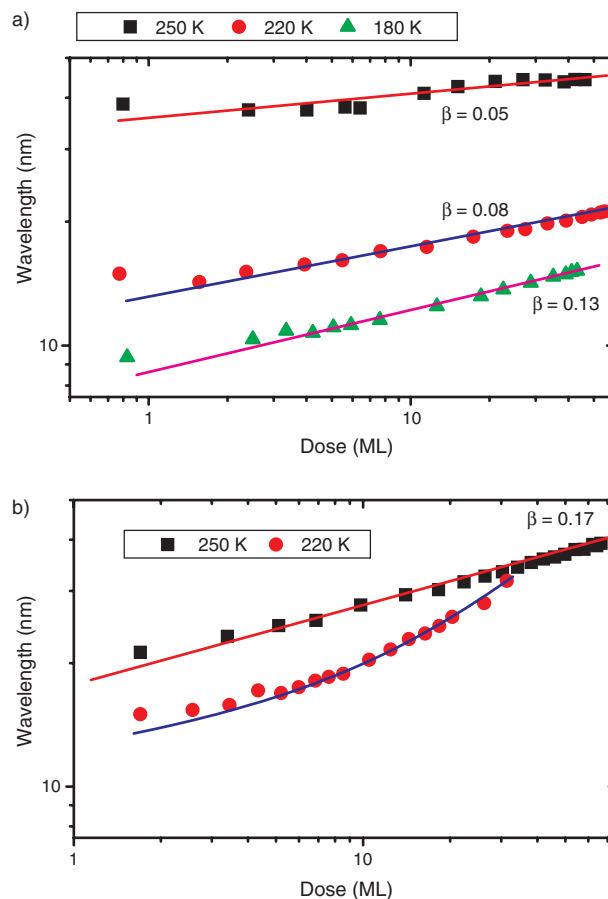

3. At 270 K, there is a balance between the rate at which the adatom can surmount the ES barrier along the in-channel direction and the probability to form islands in the cross-channel direction. Thus, almost rectangular mounds appear on the surface. We call this phase intermediate-temperature mounds (ITMs).
4. At 290 K, the bond between adatoms in adjacent channels is not more sufficient to stabilize the cross-channel islands, and so the condensation nuclei are now formed by islands elongated along the channel. The ES barrier along  $\langle 1-10 \rangle$  can be surpassed, and a relevant mass transport sets in along the in-channel direction. Then the original islands become more and more elongated, but also increase in height. Ripples are now formed along the easy diffusion direction. That is the high-temperature ripple phase (HTR).
5. At higher temperatures, the adatoms have sufficient energy to overcome the ES barrier along both directions: the recovery of the damage is now very effective, and the surface becomes flat.

The model depicted briefly above has been tested by means of kinetic Monte Carlo simulations [25] in a more simple situation, when only adatoms are deposited on the surface. The results are in good agreement with an experiment done under similar conditions [26].

Up to now, we have established that ion bombardment induces the formation of regular nanostructures on anisotropic surfaces, and that these nanostructures can assume different shapes, depending on temperature. However, the STM studies cannot answer the following question: How do these structures grow, starting from a flat surface? As mentioned in Section 3, the experiments based on microscopy generally do not allow following in real time the evolution of the surface morphology. For this reason, we performed a series of experiments by using X-ray diffraction. These experiments were carried out at the European Synchrotron Radiation Facility in Grenoble, France. We did two different kinds of diffraction experiments: in the first, the X-ray beam impinges on the sample at grazing angles (about  $1^\circ$  from the surface), and the scattered intensity is taken again at very low angles. In this way, the scattering of the photon holds in a few microns under the surface: the out intensity is modulated by the surface morphology, and collecting it as function of the exit angle, we can analyze the periodicity of the structures on the surface. This method is called grazing incidence small-angle X-ray scattering (GISAXS).

The second method consists of collecting the scattered intensity around a Bragg peak: in this case, called a crystal truncation rod (CTR) scan, the intensity is modulated by the shape of the nanostructures. Both methods can be applied during ion sputtering, so they allow following the growth of the nanostructures in real time.

In Figure 8, we report the spatial periodicity as a function of the ion dose in the case of Cu(110). The experimental conditions were:  $\text{Ar}^+$  ions, ion flux 0.015 ML/s, and ion

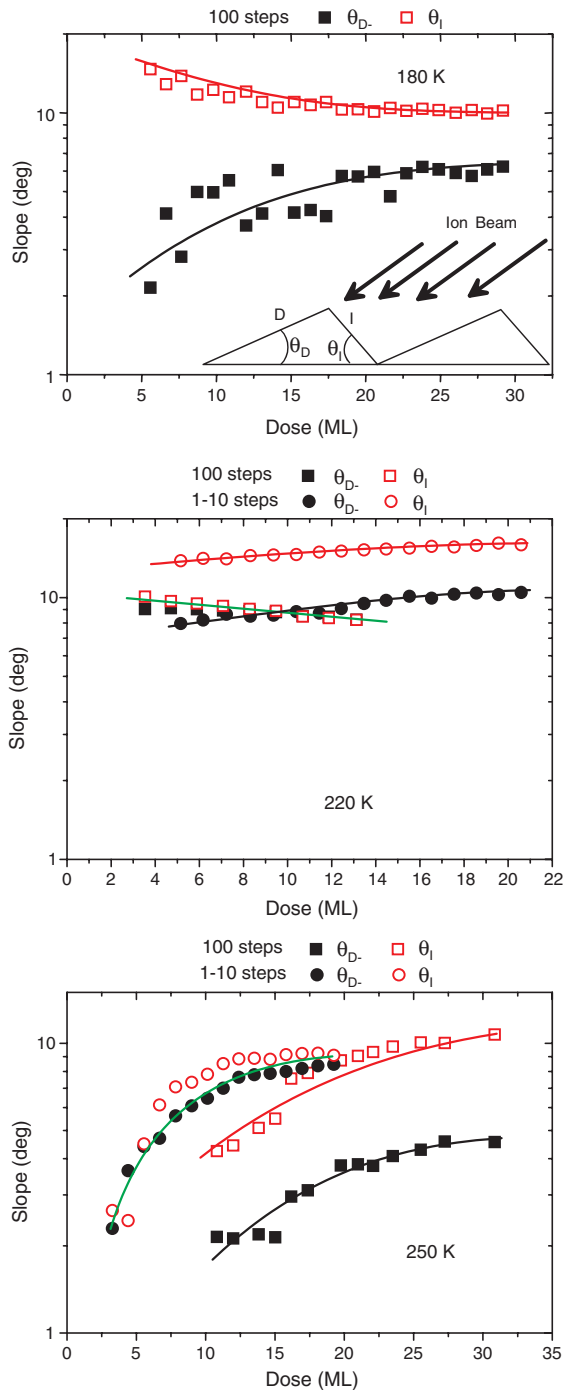

**Figure 8.** Ripple wavelength as a function of the ion dose in the case of Cu(110) at different temperatures, as determined by X-ray diffraction. (a) shows the slope of the facets along the  $\langle 100 \rangle$  direction, and (b) the slope of the facets along the  $\langle 1-10 \rangle$  direction.

energy 1 keV. The spatial periodicity was measured along the two principal surface axes,  $\langle 1-10 \rangle$  and  $\langle 100 \rangle$ . At 180 K, only the periodicity along  $\langle 100 \rangle$  can be observed: this situation corresponds to the LTR phase described before. The wavelength increases with the dose, following a simple power law  $L \sim D^b$ , with  $b = 0.13$ . At other temperatures, periodicity is seen along both directions, indicating that we were in the ITM phase. Also in this case, the distance between features increases with the dose, but with a different  $b$ . We notice that, within the experimental time range, no saturation in the wavelength has been observed.

The increase of the spatial periodicity with dose indicates that, during sputtering, a coarsening of the ripples occurs. We do not have any clear indication, but it seems that, at the beginning, small ripples are formed, which coalesce and mix in greater structures when sputtering proceeds. This result is quite important since, in nonmetallic materials, as will be shown in the next paragraph, the spatial periodicity does not change with the dose, indicating that, in these two classes of material, the formation of ripples or mounds has a common origin, but a different time evolution. This has to do with the much higher diffusivity on the metal surfaces.

In Figure 9, we report the evolution of facets slope for Cu(110) as deduced from CTR scans acquired during sputtering. Due to the particular geometry used in the

**Figure 9.** Time evolution of the local slope in the case of Cu(110). In the inset, the sputtering geometry is shown. The incident angle is  $54^\circ$  with respect to the flat surface.

experiment (see the inset in Fig. 9), the nanostructures formed on the surface are asymmetric: the side in front of the beam (illuminated *I* side) has a slope different from the other (dark *D* side). The results are quite interesting: at 180 K, the *I* side is very steep at the beginning, while the *D* side is almost flat. Increasing the dose, the system evolves toward a more symmetric shape, gaining an equilibrium value after about 20 ML. At 230 K, the situation is

completely different: for the step along  $\langle 100 \rangle$ , the slopes of both sides change very slowly with the dose, and they have almost the same value; also, for the steps along  $\langle 1-10 \rangle$ , the change is not too great, but the difference between the *I* and *D* sides is more relevant. Increasing the temperature to 250 K, the situation changes again: now, the evolution of the slopes along the two directions is quite high, with the difference that also, at this temperature, the steps along  $\langle 100 \rangle$  have the same slope, while there is a difference of about  $5^\circ$  in the other direction.

How can we interpret these results? First, it is clear that the nanostructures evolve in time, not only in spatial periodicity, but also in their shape. The system gains an equilibrium only after about 20 ML. Moreover, this evolution depends on the temperature, indicating again that are diffusion processes which play a key role in the determination of the surface morphology. Another important aspect to consider is the nature of the ion impacts: as depicted in [16], the effect of an ion hit is different, depending on the surroundings of the impact point. If it is in a flat region (like a large surface terrace), adatom and vacancy islands are created, and they can move or coalesce, as explained before. But if the ion impinges on a stepped region (i.e., a region in which the terraces have a size of a few atomic spaces), the defects created by the impact are efficiently annihilated and incorporated at steps, leaving the morphology unchanged (cf. [20, Fig. 6]).

We notice that, unfortunately, the simulations of the sputtering process are more complicated than the molecular growth. First, two different time scales are involved: the damage is completely determined in a few picoseconds, while the diffusion of the surface defects (adatoms and vacancies) occurs in milliseconds. This great difference in time scale does not allow us to develop practical codes for the simulations. Second, since the defects created by the ions are mainly clusters, the number of possible atomistic processes increases considerably (movement of the clusters, detachment of atoms and vacancies from the clusters, coarsening, periphery diffusion), again hindering the development of a suitable code.

GISAXS measurements, but also He beam scattering and SPA-LEED experiments, have been applied to study another important aspect of the ripple or mound morphology: the decay in time of these nanostructures. In fact, in metals, the nanostructures are unstable in time since the diffusion processes tend to smoothen the surface in order to obtain a lower free energy. Of course, this process depends on temperature and on the particular material: for Cu and Ag, room temperature is high enough to cause a smoothening of the surface in few hours, while for Rh and Pt, it is necessary to increase  $T$  up to about 600–700 K before observing the disappearance of the nanostructures.

The decay of the nanostructures induced on metals can prevent their use in applications like nanostamping or as substrates to induce order in organic or nematic thin films (see Section 6). In some cases, we can prevent the decay by a simple oxidation procedure. The method has been tested on Ag, Cu, and Al. In Cu(100) [27], the method allows us to stabilize for several days nanostructures that would otherwise decay in a few hours at room temperature.

### 3.5. Erosive Regime

In the previous paragraphs, we summarized the results obtained on simple metals, but in all of the experiments reported, a common aspect must be emphasized: the angle of incidence of the ions was always close to normal (say in a cone of about  $30^\circ$ ). In this condition, the damage induced is well described as in Section 3.1, and the final morphology is mainly due to the diffusion processes as reported in Sections 3.2 and 3.3. We call this experimental condition a “diffusive regime.” The nanostructures do not depend on the azimuthal angle, that is, nothing changes if the ion impinges on the target along one surface direction or another.

What happens if this condition is not fulfilled, that is, if the ion impinges on the target at angles close to grazing incidence? The answer to this question is the topic of the present paragraph.

We have seen that the damage caused by a single ion does not depend on temperature since the energy released is much higher than the cohesive energy between atoms in the target, but temperature is important to determine how this damage can be removed. If the sputtering is done at grazing incidence (angle  $\vartheta > 60^\circ$  from normal), nothing changes if the temperature is high enough. The picture changes completely if the sputtering is done at grazing incidence and low temperature: in this case, the defect diffusion is very slow, and increasing the dose, a pile up of defects occurs. When the roughness is high enough, the dominant effect becomes the erosion caused by the impinging ion. The evolution of this particular morphology is shown in Figure 10. Ag(100) is bombarded with  $\text{Ar}^+$  ions (energy 1 keV) at a very low flux (0.01 ML/s). The incidence angle is fixed at  $70^\circ$ . The white arrow in the first image corresponds to the projection on the surface of the ion beam. After 1 s, the single impact defects are visible on the surface; they are completely equivalent to that reported in Figure 2 (produced at normal incidence). If we look at the spatial distribution of the adatom islands around the ion crater, we do not recognize any elongation along the beam direction, but only an isotropic distribution around the impact point. This observation is very important: the single impact induces the same kind of defects independently on the impact angle at least in the range  $0\text{--}70^\circ$ . Then the formation of ripples cannot be attributed to the shape of the damage caused by a single ion.

After 30 s ( $D = 0.3$  ML), we see that the damage is accumulated on the surface, but there is still no evidence of any self-organization. After 720 s ( $D = 7.2$  ML), the self-organization along the ion beam direction is evident. The last image shows the autocorrelation function of the STM image, which clearly evidences the orientation of the structure along the ion beam.

To distinguish this experimental condition from the ones described in the previous paragraphs, we call it an “erosive regime.” The surface diffusion still plays a role: in fact, if the temperature is lowered enough, the time to observe ripples increases substantially. Now, the ripple direction is not related to any surface direction; it is only determined by the ion beam, as clearly shown in Figure 11. In this experiment on Cu(110) [24], we fixed  $T = 180$  K,  $E = 1$  keV,  $F = 0.03$  ML/s, and  $D = 27$  ML. Only the incidence angle

**Figure 10.** STM topographies of the initial stages of the nanostructuring of Cu(110) in erosive regime ( $\text{Ar}^+$ , ion energy 1 keV, ion flux 0.01 ML/s,  $T = 180$  K). The (a) image has been acquired after 1 s (scan size  $90 \times 90$  nm<sup>2</sup>), (b) after 30 s (scan size  $200 \times 200$  nm<sup>2</sup>), and (c) after 720 s (scan size  $200 \times 200$  nm<sup>2</sup>). In (d), the autocorrelation function of the (c) image is reported.

**Figure 11.** The role of the incidence angle  $\theta$  in the transition from the diffusive to the erosive sputtering regime for Cu(110) at  $T = 180$  K. The white arrow shows the ion-beam scattering plane. For all images,  $\text{Ar}^+$  sputtering at  $E_i = 1$  keV, ion flux 0.03 ML/s, ion dose 27 ML. Image size  $400 \times 400$  nm<sup>2</sup>.

is varied from 0 to 70°. At normal incidence, the surface appears rough, while for  $\vartheta$  between 15 and 55°, the ripples are aligned along the  $\langle 100 \rangle$  direction: the system is in the LTR phase depicted in Section 3.3. For  $\vartheta > 65^\circ$ , the ripples rotate along the ion beam projection, which in this experiment was along the  $\langle 1-10 \rangle$  direction. We emphasize that this 90° rotation is quite different from the previously reported (Section 3.2) as there, the temperature is fixed.

In the “erosive regime,” the surface symmetry directions play no role in determining the final ripple alignment: we observed quite similar ripples on Ag(110), Ag(100), Cu(100), and Cu(110) [28], independent of the direction on which the ions hit the target. The spatial periodicity increases with the dose, but more slowly than in the diffusive regime. In this sputtering regime, mound formation has never been observed. In many aspects, the ripples so created are similar to those produced on nonmetallic materials (see Section 4).

Before concluding this paragraph, we want to mention an interesting work done by Poelsema and collaborators [29] on Cu(100). They bombarded the surface at a very grazing incidence (about 80°). Under these conditions, vacancy islands one or two layers deep are formed, with a spatial periodicity that can be changed by varying the temperature. Also in this case, the elongation direction is independent of the surface symmetry, but is parallel to the ion beam.

### 3.6. Sputtering and Growth

So far, we have investigated the effect of ion sputtering on metal surfaces, showing that all of the observed morphologies are related to the damage from the ion impact and the recovery of it via surface diffusion of defects. Since a single impact causes the formation of a vacancy cluster and few adatom clusters, it is a natural consequence to suggest that ion sputtering is quite similar to the deposition process, with the only difference being that, in the latter, only (single) adatoms are deposited. This analogy is the topic of this paragraph.

In a recent experiment, Buatier de Mongeot et al. [30] deposited Ag on Ag(110) at different temperatures, following the morphology with high-resolution electron diffraction (SPA-LEED). Also in this case, the presence of regular structures is evident: at 130 K, they observed elongated features (ripples) oriented along the  $\langle 001 \rangle$  direction, exactly what happens on the sputtered surface at a low temperature (LTR phase). Increasing  $T$ , the symmetry of the diffraction pattern becomes fourfold, indicating that rectangular mounds are now present (ITM phase). Finally, ripples appear again at 210 K, but rotated by 90° with respect to those observed at low  $T$  (HTR phase).

However, the temperature at which the rotation sets in is different between the two cases: about 170 K in growth and about 270 K in sputtering. This difference is easily explained since the movement of the clusters produced in the ion impact requires a greater activation energy. The observation that the morphologies created by the two methods (erosion and deposition) are quite similar, eventually in a different temperature range, also has been done by Busse et al. [11] on Al(111). They bombarded the surface with different rare gas ions, and surprisingly, they did not

observe an “eroded” surface like on Pt(111) (cf. Fig. 4), but an unexpected island and mound structure, typical of atomic deposition.

Before we conclude this paragraph, we want to emphasize another aspect of the analogy sputtering—deposition. In many computer simulations, ion erosion has been seen as a “vacancy deposition,” in which a beam of “vacancies” is directed against a surface [31, 32]. This method allows us to obtain results in agreement with experimental data, but can be applied only if the sputtering temperature is high enough [33].

## 4. OTHER MATERIALS

In 1956, Navez et al. [34], by bombarding a glass surface with an ion beam of air, observed for the first time a curious phenomenon: the bombardment produced a new morphology depending mainly on the incidence angle  $\theta$  of the ion beam. A clean glass surface was exposed for 6 h to the ion beam at incidence angles ranging from 30 to 80°. The surface was covered by wave-like structures (ripples) separated by distances ranging from 30 ( $\vartheta = 80^\circ$ ) to 120 nm ( $\vartheta = 30^\circ$ ), which are stable under ambient conditions after the ion bombardment is finished. For incident angles close to  $\vartheta = 0^\circ$ , the ripples are perpendicular to the ion beam direction, while they rotate by 90° when the beam reaches the surface at grazing incidence. In contrast, when the bombardment is performed at normal incidence, one observes a regular structure formed by elements of a diameter of about 40 nm. The authors did not provide an accurate explanation at that time, but simply tried to find analogies with macroscopic phenomena such as the ripple structures formed by wind over a sandbed. After this pioneering experiment, other groups investigated the effects of ion bombardment on semiconductor and amorphous materials.

First, we examine the results of a single ion impact on a semiconductor surface. At low energies (<5 keV), which are of interest in this chapter, sputtering of atoms by direct knock-on effects is observed [35, 36]: each ion causes the ejection of one or a few atoms from the surface, but not the growth of adatoms islands around the crater. Sometimes, bumps have been observed, but they have been interpreted as a mechanism to relax strain, induced in a subsurface region by the collision cascade caused by the ion. Similar effects also have been reported for HOPG.

These results represent the first important difference between the sputtering on metal and nonmetal materials: in the latter, the surface morphology is dominated only by vacancies, and the internal damage is quite relevant, leading to the amorphization of the near surface layers as sputtering proceeds. Basing on this conclusion, we can foresee that the accumulation of damage (i.e., for increasing doses) has quite different consequences in the two classes of materials.

Ripples produced by off-normal ion scattering have been observed on SiO<sub>2</sub> [37], HOPG surfaces with (0001) orientation [38, 39], diamond [40], Si [41], GaAs [42], and Ge [43].

The results obtained on nonmetal materials can be summarized in the following way.

1. Ripples can be produced, but only at nonnormal angles of incidence.

2. A critical angle  $\vartheta_c$  exists, for which, if  $\vartheta < \vartheta_c$ , the ripples are perpendicular to the ion beam, and if  $\vartheta > \vartheta_c$ , they are parallel. Thus, the ripple orientation is determined by the beam direction, and not by the crystal symmetry.
3. The spatial periodicity does not change in time, but it depends on ion flux and temperature.
4. The time evolution is much slower than in metals: for comparable ion fluxes, ripples appear on nonmetal material in a time which can be ten times greater. That means that the mass transport on such materials is quite reduced with respect to metals.
5. Mounds can be formed only if  $\vartheta = 0^\circ$ .
6. Structures are stable in time up to elevated temperatures.

It is evident from these considerations that nanopatterning by ion sputtering leads to quite different results in the two classes of materials. The closest results are found in the “erosive regime” since, here also for metals, the surface symmetry does not influence the ripple morphology. However, as we will show briefly in the next section, from a theoretical point of view, the sputtering process can be described in a quite general framework.

## 5. THEORETICAL MODELS

Starting from Sigmund’s theory of sputtering, Bradley and Harper in 1988 [44] proposed the first model (in the following, referred to as the BH model), which explains why ion bombardment produces periodic height modulations on the surface of amorphous solids.

The rate at which the material is sputtered from a point  $O$  of a surface is proportional to the power dissipated there by the random distribution of the incoming ions. They penetrate the surface and transfer their kinetic energy to the atoms of the substrate, which may start secondary collisions, thereby generating other recoiling atoms. A small fraction of the atoms is sputtered away, while some of them are permanently removed from their sites, making the substrate locally amorphous. In the limit of low energy of the incoming ions, the average energy deposited at  $O$  because of an ion penetrating into the crystal follows the Gaussian law:

$$E(r') = \frac{\varepsilon}{(2\pi)^{3/2} \alpha \beta^2} \exp[-(z')^2/2\alpha^2 - (x'^2 + y'^2)/2\beta^2] \quad (2)$$

where  $a$  is the mean range of ion penetration,  $\alpha$  is the longitudinal and  $\beta$  is the lateral straggling width, and  $\varepsilon$  is the total energy deposited;  $a$ ,  $\alpha$ , and  $\beta$  define the atomic collision cascade. The model calculates the normal component of the velocity of erosion at a generic point  $O$  of the interface when a uniform flux  $J$  hits the surface. The details are reported in [44].

Here, we limit ourselves to reporting the most important steps. For simplicity, let us reduce the model to a (1 + 1)-dimensional one. The incoming beam direction forms an angle  $\varphi$  with the direction normal to the surface  $Y$ .  $Y$  and the trajectory of the incoming ion beam form a plane containing the  $X$  axis. We point out that  $\varphi$  changes from point to point along the surface. The radius of curvature at  $O$

is  $R_X$  (positive when the surface is concave, and negative when the surface is convex). Let us define the velocity of erosion  $v(\varphi, R_X)$  as the velocity at which the surface retracts because the atom loosens. The sputtering yield  $Y(\varphi)$  is related to  $v(\varphi, R_X)$  by the following expression:

$$Y(\varphi) = nv(\varphi, R_X)/J \cos(\varphi) \quad (3)$$

where  $n$  is the number of atoms per unit volume in the amorphous solid and  $J$  is the flux of the incoming ions. Bradley and Harper showed that Eq. (3) in the limit  $a/R_X \ll 1$  can be approximated to the first order in  $a/R_X$ , giving the following expression for the erosion velocity:

$$v(\varphi, R_X) = \frac{J}{n} Y_0(\varphi) [\cos(\varphi) - \Gamma_X(\varphi) a/R_X] \quad (4)$$

In Eq. (4),  $Y_0(\varphi)$  corresponds to the sputtering yield of a flat surface, and depends only on the parameters that define the collision cascade ( $\varepsilon, \alpha, \beta$ ) and on the angle  $\varphi$ . The expression  $Y_0(\varphi)$  deduced by Bradley and Harper is an increasing function of  $\varphi$ , and therefore limits the model to angles not too close to grazing incidence, where the sputtering yield starts to decrease with  $\varphi$ .  $\Gamma_X(\varphi)$  is a function of  $\varphi$  and of the parameters  $\alpha$  and  $\beta$ . For  $a = \alpha = \beta$ , that is, for a spherical distribution of the deposited energy,

$$\Gamma_X(\varphi) = \sin^2(\varphi) \sin^2(\varphi/2) - \cos^2(\varphi/2) \quad (5)$$

The dependence of the erosion velocity on the curvature is in the term  $\Gamma_X(\varphi) a/R_X$ . For instance, for normal ion incidence,  $\Gamma_X(\varphi = 0)$  is negative, while the curvature is positive in the trough and negative in the crest; then the product  $\Gamma_X(\varphi = 0) a/R_X$  is negative in the trough and positive in the crest. The velocity of erosion is therefore faster for the trough than for the crest. The results are easily generalized [44] to arbitrary surfaces:

$$v(\varphi, R_X, R_Y) = \frac{J}{n} Y_0(\varphi) [\cos(\varphi) - \Gamma_X(\varphi) a/R_X - \Gamma_Y(\varphi) a/R_Y] \quad (6)$$

Until now, the above equations are written in a local frame, referred to the impact point  $O$ . More useful expressions can be expressed in the laboratory frame  $(x, h)$ , where  $h$  is the normal to the initial flat surface. The ion beam forms with  $h$  an angle  $\theta$ , while the plane containing  $h$  and the ion trajectory identifies the  $x$  axis. The time evolution of the surface is described by the height function  $h(x, t)$  measured from the initial flat configuration and  $\varphi = \theta + (\partial h/\partial x)$ .  $\theta$  is a fixed angle, while  $\varphi$  changes from point to point along the surface. The equation of motion is obtained by writing the normal component along  $h$  of the velocity of erosion, assuming that the surface height varies slowly. Equation (3) becomes

$$\begin{aligned} \frac{\partial h}{\partial t} = & -\frac{J}{n} Y_0(\theta) \cos(\theta) + \frac{J}{n} \frac{\partial}{\partial \theta} [Y_0(\theta) \cos(\theta)] \frac{\partial h}{\partial x} \\ & + \frac{Ja}{n} Y_0(\theta) \left[ \Gamma_X(\theta) \frac{\partial^2 h}{\partial x^2} \right] \end{aligned} \quad (7)$$

The first term is the rate of erosion of the unperturbed planar surface and the two other terms contain the dependence of the sputtering yield on the local curvature. This is the

fundamental equation in the BH model, written in (1 + 1) dimensions.

It is easy to generalize it to an arbitrary surface  $h(x, y, t)$  [44]. In Eq. (7), all terms concern the erosion of the surface by ions, but Bradley and Harper recognized that a smoothing mechanism is needed to explain the presence of ripples. Then they added a term which takes into account the diffusion of atoms on the surface. After some manipulation, Eq. (7) becomes

$$\frac{\partial h}{\partial t} = -v_0(\theta) + \frac{\partial v_0(\theta)}{\partial \theta} \frac{\partial h}{\partial x} + v_x(\theta) \frac{\partial^2 h}{\partial x^2} + v_y(\theta) \frac{\partial^2 h}{\partial y^2} + K \nabla^2 \nabla^2 h + \eta(x, y, t) \quad (8)$$

where  $K$  is a coefficient which depends on the surface self-diffusivity  $D$ , the free energy per unit area  $\gamma$ , and the number of atoms per unit area moving across the surface, and  $\eta(x, y, t)$  is a Gaussian white noise with zero mean and variance proportional to the ion flux  $J$ , which takes into account the stochastic arrival of the ions.

In this expression, the sputtering yield dependence on local curvature is now in the terms  $v_x(\theta)$ ,  $v_y(\theta)$ , which can change sign as the angle of incidence of the ion is varied.

Bradley and Harper did a stability analysis of this equation, imposing a sinusoidal form for the function  $h(x, y, t)$ , and looking for its time evolution. This approach is based on the observation that any periodical corrugation, as ripples are, can be expressed as a sum of sinusoidal amplitudes. Applying this analysis to the BH model, it is possible to demonstrate that a ripple with a defined wavelength can grow during the sputtering process. Its spatial periodicity is equal to

$$\lambda_i = 2\pi \sqrt{2K/|v_i|} \quad (9)$$

where  $i$  refers to the direction ( $x$  or  $y$ ) along which the associated  $|v_i|$  is the largest. We point out that the direction  $x$  is along the ion beam, while  $y$  is perpendicular to it. Since the coefficients  $v_x(\theta)$ ,  $v_y(\theta)$  change magnitude and sign in dependence on the incidence angle, a critical value  $\theta_c$  exists so that, for  $\theta < \theta_c$ , the ripple is perpendicular to the ion beam, and for  $\theta > \theta_c$ , it is parallel. Due to its intrinsic approximations, the BH model works well at intermediate ion doses, when erosion produces ripples with a small local slope.

The consequences of the BH model have been verified in many experiments on amorphous and semiconductor materials. The ripple rotation at grazing incidence angles has been verified in graphite, glass, SiO<sub>2</sub>, diamond, Si, GaAs, and Ge.

The dependence of the ripple structure on the ion energy is in the erosive terms  $v_{x,y}(\theta)$ : they depend on the way in which the energy is released in the surface, and then they are related to the penetration depth of the ion, which is a function of energy. Then we expect that the ripple wavelength is a function of the energy. More precisely, we expect that

$$\lambda_{x,y} \propto E^p \quad (10)$$

Such a behavior has been verified on graphite [39] ( $p = 1$ ), Si [45] ( $p = 0.8$ ), and diamond [40] ( $p = 1$ ). However, the

BH model foresees a flux dependence of the ripple wavelength ( $\lambda \sim \Phi^{1/2}$ ) which has been observed only in Si [41].

In the BH model, the behavior of the wavelength with temperature is determined by the surface mobility of the diffusing species. By writing the surface diffusivity  $D$  as

$$D = D_0 \exp\left(-\frac{E_a}{k_B T}\right) \quad (11)$$

where  $E_a$  is the activation energy for surface self-diffusion, the coefficient  $K$  of Eq. (8) depends on the temperature as

$$K = \frac{D_0 \gamma^\sigma}{n^2 k_B T} \exp\left(-\frac{E_a}{k_B T}\right) \quad (12)$$

and on the wavelength as

$$\lambda_{x,y} \propto T^{1/2} \exp\left(-\frac{E_a}{2k_B T}\right) \quad (13)$$

The effect of surface mobility during ion-beam treatment has been studied experimentally on graphite. The experiment shows that the ripple wavelength increases slowly with temperature, from 70 to 110 nm between 300 and 450 K as expected, due to the increase of the surface mobility. Comparing the results with the BH model, Habenicht obtained an activation energy of  $E_a = 0.14$  eV, which is rather small compared to others. He ascribes this fact to radiation-enhanced diffusion effects that should be taken into account. However, the energy deposition of the ion beam into the near surface region can affect several parameters of the surface mobility, such as the density of diffusing species, the surface free energy, and the activation energy for surface diffusion.

The model cannot account for the formation of ripples at low temperature since it considers only a thermal mechanism of smoothing. Additional mechanisms have been proposed to explain the inadequacy of BH model. In particular, Makeev and Barabasi [46] demonstrated that ion sputtering could produce an effective surface diffusion (ESD) that does not imply mass transport. The ESD explains the presence of ripples at low temperatures where the surface diffusion is not activated, and was predicted in the computer simulation of the ripple formation on amorphous carbon [47] and observed in the case of GaAs [48].

Besides its ability to explain most of the experimental results, the BH model fails when the ion dose becomes larger and larger. Cuerno and Barabasi [49] revisited the BH model, introducing two new terms in the equation:

$$\frac{\partial h}{\partial t} = -v_0(\theta) + \frac{\partial v_0(\theta)}{\partial \theta} \frac{\partial h}{\partial x} + v_x(\theta) \frac{\partial^2 h}{\partial x^2} + v_y(\theta) \frac{\partial^2 h}{\partial y^2} + \frac{\eta_x}{2} \left(\frac{\partial h}{\partial x}\right)^2 + \frac{\eta_y}{2} \left(\frac{\partial h}{\partial y}\right)^2 + K \nabla^2 \nabla^2 h + \eta(x, y, t) \quad (14)$$

The coefficients  $\eta_x$ ,  $\eta_y$  depend on parameters such as the penetration depth and the angle of incidence. In this way, the equation becomes nonlinear, and the temporal evolution of the height  $h$  shows a transition from a periodic to a fractal behavior, as found in the experiments.

We have seen that the BH model (and its modifications) is able to reproduce most of the experimental findings in semiconductors and amorphous materials. But when we try to apply it to the metal case, some difficulties arise. First, the spatial periodicity increases in time, both in the diffusive and erosive regime. This effect is out of the model. Second, periodic patterns also appear at normal incidence, while in the model, no regular pattern can grow if  $\vartheta = 0^\circ$ . Finally, the nanostructures on metals are crucially dependent on temperature (in shape and periodicity). On the other hand, many features have their behavior foreseen by the model: the periodicity depends on the ion flux as  $\Phi^{1/2}$ , at grazing incidence the ripples are always parallel to the ion beam, and so on.

In order to explain these differences, we proposed to modify the diffusion terms in Eq. (14) [24]. In fact, while the erosive terms have an expression that is quite general, which depends only on the parameters of the sputtering, the diffusion terms are too simple, as they do not take into account many aspects of the diffusion processes in metals: the existence of different energetic barriers, the directionality of the diffusion, and the existence of different diffusing species. However, a detailed study of the equation and its consequences is still in progress.

## 6. APPLICATIONS

In this section, we illustrate some applications of the ion sputtering in different fields. The advantage of the method is that it is very easy to perform, can be used to nanostructure large samples (several  $\text{cm}^2$ ), and the results depend on easily controlled parameters, such as ion beam energy, incidence angle, ion species, ion flux and dose, and substrate temperature.

Ion erosion has interesting applications in chemistry. Creating and controlling the density of artificial defects may lead to the growth of materials with unusual catalytic properties. In fact, artificially created surface defects can enhance the surface reactivity. One illuminating example of this possibility is the experiment of Costantini and co-workers [50, 51], who recently demonstrated that the dissociation probability of  $\text{O}_2$  on  $\text{Ag}(100)$  can be enhanced by orders of magnitude after modification with ion sputtering. The most interesting result is that the reactivity can be tuned by changing the angle of sputtering. The dissociation probability of  $\text{O}_2$  molecules changes from less than  $10^{-3}$  on the flat surface to 0.1 on the rippled surface. In perspective, this straightforward result opens up the possibility to control the chemical properties of a surface by modifying *in-situ* its morphology, that is, by creating different amounts and different kinds of defects, like kinks at step edges, on which the reactivity of the chemisorbed species can be enhanced. The recent observation of similar structures on  $\text{Rh}(110)$ , which were investigated by X ray diffraction, suggests possible applications in catalysis.

The fabrication of quantum dots (QDs) is currently a topic of great interest due to the potential applications in optoelectronics. However, the methods available for their fabrication are rather limited because the actual lithographic techniques cannot produce QDs of appropriate size and density for device applications. Facsko et al. gave the first

evidence of QD fabrication via ion erosion in the case of  $\text{GaSb}(100)$  [52, 53]. They observed that ion erosion creates dots remarkably well ordered and uniformly distributed. The method of ion erosion may therefore open a new road for nanofabricating large-area surfaces patterned at low cost.

But the potential applications are also in other fields of material science. Using ion erosion, it was recently possible to fabricate magnetic wires structures in the case of a Co film deposited on a  $\text{Cu}(100)$ . The experiment shows a remarkable change in the magnetization anisotropy of the film after bombardment by ions. 5 ML of Co have been deposited on a  $\text{Cu}(100)$  surface at  $T = 180$  K. The sample has been successively bombarded with  $\text{Ar}^+$  ions at an incident angle of  $70^\circ$  (erosive regime),  $E = 1$  keV; in this condition, the ripples supported on  $\text{Cu}(100)$  are elongated along the projection of the ion beam on the surface.

Finally, ion erosion can produce nanoscale patterned substrates for deposition methods either on metallic substrate or glasses [54]. Rippled glasses are also expected to be good candidates as templates, for instance, for aligning liquid crystals or organic molecules.

## 7. CONCLUSIONS

In this chapter, we reviewed the results on surface nanostructuring by ion sputtering, mainly in the case of metal surfaces. The surface morphology is found to be dependent on surface symmetry if the temperature is high enough and the incidence angle is close to zero (normal incidence). In this diffusive regime, the diffusion of the surface defects (adatom and vacancy clusters) created by the ion impact determines the evolution of the morphology. On the contrary, in the erosive regime (low temperature and grazing incidence), the ripples created are determined only by the ion beam direction. The possibility to pattern metal surfaces on a nanometer scale opens a new route to many applications in nanotechnology since the ion sputtering method can be applied easily and also adapted to large-scale production.

## GLOSSARY

**Atomic force microscope (AFM)** Microscope based on a cantilever with a sharp tip, which is deflected by the forces acting between the surface and the tip. An AFM can resolve atoms on insulating materials.

**Low energy electron diffraction (LEED)** Instrument based on the reflection of electrons from a surface. It gives information on the symmetry of the surfaces.

**Scanning tunneling microscopy (STM)** Microscope based on the tunneling effect, able to resolve atoms on a metallic surface.

**Secondary ions mass spectroscopy (SIMS)** Analytical technique that uses ion sputtering to extract other ions from the surface. These secondary ions are analyzed with a mass spectrometer, in order to get information on the chemical species present on the surface.

**Spot profile analyzer-LEED (SPA-LEED)** A variance of normal LEED, used to observe symmetry on a larger scale.

Electrolytes, as respects their insulating and conducting forces, belong to the general category of bodies; and if they are in the solid state (as nearly all can assume that state), they retain their place presenting then no new phenomenon.

Michael Faraday On induction, in "Experimental Researches in Electricity," Volume 1, p. 1344, Series XII. Taylor and Francis, London, 1839.

## 1. INTRODUCTION

Ceramics have been a part of human culture for thousands of years. Ceramic objects, including bricks, tiles, and pottery, can be traced back to the ancient civilizations of Mesopotamia, Egypt, and Asia. From a materials scientist's point of view, ceramics can be defined as nonmetallic, dense, polycrystalline solids that are prepared by shaping and high temperature firing, typically around 1000 °C. A large part of conventional ceramics is based on aluminosilicates, especially clay. From the 19th century on, the physical and chemical properties of these ionocovalent materials were investigated in earnest. It was then recognized that their electrical properties were quite different from those of the earlier investigated metallic solids.

As early as 1833, Michael Faraday reported experiments on ionic conducting inorganic solids: "There is no other body with which I am acquainted, that, like sulphuret of silver, can compare with metals in conducting power for electricity at low tension when hot, but which, unlike them, during

cooling, loses in power, whilst they, on the contrary, gain. Probably, however, many others may, when sought for, be found" [1]. The large enhancement of the electrical conductivity of silver sulfide  $\text{Ag}_2\text{S}$  with increasing temperature was difficult to interpret at that time, because it was in strong contradiction to the behavior of metals.

The first major invention based on solid electrolytes was an electric lightning device using the "Nernst mass," a mixture of zirconia with rare earth oxides, including the particularly favorable composition 85% zirconia and 15% yttria [2]. Although the Nernst lamp was finally not used extensively in practice—it was replaced in 1905 by the simpler tungsten filament lamp—this discovery gave a major impulse to the development of solid state ionics. Around 1850, Gaugain had already discovered the principle of solid electrolyte fuel cells: "air and alcohol vapor separated by a glass envelope and heated up to high temperature can form a couple capable to develop electricity" [3]. Gaugain obtained similar results with a porcelain tube and with other gaseous fuels. Nearly one century later, after fruitless efforts with liquid electrolytes, Baur and Preiss proposed a great number of solid electrolytes for fuel cells, including glasses, porcelains, clays, and different oxide mixtures, and concluded that "unsurpassed is the Nernst mass" [4], even if degradation problems remained.

The role of temperature, doping, and stoichiometry variations influencing the electrical conductivity and ionic diffusivity in solids, often described as "defect chemistry," was treated in pioneering papers in the 1920s and 1930s. Joffé investigated the ionic conductivity of  $\text{NaCl}$ ,  $\text{SiO}_2$ , and  $\text{CaCO}_3$  crystals [5]. Based on these observations, Frenkel postulated the existence of point defects in order to understand the diffusion properties of solids [6]. Wagner and Schottky applied the methods of statistical thermodynamics to the problem of disorder in an ordered binary compound  $\text{AB}$  in 1930 [7]. Wagner also introduced the term excess electron and electron defect and comprehensively discussed the consequences of electronic and ionic disorder on the electrical conductivity of ionic solids [8]. He had already noticed that these concepts could be used to deduce quantitatively

the dependence of conductivity on the partial pressure of the electronegative component.

The main conclusion of these researches is that the electrical conductivity at moderate temperatures of many ionocovalent solids is not due to electronic carriers only but contains a more or less important contribution of mobile ions. The discipline that deals with the preparation, characterization, modeling, and applications of such solid materials supporting ionic motion is called “solid state ionics.” Progress in solid state ionics is related to major technological developments in the domains of energy storage and conversion (batteries and fuel cells) and environmental monitoring and control (chemical sensors).

The presence of interfaces, recognized 50 years ago to play a key role in semiconductor science and microelectronics, strongly impacts also the ionic conductivity. The evaluation of multiphase materials, commonly designated as “composites,” containing heterophase boundaries was started after Liang discovered in 1973 an ionic conduction enhancement in a heterogeneous material: dispersion of small alumina particles in a matrix of the moderate ionic conductor LiI leads to 50 times higher ionic conductivity as compared with pure LiI [9]. The conductivity enhancement is a consequence of the formation of space charge regions with enhanced ionic carrier concentration near the interfaces. Similar effects, although somewhat smaller, are expected in polycrystalline materials, where grain boundaries are present. Logically, the enhancement should be particularly significant in systems with a high density of grain or phase boundaries, like in nanocrystalline ceramics and thin films or in nanocomposites. The objective of this chapter is to present the current knowledge on this topic and to review different classes of nanomaterials where an important ionic conductivity has been reported. But before that and for those not familiar with the subject, let us summarize the essential concepts on ionic conduction in the bulk and at, or near, interfaces.

## 2. THEORY OF IONIC CONDUCTION IN THE BULK

The total electrical conductivity  $\sigma$  of a solid at a given temperature is the sum of the partial conductivities of ionic and electronic charge carriers:

$$\sigma = \sum_i q_i \mu_i c_i \quad (1)$$

In this equation,  $q_i$  is the charge,  $\mu_i$  is the mobility, and  $c_i$  is the concentration of the charge carrier  $i$ . It is thus apparent that two parameters can be modified in order to increase the conductivity of a solid: the carrier concentration and/or mobility.

The **concentration** of ionic defects may be increased in one of several ways, as shown in Figure 1 for the case of silver chloride AgCl.

- (1) Deviation from stoichiometry (Fig. 1a and b): a reduction or oxidation of the compound produces simultaneously electronic species and point defects, thereby leading to mixed conduction.

**Figure 1.** Defect chemistry in the bulk of AgCl. From top to bottom: (a) charge carrier concentration as function of compound stoichiometry, (b) “phase diagram”: composition range of the homogeneous compound, (c) influence of doping by  $\text{Cd}^{2+}$  ions, (d) Arrhenius diagram of silver vacancy concentration. The Kröger–Vink nomenclature is explained in Section 2. Reprinted with permission from [48], J. Maier, Nanoionics and soft materials science, in “Nanocrystalline Metals and Oxides—Selected Properties and Applications” (P. Knauth and J. Schoonman, Eds.), p. 84. Kluwer Academic, Boston, 2002. © 2002, Kluwer Academic Publishers.

- (2) Doping (Fig. 1c): the addition of aliovalent impurities requires the generation of ionic defects with opposite charge in order to maintain electrical neutrality.
- (3) Intrinsically disordered solids: many solids pass through an order–disorder transition as the temperature is increased (e.g., point 4 in Fig. 1d or the  $\beta$ – $\alpha$  transition in AgI, three-dimensional disorder). In other cases, the disorder is limited to disordered

planes (intercalation compounds, e.g., Na- $\beta$ -alumina) or one-dimensional channels (tunnel compounds). Likewise, amorphous phases (inorganic glasses and polymers) present a high intrinsic disorder and, in certain cases, also exhibit ionic conductivity.

- (4) Formation of space charge regions in the vicinity of interfaces: the space charge forms in response to a plane of opposite charge adsorbed on the surface or segregated at a grain boundary. This phenomenon will be discussed in some detail.

The ionic **mobility** depends on a number of factors. The most important is the height of the potential barrier that the ion must overcome in order to pass from one well to an adjacent well. In general, the barrier height depends on a number of factors, including the strain energy that needs to be expended for the ion to “squeeze” through the bottleneck, the polarizability of the lattice, and the electrostatic interactions between the ion and its surroundings. Perhaps the easiest to visualize is the strain energy and one is therefore tempted to assume that solids or interfaces with the highest free volume should exhibit the highest mobility. While this is often the case, as in short circuit diffusion at extended defects (e.g., grain boundaries and dislocations), there are many examples where solids with smaller channels support higher mobilities than those with larger channels, due to polarization effects.

## 2.1. Defect Chemistry: Kröger–Vink Nomenclature

Let us introduce now the commonly used nomenclature for the description of defect chemical reactions, proposed in 1956 by Kröger and Vink [10]. The point defects are considered as dilute species and the solid plays the role of the solvent. Several analogies can be found between intrinsic defect formation and self-dissociation of water.

- (1) A pair of charged defects is formed, which is responsible for electrical conduction.
- (2) Defect formation is thermally activated. A mass action law constant using defect activities (or concentrations for dilute species) describes the defect equilibrium.
- (3) An acidity–basicity concept can be introduced [11].

In the Kröger–Vink notation, the subscript shows the site of a defect; the subscript  $i$  stands for an interstitial site. The effective defect charge is written as a superscript, relative to the ideal lattice: a dot ( $\cdot$ ) stands for a positive and a prime ( $'$ ) for a negative charge. The vacancy is written V. For example,  $O_i^{\cdot\cdot}$  represents a doubly charged oxygen interstitial ion,  $V_O^{\cdot\cdot}$  is a doubly charged oxygen vacancy. Bulk defect chemical reactions must obey:

- (1) mass balance,
- (2) balance of lattice sites,
- (3) charge balance (global electrical neutrality).

The electrical neutrality condition is, however, not respected near interfaces, where deviations can occur.

In a binary ionic compound  $M^+X^-$ , four types of intrinsic ionic disorder can be generated by permutation of the elementary defects, ion vacancies, and interstitial ions, but only

three types are experimentally observed. The predominant disorder type depends mainly on the solid’s crystal structure.

(1) **Cation Frenkel disorder** corresponds to the formation of a cation interstitial plus a cation vacancy:

$K_{Fr}$  is the Frenkel equilibrium constant:

$$K_{Fr} = c(M_i)c(V'_M) = \exp(-\Delta_{Fr}G^\circ/kT) \quad (3)$$

$\Delta_{Fr}G^\circ$  is the standard Gibbs free energy of the Frenkel reaction. Obviously, interstitial formation is easier for small ions and/or in relatively open lattices. Therefore, cationic Frenkel disorder is more often found than the corresponding anionic Frenkel disorder (also called anti-Frenkel type), because anions are generally larger. The **anion Frenkel reaction** can be written

Due to the small radii of silver and copper ions, silver halides (such as AgCl, see Fig. 1) and copper halides belong to this group, but also certain anion conductors with the relatively open fluorite-type lattice (e.g., ceria or zirconia).

(2) **Schottky disorder** is due to the coupled formation of cation and anion vacancies:

$MX$  represents ions, which have been displaced to “new” interfacial sites.  $K_{Sch}$  is the Schottky equilibrium constant:

$$K_{Sch} = c(V'_M)c(V'_X) = \exp(-\Delta_{Sch}G^\circ/kT) \quad (6)$$

$\Delta_{Sch}G^\circ$  is the standard Gibbs free energy of the Schottky reaction. One already imagines that this type of disorder will be found mainly in dense crystal lattices. For example, close-packed alkali halides (including NaCl) show Schottky-type disorder. The fourth theoretically possible defect combination, a pair of cation and anion interstitials, is not found in reality, because it is very difficult to create interstitials on both sublattices.

(3) In addition to intrinsic ionic disorder by point defects, one must take into account **intrinsic electronic disorder** by creation of electron–hole pairs, which can be written

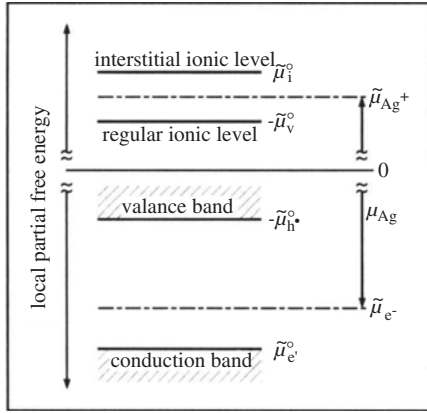

This process can be thermally activated or due to photons. The excess electrons are in the conduction band, whereas electron holes are located in the valence band of the compound. The temperature-dependent equilibrium constant of this reaction is

$$K_{el}(T) = c(h')c(e') = A \exp(-E_g/kT) \quad (8)$$

The prefactor  $A$  contains the effective mass of hole and electron;  $E_g$  is the bandgap energy of the compound.

Intrinsic electron–hole pair formation and vacancy–interstitial pair creation (Frenkel reaction) can both be represented in level diagrams, like those used in solid state physics. Figure 2 shows this type of diagram for the case

**Figure 2.** Level diagrams of ionic and electronic disorder in AgCl. The electrochemical potentials  $\mu_i$  of silver ions and electrons are connected via the chemical potential of silver  $\mu_{Ag}$ , in other words the exact stoichiometry of the compound. The indicated prevailing  $n$ -type semiconductivity corresponds to a slight Ag excess in AgCl. Reprinted with permission from [48], J. Maier, Nanoionics and soft materials science in “Nanocrystalline Metals and Oxides—Selected Properties and Applications” (P. Knauth and J. Schoonman, Eds.), p. 82. Kluwer Academic, Boston, 2002. © 2002. Kluwer Academic Publishers.

of AgCl. If equilibrium is established, the electrochemical potentials of electrons [ $\eta(e^-)$ , i.e., the Fermi level] and ions [ $\eta(\text{Ag}^+)$ ] are connected via the chemical potential of one of the components, here Ag [ $\mu(\text{Ag})$ ] (i.e., by the exact compound stoichiometry):

$$\mu(\text{Ag}) = \eta(\text{Ag}^+) + \eta(e^-) \quad (10)$$

(4) “**Antisite**” disorder describes the interchange of ions between two sublattices. While such exchange between cation and anion sites is not observed in binary ionic systems due to trivial electrostatic reasons, “antisite” disorder can be observed in ternary and higher order compounds in which cations disorder between two different cation sublattices: this is common, for example, in solids with the spinel structure [12].

(5) As one can easily verify in Eqs. (2), (4), and (5), the intrinsic defect reactions do not modify the composition of the exactly stoichiometric solid (the “Daltonide”). In addition to these intrinsic disorder types, one can also observe “**extrinsic**” disorder due to composition changes of the solid, be it the presence of foreign ions (impurities or dopants) or a nonstoichiometry. The latter is induced by chemical potential changes of one of the components, for example oxygen in the case of oxides. Oxidation or reduction of the material results in deviations from stoichiometry (corresponding to a “Berthollide”) and the formation of both ionic and electronic charge carriers. For example, electron holes and oxygen interstitials are created in a Frenkel-disordered oxide by the oxidation reaction

$$K_{\text{ox}} = c(\text{O}_i')c(h)^2P(\text{O}_2)^{-1/2} = \exp(-\Delta_{\text{ox}}G^\circ/kT) \quad (12)$$

$K_{\text{ox}}$  is the equilibrium constant and  $\Delta_{\text{ox}}G^\circ$  is the standard Gibbs free energy of the oxidation reaction. Excess electrons and oxygen vacancies are formed in the reduction reaction

$$K_{\text{red}} = c(\text{V}_\text{O}'')c(e')^2P(\text{O}_2)^{1/2} = \exp(-\Delta_{\text{red}}G^\circ/kT) \quad (14)$$

$K_{\text{red}}$  is the equilibrium constant and  $\Delta_{\text{red}}G^\circ$  is the standard Gibbs free energy of the reduction reaction.

As a consequence, the  $p$ -type or  $n$ -type conductivity increases together with the deviation from stoichiometry. At reduced temperature, impurities (or dopants) will dominate near stoichiometry, while under reducing or oxidizing conditions, defects associated with nonstoichiometry will control the electrical properties of the material. The electrical properties eventually become intrinsic when the temperature increases to sufficiently high values. Kröger and Vink discussed various aspects of stoichiometry deviations in inorganic compounds and developed diagrams that show defect concentrations as a function of the chemical potential of the components. These diagrams can be much simplified under the assumption of only two majority defects, according to the so-called Brouwer approximation [13]. A general discussion of these phenomena is outside the scope of this chapter but can be found in many standard texts [14].

## 2.2. Ionic Conduction in the Bulk: Hopping Model

Ionic conduction in solids [15] is due to thermally activated ion hopping [16, 17]. Assuming Boltzmann statistics, the diffusion coefficient  $D_i$  is a function of the jump distance  $a$ , the characteristic attempt frequency  $\nu_0$  (typically  $\approx 10^{13} \text{ s}^{-1}$ ) and the free energy of migration  $\Delta_{\text{migr}}G = \Delta_{\text{migr}}H - T\Delta_{\text{migr}}S$ :

$$D_i = \gamma a^2 \nu_0 \exp(-\Delta_{\text{migr}}G/kT) \quad (15)$$

The factor  $\gamma$  takes into account geometrical and so-called correlation effects. For example, the backward jump has a slightly higher probability than the forward jump, but, on the other hand, cooperative motion can lead to higher diffusion coefficients than isolated jumps. The Nernst–Einstein equation relates the ionic mobility  $\mu_i$  to the diffusion coefficient ( $k$  is Boltzmann’s constant):

$$\mu_i = D_i q_i / kT \quad (16)$$

Using Eqs. (1), (15), and (16), the ionic conductivity can be expressed as

$$\sigma_{\text{ion}} = (q_i^2/kT)c_i \gamma a^2 \nu_0 \exp(\Delta_{\text{migr}}S/k) \exp(-\Delta_{\text{migr}}H/kT) \quad (17)$$

A general equation representing the ionic conductivity can thus be written with a prefactor  $\sigma_0$ :

$$\sigma_{\text{ion}} = \sigma_0 / T \exp(-\Delta_{\text{act}}H/kT) \quad (18)$$

Most crystalline and amorphous fast ion conductors (the latter below their glass transition temperature) satisfy this equation. For crystalline fast cation conductors (such as

$\alpha$ -AgI), the activation enthalpy  $\Delta_{\text{act}}H$  is typically below 0.5 eV; for anion conductors, it is normally larger (0.5–1.0 eV). The activation enthalpy can contain different contributions.

- (1) If the concentration of the mobile ionic defects is fixed by charged **background impurities and dopants**, as in the case of Y-stabilized  $\text{ZrO}_2$  [ $2c(\text{V}_{\text{O}}^{\bullet}) = c(\text{Y}_{\text{Zr}}')$ ], the activation enthalpy  $\Delta_{\text{act}}H$  represents only the defect migration enthalpy  $\Delta_{\text{migr}}H$  (cf. curve 2 in Fig. 1d).
- (2) Assuming a **thermally activated defect creation**, the carrier concentration  $c_i$  has a temperature dependence such as Eq. (3) or (6):

$$c_i = c_{i0} \exp(-\Delta_{\text{form}}H^\circ/2kT) \quad (19)$$

In this “intrinsic” case,  $\Delta H_{\text{act}}$  is the sum of the defect migration and formation enthalpies ( $\Delta_{\text{act}}H = \Delta_{\text{migr}}H + \Delta_{\text{form}}H^\circ/2$ ; cf. curve 1 in Fig. 1d).

- (3) If **deviations from stoichiometry** are observed, the activation enthalpy can be related to reaction enthalpies, such as the oxidation enthalpy for metal deficient oxides, cf. Eq. (12), or the reduction enthalpy for oxygen deficient oxides, cf. Eq. (14).
- (4) At low temperatures, **defect association** phenomena can be observed. These issues were discussed early on by Lidiard [18]. Dreyfus and Nowick investigated such point defect association phenomena in doped sodium chloride [19]. In the case of NaCl, doping with divalent cations requires the formation of sodium vacancies for charge compensation:

At low temperature, defect association due to Coulomb interactions between the oppositely charged defects begins to predominate:

$$\text{M}_{\text{Na}} + \text{V}_{\text{Na}}' = (\text{M}_{\text{Na}}, \text{V}_{\text{Na}}') \quad (21)$$

$(\text{M}_{\text{Na}}, \text{V}_{\text{Na}}')$  refers to a bound dopant–vacancy pair. In the temperature domain in which association occurs, the conductivity has an effective activation enthalpy ( $\Delta_{\text{act}}H = \Delta_{\text{migr}}H + \Delta_{\text{ass}}H/2$ , where  $\Delta_{\text{ass}}H$  is the association enthalpy; cf. curve 3 in Fig. 1d). There are other important experimental consequences from such association:

- (1) The formation of vacancy–dopant pairs leads to a weaker overall enhancement of conductivity.
- (2) The pairs act as dipoles and contribute to dielectric relaxation processes. Haven established the presence of loss peaks due to defect pairing in 1953 [20].
- (3) The dopant ion being in the immediate vicinity of a vacancy, it can be expected to diffuse faster than the host cation.

In addition to the formation of defect pairs, Lidiard showed that long-range defect interactions also play a role and adapted the Debye–Hückel theory of aqueous electrolytes

to the case of ionic crystals [18]. The resulting activity variations can often be described by a cube root law of the defect concentrations [21]. The electrostatic interactions are also the origin of the frequency dependence of the ionic conductivity and dielectric permittivity of structurally disordered solid electrolytes (cf. the “universal dielectric response”) [22, 23].

### 3. IONIC CONDUCTION AT AND NEAR INTERFACES

An interface is a two-dimensional region separating two parts of a system. The word interface is used in the following synonymous with the term boundary. One can differentiate two main types:

- (1) Phase boundaries separate two phases with different chemical composition and/or structure; they are found in polyphase materials, also called composites.
- (2) Grain boundaries separate two grains of identical composition and structure; they are found in polycrystalline materials.

At reduced temperature, boundaries can significantly enhance the ionic conductivity of polycrystalline or composite materials and thin films as compared with single crystals of identical composition. However, boundaries can also block ionic charge carriers and reduce the ionic conductivity of a material.

To understand this behavior, one has to take into account the anisotropy of boundary properties: transport might be facilitated along an interface or blocked across the interface (parallel and perpendicular effects). For microcrystalline materials, study of bulk and interface effects is experimentally possible by impedance spectroscopy, because the different electrical properties of bulk and interface regions usually lead to a significant difference of the time constants  $\tau$ :

$$\tau = \varepsilon/\sigma \quad (22)$$

In this equation,  $\varepsilon$  is the dielectric permittivity and  $\sigma$  is the electrical conductivity of the respective region. Therefore, bulk and boundary responses can often be clearly separated in the complex impedance plane as function of the signal frequency. For nanocrystalline materials, the overall electrical response is, however, more complex and the theoretical discussion of impedance spectra is not trivial [24]. For a general discussion of impedance spectra of solid ionic conductors, the reader can consult a standard textbook [25].

Let us now review the atomic mechanisms involved in the enhanced ionic conductivity at and near interfaces: one can distinguish enhanced boundary core diffusion and equilibrium (and out-of-equilibrium) space charge layer effects.

#### 3.1. Boundary Core Diffusion

High resolution electron micrographs of grain boundaries in oxides (e.g., NiO) show that the disordered region between grains is typically only a few atomic layers thick, not unlike the “grain boundary width” postulated for the interpretation of grain boundary diffusion data in metals (0.5 nm) [26]. The defects create a new periodic interface structure with

regularly repeating structural units. Ordinary boundaries are formed by portions of such special boundaries.

The boundary core is a fast diffusion path and can act as a short-circuiting pathway for diffusion at reduced temperature. This mechanism has been known in metallurgy for quite a long time but applies obviously also in ionic materials. The enhancement of the oxygen ion diffusion coefficient, due to surface and grain boundary diffusion, was already recognized in 1960 by comparison of single crystalline and polycrystalline  $\text{Al}_2\text{O}_3$  [27]. More recently, Atkinson showed that the grain boundary diffusion coefficient in nickel oxide NiO is as much as six orders of magnitude larger than the bulk one [28].

Accelerated diffusion in the boundary core can be expected for two reasons:

- (1) the large defect concentration at interface sites (high percentage of displaced atoms), corresponding to a low defect formation energy,
- (2) the large excess free volume, which enhances the defect mobility, corresponding to a low defect migration energy.

The activation energy for interfacial diffusion is therefore significantly lower than for bulk diffusion, because defect formation and migration need less energy at interface sites. This is the origin of the fast boundary diffusion at low temperature. In the “neutral core model,” the interface core is also held responsible for an ionic conductivity enhancement (see Section 4 for more details).

In usual microcrystalline materials, the cross-sectional area of grain boundaries is, however, very small: using an elementary brick layer model, the ratio of cross-sectional areas of grain boundaries (gb) of width  $d$  and cubic grains of size  $L$  is

$$A(\text{gb})/A(\text{bulk}) = 2d/L \quad (23)$$

The general conclusion from these considerations is that grain boundary diffusion is the main diffusion contribution at low temperature. It leads to a significant enhancement of mass transport in comparison with single crystals, if the grain size is sufficiently small.

### 3.2. Space Charge Layer Models

Boundary core diffusion is, however, not the only and generally not the most important origin for an ionic conductivity enhancement, but space charge effects are. Space charge regions are formed near interfaces in ionic materials to compensate charged defects and dopants, which segregate to surfaces and grain and phase boundaries. Two segregation modes are commonly recognized: one is segregation of over- or undersized dopants to the boundary core, due to elastic relaxation, and the second is segregation of charged defects in the space charge regions, due to electrostatic interactions.

Space charge effects have been known to be important in colloid systems for some time: Verwey and Overbeek established the electrostatic theory applicable to these systems in 1948 [29]. Grimley and Mott discussed boundary conditions at Ag/AgBr and AgBr/liquid electrolyte interfaces in 1947 [30]. Lehovc calculated the distribution of lattice defects

and the space charge potential at the surface of ionic crystals following a statistical thermodynamic approach in 1952 and already mentioned the implications for ionic conduction [31]. Kliewer and Koehler applied these concepts to the case of NaCl in 1965 [32]. Poeppl and Blakely extended this treatment by taking the density of surface sites into account [33]. Wagner used the space charge layer concept in 1972 to explain conductivity effects in two-phase materials, such as metallic inclusions in a semiconducting oxide or mixtures of two semiconducting oxides [34]. Space charge segregation of dopants was studied in a number of systems, for example, in  $\text{TiO}_2$  and  $\text{CeO}_2$  by Chiang and co-workers [35–37].

The first evidence for the importance of space charge effects in solid state ionics was the experimental work of Liang published in 1973. The ionic conductivity of the moderate  $\text{Li}^+$  ion conductor LiI was enhanced by a factor of almost 50 by dispersing small alumina particles in the ion conductor matrix. A large number of papers confirmed this “heterogeneous doping” effect on other ionic conductor composites, with a major contribution by the group of Saki and Wagner [38]. Similar enhancement effects can be predicted if dislocations are present. However, the number of experimental studies is smaller, given their difficulty: Nowick studied the conductivity of plastically deformed NaCl crystals [39]. Dudney investigated the enhancement of conductivity due to dislocations and stress effects in AgCl composites [40].

The space charge layer theory of ionic conductor systems was largely developed by Maier since 1984 [41]. The fundamental idea is that ionic defects (or dopants) can be trapped at an interface. This corresponds to an interfacial segregation process that can modify the excess (positive or negative) interface core charge  $\varphi$  and the interface potential  $\phi$ . All species with an opposite charge are enriched in the adjacent space charge region (accumulation layer), whereas the species with the same charge are depleted (depletion layer):

$$q_i \partial c_i / \partial \phi < 0 \quad (24)$$

A so-called “inversion” layer is observed for a species that is the majority carrier in the bulk but a minority carrier in the space charge region [42].

Space charge effects are relevant for different ionic conducting materials, including ionic conductor–insulator composites, thin films, and polycrystalline solids; the higher the interfacial area in these materials, the higher the expected conductivity effect.

- (1) Composites: The driving force for trapping can be the presence of a second phase with chemical affinity for a mobile ion. For example, “basic” oxides present many nucleophilic hydroxide surface groups, which can attract and fix cations. The space charge regions are then enriched in mobile cation vacancies, which are often majority ionic charge carriers at low temperature. The space charge layers represent then high conductivity regions that can short-circuit the bulk, if they percolate [43]. An optimized effect is expected when the two phases have a nanometric size.
- (2) Thin films: The interaction with a gas phase can also lead to a space charge effect, particularly if the solid

ionic conductor is in thin-film form [44]. For example, ammonia is known to form strong complexes with copper ions in aqueous solution. Copper ions can also be trapped at the surface of a solid copper ion conductor in contact with a gas phase containing ammonia. This effect can be used for ammonia gas detection [45]. Large conductivity effects are also expected in ionic conductor heterolayers with small periodicity (cf. Section 4.4).

- (3) Polycrystalline materials: Ions can be trapped at the grain boundary core, which has a larger free volume than the bulk [46]. Obviously, the trapping effects can be particularly important in nanocrystalline solids, which present a very large grain boundary density.

Space charge effects on conductivity depend on whether one considers:

- (1) transport along or across a boundary,
- (2) accumulation, depletion, or inversion layers,
- (3) “Gouy–Chapman” or “Mott–Schottky” situations.

However, the impact of space charge layers on conductivity can always be expressed by the relation

$$\partial \ln \sigma_i(x) / \partial (\phi(x)/kT) = -q_i \quad (25)$$

$\phi(x)$  is the space charge potential relative to the bulk, modifying the charge carrier concentration in the space charge region. Let us consider now the assumptions and detailed relations for the two cases of complete and partial charge carrier equilibrium.

### 3.2.1. Complete Equilibrium: “Gouy–Chapman” Model

If all defects are in local thermodynamic equilibrium, the boundary can be described by a model similar to the classical electrochemical model of the electrode–electrolyte interface, outlined around 1910 by Gouy and Chapman [47]. The formation of space charge layers is a consequence of local thermodynamic defect equilibrium: since the boundary core has its own defect chemistry, a defect redistribution between bulk and boundary core leads to space charge layers adjacent to the core. For a Frenkel disordered material  $M^+X^-$ , the defect reaction can be written:

Here,  $V_S$  and  $M'_S$  are respectively an empty interface site and a metal ion trapped at this site. The metal vacancies  $V'_M$  are distributed in the region adjacent to the interface, which becomes electrically charged (space charge region). It is assumed that the bulk defect thermodynamic properties, such as the standard chemical potential  $\mu^\circ$  or the Frenkel equilibrium constant [cf. Eq. (3)] and also the bulk defect mobility remain unchanged inside the space charge region, up to the boundary core. This is certainly an oversimplification, because it is known that the local structure changes more gradually and not in a steplike manner. However, a similar assumption is made in semiconductor physics and the conclusions obtained by the space charge model are validated by experiments in a number of cases, including

composite and nanocrystalline ionic conductors, as we will see later.

At equilibrium, the electrochemical potentials  $\eta_i$  of charged species are constant across the interface, but the chemical potentials  $\mu_i$  change ( $\phi$  is the internal electrical potential):

$$d\eta_i = d\mu_i + q_i d\phi = 0 \quad (27)$$

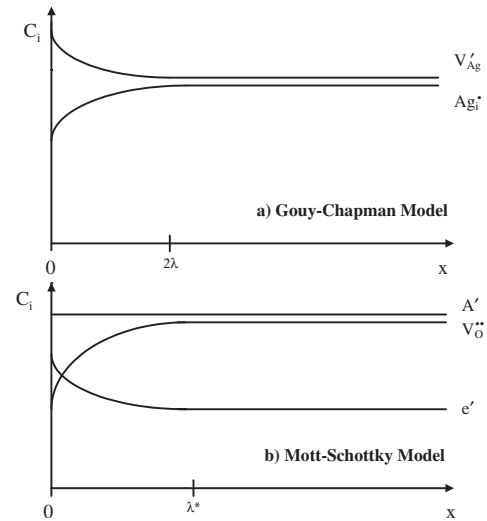

Using the relation between the chemical potential of the species  $i$  and its thermodynamic activity  $a_i$ , it follows that

$$kT d \ln a_i = -q_i d\phi \quad (28)$$

For small defect concentrations, the activity can be replaced by the concentration and the defect concentration profile in the space charge region can be formulated as function of the bulk carrier concentration  $c_{i\infty}$ :

$$c_i(x)/c_{i\infty} = \exp[-q_i(\phi(x) - \phi_\infty)/kT] = \exp[-q_i\phi(x)/kT] \quad (29)$$

The local concentration in the space charge region  $c_i(x)$  depends on the difference between the local and the bulk electrical potential,  $\phi(x)$  and  $\phi_\infty$ , which is in the following consistently taken as  $\phi_\infty = 0$  to simplify the equations. For positive values of  $\phi(x)$ , the concentrations of all negative defects are raised by the exponential factor, while those of the positive defects are reduced by the same factor and vice versa for negative values (Fig. 3a). The divergence of

**Figure 3.** Defect concentration profiles near an interface (at  $x = 0$ ) with a positive interface charge [positive interface potential  $\phi(0)$ ]. The upper part (a) represents the Gouy–Chapman situation, where complete defect equilibrium is established. The defect profiles of depleted silver interstitials and accumulated silver vacancies are observed inside the space charge layer width  $2\lambda$ , where  $\lambda$  is the Debye length [cf. Eq. (30)]. The lower part (b) represents the Mott–Schottky case, where the defect equilibrium is only partially established. Here, the acceptor dopant ( $A'$ ) is assumed to be immobile at the temperature of the experiment: its concentration is constant up to the interface. The defect profiles of depleted oxygen vacancies and accumulated electrons are observed inside the space charge zone  $\lambda^*$  [cf. Eq. (39)]. The depicted situation corresponds to an inversion layer.

defect profiles is observed over a distance proportional to the Debye length  $\lambda$  that is conveniently defined, as in semiconductor and liquid electrolyte theory, with respect to the bulk concentration  $c_{i\infty}$  of the majority defect ( $\varepsilon$  is the dielectric permittivity):

$$\lambda^2 = \varepsilon kT / (2q_i^2 c_{i\infty}) \quad (30)$$

From this relation, one recognizes immediately that an enhancement of the bulk carrier concentration, by appropriate doping or temperature increase, reduces the Debye length and thus the space charge layer width. Space charge effects are thus low temperature effects and can have a considerable influence on the electrical properties of ionic conductor ceramics with reduced charge carrier concentrations, because the space charge layer width (approximately twice the Debye length) can be orders of magnitude larger than the typical grain boundary core width of a few atomic distances.

Let us calculate now the conductivity along a boundary for charge carrier accumulation. This requires integration of the concentration profile of the accumulated carrier, called 1, from the boundary ( $x = 0$ ) to the bulk:

$$\sigma_1^{\parallel} = 1/L \int_0^L \sigma_1^{\parallel}(x) dx = q_1 \mu_1 / L \int_0^L c_1(x) dx \quad (31)$$

It is assumed that the defect mobility  $\mu_1$  takes the bulk value also in the space charge region. This total conductivity  $\sigma_1^{\parallel}$  can be separated into the bulk conductivity  $\sigma_{\infty}$  and the space charge layer conductivity  $\sigma_{\text{isc}}^{\parallel}$ . For large accumulation of carrier 1, one obtains, using Eq. (30), a square-root concentration dependence for the space charge layer conductivity [48]:

$$\sigma_{\text{isc}}^{\parallel} = q_1 \mu_1 (2\lambda)(c_{10} c_{1\infty})^{1/2} / L = (2\varepsilon k T c_{10})^{1/2} \mu_1 / L \quad (32)$$

$c_{10}$  is the concentration in the first layer adjacent to the boundary core ( $x = 0$ ). The effective concentration of the species 1 is the geometrical mean of bulk and “interface” concentration; the effective thickness of the space charge region is  $2\lambda$ .

The Gouy–Chapman model permits a quantitative interpretation of conductivity measurements where complete charge carrier equilibrium is established, for example on composite materials with a matrix of a low temperature ion conductor, such as AgCl [43]. Here, the silver vacancy concentration is enhanced in the space charge region (accumulation layer), due to  $\text{Ag}^+$  adsorption on the second phase nanoparticles. The simplified distribution topology of the two phases is expressed by geometrical factors [41]. An equation of type (32) can also be used to estimate the conductivity of  $\text{CaF}_2/\text{BaF}_2$  heterolayers [49], as long as the space charge regions can be considered semi-infinite, in other words as long as they do not overlap.

### 3.2.2. Mesoscopic Effects (Thin Films and Nanostructured Materials)

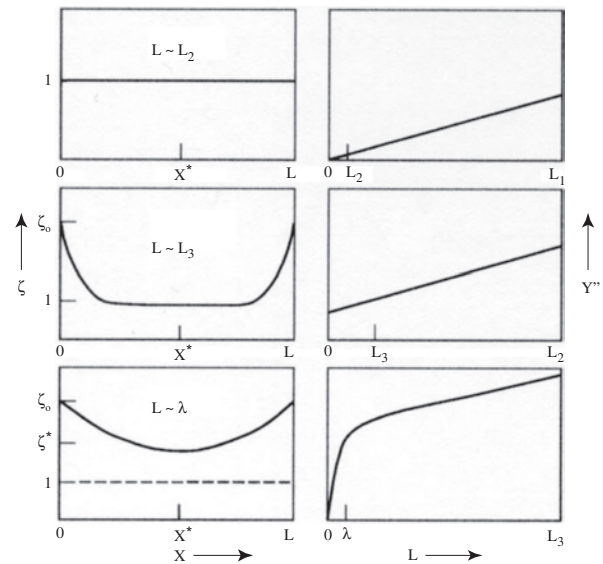

Interfaces in systems with very small lateral dimensions (e.g., extremely thin films, nanocrystalline, or nanocomposite materials) can be expected to have a more important effect

on ionic conduction. Apart from the ionic conductivity enhancement due to the increased interface area, which can easily be extrapolated, an additional conductivity increase can be observed when the Debye length becomes comparable to the grain size. In that case, the space charge regions overlap; in other words, the defect density no longer reaches the “normal” bulk value, even at the center of the particles (Fig. 4). Mathematically; the model of semi-infinite space charge layers breaks down. In the limit of very small grains, local charge neutrality is nowhere satisfied and a full depletion (or accumulation) of charge carriers can occur with major consequences for ionic and electronic conductivity. This is equivalent to a flat-band situation, where the conductivity is homogeneous over the whole nanocrystallite, and corresponds to a change of the standard electrochemical potential. The defect thermodynamic [50], electrical, and mass transport properties then cannot be extrapolated from conventional size scaling laws and become truly grain-size dependent.

In this case, the ionic conductivity should not depend linearly on the grain size  $L$ . The supplementary enhancement can be estimated introducing a “nanosize” factor  $g$  that can be obtained from [48]

$$g = (4\lambda/L)[(c_{10} - c_1^*)/c_{10}]^{1/2} \quad (33)$$

$c_1^*$  is the defect concentration in the grain center. For a large effect ( $c_{10} \gg c_1^*$ ),  $g = 4\lambda/L$ , and with a grain size  $L = 0.4\lambda$ ,

**Figure 4.** Left: Defect concentration profiles as function of the particle size  $L$ .  $\zeta$  is the normalized defect concentration (i.e., divided by the bulk concentration). The two top figures show the macroscopic situation, when the grain size  $L$  is much larger than the Debye length  $\lambda$  [cf. Eq. (30)]. Separate space charge regions are observed. Bottom: mesoscopic situation of very small particles:  $L \approx \lambda$ . The space charge regions overlap: the “normal” bulk defect concentration is not reached. Right: Parallel conductances for thin films of various thickness ( $L_3 \ll L_2 \ll L_1$ ). Reprinted with permission from [48], J. Maier, *Nanoionics and soft materials science*, in “Nanocrystalline Metals and Oxides—Selected Properties and Applications” (P. Knauth and J. Schoonman, Eds.), p. 96. Kluwer Academic, Boston, 2002. © 2002, Kluwer Academic Publishers.

the conductivity would be enhanced by a supplementary order of magnitude. A major objective of experiments is to check the validity of this prediction by studying systems with small grain size and/or low bulk carrier concentration. Mesoscopic effects due to overlapping space charge regions have for example been observed in very thin heterolayers [49].

### 3.2.3. Partial Equilibrium: “Mott–Schottky” Model

The Mott–Schottky model corresponds to the case found in doped silicon at ambient temperature: if a dopant is assumed to be immobile (frozen-in) at the temperature of the experiment, the bulk dopant concentration  $c_D$  is constant up to the boundary (Fig. 3b). In that case, Poisson’s equation must be integrated with a constant charge density related to the dopant density and the charge of the ionized dopant ( $\varphi = c_D q_D$ ), in the one-dimensional case for an acceptor:

$$d^2 \phi(x)/dx^2 = -\varphi/\varepsilon = c_D q_D/\varepsilon \quad (34)$$

The required two boundary conditions for this second-order differential equation are determined by the potential in the bulk and the absence of electric field outside the depletion layer:

$$\phi = 0 \quad \text{and} \quad d\phi/dx = 0 \quad \text{for } x > \lambda^* \quad (35)$$

A solution of Poisson’s equation gives the potential profile in the depletion region [51, 52] ( $x \leq \lambda^*$ ):

$$\phi(x) = (\lambda^* - x)^2 c_D q_D / 2\varepsilon \quad (36)$$

The interface potential at  $x = 0$  is

$$\phi(0) = \lambda^{*2} c_D q_D / 2\varepsilon \quad (37)$$

One can easily show that the relation between the two potentials is

$$\phi(x) = \phi(0)(1 - x/\lambda^*)^2 \quad (38)$$

Given that equilibrium is only partially established, the interface potential  $\phi(0)$  is not determined by the thermodynamic boundary conditions alone but can be modified externally, for example, by applying a voltage. This corresponds to so-called Mott–Schottky experiments in liquid electrolyte or to Mott–Schottky semiconductor–metal contacts. The width of the space charge region  $\lambda^*$  depends on the interface potential  $\phi(0)$  and is not exclusively determined by the bulk carrier concentration, from Eqs. (37) and (30):

$$\lambda^* = [2\varepsilon\phi(0)/c_D q_D]^{1/2} = 2\lambda(q_D \phi(0)/kT)^{1/2} \quad (39)$$

Even in heavily doped situations, where the Debye length  $\lambda$  is very small,  $\lambda^*$  can be perceptible if the boundary potential  $\phi(0)$  is large. Inserting Eq. (36) into Eq. (29) and using Eq. (39), it is easy to calculate, this time for a depleted species called 2, a Gaussian-type concentration profile:

$$c_2(x)/c_{2\infty} = \exp[-(q_2/q_D)[(x - \lambda^*)/2\lambda]^2] \quad (40)$$

$c_{2\infty}$  is the bulk carrier concentration of the depleted species.

The resistivity across a boundary  $\rho_2^\perp$  can be obtained by integration of the concentration profile of the depleted species 2 in the space charge region, using Eqs. (39) and (40):

$$\rho_2^\perp = (\sigma_2^\perp)^{-1} = 1/L \int_0^L (\sigma_2(x))^{-1} dx = 1/(Lq_2\mu_2) \int_0^L dx/c_2(x) \quad (41)$$

One can notice that

$$\lambda^* = 2\lambda(q_2\phi(0)/kT)^{1/2} = 2\lambda[\ln(c_{2\infty}/c_{20})]^{1/2} \quad (42)$$

$c_{20}$  is the concentration in the first layer adjacent to the boundary core ( $x = 0$ ). The separation into the bulk resistivity  $\rho_{\text{bulk}}$  and the grain boundary resistivity  $\rho_{\text{gb}}^\perp$  leads to [48]

$$\rho_{\text{bulk}} = 1/(q_2\mu_2 c_{2\infty}) = 1/[q_2\mu_2 c_{20} \exp(q_2\phi(0)/kT)] \quad (43)$$

$$\begin{aligned} \rho_{\text{gb}}^\perp &= \lambda^* [Lq_2\mu_2 2c_{20} \ln(c_{2\infty}/c_{20})] \\ &= \lambda^* / [Lq_2\mu_2 2c_{20} (q_2\phi(0)/kT)] \end{aligned} \quad (44)$$

The effective thickness of the space charge layer is  $\lambda^*$  and the effective concentration  $[2c_{20} \ln(c_{2\infty}/c_{20})]$ .

Two electric properties can be used to estimate the interface potential  $\phi(0)$ , which is the main parameter influencing the defect chemistry in the space charge region.

- (1) The grain boundary capacitance ( $A$ : sample cross-sectional area) is related to the effective grain boundary thickness. By insertion of Eq. (30) into Eq. (39), one easily gets

$$C/A = \varepsilon/\lambda^* = [\varepsilon q_2 c_{2\infty} / (2\phi(0))]^{1/2} \quad (45)$$

This equation is related to the well-known Mott–Schottky equation that allows determination of a dopant density in semiconductors from interfacial capacitance measurements [53].

- (2) Using Eqs. (43) and (44), one gets easily the ratio of grain boundary resistivity  $\rho_{\text{gb}}$  and bulk resistivity  $\rho_{\text{bulk}}$ :

$$\rho_{\text{gb}}/\rho_{\text{bulk}} = \exp(q_2\phi(0)/kT) / [2q_2\phi(0)/kT] \quad (46)$$

At the reduced measurement temperature generally used for nanocrystalline materials, one can often reasonably assume that dopants are immobile, so that the Mott–Schottky model will be useful for a quantitative interpretation of conductivity measurements on nanoceramics, including the model system of pure and acceptor-doped ceria discussed in Section 4. Furthermore, the Mott–Schottky model was used to interpret the grain boundary resistivity of highly pure zirconia ceramics. In this refractory compound, dopants can still be considered immobile at quite high measurement temperatures [54].

### 3.3. Percolation Models for Composites

Although analytical equations, such as Eq. (32), are in good agreement with experimental conductivity data for many ionic conductor composites, these expressions cannot describe the behavior near critical points. Two thresholds exist in ionic conductor/insulator composites. For a small concentration of insulator, the space charge regions around the phase boundaries are isolated in the matrix of the ionic conductor and do not effectively contribute to ionic conductivity enhancement. There exists a first critical concentration, where a continuous network of highly conducting paths extends through the whole sample. With further increase of insulator concentration, the conductivity increases drastically: this is the domain where the analytical equations describe the experimental data satisfactorily. At large volume fractions of insulator, a second critical concentration is attained, where conduction paths become disrupted, because continuous layers of insulator grains are formed (conductor–insulator transition). The conductivity drops sharply after this second threshold.

Effective medium theories are unable to describe the behavior near critical points, because property fluctuations are important here. Critical phenomena can, however, be described in the framework of percolation theory, first applied to the problem of ionic conductor/insulator composites by Bunde et al. [55]. However, the assumptions made in their model (i.e., randomly distributed ionic conductor and insulator particles having identical sizes) do not correspond to the experimental evidence. In the experiments, ionic conductor and insulator have usually a different mean grain size and the interfacial interactions lead to the formation of continuous layers of insulator around the ionic conductor grains. Both experimental facts were taken into account in an improved percolative transport model [56, 57]. A particularly important conductivity enhancement is predicted when both phases have nanosized grains: percolation theory was applied to discuss the ionic conductivity of nanocrystalline  $\text{Li}_2\text{O}:\text{B}_2\text{O}_3$  composites [58]. The percolation models are complementary to the analytical approach; in both cases the physical model is based on the space charge layer concept.

## 4. NANOCRYSTALLINE CERAMICS AND THIN FILMS

The synthesis, processing, and characterization of nanocrystalline ceramics (“nanoceramics”) and thin films belong to the emerging and rapidly growing field called nanotechnology. Substantial progress has been achieved in the last decades in the preparation of ultrafine grained precursor materials [59, 60]. Nanoceramics (i.e., three-dimensional solids composed of crystallites with a mean size below 100 nm [61]) can be prepared from precursor nanopowders by hot-pressing, where shaping and sintering are performed during a unique procedure, typically around 600 °C under several thousand bars [62].

Nanocrystalline ceramics can present improved mechanical properties, hardness combined with ductility [63], which

are outside the scope of this chapter. There seems to be convincing evidence now that the crystallites in nanoceramics present few extended lattice imperfections. Structural investigations of nanocrystalline oxides showed crystallites with a high degree of perfection, separated by sharp grain boundaries without indication of amorphous regions [64]. The high order in the grain interior can be understood by the existence of a large number of grain boundaries, which can act as defect sinks, in atomic proximity. Extended X-ray fine structure studies of nanocrystalline oxides showed that the grain boundary structure appears to be essentially similar to that in conventional microcrystalline materials [65, 66]. The gaslike or glasslike grain boundary structure sometimes postulated in the early literature was not confirmed.

Solute segregation at grain boundaries and surfaces in nanocrystalline solids can lead to an apparent solubility enhancement for solutes with low bulk solubility: the large increase of the apparent copper solubility in nanocrystalline  $\text{CeO}_2$  was attributed to interfacial segregation and correlated with the mean grain size of the ceria particles [67, 68]. The dopant segregation can tune the activity of nanostructured catalysts [69].

Let us review now major studies on ionic conduction in nanocrystalline ceramics and thin films, with emphasis on model investigations. The domain of “nanoionics” is currently expanding at a fast pace, like the whole sector of nanoscience and nanotechnology. A few recent reviews on this topic can be found in [70–76].

### 4.1. A Model System: Pure and Doped $\text{CeO}_2$

Ceria is the most studied nanocrystalline oxide so far, given its importance as solid electrolyte [77] and for oxygen storage [78], when appropriately doped, and for catalysis. Nominally undoped  $\text{CeO}_2$  nanoceramics [64] remain *n*-type semiconducting even at high oxygen partial pressure, in contrast to conventional microcrystalline samples that are ionically conducting, due to acceptor doping, and become mixed conducting only under reducing conditions. The large increase of the electronic conductivity, the decrease of ionic conductivity, and reduction enthalpy as compared with microcrystalline samples are striking results, confirmed by several experimental investigations [79, 80]. Similar results were also obtained for  $\text{CeO}_2$  thin films [81–83]. Grain-size dependent conductivity data of various authors are reported in Figure 5. Two competing models can be used for interpretation:

- (1) the neutral boundary core model, where charge effects are neglected,
- (2) the space charge concept, where charge effects are paramount.

#### 4.1.1. Neutral Boundary Core Model

In the “neutral core model,” the enhancement of conductivity is explained by the high disorder in the boundary core, due to a significantly lower standard reduction enthalpy

**Figure 5.** Grain size dependence of the conductivity of nanocrystalline ceria ceramics. The solid line represents the calculated electronic conductivity, based on analytical equations for grain size in the micrometer range, numerical calculations for nanometric sizes. The dotted line represents the calculated ionic conductivity. The symbols stand for electronic conductivity data of various authors. Reprinted with permission from [92], A. Tschöpe, *Mater. Res. Soc. Symp. Proc.* © Material Research Society.

$\Delta_{\text{red}}H^{\circ}$  at interface sites, making the reduction reaction much easier:

One can write the equilibrium constant of the reduction reaction at interface sites [cf. Eq. (14)] as

$$K_{\text{red}'} = c(\text{V}_{\text{O}}^{\bullet\bullet})c(e')^2P(\text{O}_2)^{1/2} = A \exp(-\Delta_{\text{red}}H^{\circ}/kT) \quad (47)$$

In order to obtain the experimentally observed slope  $-1/6$  in the  $\ln \sigma$  vs  $\ln P(\text{O}_2)$  dependence, one has to assume an electrical neutrality relation:

$$2c(\text{V}_{\text{O}}^{\bullet\bullet}) = c(e') \quad (48)$$

In other words, the defect concentrations due to the reduction reaction are assumed so high that doping can be neglected, so that the vacancy concentration is not fixed by acceptor impurities, like in conventional samples. One then obtains

$$c(e')^3 = 2A \exp(-\Delta_{\text{red}}H^{\circ}/kT)P(\text{O}_2)^{-1/2} \quad (49)$$

Using Eq. (1), one gets finally the experimentally observed power law:

$$\ln \sigma = \ln[e\mu_e(2A)^{1/3}] - 1/6 \ln P(\text{O}_2) - (\Delta_{\text{hop}}H + \Delta_{\text{red}}H^{\circ}/3)kT \quad (50)$$

$\Delta_{\text{hop}}H$  is the small polaron hopping enthalpy (around 0.4 eV in ceria [84]). Using the data of [64], the standard reduction enthalpy is strikingly lower ( $\Delta_{\text{red}}H^{\circ} \approx 2$  eV) than in conventional  $\text{CeO}_2$  (4.7 eV [85]). This implies a corresponding enhancement of the oxygen deficiency to values of the order  $10^{-6}$ – $10^{-5}$ , in comparison with typically  $10^{-9}$  for microcrystalline samples. This is not unrealistic: the fraction of reduced interface oxygen sites can be estimated from the

interface-to-volume ratio and for a 10 nm mean grain size, only one out of 10,000 grain boundary sites needs to be reduced to dominate the defect and transport behavior of the nanoceramics [64]. Even larger oxygen deficiencies, up to values of  $10^{-3}$ , were actually measured on nanocrystalline  $\text{CeO}_2$ , using coulometric titration with oxygen solid electrolyte cells [86].

An exceptionally high oxygen deficiency was also determined in nanocrystalline ceria–praseodymia solid solutions with high Pr content:  $x > 0.1$  in  $\text{Pr}_{0.7}\text{Ce}_{0.3}\text{O}_{2-x}$  at 640 °C [87]. In this system, two factors contribute to the high nonstoichiometry:

- (1) the easy valence change of praseodymium ions ( $\text{Pr}^{4+}/\text{Pr}^{3+}$ ),
- (2) the high interface density.

Large deviations from stoichiometry can significantly improve the oxygen storage capacity of nanocrystalline oxides.

The existence of many interfaces improves also the oxygen exchange kinetics and the oxygen diffusivity. Coulometric titration experiments using oxygen concentration cells gave high chemical diffusion coefficients (around  $10^{-6}$   $\text{cm}^2/\text{s}$  at 600 °C) with an exceptionally low activation energy (0.3 eV). These results are also suspected to reflect the presence of a large density of fast diffusion pathways with reduced defect migration energy [88] and can be interpreted in the framework of a “neutral core model.” This conclusion remains, however, to be validated for other solid solutions and by different techniques.

In conclusion, the “neutral core model” treats changes of defect thermodynamic and transport properties as solely related to the boundary core and neglects charge effects, so that an electrical neutrality condition, such as Eq. (48), can still be applied.

#### 4.1.2. Space Charge Layer Model

Mason and Hwang [89] found a reduced ionic conductivity and an enhanced activation energy for ionic conduction in  $\text{CeO}_2$  nanoceramics (1.6 eV, about twice the value for microcrystalline  $\text{CeO}_2$ ) that cannot be understood in the “neutral core model,” because the ionic conductivity should also be enhanced in the boundary core. Tschöpe first proposed a consistent model, where the increase of electronic conductivity and the decrease of ionic conductivity in nanocrystalline ceria is explained by the existence of space charge regions [90]. Kim and Maier checked the consistency of this model using defect thermodynamic considerations [91]. If the bulk defect thermodynamic properties are unchanged inside the space charge zone, the defect concentrations are subjected to the following consistency condition, cf. mass-action law (47):

$$\begin{aligned} c_0(\text{V}_{\text{O}}^{\bullet\bullet})c_0(e')^2 &= c_{\infty}(\text{V}_{\text{O}}^{\bullet\bullet})c_{\infty}(e')^2 \\ &= A \exp(-\Delta_{\text{red}}H^{\circ}/kT)P(\text{O}_2)^{-1/2} \end{aligned} \quad (51)$$

$c_0$  is the concentration in the first layer adjacent to the boundary core;  $c_{\infty}$  is the bulk concentration. Concerning the

$P(\text{O}_2)$  and  $T$  dependencies, one sees easily that the following equations should be observed locally:

$$\partial \ln c_0(V_{\text{O}}^{\bullet\bullet}) / \partial \ln P(\text{O}_2) + 2\partial \ln c_0(e') / \partial \ln P(\text{O}_2) = -1/2 \quad (52)$$

$$\partial \ln c_0(V_{\text{O}}^{\bullet\bullet}) / \partial (1/T) + 2\partial \ln c_0(e') / \partial (1/T) = -\Delta_{\text{red}}H^\circ/k \quad (53)$$

The excellent fulfillment of these consistency criteria, demonstrated in [91], and the quantitative interpretation of  $P(\text{O}_2)$  exponents and activation energies for ionic and electronic conduction are very strong arguments for the space charge model in the case of pure and doped ceria.

Very recently, Tschöpe [92] succeeded in determining the grain size dependence of the electrical conductivity of ceria from micro- to nanometer range in excellent agreement with the experiment, as shown in Figure 5, using analytical equations for large grain sizes and numerical calculations for the smallest ones, where analytical equations break down. The large set of experimental investigations and the detailed theoretical analysis permit one to draw already a few general conclusions:

- (1) A positive boundary charge is observed in ceria, probably due to boundary reduction. Space charge potentials between 0.3 [91] and 0.7 V [93] have been calculated; they depend only weakly on temperature and oxygen partial pressure. This leads to severe depletion of oxygen vacancies and strong accumulation of electrons in the space charge regions.
- (2) The electron accumulation strongly enhances the electronic conductivity of the nanoceramics, which becomes dominant in nominally undoped ceria.
- (3) The transition from predominantly ionic to electronic conductivity upon grain size reduction has been confirmed by measurements of the grain-size dependent thermopower [93, 94].
- (4) Experiments on very small particle sizes, to investigate quantitatively nontrivial size effects by space charge overlap, remain to be done.

The oxygen vacancy depleted space charge regions should be an obstacle to oxygen ion transport across grain boundaries, enhancing the grain boundary resistivity of nanoceramics compared with conventional samples. Experimentally, the opposite is observed: the specific grain boundary resistivity of fully dense  $\text{CeO}_2$  nanoceramics [64, 95] is orders of magnitude lower as compared with microcrystalline samples. However, it is well known that in most cases, grain boundary blocking is actually due to segregated impurities. One can assume that the dilution of segregants, given the larger grain boundary area in nanoceramics, is the origin of the enhancement of the conductivity across the grain boundary. For a more detailed study of the grain boundary blocking effect, let us turn now to the case of doped zirconia.

## 4.2. Doped $\text{ZrO}_2$

Ca- or Y-doped zirconia is the most prominent crystalline oxygen ion conductor, with paramount importance for potentiometric oxygen sensors and solid oxide fuel cells. The grain boundary resistance in this compound was studied several times. In conventional stabilized  $\text{ZrO}_2$ , Ca and Si

segregation has been correlated with variations of the blocking grain-boundary conductivity. A significant enhancement of the blocking grain boundary conductivity was observed at grain sizes below  $2 \mu\text{m}$ , because the grain boundary coverage by segregated solutes obviously decreased with decreasing grain size [95].

In nanocrystalline materials, solute segregation occurs on a large grain boundary area and the mean grain boundary concentration of segregated solutes is much lower than in microcrystalline materials with the same solute content. This should further enhance the conductivity across a grain boundary in nanoceramics. Indeed, nanocrystalline tetragonal Y-doped  $\text{ZrO}_2$  presents a grain boundary conductivity one to two orders of magnitude higher than comparable microcrystalline samples, with a low, grain-size independent activation energy [96]. Both results can be attributed to a reduced grain-boundary concentration of Si, in other words a “dilution” of segregated impurities over the very large grain boundary area.

In highly pure Y-doped zirconia, where no siliceous intergranular phases leading to flux constriction are observed, there is now sufficient evidence that the blocking grain boundary resistance is related to oxygen vacancy depletion layers, consecutive to boundary reduction. The oxygen-vacancy depletion layers can be described in the framework of the Schottky–Mott model (see Section 3.2.3), as shown recently [97]. The space charge potential and oxygen vacancy profiles can be calculated quantitatively using interfacial capacitance and resistance data [cf. Eq. (45) and (46)], obtained from impedance spectroscopy. The results are in good agreement although a discrepancy remains concerning the widths of the space charge layers.

A particular effort has been devoted to the preparation and study of phase-pure nanocrystalline zirconia samples with tetragonal or monoclinic structure. Nanocrystalline tetragonal  $\text{ZrO}_2$  was successfully prepared using electrostatic spray deposition [98] and the grain size effect on the tetragonal–monoclinic phase transition was studied by Raman spectroscopy and X-ray diffraction [99–101]. The dopant-size effect on the transport properties was also investigated [102]. In tetragonal Y-doped  $\text{ZrO}_2$  nanoceramics, the ionic conductivity was similar to that of microcrystalline samples [96].  $^{18}\text{O}$  diffusion profiles in nominally undoped fully dense nanocrystalline  $\text{ZrO}_2$  with monoclinic structure showed grain boundary diffusion at deeper penetration [103]. Within the entire temperature range between 450 and 950 °C, the grain boundary diffusion coefficient was three to four orders of magnitude higher than the bulk diffusion coefficient, the latter being similar to earlier results on monoclinic samples. The grain boundary diffusion coefficient remained, however, below the diffusion coefficient in coarse-grained cubic Ca- or Y-stabilized zirconia, which is related to a high bulk vacancy concentration [103]. A complete analysis applying the space charge models is certainly worthwhile.

## 4.3. $\text{TiO}_2$ : Anatase and Rutile

Titanium dioxide is an oxide of uttermost importance for applications in dye-sensitized solar cells, for photocatalysis or in resistive oxygen sensors, especially in metastable

anatase modification. Furthermore,  $\text{TiO}_2$  is a model mixed conductor that can be doped with acceptor or donor ions and can present departures from stoichiometry and domains of ionic or electronic conductivity. The energetics of nanocrystalline  $\text{TiO}_2$  modifications, rutile, anatase, brookite, were recently reviewed [104]; the electrical properties are only partially investigated.

Nanocrystalline anatase  $\text{TiO}_2$  ceramics show a conductivity plateau at high oxygen partial pressures, indicating an uncommon domain of ionic conductivity at reduced temperature (450–600 °C) with a plausible activation energy ( $\approx 1$  eV) [105]. Nanocrystalline rutile [106] ceramics, obtained with the addition of about 1 mol%  $\text{SnO}_2$ , show a similar plateau with an identical activation energy ( $\approx 1$  eV) [107]. Predominant ionic conduction in a rutile single crystal was found at a significantly higher temperature (900 °C) and with a higher activation energy (1.6 eV) [108]. The different behavior can be attributed to the existence of a large density of interfacial diffusion paths in the nanoceramics, where ionic transport is enhanced with reduced migration energy.

A steep increase of electronic conductivity with an unusually large partial pressure exponent ( $-1/2$ ) is observed at low  $P(\text{O}_2)$  [105]. The large pressure dependence is certainly of interest for sensor applications. The  $-1/2$  exponent can be interpreted in a neutral layer model by assuming that the majority ionic defects are not completely ionized, in other words that the concentrated ionic (titanium interstitials) and electronic defects are partially associated. The reduction reaction can for example be written with doubly ionized titanium interstitials:

$$K_{\text{red}} = [\text{Ti}_i^{2+}][e']^2 P(\text{O}_2) = B \exp(-\Delta_{\text{red}}H^\circ/kT) \quad (55)$$

Given the large  $\text{Na}^+$  acceptor concentration in these samples ( $>1000$  ppm), which remains from the precipitation process of the anatase precursor using sodium hydroxide [62], one can assume that the interstitial concentration is fixed by the acceptor impurity concentration ( $2[\text{Ti}_i^{2+}] = [A'_{\text{Ti}}]$ ). One then gets the  $P(\text{O}_2)$  and  $T$  dependence of the conductivity:

$$\ln \sigma = \ln(e\mu_e(2B/[A'_{\text{Ti}}])^{1/2}) - 1/2 \ln P(\text{O}_2) - \Delta_{\text{red}}H^\circ/2kT \quad (56)$$

The calculated standard reduction enthalpy ( $\Delta_{\text{red}}H^\circ = 7.8$  eV) is well below the value in conventional microcrystalline  $\text{TiO}_2$  ( $\approx 10$  eV), indicating a reduced defect formation enthalpy at interface sites. One can notice that the estimated Debye length, taking into account the large acceptor density, is very small so that a “neutral layer model,” disregarding space charge effects, might be sufficient to explain the experimental data in this case. A more complete investigation of nanocrystalline anatase is currently in progress.

#### 4.4. $\text{CaF}_2$ and Related Materials

Calcium fluoride is a well-known solid  $\text{F}^-$  ion conductor. In nanocrystalline  $\text{CaF}_2$  ceramics, a largely increased ionic conductivity can be observed [109], as shown in Figure 6.

**Figure 6.** Ionic conductivity of  $\text{CaF}_2$ . (1) Microcrystalline  $\text{CaF}_2$ ; mean grain size  $\sim 0.2$   $\mu\text{m}$ . (2) Microcrystalline  $\text{CaF}_2$  activated with  $\text{SbF}_5$ . (3) Nanocrystalline  $\text{CaF}_2$ ; mean grain size  $\sim 10$  nm. Adapted with permission from [48], J. Maier, Nanoionics and soft materials science, in “Nanocrystalline Metals and Oxides—Selected Properties and Applications” (P. Knauth and J. Schoonman, Eds.), p. 91. Kluwer Academic, Boston, 2002. © 2002, Kluwer Academic.

Conductivity values and activation energy suggest dominating transport in space charge layers. By simply scaling up the space charge effects observed in microcrystalline samples according to the increased interface density, the correct order of magnitude of conductivity is obtained (Fig. 5). A systematic deviation at higher measurement temperatures is related to grain coarsening during the experiments. The activation energy corresponds to the migration energy of fluoride vacancies and suggests an accumulation of  $\text{F}^-$  vacancies in the space charge regions. Given the Na background concentration in the studied samples, the computed Debye length (1 nm) is well below the grain size, so that an observation of mesoscopic space charge effects is not expected; this requires highly pure nanocrystalline samples.

Sata et al. succeeded in growing multilayer structures of  $\text{BaF}_2/\text{CaF}_2$  by molecular beam epitaxy on alumina substrates at 500 °C [110]. The multilayer period was varied between 16 and 430 nm with an overall thickness of 500 nm (Fig. 7). At low temperature, the activation energy is dominated by  $\text{BaF}_2$ , in accordance with the larger vacancy mobility in this compound, whereas the activation energy at higher temperature seems to be determined by space charge layer conduction in  $\text{CaF}_2$ . This indicates a transfer of  $\text{F}^-$  ions from  $\text{BaF}_2$  to  $\text{CaF}_2$  rather than phase boundary core segregation of  $\text{F}^-$  ions.

The conductivities along the phase boundaries increase linearly with the number of heterojunctions provided that the period is greater than 100 nm. Films with smaller periods exhibit an anomalous conductivity increase. Calculation of the Debye length (15 nm) revealed that this effect is related to an overlap of space charge regions. Such heterostructures, routinely prepared by the semiconductor community, open up the possibility to measure properties reproducibly on a scale normally inaccessible in solid state ionics and to design devices which take advantage of the size and scale of such structures.

Other papers on nanocrystalline inorganic ion conductors can be found in [111, 112].

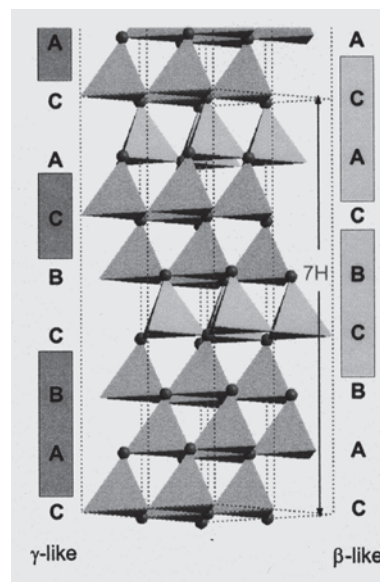

**Figure 7.** Arrhenius plots of conductivity of BaF<sub>2</sub>/CaF<sub>2</sub> heterolayers, BaF<sub>2</sub> (open triangles) and CaF<sub>2</sub> (open squares) thin films. The numbers indicate the BaF<sub>2</sub>/CaF<sub>2</sub> period. The inset shows the thickness dependence of conductivity at 320 °C. One observes an anomalous increase of conductivity for thicknesses comparable to 4  $\lambda$ , where  $\lambda$  is the Debye length. Reprinted with permission from [49], N. ## 5. NANOCOMPOSITES

### 5.1. Ceramic and Glass Nanocomposites

The development of ionic conducting ceramic and glass nanocomposites started with the discovery by Liang of a conductivity enhancement in a two-phase material and, in the same period, of ionic conducting glasses.

Mesoscopic effects highlighting the importance of interfaces in nanocomposites are the stabilization of metastable phases and the variation of phase transition temperatures [113]. Interfacial interaction energies of the order of 0.5 eV in composite materials with alumina are great enough to cause phase transitions in a polymorphic compound, such as AgI. Furthermore, Coulomb interactions at high defect concentrations near interfaces can naturally lead to order-disorder phase transitions. The considerable enhancement of ionic conductivity observed in AgI–Al<sub>2</sub>O<sub>3</sub> composites, by more than three orders of magnitude [114], is outside the range of conventional space charge effects but can be explained by a nanosized ionic heterostructure  $\beta$ -AgI/ $\gamma$ -AgI with a layer thickness below the Debye length, so that mesoscopic conductivity effects result from overlapping space charge regions with considerable disorder in the Ag<sup>+</sup> sublattice. This kind of heterostructure can also be viewed as a succession of stacking faults (Fig. 8). The total AgI exists in the seven-layer polytype form if the alumina concentration exceeds 30 mol% [115]. This striking enhancement of ionic conductivity may also be expected for other structures in which structural units alternate with a typical distance below the Debye length and efforts should be directed to such ionic heterostructures. The study of ionic conductivity in microporous materials, such as zeolites [116–118], that contain tailored channels with nanometric dimensions might become another future highlight.

**Figure 8.** Stacking fault arrangement at the Al<sub>2</sub>O<sub>3</sub>/AgI boundary, which is equivalent to a sequence of subnanometer heterolayers of  $\beta$ - and  $\gamma$ -AgI, leading to pronounced disorder in the cation sublattice. Reprinted with permission from [48], J. Maier, *Nanoionics and soft materials science*, in “Nanocrystalline Metals and Oxides—Selected Properties and Applications” (P. Knauth and J. Schoonman, Eds.), p. 103. Kluwer Academic, Boston, 2002. © 2002, Kluwer Academic.

Glass ceramics, formed by crystalline inclusions inside a glassy matrix, are often nanocomposites, because the size of the crystallites is very small. Dispersed  $\alpha$ -AgI nanocrystals in AgI-based glass matrices of composition AgI–Ag<sub>2</sub>O–M<sub>x</sub>O<sub>y</sub> (M<sub>x</sub>O<sub>y</sub> = B<sub>2</sub>O<sub>3</sub>, GeO<sub>2</sub>, WO<sub>3</sub>) were discovered by Tatsumisago et al. [119–121]. These glass ceramics exhibit high ionic conductivities and low activation energies at room temperature. The larger activation energies observed at lower temperatures were attributed to a positional ordering of Ag<sup>+</sup> ions in the microcrystals. The pronounced conductivity increase observed during initial stages of devitrification of some AgI–Ag<sub>2</sub>O–M<sub>x</sub>O<sub>y</sub> glasses depends on the interfacial area between the glass and the low conductivity crystalline inclusions. This suggests the existence of a highly conducting interfacial region, possibly due to a mobility change close to the interface [122]. In the AgI–Ag<sub>2</sub>O–V<sub>2</sub>O<sub>5</sub> system [123], the increase depends on the interfacial area between glass and crystalline Ag<sub>8</sub>I<sub>4</sub>V<sub>2</sub>O<sub>7</sub> inclusions. An interface related effect is also responsible for the conductivity enhancement in partially crystallized AgI–Ag<sub>2</sub>O–P<sub>2</sub>O<sub>5</sub> glasses. The absence of conductivity enhancement in the AgI–Ag<sub>2</sub>O–B<sub>2</sub>O<sub>3</sub> system was explained by formation of  $\alpha$ -AgI microcrystals. When the conductivity of the crystallites is higher than that of the glassy matrix, the interface region is short-circuited. The research activity on glass and ceramic composites slowed down in recent years due to persisting mechanical problems which are difficult to resolve.

Other papers on ceramic and glass nanocomposites can be found in [124–138].

## 5.2. Polymer Nanocomposites

Polymer electrolytes are actively developed as separator material in solid lithium batteries and proton exchange membrane fuel cells (PEMFCs). The search of polymer nanocomposites with high ionic conductivity and good mechanical properties has been pursued in the past decade with the objective to provide flexible, compact solid membranes free from leakage and available in variable geometry.

Most PEMFCs rely on the transport of protons through hydrated regions of Nafion, which has become the industry standard virtually by default, or other polymers containing sulfonate groups. Complications arise from the hydrated nature of the polymer electrolytes, because humidification is required to maintain ion conduction and prevent irreversible dehydration damage. This excludes thermal excursions to higher temperatures. However, nanocomposite Nafion + SiO<sub>2</sub> membranes can retain water at higher temperatures [139–142] and were found able to operate at 130 °C or more. Membranes with nanocrystalline TiO<sub>2</sub> were also described [143]. With too much water, on the other hand, degradation of the mechanical properties of the polymer is observed due to swelling. This is the reason for investigations on water-free systems, including polymer–ceramic composites (e.g., Nafion + SiO<sub>2</sub> membranes doped with heteropolyacids, such as phospho- or silicotungstic acid) [144–146].

An even larger effort has been devoted to polyethyleneoxide (PEO) based systems for lithium ion batteries, which include:

- (1) The solid (PEO-LiX) type. It reaches practically useful ionic conductivity values only at 60–80 °C. The ionic conductivity is often enhanced in amorphous polymer electrolytes, which behave as rubberlike “soft solids.”
- (2) The hybrid polymer electrolyte (gel type). It contains organic molecules (“plasticisers”), such as ethylene or propylene carbonate, and is gel-like, losing to some extent the advantages of solid polymer electrolytes: mechanical stability and processing flexibility.
- (3) The inorganic filler-containing composite type. A simple strategy is to blend conventional polymer electrolytes with dry ceramic powders [147], which can improve ion conductivity and mechanical stability.

The polymer composites development started in the 1980s initially to improve the elastic and tensile properties of glasses and ceramics, which are often too hard and brittle to be useful as solid electrolytes. Skaarup et al. [148] made polymer-ceramic composites using a large percentage of Li<sub>3</sub>N in doped PEO and insulating polyethylene matrices. Surprisingly, the latter, supposedly isolating, were actually more conducting than the PEO composites. This indicates that the polymer mainly holds the ceramic particles together but does not provide an ionic conduction pathway. Mixtures of Nasicon with doped PEO showed smaller dc conductivity than either the pure ceramic or the pure polymer electrolyte. The considerably enhanced interface resistance was probably due to a poor contact between the two phases [149]. Mixtures of a Li-ion conducting Li<sub>1-x</sub>Al<sub>x</sub>Ti<sub>2-x</sub>(PO<sub>4</sub>)<sub>3</sub> ceramic with an amorphous copolymer ethylene oxide-propylene oxide showed conductivities

approaching bulk ceramic values, but the importance of pores was confirmed [150]. Tortet et al. presented a percolation model of proton-conducting composites made with an inert polymer (PPS) and brushite (CaHPO<sub>4</sub>·2H<sub>2</sub>O) [151, 152].

Weston and Steele [153] first mixed PEO-LiClO<sub>4</sub> complexes with  $\alpha$ -alumina powder in order to improve the mechanical strength of the polymer electrolyte. A significant ionic conductivity enhancement was obtained using  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> as inorganic filler [154]. An important contribution was made by Croce and co-workers, who first added  $\beta''$ -alumina or LiAlO<sub>2</sub> to PEO electrolytes in order to improve the mechanical properties of the polymer [155] and later succeeded in preparing a polymer composite with dispersed TiO<sub>2</sub> nanoparticles with a largely enhanced conductivity [156, 157]. A significant increase of the ionic conductivity and of the Li ion transference number and a decrease of activation energy were observed in polyacrylonitrile composites with dispersed  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> [158].

The discussion of the mechanism of the conductivity enhancement and improvement of Li<sup>+</sup> ion transport number is far from being terminated and various explanations have been given.

- (1) It was attributed to hydroxide groups on the oxide nanoparticle surface [159], providing an additional route for fast Li<sup>+</sup> ion transport, possibly involving a space charge effect [160]. In principle, modifications of local defect distribution are expected near any type of interface, but they are more or less important, depending on the chemical affinity between the two phases.
- (2) It was ascribed to interactions between Lewis acid sites on the nanoparticle surface, probably OH groups, and anions or PEO segments, which help release more free Li<sup>+</sup> ions and suppress crystallization of amorphous regions [161–163].
- (3) A recent study using differently heat-treated SnO<sub>2</sub> nanoparticles as second phase concluded that oxygen vacancies on the oxide surface act as Lewis acid sites [164]. In this model, the oxygen vacancies are assumed to compete with Li ions to coordinate with PEO segments, preventing PEO crystallization on one hand and releasing free Li<sup>+</sup> ions on the other. Furthermore, ClO<sub>4</sub><sup>-</sup> ions are also bound to oxygen vacancies, decreasing the tendency to ion association.
- (4) Other structural factors, such as a change of the glass transition temperature, have also been discussed [165].

However, preparation problems, notably poor adhesion, pores, and gaps at the phase boundaries, make the theoretical discussion of conductivity effects in polymer nanocomposites in the present status a difficult task. More preparative and theoretical efforts are definitely needed to better understand and further improve the properties of polymer–ceramic nanocomposites. This is a major challenge that should be met in the future.

Other papers on polymer nanocomposites can be found in [166–183].

## 6. CONCLUSIONS

After the first decade of research on ionic conduction in nanostructured materials, a few general conclusions can already be drawn.

Concerning nanocrystalline materials, the main conclusion so far is that space charge theory seems to provide an adequate interpretation of “bulk” conductivity at least for the most studied model compound,  $\text{CeO}_2$ . In this case, space charge regions lead actually to a counterintuitive decrease of ionic conductivity due to oxygen vacancy depletion. So far, clear ionic conductivity enhancement has been found in  $\text{CaF}_2$ -based systems, either nanocrystalline ceramics or heterolayer thin films with small periodicity. In the case of the most prominent oxygen ion conductor, doped  $\text{ZrO}_2$ , the results are ambivalent. However, the effect of impurity segregation and charge carrier depletion layers on the grain boundary resistance seems now to be reasonably well understood.

Concerning nanocomposites, especially polymer-based systems, there is much greater uncertainty on mechanistic details related to less mastered synthesis conditions. This leads to a wide variety of interpretations for conductivity changes, including microstructural effects, like amorphous versus crystalline regions in the polymer, and defect chemical ones, like the existence of cation–anion pairs or cation adsorption on inorganic filler particles. A more careful sample preparation will be necessary before better understanding and predictability of nanocomposite performance can be achieved. Given the importance of polymer nanocomposites in energy storage and conversion, continuing progress in this field can safely be foreseen.

## GLOSSARY

**Interface (synonym: boundary)** Two-dimensional transition region in a material separating (a) two phases (e.g. in composites), also called phase boundary, (b) two crystallites with different orientation (e.g. in ceramics), also called grain boundary. The interface core has a width of a few atomic layers only. The presence and density of interfaces greatly influence many materials properties, including the electrical conductivity.

**Percolation** Geometrical model used for the description of disordered or random systems, introducing scaling laws with universal parameters. Near a critical value, property fluctuations become important: e.g. ionic conductor-insulator transitions in solid state ionics.

**Solid ionic conductor** Ionocovalent solid, in which the electrical conduction is essentially due to mobile ions.

**Space charge layer** Region in proximity of extended defects (such as interfaces or dislocations), where electroneutrality is not observed due to the symmetry break. The space charge compensates the interface core charge. These regions can present very different electrical properties than the bulk, due to enhanced or reduced charge carrier concentrations.

## 1. INTRODUCTION

The Kelvin probe technique has established itself as an important tool in material characterization. Named after Lord Kelvin, the technique was first demonstrated by him to the Royal Society in 1897 [1]. In his experiment, he demonstrated for the first time the use of a null method to quantitatively measure the work function difference between two dissimilar metals, such as copper and zinc. As the technique became more popular, modifications were made to the original measurement apparatus as well as to the measurement procedure. In 1932, Zisman [2] modified the measurement procedure by mechanically vibrating one plate of the condenser (consisting of two plates of dissimilar metals) and nullifying the contact potential difference (CPD) by an audiofrequency amplifier arrangement. Later, in 1976, Besocke and Berger [3] replaced the mechanical drive and feedthrough with a piezoelectric oscillator and used a lock-in amplifier and feedback mechanism to nullify the CPD automatically and continuously. A further modified version of the ac Kelvin probe was demonstrated by Weaver and Abraham in 1991 [4], in which an ac voltage was applied to the probe tip in addition to a dc voltage that was used to nullify the CPD (through measurement of force rather than current as before). In the same year, Nonnenmacher, O'Boyle, and Wickramasinghe reported on Kelvin probe measurements performed in conjunction with atomic force

microscopy (AFM) [5]. With this technique the lateral resolution of the potential measurement could be improved quite significantly ( $<50$  nm), and simultaneous imaging of the surface morphology and the surface potential was made possible. In modern systems (e.g., those manufactured by TM Microscopes, Veeco Metrology Group) the Kelvin probe measurements are usually performed in a scanning mode together with the surface morphology imaging. This mode of operation is called scanning Kelvin probe microscopy (SKPM) and has become very popular for various materials and semiconductor device characterization. Another common electrical characterization technique is called electrostatic force microscopy (EFM), which is based on the same basic principles as SKPM and is performed in a similar way. However, in EFM the output signal is the electrostatic force between the tip and the sample, whereas in SKPM a feedback loop is used that generates a voltage (the output signal) that is applied to the probe tip to nullify the force between the tip and the sample. This feedback voltage is exactly equal to the CPD if the electrostatic force can be totally nullified. Thus with the Kelvin probe technique a direct and quantitative measurement of the surface charge density, work function, and applied bias is possible.

Over the years, the Kelvin probe technique has become quite popular, and much work has been done to characterize a wide variety of materials. In this article, we have discussed the underlying principles, experimental procedures, and important practical applications of this method (as relevant to nanotechnology). Not much coverage has been provided to hardware and detection systems, detailed treatment of which can be found elsewhere [6]. Freedom has been exercised in treating different topics at different depths as found necessary. Efforts have been made to make this review more practically oriented without being superficial in discussing the underlying physical principles. Since modern instruments available today perform simultaneous imaging of surface potential (by SKPM) and surface morphology (by AFM), we have discussed the various aspects of Kelvin probe measurement from that viewpoint. We start with a discussion of the basic concepts involved with this technique

in Section 2. The different origins of the electrostatic force between the probe tip and the sample have been discussed, and the basic equations governing the Kelvin probe operation have been developed in this section. Section 3 is devoted to the experimental procedures pertaining to this technique. Here we discuss the basic components of this system and the possible modes of operation. An overview of the different forces acting on the tip is also presented. The versatility of this technique leads to a host of important applications, which are discussed in Section 4. A general discussion of the applications of this technique to the characterization of materials important to nanotechnology (such as insulators and semiconductors) is presented first, followed by the applications specific to nanotechnology. Applications to surface photovoltage (SPV) measurements and devices and integrated circuits have been treated separately as deemed necessary. Additionally, the limitations of this technique and possible sources of inaccuracies have been pointed out. We conclude this chapter with a summary of this technique and some pertinent remarks in Section 5.

## 2. KELVIN PROBE TECHNIQUE: BASIC CONCEPTS

### 2.1. Origins of the Electrostatic Force

The Kelvin probe measurement technique, in its present form, is based on the detection of the electrostatic force between the tip and the sample. This electrostatic force can originate from a number of different factors, such as (i) the electrochemical potential difference between the tip and the sample, (ii) an external electrical bias applied to the sample, and (iii) uncompensated charges on an insulating sample. The total force acting on the tip can be, in general, a sum of the individual forces arising from the factors mentioned above. However, in most cases the situation can be simplified and useful insight can be obtained by eliminating one or two of the above factors. The total electrostatic force on the tip depends on the three factors described above, as well as on the capacitance gradient of the system consisting of the sample and the tip-cantilever assembly. So, to obtain information about those three factors, through measurement of the electrostatic force, the capacitance gradient has to be determined. In general, because of the complicated and often unknown geometry of the tip, the theoretical computation of this capacitance gradient is extremely difficult and unreliable. The other way is to measure it directly with a lock-in amplifier, as will be discussed later. However, in the Kelvin probe technique, there is no need to compute or measure the capacitance gradient because the desired information can easily be obtained by nullifying the electrostatic force between the tip and the sample with the use of a feedback loop. This is discussed in detail later in this section, where a quantitative formulation is developed. Each of the individual factors responsible for the electrostatic force is briefly discussed.

#### 2.1.1. Contact Potential Difference

In general, any two dissimilar materials will have different electrochemical potentials. So, when two different materials are brought into intimate contact, they equilibrate via

transfer of electrons from one to the other (see Fig. 1a and b). For example, if two metals, Zn and Cu, are brought into intimate contact, then electrons will flow from Zn to Cu because of the higher work function of Cu. Thus Cu will be negatively charged and Zn will be positively charged. The electrostatic potential difference arising from such a transfer of charges is called the contact potential difference (CPD). Since the electrons will continue to flow until the electrochemical potentials of the two materials are the same, the CPD is given by

$$V_{\text{con}} = (\phi_{\text{Cu}} - \phi_{\text{Zn}})/q \quad (1)$$

where  $\phi_{\text{Cu}}$  and  $\phi_{\text{Zn}}$  are the work functions of Cu and Zn, respectively. In an actual measurement, the probe tip and the sample, when connected externally, exchange charges and equilibrate to give rise to the CPD. This charge exchange causes an electrostatic force of attraction between the tip and the sample. Such an attractive force forms the basis of measurement by the Kelvin probe technique (in its modern form) and can be nullified by an externally applied bias, leading to the measurement of CPD (Fig. 1c). The knowledge of CPD is very important for the characterization of materials, especially semiconductors.

#### 2.1.2. Charges on the Surface

Charges present on the surface of a sample will induce image charges (of opposite polarity) on the tip and therefore give rise to electrostatic forces between them. The charges on the sample can be present naturally, like charged domains in triglycine sulfate (TGS) [7], or can be deposited by external means, such as the probe tip itself [8, 9]. For charges to be deposited by the tip, and for the deposited charges to stay for a sufficiently long time to be measured again by the tip, the surface of the sample should be fairly insulating. Insulators such as polymethyl methacrylate (PMMA) and  $\text{SiO}_2$  are well suited for such measurements [8, 9]. Usually for the measurement of surface charge the operating distance between the tip and the sample is kept as small as possible for higher measurement accuracy [7].

#### 2.1.3. Externally Applied Bias

When an external bias is applied to the sample the situation is quite similar to the cases discussed above. The only difference is that in this case the charge separation is deliberately created between the tip and the sample by the externally applied bias. Measurement of such biases becomes very important for the study of nanoscale devices and integrated circuits (ICs). In such cases the SKPM probe tip can act as a “nano-voltmeter” and can be used for troubleshooting and reliability studies.

## 2.2. Quantitative Formulation

One of the principal advantages of the Kelvin probe technique is that it can be very accurate quantitatively. With modern lock-in and feedback techniques, it is possible to obtain a high degree of accuracy that is sufficient for most practical purposes. Figure 2a shows the tip-sample configuration during measurement along with the electrical biases,

**Figure 1.** Schematic band diagrams showing the principles of operation of the Kelvin probe technique. The Fermi levels (denoted by  $E_F$ ) and the local vacuum levels (denoted by  $E_v$ ) are shown for two dissimilar metals (a) before contact, (b) after they are brought into contact and the Fermi levels reach equilibrium by transfer of charges creating an electric field between them, and (c) after the electric field is nullified by the application of an external potential  $V_{con}$ .

and Figure 2b shows the schematic band diagrams for the tip and the sample. Two different voltages are applied to the tip, namely, a sinusoidal ac voltage at a certain reference frequency,  $\omega$  (usually a few kHz), and a dc feedback voltage. Based on the discussions in the previous section, the total electrostatic force of attraction between the tip and the sample (the effect of the cantilever has been neglected for simplicity and is dealt with in Section 4.3),  $F_{tot}$ , is given by a capacitive component,  $F_{capa}$ , and a coulombic component,  $F_{coul}$ . The capacitive component itself comprises two parts: a part due to the difference in work function between the tip and the sample, and another due to any externally applied bias. The total force on the probe tip (at a distance  $z$  from the sample) is therefore given by the expression [8, 10–12]

$$F_{tot} = F_{capa} + F_{coul} = \frac{1}{2} \frac{\partial C}{\partial z} (V_{app} - V_{con})^2 + \frac{Q_s Q_t}{4\pi\epsilon_0\epsilon_r z^2} \quad (2)$$

where  $Q_t$  is the charge on the tip,  $Q_s$  is the charge on the surface,  $V_{con}$  is the CPD (where  $qV_{con}$  is equal to the difference in work functions of the tip and the material to be probed ( $\phi_{tip} - \phi_{mat}$ )), and  $\epsilon_r$  is the dielectric constant

**Figure 2.** (a) Schematic diagram illustrating the tip-sample configuration and the electrical biases applied to the tip and the sample during measurement. An external bias can also be applied to the sample, if desired. (b) Schematic band diagram showing the Fermi levels and the vacuum level for the tip and a semiconductor sample. A  $p^+$ -doped Si tip is shown here, for which the Fermi level will almost coincide with the valence band. For a typical semiconductor, a surface band bending exists because of the presence of the surface space charge region. The Kelvin probe technique can be used to measure the surface barrier height  $\Phi_{mat}$  directly from the knowledge of  $V_{con}$  if the electron affinity of the semiconductor  $\chi_{mat}$  is known.

of the medium between the tip and the sample (air here). The capacitive term arises because of changes in the capacitive energy stored in the tip-sample capacitance ( $C$ ), and the Coulombic term arises because of the interaction between charges present on the surface and those on the tip. The negative sign in the capacitive component has been absorbed in the  $\partial C/\partial z$  term, which is a negative quantity. We have  $V_{app} = V_{dc} + V_{ac} \sin(\omega t)$ , and  $Q_t$  is given by the sum of the image charge on the tip,  $-Q_s$  and  $Q_c = CV_{app}$ . The total force,  $F_{tot}$ , is then obtained after simplification of Eq. (2) as

$$\begin{aligned} F_{tot} &= \frac{1}{4} \frac{\partial C}{\partial z} V_{ac}^2 + \frac{1}{2} \frac{\partial C}{\partial z} (V_{dc} - V_{con})^2 - \frac{Q_s(Q_s - CV_{dc})}{4\pi\epsilon_0\epsilon_r z^2} \\ &\quad + \left[ \frac{\partial C}{\partial z} (V_{dc} - V_{con}) + \frac{CQ_s}{4\pi\epsilon_0\epsilon_r z^2} \right] V_{ac} \sin(\omega t) \\ &\quad - \frac{1}{4} \frac{\partial C}{\partial z} V_{ac}^2 \cos(2\omega t) \\ &= F_{const} + F_{\omega} + F_{2\omega} \end{aligned} \quad (3)$$

Thus the total force is a sum of three components: a constant term,  $F_{\text{const}}$ ; one varying with frequency  $\omega$ ,  $F_\omega$ ; and another varying with frequency  $2\omega$ ,  $F_{2\omega}$ . From Eq. (3),  $F_\omega$  is given by

$$F_\omega = \left[ \frac{\partial C}{\partial z} (V_{\text{dc}} - V_{\text{con}}) + \frac{CQ_s}{4\pi\epsilon_0\epsilon_r z^2} \right] V_{\text{ac}} \sin(\omega t) \quad (4)$$

where  $V_{\text{dc}}$  is the dc feedback voltage generated by the feedback loop with respect to the sample bias (ground potential). In feedback mode,  $V_{\text{dc}}$  applied to the probe tip nullifies  $F_\omega$ .  $V_{\text{dc}}$  is therefore given by simplification of Eq. (4) as

$$V_{\text{dc}} = V_{\text{con}} - \frac{CQ_s}{4\pi\epsilon_0\epsilon_r z^2 \left( \frac{\partial C}{\partial z} \right)} \quad (5)$$

When operated in feedback mode at a distance sufficiently far from the surface, it is possible to neglect the Coulombic term, and the dc feedback voltage  $V_{\text{dc}}$  becomes exactly equal to the contact potential  $V_{\text{con}}$ . The work function is then given by

$$\phi_{\text{mat}} = \phi_{\text{tip}} - qV_{\text{dc}} \quad (6)$$

Equation (6) is of course valid if surface charges are altogether absent. For semiconductors, often the bare surface barrier height (BSBH),  $\Phi_{\text{mat}}$ , of the sample (see Fig. 2b) is an important parameter to measure. From Eq. (6) and Figure 2b, we obtain

$$\Phi_{\text{mat}} = \phi_{\text{tip}} - \chi_{\text{mat}} - qV_{\text{dc}} \quad (7)$$

where  $\chi_{\text{mat}}$  is the electron affinity of the semiconductor sample. From Eq. (3) it can be observed that the expression of  $F_{2\omega}$  explicitly contains the capacitance gradient of the tip-sample configuration,  $\partial C/\partial z$ . Thus, from the measurement of the magnitude of  $F_{2\omega}$ ,  $\partial C/\partial z$  can be obtained directly. Knowledge of  $\partial C/\partial z$  can be quite important, as pointed out in Section 4.3.

For electrostatic force microscopy, which is performed without a feedback loop, Eqs. (2) and (3) are still valid, and the surface work function,  $\phi_{\text{mat}}$ , or the BSBH,  $\Phi_{\text{mat}}$ , can be obtained by taking the ratio of  $F_\omega$  and  $F_{2\omega}$ . In the absence of any surface charge, we have from Eq. (3) after simplification

$$V_{\text{con}} = V_{\text{ext}} + \frac{1}{4} \frac{F_\omega V_{\text{ac}}}{F_{2\omega}} \quad (8)$$

where  $V_{\text{ext}}$  is the known external dc bias applied to the tip instead of the feedback voltage  $V_{\text{dc}}$ . Therefore,  $\Phi_{\text{mat}}$  can be obtained from Eq. (7) as

$$\Phi_{\text{mat}} = \phi_{\text{tip}} - \chi_{\text{mat}} - q \left( V_{\text{ext}} + \frac{1}{4} \frac{F_\omega V_{\text{ac}}}{F_{2\omega}} \right) \quad (9)$$

The coulombic term in Eq. (2) was written simply as an interaction between two point charges (on the sample and on the tip). This is valid to an appreciable extent when the diameter of the localized charged area to be measured is less than or equal to the diameter of the tip. Such situations are possible when nanoparticles are being characterized [10]. However, in cases where extended areas of charges are present on the surface, such as charged domains, it is

more convenient to use an alternative expression developed by Hong et al. [7]. The coulombic component of the total force in that case is given by the interaction between the charge on the tip and the electric field created by the uniform charge density,  $\sigma_s$ , on the surface. Neglecting any effect of contact potential for insulators, and assuming half the field lines going outward from the surface toward the tip,<sup>1</sup> we have  $F_\omega$  given by

$$F_\omega = \left[ \frac{\partial C}{\partial z} V_{\text{dc}} + \frac{\sigma_s C}{2\epsilon_0\epsilon_r} \right] V_{\text{ac}} \sin(\omega t) \quad (10)$$

When the feedback loop is employed to make  $F_\omega$  zero, we get  $\sigma_s$  as

$$\sigma_s = -\frac{2\epsilon_0\epsilon_r}{C} \frac{\partial C}{\partial z} V_{\text{dc}} \quad (11)$$

Using the parallel plate approximation, we have

$$\sigma_s = \frac{2\epsilon_0\epsilon_r}{z} V_{\text{dc}} \quad (12)$$

As discussed earlier, an external electrical bias applied to the sample can be measured in the same way as the work function difference. Therefore, if a dc bias,  $V_{\text{ext}}$ , is applied to the sample, then to make the electrostatic force between the tip and the sample go to zero, the feedback voltage applied to the tip has to be incremented by the exact amount,  $V_{\text{ext}}$ . Using Eq. (5), and assuming an absence of any surface charge, the feedback voltage is then given by

$$V_{\text{dc}} = V_{\text{ext}} + V_{\text{con}} \quad (13)$$

Incidentally, a quick way to verify that proper feedback mode operation of the SKPM has been achieved is to check whether  $V_{\text{dc}}$  changes appropriately with a change in dc sample bias. If the change in  $V_{\text{dc}}$  equals the change in the sample bias, then proper feedback has been established. Any external dc bias applied to the sample can be measured easily and quite accurately if the area to which it is applied is much larger than the projected area of the tip and the cantilever (on the sample surface). However, for smaller features where the applied bias varies rapidly within the projected area, such measurements are not always accurate, because of the finite tip size and the effect of the cantilever. These effects are discussed in Section 4.3. In addition, if the externally applied bias varies rapidly with time (faster than the feedback loop response), then the measurements will be inaccurate and might be altogether impossible.

<sup>1</sup> The charge on the surface of an insulating layer is usually modeled as having the probe tip on one side, separated by the air gap, and a conducting plane on the other, separated by the insulating layer (see [68]).

### 3. EXPERIMENTAL DETAILS

#### 3.1. Components of the SKPM System

The primary components of the SKPM measurement setup are the tip, the cantilever holding the tip, and the sample that is to be probed. The configurations of each of these components are important for proper measurement of the surface potential. We discuss each of these individual components in detail in what follows. Apart from these core components, there are hardware and electronics that are used for the measurements, which are mentioned briefly in the discussion of the measurement procedure. We start with the basic operational procedure to get an overview of the measurement technique and then move on to discuss the tip-cantilever assembly and the sample.

##### 3.1.1. Basic Operational Procedure

As mentioned earlier, the SKPM is performed in conjunction with AFM (almost always in noncontact mode). This is important because, apart from providing valuable surface morphology information simultaneously, it helps maintain a constant distance between the tip and the sample during measurements, so that a clean and stable surface potential signal is obtained. Therefore, two feedback loops are used for the measurements, one for surface morphology, and the other for surface potential [11]. The cantilever and the tip are usually mounted on a ceramic holder, and the whole assembly is made to oscillate at a particular frequency near the resonance frequency,  $\omega_{\text{res}}$ , of the tip. Usually the natural frequency of oscillation of commercially available tips ranges from a few tens to a few hundreds of kHz, depending on the spring constant. A laser beam is directed toward the tip, and the reflected light is sensed by an array of photosensitive position detectors (PSPDs). The output of the PSPDs is used by both the surface morphology loop and the surface potential loop as the input signal. As the tip approaches the surface, the van der Waals force field causes the resonance frequency of the cantilever to shift. From the shift in resonance frequency the surface morphology image is obtained in noncontact mode. Detailed discussion of the principles of AFM can be found elsewhere [6].<sup>2</sup>

For the measurement of surface potential, an ac signal,  $V_{\text{ac}} \sin(\omega t)$ , is applied to the probe tip in addition to a dc feedback voltage,  $V_{\text{dc}}$ , as discussed in Section 2.2. In the surface potential loop, the output of the PSPDs is used as an input to the lock-in amplifier, and the amplitude of the signal varying at frequency  $\omega$  is obtained at the output of the lock-in amplifier. That signal is used by the feedback circuitry to eliminate the electrostatic force of attraction between the tip and the sample, as described in detail in Section 2.2. To keep the topography feedback loop from interacting with the surface potential feedback loop, the frequencies are usually chosen to be wide apart. However, away from the resonance frequency the amplitude of oscillation decreases, and therefore the sensitivity of the measurement decreases. One remedy to this problem is to have a tip that has two different resonance frequencies that are

**Figure 3.** (a) The geometrical configuration of the tip-cantilever assembly and the sample during actual measurements. Note that the cantilever is slanted at an angle  $\phi$  with respect to the horizontal. (b) A magnified image of the tip apex is shown, assuming a cone and a sphere model, with the cone half-angle  $\theta$  and the sphere radius  $r$ .

widely separated. In that case the topography signal could be obtained near one of the resonance frequencies while the Kelvin probe signal could be obtained at another resonance frequency [13, 14]. However, manufacturing such tips is not easy, and usually, with a frequency sufficiently far from the resonant frequency, reasonably good results can be obtained. For resonance frequencies of  $\sim 100$  kHz, an ac signal frequency of  $\sim 17$  kHz has been used to obtain good results [10, 11, 15].

##### 3.1.2. Tip and the Cantilever

The nature and geometry of the tip and the cantilever play a very important role in the SKPM measurements. Different types of tips manufactured for AFM can also be used for SKPM, with the requirement that the tip must be electrically conducting so that it can interact with the sample. Commercial tips available today are usually made of *n*-doped or *p*-doped Si and are sometimes coated with metals. A schematic diagram of the tip-cantilever assembly is shown in Figure 3a, and a magnified view of the tip (spherical apex with a truncated conical body) is shown in Figure 3b. For commercially available Si tips, the radius  $r$  usually varies from 10 to 20 nm, and the length  $L$  can vary from a few to more than 10  $\mu\text{m}$ . The cone half-angle  $\theta$  of the tip apex is usually  $10^\circ$  to  $20^\circ$ . For special applications such as imaging deep trenches with very steep sidewalls, 3-D micro-optics, etc., very high-aspect-ratio tips fabricated with a focused ion beam (FIB) technique can be used. These tips can have a base diameter of  $\sim 0.4$   $\mu\text{m}$ , an apex radius less than 20 nm, and a tip height greater than 4  $\mu\text{m}$ .<sup>2</sup> Another type of high-aspect-ratio tip is made of high-density carbon (HDC). High-density or amorphous carbon is very hard and hydrophobic, and tips manufactured from it can have an apex radius less than 10 nm, an apex half-angle less than  $4^\circ$ , and a length that is easily up to 5  $\mu\text{m}$ .<sup>3</sup> Sometimes for special purposes, such as for calibration, tips can be coated with different metals. However, it has been found out that metal-coated tips are usually much more unstable compared with

<sup>2</sup> Refer to Thermomicroscopes (Veeco metrology group) website at [www.tmmicro.com](http://www.tmmicro.com).

<sup>3</sup> Refer to NanoTOOLS website at [www.nano-tools.com](http://www.nano-tools.com).

normal Si tips, as the metal coating can easily be destroyed [16, 17]. In the past few years, carbon nanotube tips have been used for AFM, yielding much superior results compared with conventional tips [18]. Recently these tips have also been used for EFM and SKPM [19–22]. These tips are particularly suited for SKPM applications because they are strong and less prone to surface contamination or electrical conduction, and have a very high aspect ratio, minimizing the finite tip size effect [19]. However, the manufacturing process for carbon nanotube tips is quite complicated, time consuming, and not very well controlled, which results in their being very expensive at present. Nevertheless, it has been demonstrated that these tips yield enhanced spatial and voltage resolution [19, 21] and may be used more commonly once larger demand brings down their price. The dimensions of the cantilever holding the tip can vary from tens to hundreds of micrometers. As mentioned earlier, the finite size of the tip and the cantilever reduces the measurement accuracy for very small features at a surface potential different from that of their surroundings. This is due to the fact that the tip and the cantilever “feel” the total electrostatic force arising from all of the individual features, rather than that arising from only the intended one. For features with dimensions much larger than the tip diameter but smaller than the projected area of the cantilever, only the effect of the cantilever is relevant. However, for feature sizes smaller than or comparable to the tip diameter, both the tip and the cantilever will contribute to measurement inaccuracies. It will be shown later that tips that are longer and held by cantilevers that have a smaller projected area will result in more accurate measurements. Alternatively, to reduce the parasitic effects of the measurement probe, it can be shielded from its surroundings by a guard electrode [23, 24]. More recently probes with fully integrated guard rings, to probe nanostructures, were fabricated by Nabhan et al., which resulted in enhanced sensitivity and lateral resolution [25]. The use of dielectric cantilevers, with a narrow conductive layer up to the tip apex, has also been suggested as a way to reduce parasitic capacitances [26]. In their design, Nabhan et al. used a tungsten probe on which they deposited a thin layer of aluminum that was oxidized electrochemically. On the aluminum oxide layer, they deposited a fresh layer of aluminum that acted as the guard ring (kept grounded) and prevented parasitic interaction between the cantilever and the body of the tip with the sample. The method can be easily modified for commercially available silicon tips [27]. In this technique, the tip-cantilever assembly is covered with a thin layer of native oxide, and a metal film is deposited to act as the guard ring. This process is currently under development.

### 3.1.3. Sample

Characteristics of the sample are very important and influence the surface potential measurements to a significant extent. Since the Kelvin probe feedback voltage applied to the tip is with respect to the sample Fermi level, a good ohmic contact must be made with the sample to keep the sample Fermi level at a reference potential, usually ground. The feedback voltage (and the ac signal) can also be applied to the sample, which will then be equal in magnitude but

opposite in sign to the normal tip feedback voltage [28]. Samples stored in air can become covered with a thin film of water, and some samples may form oxides etc. on their surface. These layers can affect the surface barrier as well as the electron affinity of the sample and reduce the accuracy of the surface potential measurements. For surface potential imaging over an extended area (especially by EFM), unwarranted potential fluctuations can occur because of variations in oxide layer thickness, surface depletion depth, and dielectric constant of the contaminant layers [15]. Additional variations may also be caused by charging of the contaminant layers and dust particles present on the surface. Therefore, it is important to carefully prepare the sample before surface potential measurements. The native oxide layer on semiconductors can usually be etched away with HF-based solvents. Organic contaminants on the surface can be removed by ultrasonic cleaning with organic solvents to yield good results [11, 28]. For semiconductor samples it has been found that air-exposed samples (due to chemisorption of  $O_2$ ) can have different electron affinities compared with samples under high vacuum by as much as  $\sim 0.6$  eV [29]. Therefore, for accurate measurements of the surface barrier it is advisable to conduct the measurements in an ultrahigh vacuum. Reference samples (usually metals such as gold) should also be used for good quantitative measurements.

## 3.2. Forces on the Tip

There can be several forces acting on the tip when it is in close proximity to a surface. A detailed discussion of the intermolecular and surface forces can be found elsewhere [30]. For our purposes, the most important forces are the van der Waals force and the electrostatic force. As mentioned before, the former is the basis for surface morphology image, and the latter is the basis for a surface potential image. These two forces will be discussed in some detail below. Of the other forces, the capillary force can also become significant. This arises because of the presence of a thin layer of water on the surface and the tip and becomes important only in a sufficiently humid environment [31].

### 3.2.1. Interatomic Forces

When the tip is sufficiently close to the sample the interatomic forces become significant. Very close to the sample surface (within a few Å) there is a repulsive interaction between the tip and the sample as the electron clouds of the respective atoms start to overlap. Farther from the sample the force first becomes zero and then becomes attractive. This is the van der Waals force regime arising from the dipolar interaction between the atoms, which can exist up to hundreds of angstroms from the sample surface. The repulsive potential is usually given by one of several empirical forms, such as  $A/z^{12}$  or  $Be^{-z/z_0}$ , and the van der Waals potential is of the form  $-C/z^6$ , where  $A$ ,  $B$ ,  $C$ , and  $z_0$  are constants and  $z$  is the tip-sample distance [32]. The total potential of the tip-sample system can be obtained by integration over the volume of the tip and the sample. The force can then be obtained by simple differentiation [33]. The variation of the force on the tip and its gradient (with its axis reversed for easier comparison) with tip-sample distance is shown

**Figure 4.** Variation of the total interatomic force on the tip and its gradient with the tip-sample distance. The repulsive force is considered positive. The force gradient axis has been reversed for easier comparison of the force gradient curve with the force curve. The magnitude of the force gradient (always positive in the noncontact region) determines the shift in noncontact mode oscillation frequency. At  $z_0$ , the force gradient is zero.

schematically in Figure 4. In contact-mode AFM the tip is very close to the surface, so that it experiences a repulsive force, whereas in the noncontact mode the tip is much farther away and experiences an attractive force. The contact and noncontact modes of operation, as relevant to SKPM, will be discussed in detail later.

### 3.2.2. Electrostatic Force

As discussed before, the electrostatic force on the tip originates from (a) the contact potential difference between the tip and the sample, (b) externally applied bias, and (c) charges on the surface. Since electrostatic force is a long-range force, at larger distances from the surface, that is, in the noncontact force regime, it can easily dominate the van der Waals force [33]. The respective force gradients can also be comparable. This has important consequences in the coupling of the morphology and surface potential feedback loops, as will be discussed in the next section. The expression for the total electrostatic force with an ac voltage applied to the tip was developed before (Eq. (3)). It depends directly on the differential capacitance of the tip-sample system. A theoretical calculation of the total electrostatic force on the tip can be made, assuming a special shape of the tip, usually as a truncated cone with a spherical apex, as shown in Figure 3b. It can be shown that for  $z \ll r$ , the contribution of the spherical apex is dominant, whereas for  $z \gg r$ , the contribution of the conical part is dominant [33]. In general, for noncontact mode operation where  $z$  is usually a few times  $r$ , the forces arising from both the parts are important and should be taken into consideration [33, 34].

## 3.3. Modes of Operation

During simultaneous measurements of surface morphology and surface potential, two separate feedback loops are in operation, as mentioned before. The morphology (usually

noncontact AFM) feedback loop is useful for surface morphology imaging as well as maintenance of a constant tip-sample distance for stable surface potential measurements. In the process, however, the two feedback loops may interfere and spurious signals may be obtained [7, 35, 36]. To avoid such interference, contact-mode operation has been proposed, with better isolation between the feedback loops [7, 36]. Following we will discuss the operation of SKPM in both contact and noncontact AFM modes.

### 3.3.1. Noncontact Mode

The noncontact-mode AFM is operated at a relatively larger  $z$  of a few to a few tens of nanometers. The operating regions for noncontact and contact modes are shown in Figure 5. The noncontact mode operation is in the region of the positive force gradient (refer also to Fig. 4 and note that the axis for the force gradient is reversed). The force on the tip is attractive, but its magnitude is much smaller in comparison with the contact mode. Therefore, a very sensitive detection technique, based on the shift in resonance frequency of the cantilever (due to the presence of the positive force gradient), is employed to get the surface morphology image. However, in noncontact mode, if the surface potential feedback loop is not operating properly, the electrostatic force gradient cannot be distinguished from the actual van der Waals force gradient, and the morphology feedback loop will pick up spurious signals. This can also happen the other way around, especially at the edge of large morphology features. Thus, there is always a chance of undesirable intermixing of the two signals [7, 36]. Usually the morphology signal becomes corrupted, as the force gradient associated with the electrostatic forces can be quite large. A possible way to avoid intermixing of the signals is to measure the surface morphology first and then measure the surface potential after the tip is lifted to a certain height from the sample surface [9]. However, in that case a constant distance from the sample surface is not guaranteed during surface potential imaging and the measurement resolution may be reduced.

**Figure 5.** Contact and noncontact mode operation regions in the force vs. distance curve.

### 3.3.2. Contact Mode

In contact mode operation the tip is very close to the surface (within a few angstroms) in the repulsive force regime (see Fig. 5). Since the repulsive force is much larger in magnitude compared with the van der Waals force, the morphology signal is obtained by detecting the cantilever deflection directly. It has been shown that the intermixing of the surface morphology and surface potential signals can be avoided by operating SKPM with contact-mode AFM [7, 36]. This is due to the fact that the morphology signal in this case is obtained by monitoring the static deflection of the cantilever caused by a large repulsive force instead of the resonance frequency shift caused by a change in the force gradient. The disadvantage of this technique is that it is not easy to get sufficiently large oscillation amplitude of the tip in contact mode to generate the surface potential signal. Furthermore, since the tip is placed very close to the sample surface, there can be a tunneling current between the tip and the sample, which can alter their electrostatic configuration. Furthermore, the geometrical configuration of the tip can change rather dramatically because of the enhanced probability of crashing.

## 4. APPLICATIONS

The Kelvin probe measurement technique has numerous applications in a large number of fields ranging from biological sciences to electrical engineering. Since this technique is noncontact, quantitative, and straightforward and has nanoscale resolution (achieved through simultaneous operation with AFM), it is very suitable for the characterization of a wide range of materials and devices. In this review we will focus mainly on the applications that are relevant to nanotechnology. First we will discuss the applications to materials important to nanotechnology, such as insulators and semiconductors, and then move on to discuss applications that are specific to nanotechnology. Applications of this technique to SPV characterization and to devices and integrated circuits will be treated in separate subsections because of their importance. Since the EFM and SKPM are based on the same principles and are performed in almost the same way, we will discuss the applications of both techniques.

### 4.1. Insulating Materials

Insulators form a class of materials in which charges cannot move around freely. Therefore, if some charges are deposited at a certain position, they are expected to remain there for a long time. Characterization of insulators is important for a variety of reasons, including their ability to provide electrical isolation, passivate exposed surfaces of semiconductors, and act as a dielectric layer between the semiconductor and the gate of a device. Studies of charge storage and decay in insulators are also important because of their possible applications in memory devices. A large number of studies have been made on charging and discharging of insulators. Charge exchange processes between the probe tip and insulators (such as polycarbonate and PMMA) with submicron resolution were studied by Terris et al. by EFM

[37]. Decay of charges deposited on  $\text{Si}_3\text{N}_4$  film by thermionic emission was studied by Schönenberger et al. by EFM [38], where a single charge carrier resolution could be obtained. Moreover, storage and decay of charges in Co nanoclusters embedded in  $\text{SiO}_2$  were studied by Schaadt et al. [9], and charging of self-assembled silicon quantum dots was studied by Shimizu et al. [39] by EFM and SKPM, respectively. In all of the above cases the tip itself was used to deposit charges by applying a suitable bias to it with respect to the sample. An elegant demonstration of charge storage and measurement with the SKPM technique was made by Jacobs and Stemmer [40], in which an entire picture was imprinted on  $\text{SiO}_2$  and subsequently read out. Studies have also been reported on charging and discharging of electron beam resist films [41], as well as of polyethylene samples obtained from industrial cables [42]. Apart from intentionally deposited charges on insulators, charged domains already present on samples have also been characterized by SKPM [7].

### 4.2. Semiconductors

The Kelvin probe measurement technique has been widely used to characterize several important properties of semiconductors, such as surface work function, surface barrier, doping, diffusion length, and surface state density. The Kelvin probe technique is a unique way to measure surface work functions of semiconductors, which leads to an estimation of surface barrier height if the electron affinity of the semiconductor is known (refer to Section 2.2). The other quantities, such as doping, diffusion length, and surface state density, can be determined from the knowledge of either the surface work function or the surface barrier height. It is quite easy to make measurements on a homogeneous material, but measurements on a heterogeneous material are more complicated, as several optimizations are necessary. Of course, it is always advisable to standardize these measurements against metal work functions that can be measured easily and fairly accurately. It has been observed that measurement of the surface work function for a homogeneous sample can be made most accurately more than a micrometer from the sample surface, as the van der Waals and other short-range interactions can be completely avoided at such a distance [11]. Such techniques have been fruitfully employed for the measurement of the surface barrier height of GaN [11]. However, for nonhomogeneous materials, the measurement resolution will be much reduced at large distances from the sample surface. Therefore, for characterization of such samples the tip has to be operated very close to the surface. This might not be a problem for most cases if only relative values are important. Tanimoto and Vatel reported Kelvin probe measurements on Si  $p^+-p$ ,  $p^+-n$  junctions (with and without illumination) and cleaved AlGaAs/GaAs multilayer structures with a lateral resolution of 40 nm [43], and Chavez-Pirson et al. measured the band profile for a GaAs/AlGaAs  $n-i-p-i$  multiple quantum well structure [44]. Measurements of cross-sectional potential distribution (and electric field from it) were made on a cleaved  $n^+-\text{InP}/\text{InGaAs}/p^+-\text{InP}$   $p-i-n$  laser diode [45], and band profile changes under different illumination conditions were studied for cleaved GaAs/GaInP layers [40]. Antiphase

boundaries in GaAs film grown on Ge were also characterized with the use of EFM [15]. Surface state density and the corresponding energy level for GaN were found by EFM measurements with tips coated with different metals [12]. The surface state density has also been calculated from the measurement of surface barrier height of GaN films with different doping [11]. Characterization of dislocations in GaN and AlGaIn/GaN heterostructures by SKPM has also become quite popular [28, 46, 47] since the initial demonstration [46]. There is considerable interest in dopant profiling by the Kelvin probe technique; however, quantitative measurement with high lateral resolution is not easy [48]. In addition, the doping resolution that can be obtained is not very satisfactory [49]. Further applications of this technique to semiconductor materials are presented in Section 4.4, where SPV effects are discussed. SPV studies are very important and form a separate branch by themselves; therefore they merit a separate discussion. In the studies on heterogeneous materials, though qualitative agreements with theoretical predictions could be achieved, it was found to be difficult to obtain exact quantitative results. This is because of the finite size of the tip and the cantilever contributing to stray capacitance effects in the surface potential measurements. This is discussed in detail in the following section.

### 4.3. Devices and Integrated Circuits

The SKPM technique can be used very fruitfully to characterize devices and ICs because of its nanoscale resolution. The surface potential studies can provide rare insight into actual device operation, as well as help in troubleshooting and reliability studies. Since the morphology information is available simultaneously with potential, the tip can be positioned virtually anywhere on the device or IC. Furthermore, as the measurements are noncontact, there is no device degradation due to the measurements, and even working devices can be characterized. However, certain problems are usually faced in the application of this technique to characterize nanoscale devices or ICs. Perhaps the biggest challenge is to avoid the effect of stray (parasitic) capacitances contributed by the finite tip size and the cantilever. This leads to inaccurate measurements and reduced spatial resolution, as mentioned in the previous section. If the area to be measured is small compared with the area of the cantilever but much bigger than the tip diameter, then only the cantilever will cause most of the inaccuracies. However, if the area is smaller than or comparable to the tip diameter (a few tens of nanometers), then even the tip (and its sidewalls) will contribute to the inaccuracies. However, it should be noted that if the potential at the surface is homogeneous, then there will not be any inaccuracy in the measurements due to stray capacitances. In this section we will develop the mathematical formulation highlighting the effect of the cantilever only, with the assumption that the tip measures an accurate potential (of the region directly below the tip). In this way the effect of the cantilever can be deconvoluted to get more accurate results. The cases where the finite size of the tip also contributes to the inaccuracies are not easy to deconvolute without computer simulations.

Figure 6 shows a schematic diagram of the different capacitances associated with the tip and the cantilever when measurement is made over regions with different potentials. The parasitic capacitances associated with the tip sidewalls have been omitted for simplicity. Neglecting any fixed charge on the surface of the sample, the total amplitude of the  $\omega$ -component of the force  $F_{\omega, \text{tot}}$  acting on the tip is given by [11, 34]

$$F_{\omega, \text{tot}} = V_{\text{ac}} \left[ \frac{\partial C_{\text{tip}}}{\partial z} (V_{\text{dc}} - V_{\text{con}} - V_{\text{surf}}) + \frac{\partial C_{\text{canti}}}{\partial z} (V_{\text{dc}} - V_{\text{con}} - \langle V_{\text{surf}} \rangle) \right] \quad (14)$$

where  $V_{\text{con}} = (\phi_{\text{tip}} - \phi_{\text{mat}})/q$ ,  $V_{\text{surf}}$  is the electrostatic potential applied to the region of the sample directly below the tip (the intended region of measurement),  $\langle V_{\text{surf}} \rangle$  is the average potential measured by the cantilever (this is due to the projection of the cantilever over regions with different electrostatic bias), and  $(\partial C_{\text{tip}}/\partial z)$  and  $(\partial C_{\text{canti}}/\partial z)$  are the capacitance gradients of the tip and the cantilever, respectively. In feedback mode, the force on the tip  $F_{\omega, \text{tot}}$  is made to go to zero, and therefore from Eq. (1) after rearrangement,  $V_{\text{dc}}$  is given by

$$V_{\text{dc}} = V_{\text{con}} + [V_{\text{surf}} + \langle V_{\text{surf}} \rangle R] / [1 + R] \quad (15)$$

where  $R = (\partial C_{\text{canti}}/\partial z) / (\partial C_{\text{tip}}/\partial z)$ . The estimate  $V_{\text{est}}$  of the applied bias  $V_{\text{surf}}$  is given by  $V_{\text{dc}} - V_{\text{con}}$ .  $V_{\text{est}}$  tends to  $V_{\text{surf}}$  for very small tip-sample distance ( $R \ll 1$ ) and to  $\langle V_{\text{surf}} \rangle$  for large distances ( $R \gg 1$ ). However, if the whole sample surface has a single bias  $V_{\text{surf}}$  everywhere, then  $\langle V_{\text{surf}} \rangle = V_{\text{surf}}$ , and so  $V_{\text{est}}$  is equal to  $V_{\text{surf}}$ , and there is no effect of the cantilever on the measurements. For simplicity we have assumed the same value of  $V_{\text{con}}$  for all of the different regions with different potentials. If  $V_{\text{con}}$  differs significantly for these regions, then an average  $V_{\text{con}}$  should be used, which can be clubbed together with  $\langle V_{\text{surf}} \rangle$  in Eq. (14). The ratio  $R$  can be obtained theoretically by calculating  $(\partial C_{\text{tip}}/\partial z)$  and  $(\partial C_{\text{canti}}/\partial z)$ , assuming a particular geometry of the tip (see Fig. 3b), and from the dimensions specified by the manufacturer [34]. Alternatively, and more realistically,  $(\partial C_{\text{canti}}/\partial z)$  can be measured at a large distance from the sample where

**Figure 6.** Schematic diagram showing the main tip capacitance and the parasitic capacitances associated with the cantilever when measurement is made over regions with different surface potentials. As a result of the parasitic capacitances the cantilever “senses” an average potential (in addition to the correct potential  $V$  measured by the tip apex) and reduces the measurement accuracy. The parasitic capacitances associated with the sidewalls of the tip are not included for simplicity.

( $\partial C_{\text{tip}}/\partial z$ ) will be negligible.<sup>4</sup> Then ( $\partial C_{\text{tip}}/\partial z$ ) at any  $z$  can be obtained by simply subtracting ( $\partial C_{\text{canti}}/\partial z$ ) (modified appropriately to include the distance dependence of a slanted plate capacitor [34]) from the total capacitance value at that  $z$ . Thus from the knowledge of  $R$  and the average potential measured by the cantilever,  $\langle V_{\text{surf}} \rangle$ , the deconvoluted value of the surface potential,  $V_{\text{surf}}$ , can be obtained from Eq. (15) after rearrangement as

$$\begin{aligned} V_{\text{surf}} &= (V_{\text{dc}} - V_{\text{con}}) + R(V_{\text{dc}} - V_{\text{con}} - \langle V_{\text{surf}} \rangle) \\ &= V_{\text{est}} + R(V_{\text{dc}} - V_{\text{con}} - \langle V_{\text{surf}} \rangle) \end{aligned} \quad (16)$$

It follows from Eq. (16) that longer tip lengths and smaller areas of cantilevers give more accurate results as  $R$  decreases (refer also to Fig. 6). It should be noted that in the above derivation it has been assumed that the sidewalls of the tip do not contribute a significant capacitance gradient, and whatever it contributes can be mostly grouped with that of the cantilever. This is true to a large extent since the area of the sidewalls increases significantly only near the base of the tip, which is much farther from the sample. More accurate measurements can perhaps be made with tips with integrated guard rings (see Section 3.1.2). However, the effectiveness of such designs has yet to be adequately studied.

Measurements on a saw device, where alternate fingers were maintained at 0 and 5 V, have been made to illustrate the effect of the cantilever [34]. Back in 1991, measurements on an operational amplifier IC were performed by Weaver and Abraham [50]. Jacobs et al. reported measurements on a test structure with different finger widths [51] to study resolution, and on externally biased high electron mobility transistors (HEMTs) [40], and potentiometry measurements on polymer field-effect transistors have been reported by Bürgi et al. [52]. Mizutani et al. performed detailed measurements of the two-dimensional potential profile of a cleaved GaAs/AlGaAs/InGaAs/AlGaAs HEMT in operation by SKPM [53]. Simultaneously obtained surface potential and surface morphology images on a dc biased AlGaN/GaN heterostructure field effect transistor (HFET) are shown in Figure 7. As can be seen, the measurement accuracy is about 80–85%. Work is under way to automatically deconvolute the effect of the cantilever for more accurate measurements. The ability to place the tip at any position on the device has led to certain rare insights into device degradation mechanisms. Simultaneous measurements of drain current and surface potential near the gate (on the drain side) of an AlGaN/GaN HFET device after it is subjected to high stress has led to the conclusion that charges (electrons) are injected from the gate into the surface states. These electrons trapped at the surface states can increase the surface depletion region near the gate, causing the observed drain current degradation commonly associated with these devices [54]. Recently, Wang et al. observed the movement of charges under applied drain

**Figure 7.** (a) Surface morphology and (b) surface potential images obtained simultaneously for a dc biased AlGaN/GaN heterostructure field effect transistor device. A drain bias of 2 V and a gate bias of  $-1.5$  V were applied for surface potential imaging. A potential offset is applied by software to the surface potential image for better rendering and clarity.

bias in silicon nitride film deposited on an n-channel Si field effect transistor under applied drain bias and calculated the surface charge density [55]. Furthermore, measurements on GaAs metal-semiconductor field effect transistors with and without a low-temperature-grown GaAs cap layer have been made by Matsunami et al. [56]. So far we have only dealt with the measurements of dc potential applied to the sample. For applications to integrated circuits it is sometimes useful to be able to measure the high-frequency ac periodic signal applied at different points in the circuit. Such measurements can be made with various techniques such as heterodyne/nulling, pulse width modulation, and amplitude modulation techniques [57–59].

#### 4.4. SPV Measurements

SPV measurements form a separate field by themselves, though they are commonly based on Kelvin probe measurements. In the SPV technique, which has been exclusively developed to study semiconductors, the sample is subjected to super bandgap or sub-bandgap illumination, and the change in surface barrier height is measured. From these measurements, a large variety of semiconductor surface and

<sup>4</sup> At any distance from the sample surface  $z$ ,  $F_{2\omega}$  in Eq. (3) will be given by  $-\frac{1}{4}(\partial C_{\text{tip}}/\partial z + \partial C_{\text{canti}}/\partial z)V_{\text{ac}}^2 \cos(2\omega t)$  when the force on the cantilever is also included in the total force. At a large distance from the sample  $\partial C_{\text{tip}}/\partial z$  will be negligible and  $\partial C_{\text{canti}}/\partial z$  can be obtained from the magnitude of  $F_{2\omega}$ .

bulk properties can be determined. Excellent in-depth treatment of this technique is available elsewhere [60]. In this section we will discuss only three of the most important measurements that can be made with this technique, namely, (a) minority carrier diffusion length, (b) surface band bending, and (c) surface state density. It is hoped that a discussion of these applications will provide some flavor of the usefulness and versatility of the SPV technique.

#### 4.4.1. Measurement of Minority Carrier Diffusion Length

The measurement of diffusion length is perhaps one of the most important direct applications of the SPV technique. We will discuss briefly the underlying principles for this measurement. More detailed treatment can be found in [60]. For front surface illumination, the generation rate as a function of distance is given by

$$G(x) = \alpha I \exp(-\alpha x) \quad (17)$$

where  $I$  is the effective photon flux (incident photon flux times the surface optical transmission and quantum efficiency), and  $\alpha$  is the absorption coefficient. Assuming a low-level injection condition, the continuity equation for electrons (assumed minority carriers here) is then given by [61]

$$D \frac{d^2 \delta n(x)}{dx^2} - \frac{\delta n(x)}{\tau} + \alpha I \exp(-\alpha x) = 0 \quad (18)$$

where  $\tau$  is the minority carrier lifetime and  $D$  is the diffusion coefficient. With the boundary conditions  $\delta n(\infty) = 0$  (at the back surface of a thick sample), and  $D \frac{d\delta n(x)}{dx} \Big|_{x=w} = S \delta n(w)$  (at the edge of the space charge region), and assuming  $w \ll 1/\alpha$  and  $w \ll L$ , we have the excess minority carrier density at the edge of the space charge region given by

$$\delta n(w) = \frac{\alpha L}{1 + \alpha L} \cdot \frac{1}{S + D/L} I \quad (19)$$

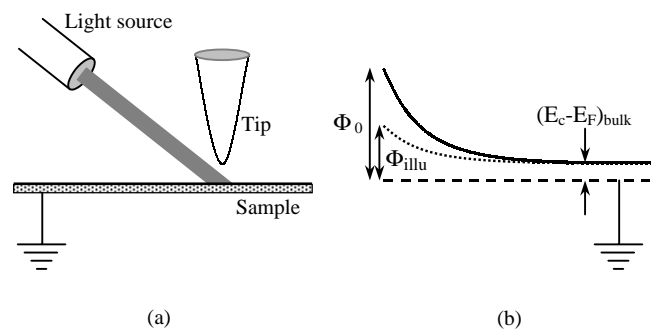

Equation (19) forms the basis for measuring the minority carrier diffusion length. Indeed, if at different wavelengths the SPV is kept constant (see Fig. 8a for the measurement setup), then  $\delta n(w)$  is also expected to remain constant and Eq. (18) can be rearranged (showing explicit variations with wavelength  $\lambda$ ) as

$$I(\lambda) = C_1 \left( \frac{1}{\alpha(\lambda)} + L_n \right) \quad (20)$$

where  $C_1$  is a constant. Thus, from the plot of  $I(\lambda)$  vs.  $\alpha^{-1}(\lambda)$  we can find the diffusion length,  $L_n$ , from the intercept on the negative  $x$  axis. This technique is very useful for the solar cell community, as the minority carrier diffusion length is one of the most important parameters controlling the conversion efficiency of solar cells. Moreover, this technique can be used to monitor the presence of metallic impurities such as iron in silicon and has become quite popular in the silicon industry.

#### 4.4.2. Measurement of Surface Band Bending

Surface band bending for a semiconductor material is an important parameter that can be measured with the SPV technique. Figure 8a shows the general experimental setup, and Figure 8b shows the steady-state band diagrams with and without illumination. We can see from Figure 8b that the surface band bending and the  $(E_c - E_F)$  value in the bulk together determine the surface barrier height. The surface barrier height can also be calculated from the surface work function if the electron affinity of the semiconductor is known (see Section 2.2). However, the electron affinity of a semiconductor may not always be known unambiguously. The surface band bending is caused by trapping of charges by the surface states present within the bandgap. These trapped charges are compensated for by opposite charges in the bulk forming a charge dipole near the surface. Under super bandgap illumination electron-hole pairs are generated, which reduce the surface band bending (Fig. 8b). This can happen in two ways [60]: (a) by the screening of the built-in electric field at the surface by the excess carriers, and (b) by preferential trapping of the charges of opposite polarity at the surface, reducing the net surface charge. Therefore, referring to Figure 8b, it is intuitively expected that under illumination of high enough intensity, the surface band bending will disappear. Thus, from the change in surface potential (SPV) measured by the Kelvin probe, the surface band bending can be determined, as well as the surface barrier if the  $(E_c - E_F)$  value in the bulk is known. The way to check if a flat-band condition has been achieved is to increase the illumination intensity and see if the SPV saturates with increasing intensity. The value at which the photovoltage saturates is the value of the surface band bending (with opposite sign). This technique is not applicable if the SPV does not saturate. In such cases other techniques have to be adopted [60]. An interesting case has been observed for AlGaIn/GaN heterostructures, where the photogenerated carriers under super bandgap illumination become spatially separated and reduce the surface barrier by screening the built-in electric field in the AlGaIn layer. However, after the illumination is turned off, the charge carriers cannot recombine immediately, and a long tail of the

**Figure 8.** (a) Schematic diagram showing the surface photovoltage measurement setup. (b) The surface barrier of the sample decreases from  $\Phi_0$  before illumination to  $\Phi_{\text{illu}}$  under illumination. With increasing intensity of illumination the flat-band condition can be achieved, and hence the surface band bending (before illumination) can be measured.

surface potential recovery transient is observed (stretched over a few days or even weeks!). This long decay transient can be modeled by a thermionic emission process, and the surface barrier before illumination can be calculated without the photosaturation technique [62].

**4.4.3. Measurement of Surface State Density**

Surface state density,  $\sigma_s$ , of a semiconductor is another important material parameter that one often needs to know for many reasons, including its effects on Schottky barrier height. Surface state density can also be determined from surface photovoltage measurements. The basic procedure for this technique was described by Lam [63]. Though Lam used a SiO<sub>2</sub> dielectric for his metal-insulator-semiconductor (MIS) structure, a contactless MIS structure can be used with the air film as the dielectric between the “gate” and the semiconductor. Through a change in the voltage  $V_g$  on the metal “gate,” the surface charge density  $Q_{ss}$  and the bulk compensating charge density  $Q_{sc}$  can be altered. Naturally, this will also alter the surface barrier  $\Phi_s$ . Using the charge conservation law,  $dQ_g + dQ_{ss} + dQ_{sc} = 0$ , where  $Q_g$  is the charge density on the “gate.” Moreover, from Kirchhoff’s voltage law, we have  $dV_g = dV_{ins} + d\Phi_s$ . From these equations, the surface state density,  $N_t$ , ( $= -(1/q)dQ_{ss}/d\Phi_s$ ) at any surface barrier  $\Phi_s$  can be obtained as

$$qN_t(\Phi_s) = C_{ins} \left( \frac{dV_g}{d\Phi_s} - 1 \right) + \frac{dQ_{sc}}{d\Phi_s} \quad (21)$$

where  $C_{ins}$  is the capacitance of the air layer per unit area. For a particular  $\Phi_s$ , the term  $dV_g/d\Phi_s$  can be obtained experimentally from the curve of gate voltage vs. surface barrier (obtained with the photosaturation technique described in Section 4.4.2 for each  $V_g$ ), and  $dQ_{sc}/d\Phi_s$  can be obtained

from the standard relation that exists between  $Q_{sc}$  and  $\Phi_s$  for a known bulk doping level [61].

**4.5. Applications to Nanotechnology**

In the previous sections we discussed the important applications of the Kelvin probe technique in general. In this section we discuss the applications that are specific to nanotechnology. As pointed out earlier, because of its inherent nanoscale resolution, this technique is very suitable for characterizing nanoscale devices and systems (through measurement of electrical quantities such as surface charge, surface work function, and applied bias). The applications of this technique in different areas of nanotechnology are shown in Figure 9. Following we will discuss each of these areas of application, except for the nanoscale devices that have already been treated in detail in Section 4.3.

Thin films, especially of semiconductors, are very important for nanotechnology. This due to the fact that a vast majority of nanoscale devices, such as transistors, emitters, detectors, etc., are made of semiconductor thin films. The electrical characterization of these thin films becomes especially critical for epitaxially grown layers (required for high-speed and optoelectronic devices) because strict control of the electronic properties of such layers is required for proper device operation. This technique has been used to characterize Langmuir-Blodgett (LB) films. LB films consisting of a 1:1 molar mixture of arachidic acid and partially fluorinated carboxylic acid on a silicon (100) substrate were studied by Yasutake et al. [64]. They measured a potential difference of ~50–60 mV between the two regions with an improved version of SKPM capable of 1-mV voltage resolution and 10-nm lateral resolution. Iwamoto and Itoh [65] systematically studied the surface potential variation with film thickness for LB films of polyimide and Cu-tetra-(*tert*-butyl)-phthalocyanine deposited at different temperatures

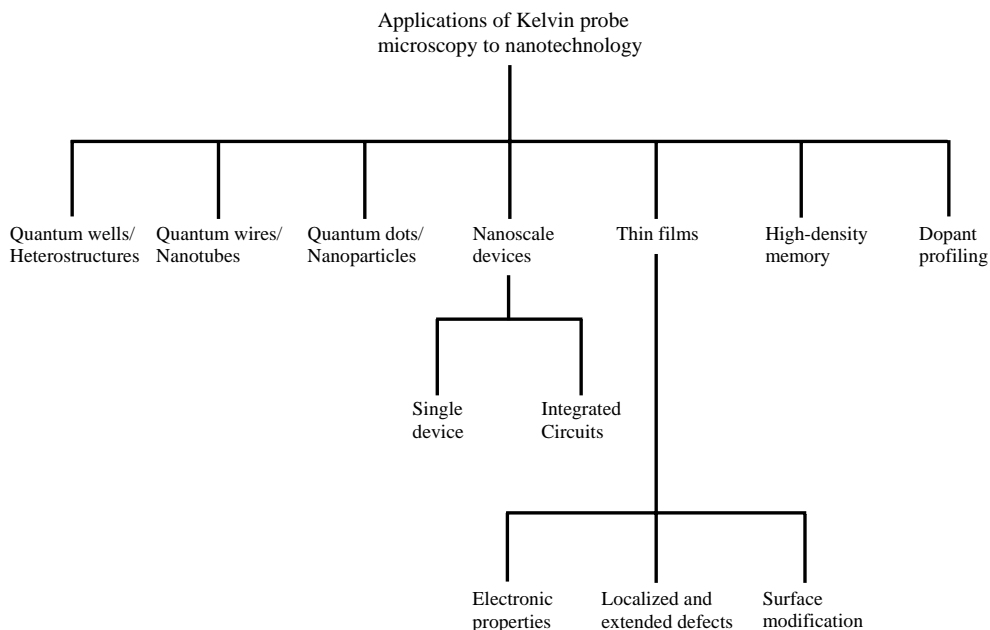

Figure 9. Schematic chart showing different applications of Kelvin probe microscopy to nanotechnology.

on Au-, Cu-, and Al-based electrodes. From the variation of surface potential with thickness, the charge density in the LB film could be obtained for each thickness corresponding to each base electrode. O'Boyle et al. [66] applied this technique to the study of Al/Cu intermetallic decorating Al/Cu lines (Cu 5%) deposited on silicon. Whereas the intermetallic regions were not distinguishable in the regular topography image, they readily showed up in the surface potential image, underlining the efficacy of this technique in alloy surface studies. Using dynamic contact-mode EFM, Hong et al. [7] characterized nanoscale charged domains in single-crystal triglycine sulfate. They measured the charge density in the domains as well as the domain charge dynamics after the sample was heated above Curie temperature. The semiconductor surface work function is strongly dependent on the presence of surface layers, atomic arrangement, and chemical composition. Therefore, to obtain information about the surface contaminant layers the measurement of the surface work function becomes very useful. Baikie et al. [67] compared the variation of surface work function of silicon (111) with oxide layer thickness for a clean Si surface and an Ar ion-bombarded Si surface. The Ar-sputtered Si surface showed a dramatic reduction in the magnitude of surface potential change due to oxygen incorporation at the surface. The variation at higher temperature was also correspondingly lower. They also studied Al (lower work function than Ru) deposition on Ru (0001) and found that with increasing Al deposition thickness the work function decreases as the film growth progresses from the initial island growth to flat island growth to monolayer growth. Kitamura and Iwatsuki [68] studied a Si (111) surface with Au deposited and observed a potential difference of 0.5 eV between the  $7 \times 7$  (higher) and  $5 \times 2$  (lower) phases. They also observed a potential difference of 20 mV between the work function of the Ag islands (higher) compared with the clusters. They demonstrated atomic-level resolution for both noncontact AFM images and surface potential images. The Kelvin probe technique has also been used by DeVecchio and Bhusan [69] to study nanoscale wear on Al, Au, Si, and alumina samples. Wear studies are important to the magnetic recording industry, microelectromechanical systems industry, and other nanoscale industries. In their studies, the initial nanoscale wears were simulated by abrading the samples in contact mode, which was followed by tapping-mode morphology imaging and lift mode (see Section 3.3.1) surface potential imaging. They observed very significant changes in surface potential caused by the nanoscale wears, and they attributed these to a combination of chemical and structural changes in the sample surface.

A large number of defect studies of materials, especially semiconductors, have used the Kelvin probe technique. This is due to the fact that the defect sites usually become electrically charged and can easily be studied by Kelvin probe or EFM. Sommerhalter et al. [14] studied work function variations on highly oriented pyrolytic graphite (HOPG), *n*-GaAs, and *p*-WSe<sub>2</sub>. They could identify the positively and negatively charged defects on *p*-WSe<sub>2</sub> and measure the work function difference between the stepped edges and flat surfaces for HOPG and *n*-GaAs. The work functions for different crystal facets of polycrystalline CuGaSe<sub>2</sub> deposited on ZnSe (100) and Mo/glass substrates were measured by

Sadewasser et al. [70] with a lateral resolution of 25 nm and a voltage resolution of 5 mV. CuGaSe<sub>2</sub> films are used in making solar cells based on chalcopyrite materials. Constant surface work functions were observed for different well-defined faces of the nanosized crystals of the film grown on ZnSe. For the film grown on Mo/glass the absolute values of the work functions for different faces were different from the film on ZnSe, though the difference between any two faces was almost the same. Xu and Hsu [15] studied antiphase boundaries of GaAs grown on Ge by EFM and found that the surface potential at the antiphase boundaries (APBs) are consistently higher than the domains by about 30 mV because of Fermi-level pinning at the APBs closer to the valence band than at the domains. They also observed wedge-shaped depressions where the surface potential was lower by about 25 mV compared with the surroundings, indicating that the Fermi level shifted relatively closer to the conduction band. The two positions of the Fermi level for the two defect types can be attributed to the difference in defect state densities (as a function of energy) in the two cases. Recently studies have been made of electronic characteristics of dislocations in GaN [28, 46, 47]. It has been observed that dislocations in GaN and AlGaN/GaN heterostructures are negatively charged, as indicated by the upward bending of the conduction band at the dislocation sites (by a few tenths of an eV). Although the exact magnitude of the band bending is difficult to measure because of the parasitic capacitance effects, the fact that dislocations charge is nevertheless important, as they are widely believed to scatter electrons during AlGaN/GaN HFET operation.

Because the Kelvin probe can measure the surface barrier height there is considerable interest in using this technique for dopant profiling of semiconductors. However, there are several limitations to such use. The surface barrier obtained gives only a relative estimate of the separation between the conduction band and the Fermi level, and therefore quantitative measurement is difficult. Frequently, for atmospheric measurements, the electron affinity of the semiconductor might change, giving rise to errors. Moreover, calibration samples have to be used for better measurement accuracy. Last, the spatial resolution is limited by parasitics, and the voltage resolution (which controls the doping resolution that can be achieved by this technique), by noises. In spite of the above limitations, good qualitative characterization of the doping profile is possible with this technique. Si and GaAs *p-n* junctions have been studied by several groups [13, 43, 48] and the limitations have been pointed out [13, 48]. A good review of the Kelvin probe technique in comparison with other scanning probe microscopy techniques for the measurement of doping has been made by De Wolf et al. [49].

The Kelvin probe technique can also be used to "write" potential images in insulating films as well as "read" them. A Kelvin probe was used to measure charge storage effects and effects of UV illumination in aluminum oxide films as early as 1977 by Rageh et al. [71]. However, writing on insulating films and reading them was first successfully demonstrated by Stern et al. [72] and Terris et al. [8]. They used a bias of 100 V for 25 ms to deposit the charges (writing) and obtained a lateral resolution of  $\sim 1 \mu\text{m}$  in reading. A positive or a negative charge on sufficiently insulating film

can be deposited by applying a suitable bias to the probe tip (placed very close to the surface) for a certain interval of time. Schönenberger and Alvarado [38] studied the deposition ( $\sim 10$  V dc for 10 ms) and subsequent decay of charge in  $\text{Si}_3\text{N}_4$  films. They found that the charge decay follows a thermionic emission process and could obtain single-electron resolution in their measurements. Usually the insulators used for writing and reading charges are of four types: polymers, silicon dioxide, nitride-oxide-silicon (NOS), and oxide-nitride-oxide-silicon (ONOS), as discussed in detail by Wright and Chetwynd [73]. They concluded that the NOS and ONOS structures give the best lateral resolution, and the charges persist for days or months. In 1999, Jacobs and Stemmer [74] reported on the use of computer control to write patterns on  $\text{SiO}_2$  film (2–4-nm native oxide on Si) with pulses of selectable duration (2.5–400  $\mu\text{s}$ ) and magnitude (10–30 V). With their technique they could even write a photograph on a  $\text{SiO}_2$  surface and successfully read it. They have obtained a resolution of around 200 nm, and the patterns stayed for at least 24 h. Recently, charge writing on fluorocarbon polymer film has been demonstrated by Mesquida et al. [75]. For writing they used pulses of 10- $\mu\text{s}$  to 1-ms duration with a magnitude varying from  $-60$  to  $60$  V and obtained a lateral resolution of 20 nm for fluorocarbon film on Si. They also studied the influence of the film thickness and the substrate on the measured potential and the influence of the humidity and the substrate on the charge decay time. Apart from the charge storage in films, storage on nanoparticles has also been studied. Schaadt et al. [9] reported on the charging of Co nanoclusters embedded in  $\text{SiO}_2$  layer by applying  $\pm 12$  V for 10 s. They estimated the radius of the charged area to be 20 nm and showed that one electron per Co nanocluster is added or removed under the charging conditions they used. The advantage of writing charges with the Kelvin probe technique is that charges and patterns can be stored virtually without any processing steps, and the bits can be a few tens of nanometers in diameter. However, the disadvantage is that both reading and writing have to be done serially and cannot be done too fast without compromising the accuracy of the reading and writing steps.

A large number of measurements of heterostructures and quantum wells made with the Kelvin probe technique have been reported in the literature. These studies are important, as they give an idea of the band profile along the interface, which can be used to obtain the electric field and in some cases the charge densities in the various layers. These data are very important for ensuring proper operation of the devices, especially those consisting of structures grown by epitaxial techniques. Early characterization results of semiconductor devices and processes were reported by Tanimoto and Vatel [43]. They measured the surface potential profile on cleaved  $\text{AlGaAs}/\text{GaAs}$  heterostructures and cleaved Si  $p^+-p$ ,  $p^+-n$  junctions with and without illumination. They found that the potential measurements (performed with  $<40$ -nm resolution) were sensitive to the Al mole fraction and helped in the estimation of band structures of the cleaved samples. In addition, they could determine the lateral impurity profile under an ion implantation mask through calibration of the potential profile with the use of spreading resistance measurements. Chavez-Pirson et al. [44] measured the potential

profile of a cleaved  $\text{GaAs}/\text{AlGaAs}$   $n-i-p-i$  multiple quantum well (MQW) structure with and without illumination. They found that the measured potential profile was in good agreement with the calculated profile, taking into account the estimated surface band bending corresponding to the doping level in the layers. Under illumination the potential modulations of the  $n-i-p-i$  layer decreased because of screening of the built-in electric field by the photogenerated carriers. Similar cross-sectional potential measurements on a cleaved  $n^+-\text{InP}/\text{InGaAs}/p^+-\text{InP}$   $p-i-n$  laser diode were made by Robin et al. [45]. The potential measurements were corrected for tip convolution for comparison with two-dimensional simulation with a commercially available package from Silvaco (Santa Clara, CA). Very good agreement between the measurements and the simulation could be obtained by taking into consideration partial ionization of the  $n^+-\text{InP}$  layer and the presence of surface states. Similar measurements were also made on cleaved  $\text{GaAs}/\text{AlAs}$  MQWs and  $\text{InAlAs}/\text{InGaAs}$  layered structures with a resolution of 40 nm [76]. Breymesser et al. [77] measured cross-sectional potentials of cleaved Si  $p-i-n$  diodes (solar cells) and obtained the charge density profile by differentiating the potential profile twice. The potential measurements led to the conclusion that a graded donor like defect distribution and a constant boron concentration were present in the intrinsic layer. Ruzin et al. [78] also applied this technique to the study of neutron implantation effects in a silicon  $p-i-n$  particle detector. Weitz et al. [79] applied the Kelvin probe technique (modified for low-temperature applications) to investigate the 2DEG under quantum Hall conditions with submicron resolution. They succeeded in observing the sawtooth-like variation of the chemical potential with increasing magnetic field resulting from the expected depopulation of the Landau levels. To avoid the undesirable retarding effect of the high-frequency signal used for minimizing force (in high resistive areas) and to enhance the contributions of the tip-sample interactions, they minimized the force gradient with the use of an ac signal with very low frequency (3.4 Hz) to measure the shift in resonance frequency. They also developed a normalized measurement technique and used it to measure the Hall-potential profiles under an applied magnetic field.

Lower dimensional structures, like quantum wires and nanotubes, have also been characterized with this technique. Characterization of quantum wires grown by MBE on patterned  $\text{GaAs}$  surfaces ((100) and (311)) was done by Yoh and Takabayashi [80]. From EFM measurements they could identify the amphoteric nature of the Si dopants (depending on the facet orientation) and could clearly determine the width of the quantum wire, which was not unambiguously possible with AFM alone. Ono et al. [81] characterized  $\text{InAs}$  nanowires grown on a  $\text{GaAs}$  (110) plane with a  $3^\circ$  offset toward the (111) plane and found evidence of electron accumulation in the nanowires. Carbon nanotubes have been successfully characterized with EFM by Bachtold et al. [82]. They found that this technique can be used very fruitfully to identify a break in the nanotube, which would be very difficult to identify from the morphology image. Through potential measurements on nanotubes they could also conclude that multiwalled carbon nanotubes (MWNTs) behave as diffusive conductors (since they had a linear voltage drop

along their length), whereas single-walled carbon nanotubes (SWNTs) support ballistic transport (since there was no voltage drop along their length). Using potential measurements, they could also measure the nanotube resistance per unit length, as well as the contact resistances between the carbon nanotube and the gold electrodes. Gekhtman et al. [83] studied the thermodynamic density of states (TDOS) of Bi quantum wires by measuring the electrostatic force gradient as a function of diametrical ( $x$ ) position, axial ( $z$ ) position, and bias voltage. From their measurements they could estimate the L-point quasi-gap for various radii of the quantum wires. They also found out that the TDOS increases toward the wire boundaries compared with the center, and this difference increases with decreasing radius.

Quantum dots (QDs) and nanoparticles have been characterized quite extensively with this technique. Silver nanoparticles dispersed on graphite have been characterized by NCAFM and EFM with a lateral resolution of 4–5 nm [10]. It was found that the silver particles were positively charged, as expected from the lower work function of silver with respect to the graphite basal plane. As discussed before, cobalt nanoclusters embedded in  $\text{SiO}_2$  have been charged and imaged with the use of EFM [9]. Krauss and Brus [84] used EFM to study the dielectric constant and electrostatic charges in CdSe nanocrystals. They found that the dielectric constant was uniform; however, the charge per nanocrystal was nonuniform. They also found that photoexcitation with light of frequencies greater than the bandgap of the nanocrystals resulted in their becoming positively charged. There has been considerable interest in the study of Si nanocrystals and nanostructures, especially for the fabrication of nonvolatile floating gate memory that can be directly integrated into the baseline Si process. Shimizu et al. [85] studied the charging (both positive and negative) of Si QDs (average height 5.4 nm) formed on  $\text{SiO}_2$  and was able to calculate the number of electrons added to or removed from the QDs. Guillemot et al. [86] also studied charging

of Si QDs embedded in  $\text{SiO}_2$  by phase-contrast EFM imaging and calculated the charge present in each QD and the charge decay time (30 min to 3 h). Shiota and Nakayama [87] used NCAFM to create nanostructures on a Si (111)  $7 \times 7$  surface that were higher by  $\sim 1 \text{ \AA}$  and showed a surface potential lower by  $\sim 0.1 \text{ V}$  compared with the surrounding regions. From SKPM and NCAFM measurements made on quenched Si they concluded that the nanostructure was indeed  $1 \times 1 \text{ Si}$ . Takahashi et al. [88] characterized the near-surface band structure of InAs dots covering an  $n\text{-GaAs}$  (100) surface with a lateral resolution better than 20 nm. They found from the force images of  $\omega$  and  $2\omega$  that the surface depletion is more suppressed under the dots, possibly because of electron accumulation in the InAs dots. From the above discussion it should be quite obvious that the Kelvin probe technique (or the EFM) has been used extensively by the scientific community to characterize nanostructures. A summary of the different applications of this technique to nanotechnology is given in Table 1. In spite of the extensive use of this technique for nanocharacterization, its resolution (lateral) and accuracy are limited by parasitics, as discussed in Section 4.3. This problem will be discussed again in the following section.

#### 4.6. Miscellaneous Applications

In the previous sections we discussed the important applications of the Kelvin probe measurement technique to nanotechnology and related materials. The versatility of this technique allows itself to be used for many more applications than the ones discussed above. We will briefly mention some of the other interesting applications in this section. Biological applications of the Kelvin probe technique were demonstrated by Baikie et al. [89] with the use of a multitip setup, where they measured biopotentials developed along a growing plant shoot (corn seedling). Measurements of surface photovoltage on a semiconductor ( $p\text{-InP}$  (100))

**Table 1.** Summary of the applications of Kelvin probe technique to nanotechnology.

Type of application	Quantity measured	Significance of measurement	Comments
Thin films	Charge, potential	Defects, electronic properties, surface modification studies	Characterization very important for thin film growth and deposition
Quantum wells/heterostructures	Charge, potential	Study of conduction band profile, electric field, defects, 2DEG	Quite important for characterization, but lateral resolution limited by parasitics
Quantum wires/nanotubes	Charge, potential	Band profile, conduction, carrier properties	Quite useful, but lateral resolution limited by parasitics
Quantum dots/nanoparticles	Charge, potential	Study of charging and discharging	Quite useful, but lateral resolution limited by parasitics
Nanoscale devices	Charge, potential, applied bias	Potential profile, troubleshooting, reliability studies	Quite useful for surface and cross-sectional measurements; holds good promise if parasitics can be reduced
High-density memory	Charge	Memory write and read in insulators and nanostructures	Slow and serial reading and writing; lateral resolution limited by parasitics
Dopant profiling	Potential	Doping variation data	Lateral resolution limited by parasitics; surface-related problems

immersed in different liquid etchants were made by Bastide et al. [90]. Though only relative changes in surface potential could be measured with their setup, the validity of such measurements was nevertheless established by comparison with measurements performed directly on the InP sample. Measurements of liquid “work functions” are also possible and have been discussed in [91] and [92]. Development of a special probe to carry out such measurements has also been discussed [93]. This technique has also been widely used to measure the modification of the work function and corrosion of metals [94–97]. Examples of some other applications of this method include studies of organic light-emitting diodes [98, 99], the study of diamond work function variation [100], and chemistry [101].

In spite of the versatility of the Kelvin probe measurement technique, it has several limitations that should be addressed. In addition, certain issues must be kept in mind to ensure proper operation of the technique. Surface contamination and consequent alteration of the contact potential can be an issue if the measurements are performed in an atmosphere. However, contamination-related problems can be avoided to a large extent by proper cleaning of the samples just before measurement, or best by performing the measurements in a vacuum. Another possible source of inaccuracy is the ac signal applied to the tip, which has been shown to cause significant changes in the surface potential [102]. However, if the ac signal magnitude is kept low enough, such problems can be avoided [15]. The Kelvin probe station itself must be isolated from the environment with a floating air table to avoid errors resulting from mechanical vibrations. Measurement inaccuracies can also be caused by the microphonic signals (ac electrical signals produced by vibrating conductors and insulators) associated with the vibration of the tip-cantilever assembly (in noncontact mode). This can give rise to spurious distance variation of the feedback signal. However, it has been shown that the effects of microphonics can be minimized with the use of coaxial cables together with vibration damping and isolation, or by the introduction of a suitable dc offset in the feedback loop [103]. As discussed before, simultaneous measurement of surface potential and surface morphology in the scanning mode can lead to a significant error in surface potential measurements due to intermixing of signals (when the morphology feedback cannot maintain a constant  $z$ ), especially if the morphology features are big enough. Furthermore, changes in the tip work function, especially if the tip is coated with a metal film (due to peeling of the metal film), can contribute to errors. In addition, stray charges on the surface can give rise to irregularities in the potential scan.

Apart from the above causes of inaccuracies, there are problems of spatial and potential resolution. The spatial resolution is limited by the stray capacitances associated with the cantilever and the tip. Such stray capacitances depend on the geometry of the tip-cantilever system, as well as on the operating distance,  $z$ . Based on semiempirical techniques, McMurray and Williams [104] obtained a relationship between the probe diameter  $d$  and tip-sample distance  $z$ , with the distance  $\Delta L_{50}$  between the points corresponding to 25% and 75% of the total change in Kelvin potential (measured across a step change in potential between two regions with a straight line boundary) in the form

$\Delta L_{50} = K_1 z + K_2 d$ , where  $K_1$  and  $K_2$  are constants. They found that  $\Delta L_{50}$  (and hence the lateral resolution) is dominated by  $d$  for smaller  $z$ , and by  $z$  itself at larger  $z$ . To minimize parasitic effects it is important to use long tips and cantilevers with the smallest possible areas and perform the measurements as close to the sample as possible (see discussion in Section 4.3). In addition, a metal shield can be fabricated around the tip cylindrical body and the cantilever bottom face to avoid parasitic capacitance effects [25, 27]. Therefore, a shielded tip with a very small radius and high aspect ratio (like a carbon nanotube) should be ideal for obtaining the highest resolution. Alternatively, it has been proposed that the resolution can be improved by using the force gradient as the signal source [105, 106], because the contribution of the tip apex to the total force gradient is much greater than that of the cantilever and the tip sidewall for small  $z$  (which is experimentally important).

The voltage resolution of the Kelvin probe technique is limited by the electrical and thermal noise. These noises can be generated by the electronics, the signal wires, the ac signal source for tip bias, the piezoelectric chip, the laser, and the photodetectors [5, 6, 106, 107]. Usually, the combined effect of all of these sources leads to a voltage resolution of  $\sim 1$  mV to  $\sim 10$  mV. Moreover, since a lock-in amplifier and feedback loop are used in the measurements, there is an inherent reduction in the signal-to-noise ratio as the signal is minimized to achieve a null condition. To avoid such a problem, a data acquisition-based off-null measurement technique has been proposed by Baikie et al. [107]. One of the significant drawbacks of the Kelvin probe technique is that its temporal resolution is not good because of the large time constant usually associated with the lock-in amplifier to reduce noise. Usually the overall time constant of measurement varies from a few tens to a few hundreds of milliseconds. Therefore, it is not easy to measure time-varying signals with this technique.

## 5. SUMMARY

In this chapter we have discussed the various aspects of the Kelvin probe measurement technique in a fairly detailed manner, covering the origins of the electrostatic force, the components of the measurement system, the forces on the tip, and the modes of operation. We have also discussed the applications (with a particular focus on nanotechnology) and the limitations of this technique. The technique has been used for about a century, and it was not possible to cover every aspect of this technique in the limited span of this review. Instead, we have tried to explain the more important aspects of this technique fairly rigorously (both in words and by equations, wherever appropriate), keeping in mind the broad spectrum of readers for whom this article is intended. The Kelvin probe technique is rapidly evolving, and newer applications are discovered every year. Therefore, while writing this review we put a strong emphasis on bringing out the general principles of the measurements, without merely trying to list all of the experiments that have been performed. Of course, special attention was paid to covering as fully as possible the various applications of this technique to nanoscience and nanotechnology. Today, the Kelvin probe technique has wide-ranging applications in the

fields of basic sciences, material science, and engineering. Because of its inherent nanoscale resolution (made possible by using it simultaneously with AFM), the technique is very suitable for nanocharacterization, as has been stressed again and again in the review. Kelvin probe measurements using carbon nanotube tips are just becoming popular and hold much promise for the future. The applications to integrated circuits and biopotentiometry are also very promising. Additionally, unique applications of nanoscale charge storage and readout for high-density memory are emerging. However, to realize its full potential this technique must overcome the limitations in spatial resolution and time constant. The spatial resolution can be improved to a significant extent by special tip design and force gradient detection technique. Quantitative measurements of high-frequency periodic signals have also been made possible. Considering all of the aspects of the Kelvin probe, it is indeed safe to say that this is one of the most versatile nanocharacterization tools available today and should be found to be increasingly useful by the researchers of the “nano-world.”

## GLOSSARY

**Contact potential difference (CPD)** The potential difference that develops between two dissimilar materials (with different work functions) through transfer of charges when they are brought into contact.

**Electrostatic force microscopy (EFM)** Microscopy based on electrostatic force between the probe and the sample. It is different from SKPM in that no feedback loop is used to null the electrostatic force.

**Kelvin probe** A probe that measures the difference in work function between itself and the sample, with the use of an electrostatic force nulling technique in a two-plate capacitor configuration.

**Nanotechnology** The technology involving the fabrication and characterization of nanoscale devices and structures.

**Scanning Kelvin probe microscopy (SKPM)** The Kelvin probe measurement performed in a scanning mode in conjunction with atomic force microscopy.

## ACKNOWLEDGMENTS

Our work with the Kelvin probe measurement technique is supported by the Office of Naval Research MURI on semiconductor interface electronics under contract N00014-99-1-0714 under the direction of Dr. Colin E. C. Wood.

## 1. INTRODUCTION

Motility is a crucial feature of living matter existing in very different forms. To maintain all the diverse processes of motility on each single level of organization within a given organism, nature has evolved both *rotary motors*, including the flagellar motors of bacteria [1, 2] and the adenosine triphosphate (ATP) synthase [3–5], and *linear* (forward propulsive) *motors*, including ribonucleic acid (RNA) polymerases [6, 7] and cytoskeleton-associated motors.

Within the last two decades, it has been realized that cell locomotion, muscle contraction, and the active intracellular transport of organelles and macromolecules are generally based on the functional activity of specialized proteins called motor proteins or mechanochemical proteins. Motor proteins are defined as proteins that convert the chemical energy of adenosine triphosphate (ATP) into mechanical energy to move along the surface of suited proteinaceous filamentous rails constituting the complex cytoskeleton network. The cytoskeletal motor proteins comprise different types of myosins, dyneins, and kinesins, expressed ubiquitously in eukaryotic organisms.

From a structural point of view, the motor proteins appear as elongated (often long-stretched) molecules with characteristic head domains that attach the motor to the cytoskeletal filament and generate force for the movement. The distal end of these proteins is linked to membranous vesicles or biomacromolecule complexes, which constitute the *cargo* to be moved along the filament [8].

According to their cellular functions, cytoskeletal motors can be divided into three subgroups:

1. Motors involved in intracellular transport processes (kinesins, cytoplasmic dyneins, cytoplasmic myosins, e.g., myosin V)
2. Motors responsible for cell locomotion and cell surface transport (axonemal dynein, myosin I)
3. Motors for muscle contraction (sarcomeric myosin II)

Another classification made on the basis of the type of cytoskeletal filament along which these motors move results in the following two subgroups:

1. Microtubule-associated motors (kinesins, cytoplasmic and axonemal dyneins)
2. Actin microfilament-associated motors (cytoplasmic and muscle myosins)

The myosins (for reviews, see, e.g., [9, 10]), dyneins (for reviews, see, e.g., [11, 12]), and kinesins constitute large protein families with a great number of functionally specialized, different members. So far, nearly 150 kinesin isoforms and related proteins from 31 species have been described for animal and plant cells as well as for lower eukaryotic organisms [13]. It seems that every kind of cellular cargo requires its own motor to be transported. Besides a set of basic features that all the kinesin isoforms share, single members of the kinesin superfamily reveal specific properties, making them favorite above the others with regard to their potential usability for nanotechnological applications.

The present contribution is focused on conventional kinesin, which belongs to the KHC protein family [13]. It was first discovered in the axoplasm of the squid giant axon [14] and is now one of the best characterized motor proteins. This kinesin walks in discrete nanometer-sized steps in a defined direction along the surface of microtubules. Furthermore, it is known to be a highly processive motor protein, moving over relatively long distances without being released from its microtubule rail [15]. The energy required for the movement is delivered by the kinesin itself, using an intrinsic molecular power station hydrolyzing the ubiquitously occurring biological fuel ATP in a specialized catalytic center with ATPase activity. The microtubules do not only

fulfill static but also regulatory functions: They determine the direction the kinesin moves, and they are involved in the regulation of the efficiency of energy transformation performed by the kinesin. For these and some other reasons, conventional kinesin appears to be well suited to be used to develop novel linear motor microdevices.

## 2. KINESIN BIOCHEMISTRY AND BIOPHYSICS

### 2.1. Molecular Structure of Kinesin

Conventional kinesin is a dimer [16] consisting of two identical 120- to 130-kDa chains, commonly known as heavy chains. When kinesin is purified from brain homogenates, two light chains (60–70 kDa) are found to be associated with the dimers [17]. These light chains, which are involved in the kinesin binding to organelles, are not essential for motility generation [18] and seem to have regulatory functions [19].

In the electron microscope, the conventional kinesin molecules appear to be rod shaped. The rods were found to have a diameter of 2–4 nm and a length of approximately 80–100 nm [20]. One end of each heavy chain reveals a globular head, while the opposite end is fan shaped [21]. Combining electron microscopic observations with data from limited proteolytic digestion and sequence analyses, the kinesin molecule can be divided into distinct structural domains (Fig. 1): a N-terminal head (or motor) domain comprising the amino acids 1 to 325, the neck region (up to position 374), a long-stretched stalk (up to 800), and the C-terminal tail domain (up to 963) [17].

The kinesin head domain, which is known to be a highly conserved region characteristic of very different members of the kinesin superfamily, contains both the microtubule-binding domain and the ATP-hydrolyzing center [17]. It has the shape of an arrowhead with dimensions of approximately 7.5 nm × 4.5 nm × 4.5 nm [23]. X-ray structural analysis revealed a central, eight-stranded  $\beta$ -sheet with three  $\alpha$ -helices on either side [23, 24].

The neck domain, which is conserved within certain kinesin classes [25], is believed to be essentially implied in

**Figure 1.** Domain structure of the conventional kinesin heavy-chain dimer, showing the crystal structure of the catalytic domains and the neck. The structure of the stalk and the tail are inferred from electron microscopic images and coiled-coil prediction analyses. Regions predicted to form coiled coils (neck, coil 1, coil 2, coiled-coil tail) and flexible regions (hinge, kink, stalk-tail linker) are indicated. Reprinted with permission from [22], G. Woehlke and M. Schliwa, *Nat. Rev. Mol. Cell Biol.* 1, 53 (2000). © 2000, Macmillan Magazines Ltd.

the dimerization of the kinesin heavy chains and in processive movement (see Section 2.4). Vale and co-workers [26] reported that deleting the neck coiled coil decreases processivity 10-fold, whereas elongating it by seven residues results in a threefold increase in processivity, indicating that the structural features of the neck coiled coil can tune the efficiency of the motor. It has been shown that the sequence 330–369 is mainly responsible for the formation of a two-stranded  $\alpha$ -helical coiled coil [27, 28]. Moreover, it was concluded that the kinesin neck linker functions as a mechanical amplifier for motion [29] and that directional bias of the working stroke is dependent on interactions of the neck with the motor core [30].

The stalk region is predominantly composed of an  $\alpha$ -helical coiled coil. The percentage of  $\alpha$ -helix formation depends on the temperature: At 4 °C up to 85–90% of the stalk was found to be  $\alpha$ -helices [31]. The poorly conserved C-terminal globular tail domain is implicated presumably together with the stalk in cargo binding. Unlike the head region, which is nearly neutral and the stalk region which is acidic, the tail is basic. This feature is highly relevant with respect to the electrostatic interaction between the heavy chain and the negatively charged surfaces of, for example, glass coverslips and latex beads [32].

The activity of soluble kinesin has been found to be repressible by an interaction between the N-terminal motor and the C-terminal cargo-binding tail domains [33].

The actual molecular structure of the kinesin molecule functionally depends on the state of the mechanochemical cycle; that is, it is coupled to microtubule binding, ATP binding, ATP hydrolysis, and the release of the hydrolysis products adenosine diphosphate (ADP) and  $P_i$  [34, 35].

### 2.2. Molecular Structure of Microtubules

Microtubules are obligate proteinaceous macromolecule complexes found in nearly all eukaryotic cells. In cooperation with other components of the cytoskeleton, namely, actin microfilaments and intermediate filaments, they constitute a functional unit that is involved in diverse cell physiological processes such as segregation of genetic material, intracellular transport, maintenance of cell shape, positioning of cell organelles, extracellular cilia-supported transport, and movement of cells by means of flagella and cilia. Irreversible elimination or functional inactivation of microtubules causes cell death.

Microtubules are described as hollow cylinders with outer and inner diameters of about 25 nm and 14 nm, respectively. Their lengths vary from a few to some tens of micrometers. The main constituent of the microtubules is tubulin, which is a globular protein existing in the native state as a heterodimer of an  $\alpha$  and a  $\beta$  form. Both monomers have a molecular mass of approximately 50 kDa and a diameter of about 4–5 nm. The longitudinal dimension of the dimer, which is 8 nm, defines the unitary step size of kinesin movement.

In the electron microscope, microtubules reveal characteristic subfilaments (called protofilaments) formed by longitudinal association of  $\alpha$ - and  $\beta$ -tubulin dimers. In mammalian neuronal cells, microtubules are composed of 13 protofilaments. In particular, the microtubules of lower

eukaryotes show a greater tendency to deviate from the 13-protofilament pattern. They were observed to have between 11 and 17 protofilaments [36]. Dependent on diverse factors, the protofilament number of microtubules assembled from purified tubulin under *in vitro* conditions varies from 8 to 18 [37]. It can be affected, for example, by a set of accessory proteins (microtubule-associated proteins, MAPs) [37], ionic strength [38], or special drugs like taxol [37, 39].

MAPs are known to inhibit kinesin attachment to microtubules [40]. Therefore, to study kinesin-driven motility, *in vitro* microtubules assembled from tubulin depleted of MAPs were usually used, which were stabilized by the addition of taxol (an anticancer drug obtained from the yew tree). Such microtubules are typically composed of 12 protofilaments [37] known to be tilted with respect to the tubule long axis, resulting in a right-handed helix with a supertwist pitch of 3.4  $\mu\text{m}$  [41]. The protofilaments of microtubules with 14 protofilaments revealed a left-handed helix with a 6.2- $\mu\text{m}$  supertwist pitch [41]. In the case of microtubules with a 13-protofilament pattern, the protofilaments run nearly parallel to the tubule long axis [41]. The orientation of protofilaments relative to the long axis defines the track along which the kinesin molecule moves (see Section 2.4).

Because of the dimeric character of the tubulin and the strict alternation of  $\alpha$  and  $\beta$ , one end of the protofilament is terminated by an  $\alpha$  subunit and the opposite one by a  $\beta$  subunit. This provides the protofilament a certain kind of polarity. The microtubule wall is composed of protofilaments laterally associated with the same polarity, which is reflected in cryoelectron microscope images and in three-dimensional reconstructions [42]. Consequently, one microtubule end exposes  $\alpha$  subunits (minus end) and the opposite end  $\beta$  subunits (plus end) only [43]. When the steady state of microtubule assembly is reached, at the plus end more dimers are added than lost. Conversely, at the minus end more dimers are released than new ones reassociate. This means that the microtubule is growing at the plus end while it is shrinking at the minus end. The direction the kinesin moves along a microtubule is related to its structural and kinetic polarity.

### 2.3. Conditions of *In Vitro* Motility Generation

The molecular mechanisms of movement and transport can be studied in a cell-free environment either by gliding of taxol-stabilized microtubules across kinesin-coated glass surfaces [14, 44] or by translocation of kinesin-coated polymer beads along immobilized microtubules [45]. The velocities of motility generated by conventional neuronal kinesin are typically found to be between 0.4 and 0.9  $\mu\text{m/s}$  [14, 46–48]. To generate kinesin-mediated motility, ATP is required as an energy source and  $\text{Mg}^{2+}$  ions as an obligate co-factor [49].

The application of ATP in the absence of  $\text{Mg}^{2+}$  or of nonhydrolyzable ATP analogues results in stopping motility. The  $\text{Mg}^{2+}$  ions can be replaced by some other divalent metal ions, among them  $\text{Ca}^{2+}$  and  $\text{Mn}^{2+}$  [50, 51]. Whereas the velocities of kinesin movement in the presence of  $\text{Ca}^{2+}$  were only about one-fourth compared with  $\text{Mg}^{2+}$ , the efficiency of  $\text{Mn}^{2+}$  was similar to that of  $\text{Mg}^{2+}$ .

Binding of the kinesin heads to a microtubule boosts the ATPase activity by a factor of up to 1000 [52–54]. Cargo binding also enhances the hydrolytic activity of kinesin [55]. The kinesin–microtubule system can be regarded as a self-regulating motor that utilizes its substrate resources very economically. Nature seems to have phylogenetically optimized the energy consumption of kinesin (as well as other motor proteins). Only very small amounts of ATP are hydrolyzed by kinesin in a nonactive state, that is, when it is not linked to microtubules or a cargo.

The velocity of kinesin-driven microtubule motility is fairly uniform from pH 6 to 9, with almost no motility outside this range [48, 56]. Kinesin was demonstrated to generate motility within the temperature interval from (at least) 5 to 45  $^{\circ}\text{C}$  [57]. Using temperature pulse microscopy, it has recently been shown that under favorable conditions kinesin can work for 30 min even at a temperature of 50  $^{\circ}\text{C}$ , where its velocity reached 3.68  $\mu\text{m/s}$  [58]. However, it has to be mentioned that kinesin purified from porcine brain gradually exhibits denaturation at temperatures above 45  $^{\circ}\text{C}$  [57].

It is known that each tubulin dimer of a microtubule is able to bind one kinesin head [59]. But Howard and co-workers [60] demonstrated that one kinesin molecule is sufficient to move a microtubule over micrometer distances. To support microtubule gliding, the density of kinesin immobilized to a given surface might be as low as 3.4 and 17 molecules per square micrometer for microtubules shorter and longer than 10  $\mu\text{m}$ , respectively [61]. The gliding velocity was found to be inversely proportional to the number of kinesin molecules involved in motility generation [48, 61].

### 2.4. Mechanism of Movement, Processivity, and Duty Ratio

Each tubulin dimer of a microtubule is capable of binding one kinesin motor domain. In the case of the two-headed (dimeric) conventional kinesin, two consecutive binding sites can be occupied on the microtubule [62], depending on the phase in the mechanochemical cycle. Whereas the binding to the microtubule was shown to be realized mainly via the  $\beta$ -tubulin subunit [63, 64], recent studies demonstrated that the two flanking  $\alpha$ -monomers can also be involved [65]. Interaction of kinesin with  $\beta$ -tubulin appears to be mediated mainly by electrostatic force [65]. For microtubule binding, it does not matter whether there is an  $\alpha$ - or a  $\beta$ -tubulin monomer in the lateral neighborhood to the protofilament track along which the kinesin is moving [64]. For the fast fungal kinesin from *Neurospora*, an additional interaction of the L11 structural part with the C-terminal region of the  $\beta$ -tubulin of the adjacent protofilament has been suggested [65].

Kinesin generates motility by walking step by step and hand over hand along the outer surface of a given microtubule protofilament [66]. As alternatives to the hand-over-hand model for movement, recently an “inchworm” model [67, 68] and a biased diffusion [67] model of processive movement have been proposed. Contrary to the hand-over-hand model, in the inchworm model the two heads do not change their positions relative to the walking direction.

This means that there is no net neck rotation during the mechanochemical cycle [68].

During its movement, kinesin follows one and the same protofilament [41, 64, 69]. Corresponding to this model, microtubules with 12 and 14 protofilaments, which are helically oriented around the tubule long axis (see Section 2.2), rotate as they glide across a kinesin-coated surface, depending on the pitch and the handedness of the supertwist. In contrast, 13-protofilament microtubules, whose protofilaments run more or less parallel to the tubule axis, do not rotate during gliding [41]. Interestingly, most of the cytoplasmic microtubules of higher eukaryotic cells are composed of 13 protofilaments [36]. Due to the different protofilament arrangements, an organelle moving along a 13-protofilament microtubule should reach the microtubule end in a shorter time than an organelle moving along a 12-protofilament microtubule of the same length. Obviously, nature has favored the 13-protofilament microtubule pattern for realizing efficient organelle transport with minimal energy consumption.

The kinesin heads translocate by turns in 16-nm steps, resulting in 8-nm center-of-mass shifts [34, 70]. Using an assay that resolves nanometer displacements with microsecond accuracy, Nishiyama and co-workers [71] demonstrated that the 8-nm shifts of the kinesin can be resolved into fast and slow substeps, each corresponding to a center-of-mass displacement of approximately 4 nm.

Conventional kinesin is a highly processive molecular motor that takes several hundred steps per encounter with a microtubule without dissociating [72–74]. One of the heads remains bound to the microtubule while the second one moves [41, 75]. Kinesin processivity is based on mechanical and chemical coordination between the ATP hydrolysis cycles of the two heads [76], resulting in conformational changes and coordinated consecutive translocations. Recently, it has been shown that one-headed members of the kinesin superfamily (e.g., KIF1A) can also realize movement in a processive fashion. This was explained by the existence of two microtubule-binding motifs in one head [77].

In governing the run length, that is, the distance a single motor protein travels per microtubule encounter, the neck coiled-coil region of kinesin was shown to play an important role. By adding positive charge to the neck coiled coil, Thorn and co-workers [78] created ultraprocessive kinesin mutants with fourfold longer run lengths than the wild-type motor, but with normal ATPase activity and motor velocity. Conversely, the addition of negative charge to the neck coiled coil resulted in a decrease in the run length. Furthermore, processivity is suppressible by either proteolytic cleavage of the negatively charged C-terminus of tubulin or an increase in the ionic strength, suggesting that processivity modulation by the neck coiled coil is based on an electrostatic binding mechanism with the COOH terminus of tubulin [78].

Besides the ionic strength, the processivity of kinesin can be also affected by other physicochemical parameters adjusted in its microenvironment: For example, it has been found that the average run length at around 50 °C was approximately 9  $\mu\text{m}$ , which significantly exceeds that at 20 °C [58]. Addition of ADP, released after ATP hydrolysis and competing for the ATP-binding site, was found to

decrease the run length even in the presence of saturating ATP [79]. The greatest run lengths that have been measured in a single molecule assay performed with a GFP kinesin construct containing the motor and a part of the stalk domain of conventional kinesin were about 10  $\mu\text{m}$  [40].

The question arises as to what limits processive movement. According to Hackney [80], ATP hydrolysis at the first head that is attached to the microtubule before the tethered second head can release its ADP and become tightly bound seems to be one cause of processivity limitation. We suppose that the helical arrangement of the protofilaments within a microtubule (see Section 2.2) might also decrease the kinesin run length, especially in cases where the motor protein transports a cargo along a microtubule immobilized to a substratum. Besides, restrictions of kinesin run length might be due to irregularities in microtubule structure, for example, incorrect dimer positioning, partially denatured dimers with alterations in their kinesin recognition site, or any other discontinuities within the protofilaments that hinder the kinesin in finding the next binding place on the microtubule.

In the context of possible nanotechnological applications of the kinesin motor, methodological approaches have to be developed that enable the transport of a cargo over distances exceeding the run length of a single kinesin molecule (see Section 3.8).

There is another relevant parameter that has to be considered in characterizing the mechanism of motor protein movement along a filamentous track. This is the so-called duty ratio, which is defined as the ratio of the time an intermittently operating device is working to the total time available [81]. In the case of motor proteins, the duty ratio indicates the fraction of time that a motor domain remains attached to the track during one full ATP hydrolysis cycle [82]. Compared to skeletal muscle myosin [83, 84], conventional kinesin has a high duty ratio, which is about 0.5 [18]. This means that a kinesin head is attached to the microtubule track over half of a full mechanochemical cycle. A high duty ratio seems to be the basis for the movement of kinesin along a microtubule over micrometer distances [82].

## 2.5. Directionality and Forces Generated by Conventional Kinesin

The direction of kinesin movement depends on both the microtubule polarity and the intrinsic molecular structure of kinesin [82, 85, 86].

Conventional kinesin is known to be a plus-end-directed motor. There are a few other kinesin-like motors that move to the minus end: Examples are the nonclaret disjunctional protein *ncd* [87] and the yeast *Kar3* [88], both required for chromosome distribution, and *KIFC3*, involved in the apical transport of renal tubular epithelial cells [89]. The direction in which the kinesin motor moves obviously depends on the location of the motor domain. Dimeric constructs with the motor domains either at the N- or the C-terminal end of the heavy chain were shown to move toward microtubule plus or minus ends, respectively [90]. The directionality of kinesin seems to be also dependent on neck/motor core interactions [30].

Several approaches have been used to measure forces generated by single kinesin molecules, including movement against a viscous load [61], a centrifuge microscope-based motility assay [91], optical trapping interferometry to track movement [92, 93], and a bead assay in an optical microscope equipped with optical tweezers [94]. Forces in the range of 4–8 pN were determined. So far, we do not know what forces are generated when *more than one kinesin molecule* contributes cooperatively to the transport of a cargo (see Fig. 2) and whether or not the kinesin molecules are self-synchronizing in such a case.

## 2.6. Advantages of Kinesin for Nanoactuatoric Systems

The movement of dimeric kinesin involves a highly coordinated interaction between both heads of the kinesin molecule and the microtubule rail. Both heads alternate in their binding. When one of the heads is released from the microtubule surface, the second one is bound, resulting in a permanent attachment of the kinesin to the microtubule, which is in contrast to, for example, myosin II [95]. Consequently, the kinesin is able to walk over distances up to some micrometers before being detached, which makes it suitable for conveying a cargo steadily and reliably to its destination.

Besides dimeric kinesins, some myosins, namely, myosin V [96] and myosin VI [97] as well as cytoplasmic dynein [98],

also reveal processivity. However, their usability in artificial transport systems seems to be strongly limited for the following reasons:

- Myosins walk along the microfilaments. For microfilaments, a mean flexural rigidity of  $7.3 \times 10^{-26} \text{ N m}^2$  was measured [99], which seems to be too low to form rigid stable rails supporting a nearly straight-line movement of the motor.
- Although cytoplasmic dynein also uses microtubules as rails, its processivity seems to be a more complex mechanism, requiring the activity of additional regulator proteins [98]. Processivity of the 22S subunit of axonemal dynein has been shown to be induced at low ATP concentration [100] only. A diminished ATP supply, however, might decrease the lifetime of the motor system.
- While much progress has been made on the biochemistry and mechanochemical cycles of conventional kinesin and myosin II [101], significantly less is known about cytoplasmic dynein. One main reason for this is the high complexity of the dynein molecule, which consists of two heavy chains and 8 to 11 diverse accessory polypeptides [98].

On the contrary, kinesin has some striking advantages favoring its use for nanoactuatoric systems:

- Kinesin is known to be a motor with high directional stability. It moves along one and the same microtubule protofilament [102]; that is, the lateral deviation from the track line is within the limits of 5 nm (protofilament diameter).
- The microtubules are believed to be more suitable for forming a stable straight-line rail as they have a much higher flexural rigidity ( $2.1 \times 10^{-23} \text{ N m}^2$  [99]) than the microfilaments.
- Kinesin has a relatively low torsional stiffness of approximately  $4 \times 10^{-21} \text{ J}$ , which allows for twisting a kinesin molecule at room temperature through more than  $360^\circ$  from its resting orientation [103]. This high flexibility might explain how several motors can efficiently work together even if they are randomly oriented on the surface of a cargo or on the substratum [103].
- Kinesin is able to utilize not only ATP as fuel but also some other nucleoside triphosphates such as GTP. If some kinesins with GTP specificity could be found or created by molecular engineering, they could be involved in a transport device together with other motors requiring exclusively ATP, for example, together with the oppositely directed cytoplasmic dynein, to get shuttle systems with forward and backward movement.

**Figure 2.** Principal schemes of kinesin-based nanoactuators realizing the transport of a cargo: (a) elementary motor unit (a single kinesin molecule), involving one microtubule in the transport; (b) serial alignment of motor units, involving more than one kinesin molecule moving along one and the same microtubule rail; (c) serial and parallel (isopolar) alignment of motor units (the transport is realized by different kinesin molecules moving along different microtubule rails). C, cargo; S, substratum; K, kinesin dimer; MT, microtubule with plus and minus ends.

There is another important argument related to the present state of methodological know-how that makes the kinesin force-generating system superior to other motors for nanoactuatoric applications: This concerns the possibility of preparing chemically stabilized arrays with microtubules arranged in parallel and isopolar fashion. Such arrays were demonstrated to be suitable rails for kinesin to transport a cargo in a predetermined direction [104, 105].

### 3. CONFIGURATION OF A KINESIN-BASED TRANSPORT DEVICE

#### 3.1. Basic Requirements

A kinesin molecule can be regarded as an engine moving with nanometer precision along fixed proteinaceous rails (Fig. 2). Converting the chemical energy of the biofuel ATP into mechanical energy, it conveys different kinds of nano- and micrometer-sized cargoes to their destination points.

Within the last five years, great efforts have been made to introduce the kinesin-microtubule machinery into the development of miniaturized technical transport devices. However, before this biomotor can be really exploited, numerous methodological and technical problems have to be solved. Complex studies have to be performed to learn, for example, to regulate the velocity and to increase the lifetime of the kinesin motor, to find out technically relevant materials enabling its work in a cell-free environment, to perform transport events with nanometer precision, or to control the direction of force generation.

Another problem concerns the lengths of the transport tracks. In single-molecule experiments, the distance a kinesin molecule can move was found to be limited to its maximum run length of about 10  $\mu\text{m}$  [40] and to the lengths of the microtubules used as rails, which were on the order of magnitude of some tens of micrometers. Some special nanotechnological applications might require methodological approaches enabling the transport of a cargo over distances greater than the kinesin run length and the microtubule length.

Furthermore, the clearance allowing for kinesin force generation seems to be important to work out the basic configuration of a kinesin-driven motor device incorporated into a spatially limited system (chambers or pipes with submicrometer heights or diameters, respectively). Interesting first approaches have been published (see [106]), contributing to the solution of these problems and being large steps on the way to engineering complex nanoactuators and nanorobots driven by biomotors.

#### 3.2. Preparation of the Protein Constituents

**Microtubules** Microtubules are ubiquitous structures found in eukaryotic cells. Neuronal tissue is known for its high tubulin content. In rat brain, the percentage of tubulin in the soluble protein fraction is about 33% at birth and 20% 15 days after birth, respectively [107]. Therefore, mammalian brain routinely serves as a source for microtubule isolation.

Standard protocols, used in many laboratories throughout the world for purification of microtubule protein especially from brain tissue, are based on temperature-dependent assembly-disassembly cycles in combination with ultracentrifugation [108]. It has to be mentioned that the protein preparations obtained in this way contain a defined set of accessory proteins called MAPs. The quantity and quality of MAPs, including the high-molecular-weight MAP1 and MAP2 (280–320 kDa) and the group of  $\tau$  proteins (65–70 kDa), depend on details of the preparation protocol. The amount of MAPs co-purified can be lowered, for example,

by adding glycerol or by increasing the ionic strength within the buffer [109, 110]. Both high-molecular-weight MAPs and  $\tau$  proteins are described to hinder kinesin binding to microtubules [40]. Therefore, MAP-free microtubules have to be used in kinesin motility assays. The MAPs can be separated from tubulin by phosphocellulose column chromatography [111]. Using the assembly-disassembly protocol of Shelanski and co-workers [108] in combination with phosphocellulose column chromatography, one obtains about 100 mg tubulin from 1 kg porcine brain.

Recently, a protocol has been published that enables tubulin synthesis in *Escherichia coli* [112]. The most critical point in recombinant tubulin preparation was to get assembly-competent protein. Shah and co-workers employed rabbit reticulocyte lysate, containing both the cytoplasmic chaperonin CCT and its co-factors, to form  $\alpha$ - $\beta$ -tubulin dimers that self-assemble into microtubules of normal morphology [112]. This approach offers a good chance for large-scale production of tubulin with reproducible quality. The availability of recombinant tubulins is also a main goal of pharmaceutical biotechnology, which needs standardized tubulins for the sophisticated search of novel cancerostatic drugs and for their evaluation.

The microtubules used in kinesin-based motility assays can be formed by 20-min incubation of pure tubulin at 37 °C with 1 mM GTP and 10  $\mu\text{M}$  taxol as assembly promoter and microtubule stabilizer. It is possible to store these microtubules in a frozen state for some months.

To obtain a matrix of densely packed microtubules, about 40 ng tubulin per square millimeter or 40 mg per square meter are required.

**Kinesin** To functionalize a 1-mm<sup>2</sup> surface, approximately 2–4 ng kinesin are needed. Kinesin can be purified from different organisms, tissues, and cells. Special protocols are available for fungi (*Neurospora*) [47], HeLa cells [113], *Dictyostelium amoeba* [114], and mammalian brain [52, 115].

Besides some others (see, e.g., [70]), a standard purification procedure was published for brain tissue by Kuznetsov and Gelfand [52, 115], which includes homogenization and preparation of a high-speed supernate followed by ion-exchange chromatography, tripolyphosphate-supported microtubule affinity binding, and gel filtration. This procedure yields about 2 mg kinesin from 1 kg brain with both ATPase and motility-generating activity, which can be frozen and stored in liquid nitrogen for several months.

Biochemical isolation of motor proteins from their natural sources has some distinct advantages: First, the motor will be properly folded and has normal posttranslational modifications. Second, the motor will carry with it a normal complement of associated proteins. Studies of kinesin-associated proteins will be important in learning how this motor accomplishes its tasks *in vivo* [116]. Today, it is well proved that for motility generation in a cell-free environment kinesin does not need any accessory proteins. Therefore, recombinant kinesins are produced with constant quality in relatively large amounts. Different expression systems for conventional kinesins are described, for example, by Navone and co-workers [117] and Niclas and co-workers [118]. Moreover, genetic engineering has proved its ability to supply numerous kinesin constructs with specialized properties,

for example, with improved processivity or higher velocity [76, 119] (see also Section 2.3). Genetic engineering is also expected to contribute to prolongation of kinesin lifetime. Another task arising in connection with nanotechnological requirements might be the addition of a specific cargo-binding domain to the kinesin tail that recognizes different kinds of materials.

### 3.3. Regulation of Transport Velocity

The velocities of microtubule gliding supported by conventional kinesin, measured in a cell-free environment at  $Mg^{2+}$  and ATP concentrations both around 1 mM and at room temperature, were about 0.4–0.9  $\mu\text{m/s}$ . For comparison, a conventional kinesin from the fungus *Neurospora* was found to walk significantly faster (up to 3.8  $\mu\text{m/s}$  [47]). In contrast, the mitotic kinesin Eg5, which is another plus-end-directed motor, moves only at about 0.06  $\mu\text{m/s}$  [120].

Kinesin-driven microtubule gliding can be accelerated by increasing the ratio of  $Mg^{2+}$  to ATP concentration [48, 74] and by temperature elevation [57]. At high temperature (50–60 °C), velocities up to 3.7  $\mu\text{m/s}$  were measured for kinesin purified from brain [58].

Howard and co-workers [60] demonstrated that microtubule gliding still occurs at kinesin densities as low as one molecule within an area of about 700 nm  $\times$  700 nm. When the surface density of kinesin bound to the substratum was increased, the velocity of microtubule movement across kinesin-coated glass surfaces was found to be lowered [48, 61].

It is known that under conditions of saturation each kinesin dimer occupies two microtubule-binding sites, provided that there is a free one close by [62] and that movement does not start before the next binding site at the microtubule surface has become free. Consequently, the higher the kinesin density, the higher should be the probability that the next binding site is occupied, resulting in a decrease in the mean velocity of kinesin translocation.

Another explanation for the slowdown in kinesin movement as a result of elevating kinesin surface density might be the asynchronous work of single kinesin molecules collectively contributing to the transport of a given cargo (see Fig. 2). At high density, more than one kinesin molecule might bind to one and the same protofilament of a gliding microtubule. It seems to be even likely that in such a case kinesin molecules binding to adjacent protofilaments contribute to the movement of the microtubule. In this context, the question of the self-synchronization of kinesin work has to be discussed.

Further ways to throttle the velocity of kinesin movement are the addition of polyhydroxy compounds [121], lowering the  $Mg^{2+}/\text{ATP}$  ratio [48], or the replacement of the  $Mg^{2+}$  ions by  $Ca^{2+}$  and other alkaline earth metal ions [50]. Alternatively, certain drugs might be applied to slow down kinesin movement. In a single-molecule motility assay, local anesthetics such as tetracaine and lidocaine reversibly inhibited the motility of individual kinesin molecules in a dose-dependent manner [122].

Regulation of the velocity is tightly correlated with the problem of how to start or stop kinesin movement within the shortest time intervals. The kinesin motor works with 8-nm

feed. This means that at velocities between 0.4 and 0.9  $\mu\text{m/s}$  each step takes about 9–20 ms (in the case of *Neurospora* kinesin, even about 2 ms). To stop movement with nanometer precision, the motor should be switched off in millisecond ranges. By “chemical switching” such as the removal of ATP or  $Mg^{2+}$  or the introduction of additives slowing down kinesin movement, the motor can be started or stopped only within a few tens of seconds. A first approach to cope with this challenging task is the application of hexokinase and 1-(4,5-dimethoxy-2-nitrophenyl) ethyl-caged ATP instead of the usual (noncaged) ATP [123], which is converted from an inactive state into an active state during exposure to ultraviolet (UV) light. This system enables one to switch kinesin movement within some seconds.

### 3.4. Lifetime and Energy Supply

Kinesin-based motility generation can be maintained in a cell-free environment at least over three hours when desiccation is avoided and ATP is available in sufficient quantity [48]. Thereafter, the binding strength of kinesin to the glass support and/or the microtubule rails was found to be lowered rapidly, obviously due to protein degradation.

Our own investigations indicated that chambers with microtubules gliding across kinesin-coated surfaces can be stored for some days in a frozen state. After rethawing, the microtubules continued to move (not published).

ATP complexed with  $Mg^{2+}$  is commonly known to supply the energy for kinesin motility. Other nucleoside triphosphates, including guanosine triphosphate (GTP) and uridine triphosphate (UTP), can also be used as an energy source, but the velocity of kinesin movement is remarkably lower in these cases [56].

Both ATPase activity and kinesin-driven microtubule gliding follow Michaelis–Menten kinetics with an apparent  $K_m$  value of approximately 60  $\mu\text{M}$  [46, 48, 56]. Kinesin-driven microtubule gliding as well as the translocation of kinesin-coated beads is usually performed at an ATP concentration of 0.5 mM, corresponding to  $0.3 \times 10^{15}$  ATP molecules within a chamber of 1  $\mu\text{L}$  volume. Each kinesin molecule consumes one molecule ATP to translocate a 200-nm silica bead over a distance of 8 nm [124]. This means that with  $0.3 \times 10^{15}$  ATP molecules a bead can be theoretically moved over distances up to  $2.4 \times 10^6$  m. An alternative calculation gives  $4.8 \times 10^9$  beads that can be transported over a track length of 5 mm. However, it should be mentioned that the adenosine diphosphate (ADP) released during the mechanochemical cycle of kinesin acts as a feedback effector with inhibiting activity. Whereas the kinesin run length at zero-load condition was observed to be independent of the ATP concentration from micromolar to millimolar concentrations, the addition of ADP in the presence of saturating ATP decreased both the velocity and the run length. At 2 mM ATP and 2 mM ADP, a 50% inhibition of the kinesin run length and velocity was measured [79]. To get over this problem especially in cases of high ATP turnover rates, an ATP-regenerating enzymatic system was proposed [106]. Such a system, however, comprises further more or less sensitive proteins whose activities might be nonstable in a cell-free environment. Alternatively, the ATP concentration can be maintained on a nearly constant level by a permanent exchange of the ATP-containing soluble phase.

### 3.5. Cargo Materials and Surface Requirements

The cargoes to be transported by kinesin or the supports used to carry the biomolecular force-generating motor unit can be made from a broad variety of materials, including glass, quartz, carbon, gold, polystyrene, and the microtechnologically outstanding silicon [125]. The main transport parameters (e.g., velocity, maximum distance the load is transported, and lifetime) were found to be practically independent of the kind of material used.

For functioning of the motor system, the quality of the surface to which the kinesin binds seems to be of great importance. One main requirement on which kinesin-mediated motility generation crucially depends is a low surface roughness and a minimum of contaminating surface-bound particles. Silicon wafers with etched steps of defined height and edge steepness were used to find out the critical height difference kinesin-driven gliding microtubules tolerate. It was observed that such microtubules could overcome steps upwards up to at least 280 nm at an edge angle of 60°–70° [104]. Under favorable conditions when the gliding microtubule approaches the step at low angle, even steps of 1  $\mu\text{m}$  can be climbed up [123]. These observations suggest that knolls and dells on the surface as well as dust particles (provided that they are without any microtubule-binding affinity) with dimensions up to 1  $\mu\text{m}$  do not prevent transport processes realized by kinesin-driven gliding microtubules.

The requirements concerning surface purity and evenness seem to be remarkably higher for transport systems where kinesin drives a bead along immobilized microtubules. In this case, beads were often observed to stop when they encounter a micrometer-sized obstacle on the microtubule and/or the glass surface [105]. This problem might be solved using arrays of densely packed isopolar microtubules and loading the beads with a higher number of kinesin molecules. Under such conditions, moving beads were seen to go around the obstacle, obviously using adjacent microtubule rails [105].

### 3.6. Critical Clearance

Concrete tasks in the development of kinesin-based machinery might be the relative displacement of two thin plates against each other or the transport of a cargo into or through pipes with diameters in the nanometer range. In this context, it is necessary to determine the minimal distance between the cover and the bottom surface (clearance), which still allows kinesin-dependent force generation.

Stracke and co-workers [104] studied kinesin-driven microtubule gliding in clefts of defined height to measure the clearance the kinesin requires. Such clefts can be formed by a slightly curved coverslip (made by thermal deformation under one-sided pressure), which was approximated by a small vacuum chamber with convex side down to a glass slide. Around the contact point between the coverslip and the slide, Newton rings appear, enabling interferometric determination of the distance between both glasses. Using this approach, gliding was observed, in principle, down to approximately 100 nm [104], which crudely corresponds to

the length of the kinesin molecule (80–100 nm) plus the diameter of the microtubule rail (25 nm). When the height of the gap was lowered to values below 100 nm, only in single cases were microtubules observed to migrate and their leading edges often stuck and the tails revealed a fishtailing-like movement [104]. Thus, a height of 100 nm is proposed to be the critical clearance for kinesin moving along a microtubule.

It has to be mentioned, however, that the velocity of gliding microtubules was significantly reduced in clefts with heights just below 5  $\mu\text{m}$ . This effect is at least partially due to limitations in fuel supply and can be minimized by increasing the ATP concentration [104].

### 3.7. Regulation of Transport Direction

A crucial point in the development of cell-free kinesin-based machinery is the predetermination and control of the transport direction. Both microtubules gliding across a kinesin-coated surface and kinesin-coated beads translocating along immobilized microtubules are experimental approaches in which motility is generated in two-dimensional systems. The first step on the way to control the transport direction is the restriction of motility generation to one dimension, resulting in shuttle systems with forward and backward movements.

In recent years, it has been shown that the kinesin-dependent transport can be limited to one dimension using different kinds of guiding channels: Wittmann and Smith [126] described a shear deposition method by which glass surfaces can be coated with thin polytetrafluorethylen (Teflon) films, leaving parallel nanometer-deep grooves free of the polymer. Whereas the Teflon does not bind proteins, kinesin is attached to the polymer-free surface on the bottom of the grooves. Dennis and co-workers [127] demonstrated that such kinesin-coated grooves can serve as channels to guide gliding microtubules in nearly straight lines.

Turner and co-workers [128] prepared lithographically patterned silane surfaces to which microtubules were attached under the action of an external flow field. Under such conditions, the microtubules adhered in parallel fashion, retaining their ability to serve as rails for the transport of kinesin-coated beads [128]. Limberis and Stewart succeeded in moving even large kinesin-coated silicon microchips (10  $\mu\text{m} \times 10 \mu\text{m} \times 5 \mu\text{m}$ ) along parallel microtubules immobilized to trimethoxysilylpropyl-diethylenetriamine silane-treated glass coverslips during flow field action [129]. Remarkably, the maximum velocity at which the microchips moved (0.8  $\mu\text{m}$ ) was in the same range as determined for microtubules gliding across a kinesin-coated surface (see Section 2.3).

Another remarkable contribution toward guiding kinesin movement was made by Hess and co-workers [130]. These authors introduced a pinwheel pattern of tracks selectively binding the motor protein and open 1- $\mu\text{m}$ -deep and 2.5- $\mu\text{m}$ -wide guiding channels to realize the one-directional sorting of kinesin-based shuttles. They suggested that a Brownian ratchet mechanism is the basis of this kind of sorting in the case when the pattern includes motor protein-rich and motor protein-free surface regions and the directional change of the molecular shuttle is caused by Brownian motion.

The approaches described above allow the kinesin to be guided in linear parallel tracks. The transport direction is unpredictable, however, so that the load can be moved forward and backward, depending on the orientation of the majority of microtubules contributing to the transport. To guide the kinesin to a desired destination point, it is necessary to align the microtubule rails not only in parallel fashion but additionally with equal polarity. Otherwise, the elementary forces generated along adjacent microtubules act in a different direction and may neutralize each other more or less completely. Therefore, procedures in which the microtubules are not aligned with the same polarity are not well suited for efficient transport of large cargoes binding to more than one microtubule and, consequently, can find only a limited application in nanotechnology.

So far, three promising approaches were described to regulate the direction of kinesin-supported movement: Microtubules were aligned in parallel and isopolar fashion during gliding across kinesin-coated glass surfaces by application of flow fields (Figs. 3 and 4) [104]. However, when the flow was abolished the microtubules immediately started to move again in a directionally uncontrolled manner. It is known that microtubules treated by glutaraldehyde retained their potency to serve as tracks for kinesin movement [131]. Using this protocol, the aligned microtubules can be immobilized with isopolar orientation. When the microtubules were applied at high density, the stable microtubule arrays were formed able to transport kinesin-coated particles into a predetermined direction in the absence of flow [105]. This approach has the advantage that large areas of a given substratum surface can be densely covered with isopolar microtubules, along which the transport can be realized over

**Figure 3.** Mechanism of isopolar microtubule alignment in flow fields. (a) Especially in cases of relatively low kinesin densities, the leading end (minus end) of a microtubule gliding across a kinesin-coated substratum is often observed lifting off from the surface and wobbling in the  $y$  direction [104]. (b) When a transverse force (generated, e.g., by a flow field) acts laterally on this end, it turns in the flow direction guiding the whole microtubule in the flow direction. Blue arrow, direction of force exerted by the flow field; black arrow, lifting off of the microtubule end from the substratum; green arrow, wobbling of the microtubule end in the  $y$  direction; red arrow, direction of the resulting force driving the microtubule. The numbers indicate individual microtubules.

**Figure 4.** Flow field-induced isopolar orientation of microtubules gliding across a kinesin-coated substratum, visualized by video-enhanced differential interference contrast microscopy: (a) stochastic microtubule gliding; (b) and (c) consecutive microtubule alignment after application of a flow field. The leading (minus) end of the microtubules is turned in the flow direction. The bars represent  $5 \mu\text{m}$ .

distances exceeding the length of an individual microtubule (see Section 3.8).

Another efficient approach to obtain isopolar microtubule rails to direct kinesin-mediated transport in a desired direction has been published by Limberis and co-workers [132] who attached a histidine-tagged anti- $\alpha$ -tubulin antibody to a hydrophobic glass coverslip (Fig. 5). This antibody fixes the microtubules selectively by their minus ends onto the glass. When a fluid flow was applied, these one-point fixed microtubules turned into the flow direction. As a result, about 90% of the microtubules were found to be oriented with their minus ends pointing upstream. Reorientation of the microtubules could be prevented by the addition of a 0.2% solution of methyl cellulose [132].

Alternatively, Hiratsuka et al. [133] produced linear microlithographic tracks on glass surfaces supplemented with mechanical rectifiers of an arrowhead pattern (Fig. 6). When the surface of such channel-like tracks was functionalized with kinesin, gliding microtubules were forced to move preferentially in one direction. The efficiency of unidirectional rectification of gliding microtubules correlated to the arrowhead geometry. Using a surface on which the tracks form a complex meander, a cargo bound to a microtubule can be transported precisely from one point to another within a two-dimensional system (Fig. 7). Microlithography allows for the production of not only linear but also circular tracks, enabling unidirectional rotational movement of the microtubules (Fig. 8) [133].

**Figure 5.** Immobilization and polar alignment of microtubules. A metal-chelating Pluronic surfactant is used to immobilize the minus end of the microtubules on a hydrophobic microscope coverslip using a histidine-tagged  $\alpha$ -tubulin single-chain antibody. The microtubules are polar aligned by fluid flow in a flow chamber. Reprinted with permission from [132], L. Limberis et al., *Nano Lett.* 1, 279 (2001). © 2001, American Chemical Society.

**Figure 6.** Arrowhead pattern functioning as a rectifier of microtubule movements. A shows that a microtubule entering the arrowhead from the correct direction (from the left-side entrance) passes through the arrowhead pattern. B demonstrates schematically how a microtubule entering the arrowhead from the wrong direction (from the right-side entrance) makes a 180° turn and moves out in the correct direction. C is the actual sequence of fluorescence images showing the turning of a microtubule in an arrowhead pattern. Images were captured with an SIT camera at a rate of 8 s per frame. Reprinted with permission from [133], Y. Hiratsuka et al., *Biophys. J.* 81, 1558 (2001). © 2001, Biophysical Society.

### 3.8. Length of Transport Tracks

The parameter run length was introduced to characterize the distance a *single* motor protein molecule walks along its filament. The maximal run length of kinesin that has

**Figure 7.** Active transport between two pools of micrometer scales: (A) transmission micrograph; (B) fluorescence image of rhodamine-labeled microtubules taken before the addition of ATP; (C) taken 18 min after the addition of ATP. Scale bar, 30 μm. A movie of this movement is available online at <http://unit.aist.go.jp/genediscry/motility/biophysj/moviedl.html>. Reprinted with permission from [133], Y. Hiratsuka et al., *Biophys. J.* 81, 1558 (2001). © 2001, Biophysical Society.

**Figure 8.** Unidirectional rotational movement of microtubules along circular tracks. The photographs represent snapshots of the movement of rhodamine-labeled microtubules taken at intervals of 72 s, 20 min after the addition of ATP (B–F). A shows an image of the transmission microscopy. Selected filaments were colored to allow tracking of groups of microtubules. Microtubules in the outer circle are moving clockwise (red), whereas those in the inner circle are moving counter-clockwise (green). Scale bar, 20 μm. A movie of this movement is available online at <http://unit.aist.go.jp/genediscry/motility/biophysj/moviedl.html>. Reprinted with permission from [133], Y. Hiratsuka et al., *Biophys. J.* 81, 1557 (2001). © 2001, Biophysical Society.

been reported so far was near 10 μm [40]. This seems to be the first limitation when a cargo has to be transported by the kinesin–microtubule machinery over longer distances. The second one is related to the length of individual microtubules used as transport rails. Taxol-stabilized microtubules formed from MAP-free tubulin under laboratory conditions in a cell-free environment are usually about 5–40 μm long, depending on the tubulin concentration, the speed of increasing temperature to start assembly, and the time the microtubules were held at the assembly temperature (own observation).

Therefore, the question arises as to how to support the cargo transport over distances significantly exceeding the microtubule length. Howard [69] reported that, at high kinesin density, microtubules gliding across a surface with immobilized kinesin can cover distances much greater than their length. This can be realized only in the case when the surface density of kinesin is high enough to ensure that the moving microtubule is able to encounter in its nearer surrounding the next active kinesin molecule.

When a cargo should be transported by kinesin along microtubule rails over distances exceeding the microtubule length, a second requirement has to be fulfilled besides a sufficiently high kinesin surface density. This concerns special conditions ensuring the efficient transition of the cargo from one microtubule to an adjacent one. Using small polystyrene beads (0.1 μm in diameter) to get a high resolution, such transition events have been directly observed by real-time video interference contrast microscopy [105]. The beads were found to change microtubule rails without remarkable interruption of movement after reaching the end of the microtubule rail.

With micrometer-sized beads and densely packed isopolar microtubule arrays, the transition probability proved

to be remarkably higher. Under such conditions, different kinds of cargoes (latex, glass, gold beads, flat glass particles) were transported by kinesin over some millimeter distances. Böhm and co-workers [105] succeeded in driving large kinesin-coated flat particles ( $24 \mu\text{m} \times 12 \mu\text{m}$  and  $2\text{--}5 \mu\text{m}$  thickness) across the surface of isopolar microtubule arrays without interruption over a distance of  $130 \mu\text{m}$ . Such particles, which were shown by laser scanning microscopy to contact more than one microtubule, moved unidirectionally at velocities of  $0.5\text{--}0.6 \mu\text{m/s}$ , known for microtubule gliding or the translocation of  $100\text{-nm}$  beads. Comparable control experiments performed with microtubules nonaligned in an isopolar fashion also revealed moving particles. However, the distances they could cover were only in the range of a few micrometers. Especially, large particles were found to rotate or to go forward and within some seconds back again. Similar observations were made when the translocation of silicon microchips across arrays of geometrically parallel microtubules with different polarity was followed [129]. This behavior can be explained by counteracting forces generated by kinesin moving along nonisopolar microtubules.

The finding that the track lengths of kinesin-driven cargoes can significantly exceed the lengths of individual microtubules is of eminent practical value. It demonstrates that it is not necessary to produce long individual microtubules when distances in the millimeter range should be covered.

#### 4. POSSIBLE APPLICATIONS AND OUTLOOK

Recently, a first interesting application of the kinesin motor system has been introduced by Hess and co-workers [134], who assembled a piconewton forcemeter consisting of two microtubules (Fig. 9): Whereas the first microtubule serves as a molecular cantilever fixed with one end and freely swinging with the opposite one, the second microtubule moves across a kinesin-coated surface perpendicular to the first microtubule. After contact, the cantilevered microtubule is bent when a link through the receptor/ligand complex of interest is established. The applied force is calculated from the known flexural rigidity of the microtubules [134].

Potential applications of cell-free nanomotors and nanoactuators include the following:

- Switchable linear motor devices and molecular machines working with nanometer precision, which might be applied for directionally controlled displacement of objects or for specific and directed substance transport over nanometer, micrometer, or millimeter distances. Such devices can contribute to nanostructure assembly and nanostructure fabrication.
- Transport of chemical components or catalysts into or out of microreactors, used, for example, for enhancing and controlling reactions.
- Development of intracellular sensors for diagnostic purposes.
- Delivery systems to convey drugs to pathological targets.

**Figure 9.** The cantilevered microtubule (MT) is attached on one end to a clump of beads, while the other end is suspended above the surface. Swiveling due to Brownian motion causes the smeared-out appearance of the free end. The moving microtubule is propelled by kinesin motor proteins adsorbed on the surface and carries a clump of beads. The snapshots show how the moving microtubule approaches (0 s), makes contact (10 s), bends (20 s, 30 s), and releases (40 s) the cantilevered microtubule. Reprinted with permission from [134], H. Hess et al., *Nano Lett.* 2, 1113 (2002). © 2002, American Chemical Society.

- Screening systems for developing novel therapeutic drugs targeting cellular movement.
- Autonomously working power units to drive implantable sensors using the cell ATP.
- Cell biological tools to study functional or regulatory mechanisms of motor protein-based force generation.

Although long-term technological impacts are difficult to predict, it seems to be realistic that motor protein-based force generation might be involved in the future development of novel nanoactuatoric systems, including miniaturized energy conversion and biofuel cells, implantable microdevices and sensors, separation techniques, as well as the assembly of nanotechnical circuits or microrobots.

Taken together, the design and control of kinesin-based nanoactuatoric devices have been advanced, but several basic problems remain to be solved until such a device can be introduced as an integral part into complex nanoactuatoric machines or robots. One main point that has to be addressed in the future is the regulation of starting and stopping force generation under cell-free conditions in the millisecond range, that is, with nanometer precision. Further unsolved problems concern the maximum load mass that can be moved by a collective of kinesin molecules and the synchronization of the great number of kinesin molecules contributing to the transport of one and the same cargo.

On the ambitious way toward the nanoactuatoric application of biomotors, further cell biological, biochemical, biophysical, and developmental work has to be done to improve the technical performance of these motors.

## GLOSSARY

**Adenosine triphosphate** A ubiquitous biofuel that supplies the energy required for various biological processes of transport and movement.

**Kinesin** A specialized motor protein that, moving along microtubules, is responsible for the transport of cell organelles and biomacromolecules.

**Microtubules** Proteinaceous hollow cylindrical filaments of 25 nm diameter and lengths in the micrometer range that constitute the rail for movement of kinesin (and some other motor proteins).

**Motor protein** A protein with catalytic (enzymatic) activity that converts the chemical energy of adenosine triphosphate into mechanical energy to move along the surface of suitable proteinaceous filamentous rails. The direction of its movements is strongly related to both the intrinsic molecular structure of the motor protein and the polarity of the filament.

**Polarity** The feature of a proteinaceous filament to expose two ends with different dissociation constants of the subunits that form the filament.

**Processivity** The feature of a motor protein to remain bound to the filament it moves along and to hydrolyze substrate molecules through several repetitious hydrolytic cycles.

**Run length** The distance a single motor protein molecule walks along the filament without being released from its surface.

## ACKNOWLEDGMENT

The authors are grateful to Roland Stracke for helpful discussions, numerous advice, and a critical reading the manuscript.

## 1. CLASSIFICATION OF NANOSTRUCTURED SYSTEMS

Dispersed systems can be represented by the following structure levels:

1. atomic-molecular (0.1–1 nm)
2. macromolecular and cluster (0.5–5 nm)
3. microscopic or grain-heterophased (>5 nm to 1000  $\mu\text{m}$ )
4. macroscopic (>1000  $\mu\text{m}$ )

Nanostructured systems are a special group of physicochemical systems with unique properties determined by the small size of the structural elements composing them. Important physical and practical phenomena can be observed in the transition of structural elements up to the nanoscale. As a whole, nanostructured systems should be viewed as a part of a wider class of dispersed systems. From the viewpoint of physics, they are determined as heterogeneous systems consisting of at least two or more phases with well-developed interfaces; one of the phases is very dispersed, and the medium surrounding it is called a dispersing medium. By aggregate state, it can be gas, liquid, or solid. Depending on this, the system may be flowable or solid. The latter includes a great number of dispersed systems such as minerals, rocks, composite materials, heterophased alloys, organic tissues, and even microorganisms.

In general, dispersed systems are divided into coarsely dispersed and ultrafine ones. In the former the average characteristic size of structural elements is more than  $10^{-6}$  m. The fine systems have structural elements smaller than  $10^{-6}$  m and ultrafine ones smaller than  $10^{-7}$  m. Fine and ultrafine

systems are well known in colloid chemistry as liquid dispersed media, such as emulsions, suspensions, colloidal solutions (sols), and the products of their coagulation (gels). Such systems as sprays, vapors, smoke, and especially solid dispersed structures have not been given enough attention by colloid chemistry. Modern physics pays a lot of attention to solid dispersed structures, especially to physical methods for small-particle structural study, formation of nonequilibrium phases, and so on. Dispersed structures generated by the decomposition of supersaturated solid solutions are studied by physical materials science [1]. Such solid dispersed structures as catalysts and sorbents are studied by classical physical chemistry.

Detachment of nanostructured systems with a particle size of  $10^{-9}$  to  $10^{-7}$  m (1–100 nm) from the ultrafine class has been performed by physicists who have discovered many specific physical properties of such systems in the last 15–20 years. An interest in studies of the systems has grown after the discovery of their new unique properties as construction and functional materials. As a result of this, the central problem in understanding their nature and the possibility of controlling nanostructured material technology is the genesis and evolution of nanosized particle structure. Based on the conception of material structure, it is possible to establish the functional bonds of the chemical composition and technology with structure, on the one hand, and of the structure with the properties of the material, on the other hand. As a whole, technology consists of a number of individual technological processes, each of which influences the structure.

Technological processes are also connected with such kinetic phenomena as heterophase chemical reactions, diffusion and self-diffusion, coagulation and coalescence, sintering, phase transformation, crystallization and recrystallization, and so on.

Thus, physicochemical kinetics of solid heterogeneous nanostructured media is the scientific basis for most technological processes in the preparation of nanostructured materials with optimal structure and optimal physical, physicochemical, and mechanical properties. By investigating kinetic regularities for each physicochemical process, one can forecast all of the stages of the structural evolution from ultrafine powder to sintered nanocrystalline material.

In the study of kinetics, modern physical methods are used to examine fine structure, which is the main distinctive feature of microstructural in comparison with macrostructural physicochemical kinetics.

Dispersed systems, the structural elements of which are grains, phase components, inclusions, and layers with non-coherence interfaces, are the most important for nanoscale materials. In such systems, the structural elements are limited by free surfaces or solid-gas interfaces. First of all, nanostructured systems should be classified by topological parameters. One hundred nanometers is considered to be the upper limit for nanostructured materials [2], but the action of dimension factors is more significant in the range of 10–50 nm.

Some cluster structures, glass amorphous alloys, and nonequilibrium decomposition structures, as well as macromolecules such as fullerene, nanotubes, organic molecules, belong to nanostructured systems, too. Nanostructured objects can be subdivided into three groups in accordance with the shape of their structural elements.

Isolated or weakly bound small particles, thin fibers, and films with nanosizes in one, two, or three directions belong to the first group. The second group contains surface layers of nanoscale thickness connected with a massive base but differing from it in chemical composition and structure. Such layers can be nanostructured, because they consist of nanosized grains. Within the surface layer, the structure can be homogeneous, heterogeneous, periodically laminated, or gradient. Massive nanostructured materials, monophase (micro-uniform) or heterophase (micro-nonuniform) and remaining macro-uniform belong to the third group. Structural elements in these materials have a crystalline texture and nanosizes. In this case the interfaces are called high-angle grain boundaries.

A significant characteristic of nanostructured systems is a level of physical property anisotropy; in other words, their properties have a vectorial nature. Fibrillar and laminar structures are very anisotropic and granular ones are isotropic.

Nanostructured systems can also be distinguished by the character of the reciprocal arrangement of their structural elements. From this point of view, they can be divided into regular and irregular (or stochastic).

Regular structures, as a rule, have elements of symmetry, but there are also aperiodic regular ones [3]. Regular granular structures are characterized by the location of isodiametric particles in the sites of spatial lattice with elements of symmetry. If the structural elements have no spherical symmetry or are characterized by some particle size distribution, the structure, as a whole, reserving regularity has no corresponding elements of symmetry. However, in most cases, such structures can be regarded as regular ones, for example, in the calculation of physical properties. Irregular (stochastic) structures have many peculiarities and can be distinguished from one another.

Fibrillar structures can be regular if the fibers forming them are oriented in space. Such orientation can be in one, two, or three dimensions. Special regular structures result from weaving or netting fibers.

Regular laminar structures are formed by parallel plates with the same or periodically changing thickness. Such struc-

tures are called orthotropic. Their properties change in one direction and are isotropic on surfaces perpendicular to this direction. The orthotropic structures can also be observed in fibrillar systems formed by layers of two-dimensional net or textile. Such structures are intermediate between laminar and fibrillar ones. Nonregular laminar structures can be imagined as textures in which layers are not exactly parallel.

There are many more complicated structures that cannot be described by these simple types, for example, dendrites and similar structures with fractal properties.

Nanostructured surface layers on a massive substrate belong to the second group not having such morphological variety as the objects of the first group. These systems are divided into single-layer and multilayer ones. They can be viewed as nanosized in accordance with such characteristics as the layer thickness and the average size of grain or other structural elements composing the layer. Within the limits of the layer, the structure can be uniform or nonuniform. The layers can be unbroken or broken. There are two types of discontinuity. The first type is porosity where pores are nanosized. Such a structure is typical for relatively thick layers. For very thin layers and films the surface discontinuity is characteristic. In this case, the whole coating is divided into separate sections with the same or different composition. Such a structure of a surface layer or thin film is called a discontinuous film. As a rule, the interface between the surface layer and substrate is noncoherent, but on a monocrystalline substrate, coherent epitaxial layers can be formed.

Multilayer materials have the same structural types as single-layer materials. Structures with many layers with a thickness of 10–100  $\mu\text{m}$  or more should be viewed as belonging to the third group of nanostructured systems, that is, as massive macroscopic homogeneous solids.

There are monophased and multiphased systems in the third nanostructured group. The monophased nanostructures have one critical linear parameter only, namely, the average size of grain or crystallite. Multiphased structures are more complicated. The so-called stochastic systems consist of structural elements with the same geometry and different chemical composition and crystalline structure. The nanoporous structures regard to stochastic. A peculiarity of such systems is the structural identity of all of the phases forming them. They have a main continuous spatial matrix phase and phases of inclusions separated by the matrix. The classification of matrix structures by inclusion topology is similar to that for nanostructured systems given above. The inclusions can be equilibrium (isodiametric) or nonequilibrium (gaunt or flattened out along one axis). The former are called globular; the latter are needle- or scale-shaped. If the inclusions transform into continuous fibers or thin plates, the system loses its matrix character.

The interfaces in mono- and multiphased nanostructures are incoherent except for cluster structures (1–5 nm) with a segregate nature, in other words, they differ from the matrix in chemical composition. Cluster structures are not phases according to thermodynamics. They have no interface between a cluster and matrix; that is, there is continuous transformation of structures into one another at a distance of nearly the cluster size. The systems with cluster structure are well known in physical material science, as many alloys in which the disintegration of metastable solid solutions begins

have such structures. A typical example of a cluster is the well-known Ginye-Preston's zones appearing at the stage of preaging. It is also known that clusters are formed in disintegrating martensite.

### 1.1. Nanosized Powders

The most important feature of nanosized powders, composed of 10–100-nm particles and having very large interfaces, is an excess of free surface energy. The physical properties of solids may be considered constant only in the case if solids have no limited sizes and interfaces. In real solids, the equilibrium and nonequilibrium properties change with a change in external sizes or in the sizes of internal structure elements with interfaces.

The dependence of physical properties of solids on their linear sizes has a fundamental character because the correlation between the number of atoms on the surface and that in the crystal volume, that is, between the surface and volume crystal energies, depends on the sizes and morphology. From a microscopic point of view, the difference in energy of atoms on the surface or in the volume of crystal results from disfunction of coordination for surface atoms and a decrease in the number of neighboring atoms interacting with them. Thus the surface atoms have an excess of free energy. Direct experimental methods for the free surface energy measurement are very complex, but there are many versions of its calculation, based on experimentally determined thermodynamic quantities such as the enthalpy of sublimation or atomization [4].

One of the simplest formulas for calculation of the surface energy in metals and simple covalent compounds is as follows:

$$\sigma_s = \Delta H_s / f N_A^{1/3} V_M^{2/3} \quad (1)$$

where  $\Delta H_s$  is the enthalpy of sublimation,  $V_M$  is the molecular volume,  $N_A$  is Avogadro's number, and  $f$  is an empirical factor depending on the crystal lattice type.

For composites, another formula in which the surface energy is normalized to the enthalpy of atomization ( $\Delta H_{at}$ ) was proposed by Kisly and Kusenkova [4]. The coordination number for a volume of crystal,  $K$ , is determined as the sum of coordination numbers for atom types, the coordination number on the crystal surface with the index (hkl) being taken into account. In this case, the algebraic number of disrupted atomic bonds on the surface is  $n = (1 - K_{(hkl)}/K)$ , and the specific surface energy for a plane (hkl) may be calculated by the formula

$$\sigma_s = \Delta H_{at} n / 4 S_{at} m N_A \quad (2)$$

where  $S_{at}$  is a surface with one atom per plane (hkl) and  $m$  is the number of atoms in a molecule. The surface crystal energy can be calculated by averaging all of the crystal planes.

The two formulas have the same physical meaning, namely, the number of unrealized atomic bonds determines the free surface energy. For monoatomic crystal, formula (2) changes to (1). The specific surface energy depends on the sublimation energy and atomic density. Calculation of the

specific energy for internal interfaces is more complex. It is supposed to be equal to one-third of the specific surface energy. The surface energy in nanostructured systems is a big part of the total energy.

As a result of development of the available methods for nanosized powder preparation, many advanced new materials have appeared. There are two directions in nanosized powder preparation:

1. Physical: the phase transformation of the first type occurs without chemical reactions.
2. Chemical: the phase transformation is accompanied by chemical reactions.

In the first case, different condensation methods, in which a new material forms because of collectivization of molecules or clusters into nuclei of a new phase through a transition state after the achievement of the needed sizes and formation of interfaces, are the most prevailing. The simple breakage of coarsely dispersed particles in high-energy, high-frequency, colloidal, and ultrasonic mills is considered to be a physical method as well.

The breakage of brittle solids by mechanical or acoustic disintegration is one of the prevailing methods for ultrafine powder, suspension, and aerosol preparation. The process of disintegration includes stages of mechanical deformation and relaxation. From the atomic-molecular point of view, there are three main stages of deformation. The first stage is a disorder of structure, the result of which can be amorphization without destruction of the crystal. The second stage is considered to be a type of special mobility appearance caused by weakening of internal tensions (which, in their turn, can be caused by the multiplication and movement of dislocations) and the appearance and growth of cracks. The result of the third stage is structure relaxation connected with the moving and disappearance of defects and aspiration of the system to return to equilibrium.

During chemical transformation, the formation of a new phase can occur in two ways: because of a gradual change in properties and structure throughout the whole volume of the initial solid or because of the formation of small areas with the properties of the final or intermediate products. A strict mathematical approach to the problem is only available for the second case, that is, for the phase transformation of the first type, when a new nucleus is formed in the matrix of the initial phase. The new phase can be solid, gas, or liquid. At the same time, an interface between the new and old phases is formed; the old phase partially disappears. This new interface is responsible for the chemical reaction. For two interacting solids, a solid-phase reaction takes place; for interacting solids with a liquid or gas, a heterogeneous one does.

Reduction of metal from oxide in the presence of catalysts and surface stabilizers and the methods of thermal decomposition, solution chemistry, aqueous electrolysis and electrodeposition, hydrothermal and plasma-chemical synthesis, chemical condensation in gas, laser ablation, fast drying by dispersion, synthesis with the controlled rate of transformation, and combustion synthesis are the best known chemical methods for nanosized powder preparation [4–12]. The condensation methods for nanosized powder preparation are based on the formation of particles at the molecular level

during synthesis. The gas-phase synthesis is submitted to the main physicochemical dependencies of material deposition from a vapor-gas mixture, and the processes of volume condensation take place in the tongue of flame. The method of fast drying by dispersion is based on the dispersion of liquids containing unstable initial phases. The synthesis with the controlled rate of transformation is performed at moderate temperatures and rates of heating. By modeling the back-coupling between the transformation rate and temperature, it is possible to control the size distribution of particles.

The common characteristics of all these methods are a high rate of nucleation and a small rate of nucleus growth. On the basis of taking into account the kinetic competition of different transformation mechanisms activated by thermal treatment, an optimization of all these processes can be achieved by varying the rates of nucleation and nuclei growth. One of the most important characteristics of nano-sized particles formed under very nonequilibrium conditions is a strong interaction with the components of the surrounding medium. As a result, a common shortcoming of chemical methods is the possibility of particle agglomeration and formation of polydisperse assemblies with a wide particle size distribution.

## 1.2. Nanocrystalline Bulk Systems

The thermodynamic nonequilibrium of nanosized powder systems, connected with an excess of the free surface energy, causes relaxation processes leading to an increase in equilibrium degree, that is, to a decrease in the surface area. This demands mass transport, which results in structural changes and system transformation from powder into bulk.

The most physical properties are characterized by extreme behavior at the achievement of a certain critical grain size. Such behavior is called the “size effect” [13]. It is the key point in solving the problem of production, study, and use of nanocrystalline objects [14–20]. However, the physical properties are determined not only by the structural element size, but also by the boundary conditions under which the object exists. R. A. Andrievsky has indicated four principal features of size effect in nanocrystalline bulk systems [20]. The first is the increase in the role of interfacial defects (grain boundaries, triples, etc). The second is the properties of these interfacial defects, which can be different in nanosized and conventional materials. The third is the overlapping of the grain size with characteristic physical length. The fourth is the possibility of a quantum effect revelation. All of these can result in the presence of some specific points in size dependencies and the availability of nonmonotonous change in the properties.

### 1.2.1. Change in the Equilibrium Temperature of Phase Transformation

The temperature of phase transformation to a great extent is determined by the surface energy of a system. The size dependence of the phase transformation temperature is well known, as is that of the formation of disperse phases with small surface energy and more compact packing of atoms. Commonly, an increase in volume free energy due to the formation of a phase with nonequilibrium structure under given

conditions (temperature, pressure) is compensated for by a decrease in the free surface (interface or grain boundary) energy, provided that the corresponding decrease is caused by the phase transformation.

Another fundamental phenomenon connected with small particle sizes is Laplace (or capillary) pressure. It is defined by the surface curvature of a solid and appears to be due to the presence of surface tension. The value of the Laplace pressure is

$$P_L = \sigma_s(1/r_1 + 1/r_2) \quad (3)$$

where  $r_1$  and  $r_2$  are the main radii of curvature. If  $r_1 = r_2 = r$  (spherical surface),  $P_L = 2\sigma_s/r$ . For quasispherical particles the radius of curvature is equal to half their linear size. Thus, small particles are cramped by great Laplace pressure (equal to 150–200 MPa at  $r = 10^{-8}$  m (10 Hm) and  $\sigma_s = 1.5\text{--}2$  kJ/m<sup>2</sup>).

The main fundamental size effect connected with Laplace pressure is a decrease in the crystal lattice parameter  $a$  with decreasing particle radius [21]:

$$\Delta a/a = -2\sigma_s k_T/3r \quad (4)$$

where  $k_T$  is the isothermal compression (equal to  $10^{-11}$  (Pa)<sup>-1</sup> for metals). The interatomic distance can decrease to a critical value at which the phase transformation connected with reconstruction of the crystal lattice occurs. The size effect can result in stabilization of either high-pressure phases (under normal conditions) or high-temperature phases. The latter are very important for many oxide systems with several structural crystal modifications. With rising temperatures, transformation from less symmetric modifications to more symmetric and denser ones takes place. Some data on phase transformation connected with the size effect are given in Table 1 for some oxide systems.

### 1.2.2. Size Dependence of Kinetic and Mechanical Properties

Kinetic properties define the rate or intensity of transfer of heat (heat conduction), mass (diffusion), and charge (electroconduction). The size dependence of the phonon constituent of the heat conductivity in a polycrystalline material results from peculiarities of the phonon behavior in solids, which have inner edges able to dissipate phonons.

**Table 1.** Size dependence of phase transformation in oxide systems.

Material	Phase transformation	Structure state	Critical size (nm)
ZrO <sub>2</sub>	M–T	Powder	>30
	T–C	Powder	20
BaTiO <sub>3</sub>	T–C	Powder	100–120
		Ceramics	40–50
PbTiO <sub>3</sub>	T–C	Powder	90–100
		Ceramics	8–12
Y <sub>2</sub> O <sub>3</sub> (R <sub>2</sub> O <sub>3</sub> )	O–C	Powder	8–10

Note: Structures: M, monocline; T, tetragonal; C, cubic; O, orthorhombic

In nanocrystalline materials, the length of the free phonon run is defined by grain size. The possibility of further lowering the heat conductivity for low-heat-conducting materials is of great practical importance. It has been theoretically proved that there is a possibility of decreasing the heat conductivity of  $ZrO_2$  (having a very low heat conductivity and used as a thermo-barrier material on freezing blades) by 2–3 times with decreasing grain size to 20–30 nm, whereas the durability, heat resistance, fracture toughness, and adhesion between  $ZrO_2$ -based coating and substrate improve. The possibility of the structural regulation of heat kinetic properties is of great scientific importance.

The diffusion coefficients of nanostructured materials, as a rule, are several orders of magnitude greater than those of monocrystalline or conventional ones because of the special role of grain boundaries. A decrease in grain size increases the concentration of boundaries, for which the diffusion coefficient is bigger and the activation energy is 2–2.5 times lower [21, 22]. The self-diffusion parameters for nanosized and conventional copper and nickel are listed in Table 2.

A common empirical regularity of the grain structure influence on the mechanical properties of different materials is an increase in their hardness with decreasing grain size. In most cases, the durability increases, too, although it depends on cohesion on the grain boundary. This regularity is based on the well-known Petch-Xoll equation, according to which the stress of plastic deformation for a multicrystal is inversely proportional to the square root of the grain size. However, the hardness for many materials has an extreme size dependence, which is mostly observed for hard materials. The maximum hardness in these cases is due to the formation of structure with a grain size of some nanometers.

### 1.3. Thin and Multilayer Films

The burst of research in modern industry has become possible thanks to the development of new superhard, super-strong, heat- and wear-resistant bulk materials, especially coatings. The advancement of coating properties, particularly hardness, abrasion and corrosion resistance, and a decrease in size of some details due to coating and film deposition, has become a reality as grain has been brought into the nanorange. The appearance of new methods for

nanostructured coating and film deposition and improvement of available ones have changed, in a number of cases, the rules for using them. Among the well-known physical and chemical methods, such as thermal evaporation, chemical vapor deposition, thermal decomposition of precursors, nitration and aquation are prevalent. Different types of surface modification, deposition of new material particles, implantation of atoms and defects, and different types of interaction take place under the influence of irradiation, depending on beam type and energy. Peculiarities of coating use determine the choice of method. By controlling the process of deposition one can change the microstructure and produce mono- or multicrystals or amorphous films and coatings. [23].

Vapor atoms on the substrate surface have an energy higher than  $\kappa T$ . The rate of evaporation,  $N_e$ , can be estimated by Lengmur's equation,

$$N_e = 3513 \cdot 10^{22} p_e \sqrt{1/MT} \quad (5)$$

where  $p_e$  is the pressure,  $T$  is the temperature, and  $M$  is the molecular mass.

In spite of the fact that the molecules (atoms) move very fast, they are not transmitted at large distances, because of frequent collisions with the other gas atoms or molecules. The free path for the molecules (atoms) of gas is inversely proportional to the gas pressure:

$$\lambda = \frac{V}{N} \cdot \frac{1}{\pi d^2 \sqrt{2}} = \frac{kT}{p_e \pi d^2 \sqrt{2}} \quad (6)$$

where  $d$  is the molecular diameter and  $p_e$  is the pressure. The gas atoms gravitate toward the surface, forming doublets and quadrupoles and losing the rate of displacement.

The level of thermal equilibrium is described by the coefficient of thermal accommodation,  $\alpha_T$ :

$$\alpha_T = \frac{E_v - E_r}{E_v - E_s} = \frac{T_v - T_r}{T_v - T_s} \quad (7)$$

where  $E_v$  is the energy of vapor atoms,  $E_r$  is the energy of desorbed atoms at equilibrium with substrate,  $E_s$  is the surface energy, and  $T_v$ ,  $T_r$ , and  $T_s$  are the corresponding temperatures.

**Table 2.** The self-diffusion parameters for nanosized and conventional copper and nickel.

Object	Porosity (%)	Method	Activation energy (kJ/mol)	Self-diffusion coefficient $D_0$ (m <sup>2</sup> /c)	$D$ at 393 K, (m <sup>2</sup> /c)
Nano-Cu	20	NMR	66.5	$3 \cdot 10^{-9}$	$1.8 \cdot 10^{-17}$
Nano -Cu	20	Isotopic	61.7	$2 \cdot 10^{-5}$	$1.3 \cdot 10^{-31}$
Cu (volume)		Isotopic	197		
Cu (boundary)		Isotopic	104	$1 \cdot 10^{-5}$	$1.7 \cdot 10^{-19}$
Cu (surface)			66.5	$1 \cdot 10^{-7}$	$1.4 \cdot 10^{-16}$
Nano -Ni	7–8	Isotopic	50.7	$1.2 \cdot 10^{-3}$	$1.9 \cdot 10^{-10}$
Ni (volume)		Isotopic	275	0.48	$3.5 \cdot 10^{-37}$
Ni (boundary)		Isotopic	115		$3 \cdot 10^{-12}$
Ni (surface)			75

The use of different methods for deposition and different substrate types makes it possible to prepare different structures: discontinuous and multilayer films and columnar structures. Today multilayer structures and combinations of thin films and coatings are of great interest.

Chemical methods for thin-layer and coating deposition can be discussed on the basis of the laws of electrolysis. The mass of deposit on the unit surface,  $G/S$ , is equal to

$$G/S = JtE\alpha \quad (8)$$

where  $J$  is the current density,  $t$  is the time,  $E$  is the electrochemical equivalent, and  $\alpha$  is the current index (experimental/theoretical ratio equal to 0.5–1). The process of chemical deposition permits one to prepare deposits of metals, semiconductors, and insulators. Thin films and coatings prepared by physical or chemical vapor deposition ensure a high level of functional properties when used in optics, electronics, chemistry, and so on [24, 25].

The best properties were revealed with the transition to nanoscale multilayer coatings such as TiN-TiCN, TiN-TiC, TiN(TiC), Al<sub>2</sub>O<sub>3</sub>, and so on. Ten years ago the thickness of each layer in multilayer coating was  $\approx 0.5 \mu\text{m}$ , and the whole thickness was  $\approx 5\text{--}10 \mu\text{m}$ . In recent years, a new class of multilayer coatings deposited by magnetron scattering, with a smaller thickness (2–10 nm) and a hardness of  $>5000 \text{ kg/mm}^2$ , has appeared [26]. This hardness is not far from those of cubic boron nitride and diamond. The diffusion of dislocation is less possible in multilayer coatings than in composite ones. It is possible to prepare multilayer coatings with different shear moduli and a shear fracture close to the theoretical one.

Nanocomposite coatings are also very important for use as thermal barrier coatings [27–30]. Such coatings, in addition to their good mechanical properties, possess high-thermal and high-temperature corrosion and wear resistance. The possible creation of gradient structures in surface layers shows great promise.

In addition to the old methods for composite coating deposition with nanosized fillers, some new directions, particularly the deposition of nanocomposite electrolytic coatings under the action of pulsatile current, should be mentioned [31]. With the use of direct current, coatings with disperse fillers in the matrix structure were produced [32]. With the use of pulsatile current, composite electrolytic coatings with 30-nm Ni particles (matrix) and 80-nm filler particles were prepared [31]. Subsequent thermal, chemical thermal, and laser treatments can change the properties of the coatings prepared.

## 2. GENESIS OF NANOSTRUCTURED SYSTEMS

### 2.1. Homogeneous and Heterogeneous Systems

Homogeneous systems are physicochemical systems with one phase. They have no interfaces, in which the contiguous parts of systems usually have different compositions and properties. The constituent parts cannot be divided mechanically. Chemical components of homogeneous systems are

distributed as molecules, atoms, or ions. The best examples of homogeneous systems are ice, liquid, or solid alloys; gas mixture; water vapor; and so on. Homogeneous systems can be physically uniform or nonuniform. The composition and properties of uniform systems are the same in their different parts, whereas in nonuniform systems they can differ in different places in the system but change continuously. For example, gas is a uniform system in the absence of gravity, but under the action of gravity it has a different density in the upper substratum of the atmosphere. Aqueous solutions are chemically nonuniform systems.

Heterogeneous physicochemical systems consist of two or more phases and have interfaces between uniform parts with different compositions and properties. These parts can be separated. Colloidal systems with particles with a size between a molecule and particles of heterogeneous systems occupy an intermediate position.

Homogeneous reactions proceed in the volume of phase, while heterogeneous ones proceed on the interfaces. The reaction rate is determined by the number of chemical events taking place per unit time in a unit volume (for homogeneous reactions) or per unit interface (for heterogeneous reactions) and depends on the material composition, temperature, and other parameters, such as the electrode potential in electrochemical reactions, the light intensity in photochemical reactions, and the dosage rate in radiochemical reactions. The reactions can be one-stage or multistaged and have intermediate products.

To establish a reaction mechanism, the experimental kinetic data are compared with theoretical equations based on definite suppositions about the mechanism [33]. Practically a single method of representation for phenomena, taking place in the theory of change, is a method of mathematical modeling that includes differential equations and dimensioned correlation [34].

In the ideal gas mixture or ideal liquid solution, the reaction rates obey the law of active masses; that is, the evidence of collisions of molecules of the initial material is the first and necessary demand. A peculiarity of heterogeneous reactions is the processes of transportation of initial reaction components out of volume to interfaces and of the products in the opposite direction. The influence of the transportation processes on the reaction rate is not constant, and changes depend on many factors, including the temperature and pressure. Under slowed diffusion in the pores of a solid, the reaction with a noticeable rate occurs only on the outer surfaces or in layers bordering them. In this case, the reaction is said to take place in the internal diffusion regime. In the external diffusion regime, the reaction rate is determined by the mass transport to the outer surface of a solid reacting with a gas or liquid. With large enough diffusion rates, the reaction occurs in the kinetic region.

In chemical transformation, the formation of a new phase can be realized in two ways [4]:

- owing to a gradual change in the properties and structure of the whole volume of the initial solid;
- owing to the formation of regions (nuclei) with a small size and to the properties of the final or intermediate products.

Exact mathematical calculations are possible only in the second case, that is, for the phase transformation of the first

type, when the nucleus of a solid forms in the initial solid matrix. The new phase of chemical reaction may be a solid, gas, or liquid. The solid-phase reaction takes place in the interaction between two or more solids; heterogeneous reactions are determined by the interaction of a solid with a gas or liquid.

The main demand for nanosized powder preparation in heterogeneous reactions is a high rate of nucleation and a small rate of nuclei growth. At the high rates of chemical reactions occurring at very high temperatures or at low ones in the presence of catalyst, fast condensation and hardening are favorable for the formation of a nonequilibrium state of particles at their growth. One of the important characteristics of nanosized particles formed under highly nonequilibrium conditions is their intense interaction with the components of the medium in which they are formed. The probability of consolidation, coagulation, and coalescence is very significant, even in the case of inert media. Thus, the common deficiency of all chemical methods is the formation of polydisperse aggregates with a wide particle size distribution.

## 2.2. Topochemical Reactions

Solid and heterogeneous reactions occurring with a change of phase composition in the places of contact between two or more solids or on the surface of a solid in contact with a gas or liquid are called topochemical reactions. The reactions accompanied by partial or total transfer of one or more solid reaction components in a gas or liquid cannot be viewed as topochemical reactions. A place where a topochemical reaction can occur is the surface between phases (interface).

Most heterogeneous and solid reactions can be referred to as topochemical or gas-transport reactions, depending on temperature. For example, some reactions of metal reduction from oxide are topochemical at low temperatures. They begin with the adsorption of gas (reducing agent) on the oxide surface, and, by following the interaction with it, but at higher temperatures, one can observe a partial outlet of solid reagent in gas and the interaction of the components in gas following the transfer of the reaction product to the solid surface. The latter case is a gas-transport reaction.

The gas-transport reaction is a more complicated process, the first stage of which is heterogeneous nucleation on the solid surface, and the following one is the partial transfer of the initial phase or intermediate products to gas. Such reaction products as water vapor (in reduction by hydrogen) and carbon oxide (in reduction by carbon) can initiate a transfer of solid products to gas, and these reactions mostly occur near equilibrium. Gas-transport reactions can be avoided with the use of low temperatures.

The interface ( $S$ ) in solid and heterogeneous reactions is the sum of zones formed by all of the reacting nuclei, which appear by the time  $t$ :

$$S = \int_0^t \varphi(t, y) \left[ \frac{dN}{dt} \right]_{t=y} dy \quad (9)$$

where  $\varphi(t, y)$  is the function describing the size of the reaction zone by the time  $t$  for nuclei appearing at the moment  $y$ , and  $dN/dt$  is the change in nuclei number by the time  $t$ .

Beginning at some definite moment, the growing nuclei join one another and the reaction zone begins to decrease after the maximum size is achieved. The rate of solid or heterogeneous reaction for this stage is expressed by the equation for the shrinking reaction zone. For example, if a reaction zone of a spherical shape is formed, the rate of the process is described by the equation of the reducing zone [33]:

$$1 - \sqrt[3]{1 - \alpha} = kt \quad (10)$$

where  $\alpha$  is the degree of transformation.

The dependence of fractional conversion on time is plotted with an  $S$  curve, and the dependence of the reaction rate on fractional conversion has a maximum. A peculiarity of such reactions is evidence of an incubation period and self-catalysis. At the same time, not each reacting substance but only part of them in contact with the initial phase undergoes the self-catalyzed action. In other words, the catalytic action of the reaction product on a unit surface of the reaction zone remains constant during the whole process, provided the product state does not change during the reaction.

It has been assumed [35] that when simultaneous multiple nucleation develops at the nanometer scale, each nucleation event is confined in a supply region of radius  $R$  from which the embryo can be fed up to its critical size. The amount of atoms  $A$  in this region must be significantly larger than the number of atoms  $N^*$  in the critical nucleus. Otherwise the region would be much too depleted, giving an important increase in the barrier of nucleation able to suppress the transformation. The condition to be fulfilled for nucleation to occur is

$$R \gg \left( \frac{X_1 v_1}{X_0 v} \right)^{1/3} r^* \quad (11)$$

where  $r^*$  is the critical radius of nuclei. Taking  $r^* = 10^{-9}$  m,  $X_0 = 0.2$ , and  $v/v_1 \sim 1$ ,  $X_1 = 0.7$ , one obtains for the radius  $R$  of the supply region  $R \gg 1.5$  nm. When  $R < 1.5$  nm, nucleation is absolutely impossible. It appears that even when  $R$  is on the order of 5 nm, the nucleation barrier will be substantially larger than in the case of infinite matrix.

Dispersion of products in topochemical reduction reactions occurs because of;

1. Formation of porous agglomerates taking the form of the initial reagent particles due to the large difference between oxide and metal volumes.
2. Disintegration of matrix oxide into small particles in the absence of coherence between oxide and metal or intermediate phase.
3. Disintegration of surface layers, bursting and peeling.

In the first case, dispersion is determined by the size of some structural elements (dendrites) formed on the base of the matrix phase. In the second case, the size of particles is connected with the number of nuclei on the unit of surface or volume. In the third case, dispersion results from the high intensity of destruction of the crystal matrix, which stimulates movement of the reaction front.

### 2.3. Kinetics of Nucleation and Nucleus Growth

The main characteristic determining the size of growing nuclei is the correlation between the rates of nucleation and nuclei growth, which, in its turn, depends on the correlation between the activation energy of these processes and the number of active centers on the crystal surface. Significant characteristics are also anisotropy of crystal growth, reproduction of reaction nuclei at their development, change in surface spots where nuclei can be formed, diffusion through product layers, and so on.

The comparison of experimental kinetic data with theoretical curves describing various mechanisms of topochemical (solid and heterogeneous) reactions may help to approximate the reaction mechanism, but for its final determination a direct observation of the rates of nucleation and nuclei growth, a study of product state change during nuclei growth, and so on should be carried out. From the point of view of formal kinetics, the processes of nucleation on a surface and in a volume can be described by the same laws. In the first case, the examination is carried out in a two-dimensional area, in the second case in three-dimensional one [33]. In a description of the new phase appearance, the spatial characteristics of the forming nuclei, such as isotropy or anisotropy in both the matrix phase and nucleus, should be taken into account.

The appearance of new phase nuclei in a metastable system results in the transition of substance in a thermodynamically stable state. In a homogeneous nucleation in a metastable phase, homogeneous spontaneous formation of ensembles of different compositions from the atoms of the matrix phase occurs because of atom association. At the same time, the metastable phase is in a quasi-equilibrium state: the rate of formation of spontaneous growing associates of supercritical sizes is small, and the equilibrium statistic size distribution of the associates is not broken and almost does not change with time up to the critical size.

For topochemical (solid and heterogeneous) reactions such explicit description is not available, although nuclei of a new phase have been investigated experimentally in many chemical reactions [36–37]. Simultaneously with the new phase formation, the interface between new and old phases is formed, the surface of the old phase partially disappears, and in its place a new surface between the new phase and gas appears. For the new surface formation, some work is expended. It can be described by the following equation [36]:

$$A = \sigma S = \sigma b r^2 \quad (12)$$

where  $\sigma$  is the surface energy,  $S$  is the surface area,  $b$  is a constant depending on the nucleus shape, and  $r$  is the characteristic nucleus size.

The work expended on the new surface formation emerges as a free energy of formation ( $\Delta q_f$ ) at the transition to a thermodynamically stable state. This energy is proportional to the specific free transition energy  $q$  and nucleus volume  $V$  (or characteristic size),

$$\Delta q_f = qV = qbr^3 \quad (13)$$

By summarizing these equations, one can determine some critical size  $r_c$ ; for the lower range of  $r_c$  the energy expended on the new surface formation exceeds the free formation energy, and for the higher range of  $r_c$  an inverse relationship is observed. Thus, to form a molecular cluster or heterogeneous fluctuation exceeding the critical size  $r_c$ , an incubation period is needed. Its presence explains the possibility of overheating liquid to temperatures higher than the boiling temperature and the absence of crystallization from a supersaturated solution. At the same time, the reaction rate in a liquid or gas is proportional to the concentrations of reacting substances [37]:

$$dn/dt = K(n_a, n_b, \dots) \quad (14)$$

and in heterogeneous systems it also depends on the surface on which the reaction occurs:

$$dn/dt = K(n_a, n_b, \dots)qS \quad (15)$$

A chemical reaction can occur because of the collision of particles of different chemical natures, but not every collision results in an interaction. The probability of chemical interaction leading to new compound formation is determined by the availability of a resource of energy that is enough to overcome the potential barrier. A specificity of solid and heterogeneous reactions is their dependence not only on chemical and phase composition, but also on the state of the crystal lattice in a solid and the presence of different defects.

The normal and active states of a solid are known. A solid in the normal state is defective only because of its lattice disorder. The active state is a result of the presence of nonequilibrium defects influencing the differently reactive abilities of solids. To operate the activity of solids in concrete processes, it is necessary to know their nonequilibrium structure. This permits one to create definite defects initiating the chosen chemical reactions. The influence of defects in crystals on their reactive ability has been studied by many researchers, and now ways to realize many physicochemical processes are known.

Crystal defects are of importance not only for the acceleration of the initial stage in topochemical reactions, but also for the formation of the new phase structure. The activity of a solid can be increased in reactions accompanied by a change in volume due to the strained state at the nucleus-matrix boundary.

In heterogeneous reactions, adsorption of gas or liquid takes place on the most defective places of a solid. It can be accompanied by solution of the adsorbed reaction component in the lattice. In this case, the theory of oversaturated solution can be used. The X-ray and electron-microscopical investigations of oversaturated solid solution showed the possibility of Ginye-Preston zone formation. These zones are the smallest segregation of composition formed as a result of atom redistribution in the crystal lattice of a homogeneous solid solution. After the achievement of a definite level of oversaturation, the Ginye-Preston zones are replaced by stable or intermediate metastable phases; that is, the nucleus of a new phase appears.

The phase transformations are the result of chemical reactions also in the case when the rate of phase transformation

limits the appearance of an intermediate layer, which divides the area of chemical and phase transformation in space and time.

The problem of nucleus size and shape control is the least decisive in the investigation of phase transformation. If the deformation energy in the two-dimensionally growing nucleus prevails, a new phase aspires to follow the shape of the matrix solid phase. According to Boldurev's supposition [36] the nucleus shape can be connected with the values of two components surrounding the nucleus. They are  $K_s$  (the component of deformation depending on interfacial energy) and  $K_v$  (the component of deformation resulting in a change of volume during conversation). If  $K_s$  is large, the nucleus tries to form a shape with the minimum ratio of surface to volume. For an isotropic medium the spherical shape is characteristic. If  $K_v$  is big, the nucleus is flat and elongated along the surface. The combination of these factors results in a variety of nucleus shapes.

The most direct mathematical calculation can be made in the case where all of the nuclei appear simultaneously and have a spherical shape. Then the rates of their appearance, growth, and interarrangement should be taken into account, and the shape of product particles, their sizes, and some physicochemical properties connected with dispersion composition of powder material can be established.

Delmon [33] accomplished these tasks on the basis of the following hypotheses of the kinetic theory:

1. Samples consist of particles of the same shape.
2. Nucleation occurs with the same probability or the potential nuclei take part in the process.
3. Nuclei are distributed along the surface in such a way that the probability that each of them will stay at any point is the same.
4. Nucleus growth is isotropic; that is, it proceeds with the same rate in different directions, and the rate of growth does not change with time.

These hypotheses are the simplest and can be taken into consideration for real conditions only approximately.

The crystal structure and the presence of defects influence the nucleation rate. By increasing the number of potential nuclei or using catalytic additions, surfactant admixtures, and promoters, one can change the nucleation rate. The reaction products and the appearance of tension round the nucleus due to the difference between the volumes of matrix and product phases can also influence the nuclei growth rate. As a result, dislocations are formed and the reaction on them proceeds with a higher rate.

## 2.4. Genesis of Bulk Nanostructured Materials

The genesis of nanostructure is the key feature in the preparation of nanocrystalline materials with powder methods. The structure of particles is connected with synthesis conditions: the density of defects, such as twins, domains, stacking faults, core and shells, as well as particle aggregates and agglomerates, depends on process parameters. All of this defines the behavior of powder during consolidation and affects the structure of a monolithic sample. Such heredity was known for coarse particles and micrometer-grained bulk

materials [38]. Refining particles and grains to the nanoscale leads to the escalation of a material's structural sensitivity. Today we can make powders of the same particle size distribution and shape; however, different techniques for synthesis commonly result in different defect structures and, therefore, in different sintering behaviors and properties of sintered bodies. The most important achievement of today's techniques for synthesis and consolidation of nanoparticles is flexible control over properties [4].

Thermodynamic nonequilibrium of nanosized systems connected with a high excess of free surface energy leads to relaxation processes increasing the equilibrium extent, that is, decreasing the surface area. It can be possible only because of mass transport, which can appear only during thermal activation accompanied by increasing atomic mobility. The transport processes cause structural changes, which result in the evolution of the system from nanosized to nanostructured monolithic materials. The kinetics of transport processes has a physicochemical nature, as it depends on the chemical nature of materials of which the system consists, the state of the particle surface, the chemical activity of the gas phase, and so on. Chemical reactions occurring simultaneously in multicomponent disperse systems influence the rate and character of mass transport to a great extent.

A disperse system is characterized not only by a big free surface area, but also by its curvature, resulting in Laplace pressure. This pressure influences the equilibrium conditions along the boundary between two phases divided by a curved surface. The surface curvature of each disperse phase is equal to  $L = 2r_c$ , where  $r_c$  is the equivalent particle radius. The conditions of equilibrium of two phases divided by a curved surface were shown to correspond to local equilibrium near the surface, but the system as a whole remains in nonequilibrium because of the excess of free energy.

## 2.5. Genesis of Thin and Multilayer Films

Today, many different coating techniques for depositing thin and thick films are known. The genesis of thin and multilayer films is determined by the method chosen for deposition, materials used for films and coatings, diffusion processes, and so on. For example, in using the diffusion method for film and coating deposition, one should take into account the energetic state of gas as contributing to diffusing component transfer on the surface of the material under saturation, phenomena on the material boundary, and diffusion of chemisorbed elements into the material. The main physicochemical parameters determining the genesis of films and coatings are the same as in topochemical heterogeneous reactions.

Electrophoresis is a method for coating deposition from a highly dispersive suspension when the rate of sedimentation is lower than that of electrophoresis. The latter for each particle is  $V = f(\xi\varepsilon_1 E/\pi\eta)$ , that is, it is determined by the coefficient of particle form ( $f$ ), electrochemical potential ( $\xi$ ), medium permittivity ( $\varepsilon_1$ ), intensity of the electric field ( $E$ ), and the viscosity of the dispersive medium ( $\eta$ ). The genesis of such films and coatings is determined by the conditions of electrophoresis and the chemical nature and dispersion of deposited powder particles.

Vapor deposition of thin and thick films is defined by hydrodynamics, heat and mass transport. Here the elementary chemical reactions occurring on the surfaces do not differ from those on individual particles. The rate of product formation is proportional to the reaction rate per unit surface ( $w'$ ) and the size of active place ( $s$ ):

$$w = w's \quad (16)$$

With small reagent concentrations, the reaction rate is determined by a diffusion process.

Thus, the presence of essential deviation from the equilibrium conditions of crystallization and repression of heat-activated processes of structural and phase transformations at a solid-phase stage play the determining role in nanostructured state formation. The formation of new metastable phases (absent in the equilibrium diagrams), ultrafine dendrite or globular microstructures, and amorphization of crystal materials are the result of nanostructured thin and thick film deposition.

### 3. SURFACE RELAXATION IN NANOSIZED SYSTEMS

The technology of small particles is close to that of conventional powder materials; however, for nanosized particles, the effect of disperse system evolution on the transition of ensembles of free particles into a monolithic nanostructured material already becomes apparent at the stage of small particle formation, when the van der Waals interaction forces between particles are substantial enough to result in adhesion of particles and a decrease in the density of packing. Such a spontaneous aggregation of small particles plays an important role in the formation of mesostructure within the green body.

Heating of the ensemble of small particles leads not only to the fast growth of interparticle necks, but also to coagulation and coalescence processes in a nanosized system, which can decisively affect densification kinetics and structure evolution under high-temperature sintering.

The final high-temperature sintering stage, following the intermediate stage, has many specific features. Among them there is a distinct tendency toward local (differential) shrinkage and formation of large pores. In this case the heredity of mesostructure formed at the first technological stage develops. With the high density of a nanostructured body, an abrupt dependence of mean grain size on both the absolute residual porosity and geometry and topology of pores is observed at this stage.

#### 3.1. Coalescence and Coagulation of Nanosized Particles

When heated, the green body compacted from nanosized particles tends to undergo relaxation processes, which substantially reduce the free surface energy of particles and proceed without marked variation in the density of the system as a whole. These processes are thermally activated and can proceed at temperatures sufficient for surface and grain boundary diffusion [38]. The surface area relaxation

begins with the formation of contact necks and their subsequent growth. German proposed the use of the surface area decrease as a measure for characterizing the particulate system at the initial stage of sintering [39]. Let us consider several of the simplest relations defining the reduction of the surface area in the system of identical spherical particles due to the formation and growth of interparticle necks.

The specific surface area in such a system is equal to

$$S_v = \frac{4\pi R^2}{4/3\pi R^3} = \frac{3}{R} \left[ \frac{\text{cm}^2}{\text{cm}^3} \right] \quad (17)$$

where  $R$  is the radius of a particle.

Formation of interparticle contacts of radius  $R$  results in a specific surface area decrease:

$$S_v^{(x)} = S_v^0 \left( 1 - \frac{n_c x^2}{8 R^2} \right) \quad (18)$$

where  $n_c$  is the average coordination number for a given packing of particles and  $x$  is the neck radius. For regular and dense packing  $n_c = 12$ . In real porous structures, however,  $n_c$  can be arbitrary but less than 12, depending on relative density. For very loose packing  $n_c = 3 \div 4$ . Taking into consideration the fact that the maximum value of relative neck size,  $x/R$ , is close to 0.7 (spherical particles in dense packing transform into polyhedrons and loose, chainlike structures, and chains of particles transform into cylindrical fibers), one can estimate the maximum value of relative decrease in the specific surface area due to growth of the necks.

In accordance with formula (3.2), for the densest packing ( $n_c = 12$ )  $\Delta S_v^{\text{max}}/S_v^{(0)} = 0.74$ , and for very loose packing ( $n_c = 3$ )  $\Delta S_v^{\text{max}}/S_v^{(0)} = 0, 2$ . The kinetics of the neck radius growth is defined by the well-known relation

$$\left( \frac{x}{R} \right)^n = Mt \quad (19)$$

where  $n = 7$  for surface diffusion and the kinetic constant  $M$  is inversely proportional to  $R^4$ :

$$M \approx \frac{100 D_s \sigma \Omega \delta}{kTR^4} \quad (20)$$

where  $D_s$  is the coefficient of surface diffusion,  $\sigma$  is the surface tension, and  $\Omega$  and  $\delta$  are the atomic volume and size, respectively. Taking into consideration relations (19) and (20), the kinetics of surface area decrease follows the relation

$$\left[ \frac{\Delta S_v}{S_v^{(0)}} \right]^\gamma = M_1 t \quad (21)$$

where  $\gamma = n/2 = 3 \div 3.5$  and  $M_1 = M(n_c/8)^\gamma$ .

Elaborated in [39], the analysis of experimental data required for calculation of the specific surface area reduction during isothermal firing of ultrafine oxide systems in oxidizing media shows the validity of Eq. (21) in many cases. However, a substantial number of experiments do not correlate with this simple theory: the exponent is very often higher than 3.5 (4 and higher), and the general surface area decrease greatly exceeds the one estimated above for loose packing ( $\Delta S_v^{\text{max}}/S_v^0 \approx 0.2$ ).

Such deviations originate from particle coarsening due to coalescence and coagulation. To describe the kinetics of surface diffusion controlling coalescence in the system with small adjacent particles, the author [40] proposed the following relation:

$$R^4 = R_0^4(1 + Bt) \quad (22)$$

where  $B$  is the kinetic constant, which is close to  $1/3 M$  in Eq. (19).

It was assumed that the initial particle size distribution following the formula

$$\chi_0 = \frac{R_0^{\max} - R_0^{\min}}{\bar{R}_0} \quad (23)$$

is rather wide (about 1). Equation (22) is in good correlation with many experimental data obtained for oxide and metallic powders [39]. It follows from this that  $\gamma$  can be equal to 4 in Eq. (21).

If the initial particle size distribution is narrow ( $\chi_0 \ll 1$ ), the kinetics of coalescence substantially changes. If a particle size distribution is taken into account, the mathematic solution of this task becomes much more complicated. The general case gives

$$\begin{aligned} & \frac{1}{4} \left[ \left( \frac{R}{R_0} \right)^4 - 1 \right] + \frac{1}{3} (1 - \chi_0) \left[ \left( \frac{R}{R_0} \right)^3 - 1 \right] \\ & + \frac{1}{2} (1 - \chi_0)^2 \left[ \left( \frac{R}{R_0} \right)^2 - 1 \right] + (1 - \chi_0)^3 \left[ \left( \frac{R}{R_0} \right) - 1 \right] \\ & + (1 - \chi_0)^4 \ln \left( \frac{R/R_0 + \chi_0}{\chi_0} \right) = \frac{B}{4} t \end{aligned} \quad (24)$$

When  $\chi_0$  is small, the logarithmic addend predominates and the kinetics of mean particle size growth can be described by an S-type curve at the early stages of the process (curve 2 in Fig. 1). As the coalescence is in progress and  $\chi$  increases, the curve 2 tends to curve 1, corresponding to Eq. (25), which is a particular case derived from (24) at  $\chi_0 = 1$ . Thus, in a monodisperse system, the initial stage of coalescence has a character similar to that of chemical reactions with an explicit incubation period [40]:

$$R_m^4 = R_0^4 + B_1 \sigma_s D_s \Omega \delta t / kT \quad (25)$$

**Figure 1.** The coalescence kinetics for different values of the  $\chi_0$  parameter. 1,  $0.5 < \chi_0 < 1$ ; 2,  $\chi_0 \ll 1$  ( $\sim 0.01$ ); 3, kinetics of coagulation ( $B_1 \ll B$ ). Reprinted with permission from [4], V. V. Skorokhod et al., "Physicochemical Kinetics in Nanostructured Systems." Academperiodica, Kiev, 2001 (in Ukrainian). © 2001, Academperiodica.

where  $B_1$  is a numeral factor near 2 and  $D_s$  is a coefficient of surface self-diffusion.

The coalescence in the particulate system does not mean any mobility of particles, and mass transfer proceeds only through the diffusion mechanism.

In colloidal systems, coarsening of particles and, accordingly, a decrease in their surface area may occur through coagulation. This mechanism assumes substantial mobility of particles in the surrounding medium, their collisions, and further formation of agglomerates, which gradually transform into coarser particles.

The classic equation of kinetic coagulation can be written here:

$$\frac{dN}{dt} = -KN^2 \quad (26)$$

where  $N$  is the number of particles per unit volume and  $K$  is the kinetic constant of coagulation. If particle motion follows the Brawn law, then

$$K = \frac{4 kT}{3 \eta} \quad (27)$$

where  $\eta$  is the viscosity of a system,  $k$  is Boltzmann's constant,  $T$  is the absolute temperature. Integration results in hyperbolic dependence of  $N$  on  $t$ :

$$N = N_0(1 + KN_0t)^{-1} \quad (28)$$

and the mean particle radius  $R$  increases with time as a cubic parabola:

$$\bar{R}^3 = \bar{R}_0^3 + K_1 t \quad (29)$$

where the new constant  $K_1$  is proportional to the volume concentration of particles in the colloidal medium  $C_{\text{vol}} = \frac{4}{3} \pi \bar{R}^3 N$ .

If particles are rather mobile, processes like coagulation may proceed in systems with small contiguous particles. Indeed, such a process is a local sintering, which results in the formation of agglomerates consisting of several particles. In this case, the reduction of free surface energy occurs because of reorganization of the outer surfaces of particles into the inner surfaces of grain boundaries. Nevertheless, we can apply the formalism of coagulation kinetics to the description of such a local sintering.

To do this, it appears sufficient for the coagulation constant in Eq. (26) to be replaced by the kinetic constant defining the rate of interparticle sliding or rotation controlled by grain boundary diffusion. The driving force for such a particle rearrangement is locally asymmetric Laplacian forces [41, 42]. As a first approximation, we can write

$$K_{\text{eff}} = \frac{AD_{\text{gb}}\sigma\Omega\Delta_b}{R} kT \quad (30)$$

where  $D_{\text{gb}}$  is the coefficient of grain boundary diffusion,  $\sigma$  is the surface tension,  $\Omega$  is the atomic volume,  $\Delta_b$  is the width of the interparticle boundary, and  $A$  is a constant. Since  $K_{\text{eff}}$  is inversely proportional to  $R$ , one can derive the following relation for  $R$  as a fourth-power parabola

$$\bar{R}^4 = \bar{R}_0^4(1 + B_1 t) \quad (31)$$

where  $B_1$  is the summarized kinetic constant equal to

$$B_1 = \frac{A_1 D_{gb} \sigma \Omega \Delta_b}{kT} \quad (32)$$

and  $A_1$  is a new numerical constant.

This relation is fair for stationary coagulation because at the earliest stage the rate of interparticle sliding strongly depends on the interparticle neck size. In other words, we suggest that the specific time necessary to double  $R$  is substantially more than that of neck growth up to value  $x/R \approx 1$ . Equation (31) coincides with Eq. (22) for coalescence kinetics; the kinetic constant  $B_1$  in (31), however, is substantially less than in (22), as their ratio is proportional to the ratio of the grain boundary to surface diffusion coefficients at the same temperature.

Despite this fact, the coagulation in the system of ultrafine particles with a very narrow size distribution can prevail over coalescence because of the reasons stated above. It should be noted that the surface diffusion controlling coalescence is not accompanied by change in the mean density of a system (no change in distance between particles), and coagulation like a local sintering can lead to some densification of the system as a whole.

Experimental study of the competitive role of both coalescence and coagulation at the second stage of technology is of interest because surface impurities are inevitably inherent in ultrafine media. These impurities behave differently in the two processes. During coalescence a substantial refinement of surface can be expected. When particles coagulate, the impurities may pinch off and place themselves on the interfaces or grain boundaries.

Both coalescence and coagulation processes play a main role in decreasing driving forces for sintering.

### 3.2. Sintering of Nanosized Systems

One of the characteristic features of sintering in the ultrafine media is a tendency toward local densification or differential shrinkage. Local densification usually becomes apparent as an increase in the mean pore size at the stage of open porosity during sintering of micron- and submicron-sized particles. At the late sintering stages, the homogeneity of densification can be restored and a high density of sintered materials can be achieved. Local densification, however, is usually irreversible, and pores, which are tens or hundreds of times larger than the particles, form and cannot be eliminated even if the temperature is increased to fusion temperatures.

It is known that in the nanosized particle system there is a tendency toward inhomogeneous spatial distribution as green packing is prepared. Such inhomogeneity may intensify because of coagulation at the early sintering stages. In addition to the formation of a mesostructure, it proves to be possible to create an inhomogeneity of much larger density than that of the mesoelement. Finally, in the systems of polydisperse powders and especially two-modal particle size distribution, the local variation of mean pore size and therefore variation of Laplacian pressure become possible [43, 44]. Under sintering, such inhomogeneity can provoke the appearance of zones with tensile stresses and, as a result,

macro-cracking inside a sintered body [45]. Thus, the characteristics of the initial powder, the methods of green sample compacting, and the degree of particle coagulation in heating play a determinant role in attainment a high-density material and conservation of homogeneous and fine-grained structure.

It was experimentally found that the main part of volume shrinkage on sintering (up to 85–95% of the theoretical density) of nanocrystalline powders occurs during heating. The sintering temperature is commonly tens or hundreds of degrees lower compared with that for micron-sized particles. The beginning of the isothermal hold is accompanied by abrupt retardation of shrinkage and intensive grain growth.

The key feature of sintering of nanocrystalline materials is a competition of two main processes: shrinkage (densification) and coarsening of microstructure. Both processes are under the control of the main mechanisms of mass transport in sintering: surface and grain boundary diffusion. Parameters of thermal activation are close for both mechanisms, and, consequently, densification and evolution of microstructure occur in parallel. Thus, to make sintering an effective technology for the consolidation of a material with a density close to the theoretical one and a grain size less than 100 nm, it is necessary to separate densification and grain growth in time and temperature. The most approved approaches are rapid-rate sintering, pressure-assisted sintering, and application of dopants, which permit the acceleration of densification and retard grain growth. The first and second of these are the basis of today's consolidation practice, and the third is a method of powder preparation.

#### 3.2.1. Volume Shrinkage in Isothermal and Nonisothermal Sintering

The temperature dependence of volume shrinkage has a classical S-like shape, which commonly consists of three ranges: interparticle necks are formed at the first stage, the cylinder-like channel pores appear and evolve at the second stage, and isolated pores define porosity at the third stage. As for nanostructured ceramics, these three stages are described carefully enough in [46].

For nanosized particles, the two initial sintering stages proceed and are complete during heating, long before an isothermal hold. The initial stage of isothermal hold often coincides with the third sintering stage. This division is rather arbitrary; however, in most experiments, this approach is quite convenient and appropriate for understanding how the residual porosity can be removed for several hours at temperatures lower than the temperature of recrystallization. For some materials this approach is actual, but for others it is not. Table 3 demonstrates several of the best examples of sintering of nanostructured ceramics.

From Table 3 one can see that the isothermal sintering regimes resulted in almost poreless materials with grain sizes less than 100 nm, but only for the ceramics characterized by the high activation energy of grain boundary migration ( $ZrO_2$ , TiN). Barium titanate demonstrates a high migration activity of grain boundaries at temperatures of 1300 °C and above, and this fact becomes a reason for abnormal grain growth, leading to isolated pore entrapment inside the

**Table 3.** Characteristics of the best samples of nanocrystalline ceramics obtained by sintering in a ramp-and-hold regime.

Material	Particle size (m)	Sintering regime	Density (% of theor.)	Grain size (nm)	Grain growth factor	Ref.
3YSZ	8	1050 °C, 5 h, air	99.9	90	11	[47]
3YSZ	6	1070 °C, 2 h, air	99.9	80	13	[48]
3YSZ	4	970, 2 h, air	99	60	15	[49]
BaTiO <sub>3</sub>	26	1300, 1 h, air	99.0	500	20	[50]
TiN	70	1600, 1 h, vacuum	98	800	11	[51]
TiN	12	1200 °C, 1 h, 0.1 MPa N <sub>2</sub>	99.0	140	12	[52]
TiN	40	1400 °C, vacuum	98	400	10	[53]

grains. Grain growth factor exceeds 10 in all of the examples; therefore isothermal sintering can be used in manufacturing dense nanograined ceramics, but for particles of sizes less than 10 nm.

Grain size is the integral of growth rate, which depends on temperature, pore structure, dopant concentration, and other factors. Therefore, it appears to be difficult to predict when the contributions of these factors to the integral become larger: either in the case of isothermal hold or during the permanent heating to higher temperatures. In any case, the sintering of nanocrystalline powders is a non-isothermal process, and transition to the final stage of densification strongly depends on "successful" implementation of the initial and intermediate stages, because they are responsible for pore and grain microstructure. Attention must be paid to both stages, initial and intermediate, especially taking into consideration their dependence on the heating rate.

The temperature dependence of the densification rate very often has two extrema, the first of which at rather low temperatures corresponds to interagglomerate sintering or rearrangement of particles. The interagglomerate pore coarsening occurs because of the action of both tensile stresses between agglomerates and surface-diffusion-controlled coalescence of pores and grains inside the agglomerates. Widening of pore size distribution was revealed in the sintered sample compared with the green one.

### 3.2.2. Rapid Sintering

Selection of heating rate is stipulated by the kinetics of heat and mass transfer, shrinkage, and the evolution of microstructure. First an idea of rapid sintering at the initial stage was postulated by Harmer and Brook [54] and was experimentally examined for alumina and barium titanate. Lynn Johnson proposed an idea of ultrarapid sintering of thin-wall tubes during transport of plasma [55]. Palmour used Harmer's idea of rapid heating at the initial stage of rate-controlled sintering [56]. The competition between different sintering mechanisms was put into the background of nonisothermal sintering and rapid sintering. The sintering schedule was rationalized by rapid heating at the first stage to surpass the temperature interval, where surface

diffusion, responsible for coarsening microstructure, predominates over grain boundary or bulk diffusion, which is responsible for densification. If the green body is rapidly heated, a high driving force of sintering is retained up to temperatures where densification prevails over coarsening. Nanocrystalline powders are an ideal object for the investigation of rapid sintering because of the huge specific surface area and, therefore, the high surface diffusion activity [57]. The heating rate, however, is restricted.

The influence of the heating rate on sintering of nanocrystalline zirconia powder was studied in [57]. Heating was carried out in the rate interval of 2–200 °C/min up to the same temperature in the range from 1050 to 1300 °C. Then an isothermal hold was provided for 2 h. The higher the heating rate was, the lower the final density of sintered ceramics was. There have been cases where the porosity increase was revealed instead of densification.

A similar result was described in [58], where BaTi<sub>5</sub>O<sub>11</sub> underwent ramp-and-hold sintering with a heating rate of 1–100 °C/min. The main reason for the porosity increase under rapid rate heating conditions is the localized shrinkage (differential sintering) [58], which, in its turn, is a sequence of agglomeration and temperature gradient. Because of the low thermal conductivity of zirconia (2 W/m K<sup>-1</sup>) and the high heating rate, the shell of the specimen was heated to a higher temperature than the core. Therefore, the shell had a higher density than the core. This phenomenon was described by Geguzin as "shell sintering" [21]. The difference in densification rates in adjacent microvolumes leads to stresses of different signs, including tensile stresses, which cause a local pore growth, or sometimes porosity. To estimate the stresses originating from the shrinkage rate difference, Evans introduced the following ratio [59]:

$$\sigma_m(t) = -\frac{4f}{1-f} \int_0^1 \Delta \dot{\epsilon}_s(t) \cdot F(G, K, \eta, t-u) du \quad (33)$$

where  $\Delta \dot{\epsilon}_s(t) = \Delta \dot{\epsilon}_s^1 - \Delta \dot{\epsilon}_s^2$ ,  $\Delta \dot{\epsilon}_s^i = \dot{\rho}^i / 3\rho^i$  is the variation in the densification rate,  $f$  is the concentration of inhomogeneities,  $\Delta \dot{\epsilon}_s^1$  is the densification rate in the microvolume where the fluctuation of density is observed, and  $\Delta \dot{\epsilon}_s^2$  is the shrinkage rate of the porous body as a whole. Thus, the

densification rate of a structurally nonhomogeneous material can be written as [59]

$$\dot{\rho} = A \left( 1 - \frac{\rho}{\rho_f} \right)^\alpha \left[ \frac{\Sigma - \sigma_m}{\Sigma} \right] \cdot l^{-a} \quad (34)$$

where  $A$  is a temperature-dependent function,  $\rho$  is the instantaneous density,  $\rho_f$  is the theoretical density,  $\Sigma$  is the "sintering potential,"  $\Sigma = \gamma_s(r + 2\gamma_b/l)$  for the homogeneous state,  $\gamma_s$ ,  $\gamma_b$  are the surface and grain boundary energies, respectively,  $l$  is the curvature radius, and  $\alpha$  and  $a$  are power indexes. From Eq. (34) it can be concluded that the densification rate approaches zero if  $\sigma_m = \Sigma$ . Thus, the higher the instantaneous densification rate, the higher the instantaneous difference  $\Delta\dot{\epsilon}_s$  and the higher the value of  $\bar{\sigma}_m$ . An increase in  $\bar{\sigma}_m$  results in a decrease in the driving force of sintering. One can conclude that for each fractional density there is a range of optimal densification rates corresponding to the minimum variation of density.

If sintering is carried out without isothermal hold, the final fractional density of sintered material depends strongly on the heating rate, and this feature is inherent in nanocrystalline powders of ceramics and metals [60]. It is worth mentioning that the heating rate corresponding to the maximum density increases with particle size decrease.

Thus, rapid heating leads to pore growth due to differential densification, owing to strong temperature gradient. On the other hand, slow heating does not result in full densification because of pore coalescence and premature pinching off of channel pores. At low temperatures, the coalescence of pores is under the control of surface diffusion and prevails over densification, which is under the control of boundary diffusion, because the surface area exceeds the area of grain boundaries and the surface diffusion coefficient is three orders of magnitude higher than that of grain boundary diffusion at the same temperature. In real nanostructure systems, it becomes impossible to avoid coalescence completely and prevent differential densification. It appears to be possible to minimize their influence by flexibly affecting the competition between coarsening of microstructure and densification during nonisothermal sintering. The optimal heating rate is the best evidence of this statement.

#### 4. THERMAL STABILITY OF NANOSTRUCTURED SYSTEMS

A dissipative system aspirates to decreasing free surface energy, which is the driving force of sintering (a thermodynamically reversible process). Let us consider densification as a rheological process, where the densification rate is defined by the effective viscosity of the dissipative system and the value of the driving force. On the other hand, a decrease in free surface energy proceeds through surface diffusion-controlled coalescence. The two processes are in temperature-driven competition, which can be controlled by temperature variation in the course of sintering. Since the technological purpose of sintering is to bring the density of a material close to its theoretical value, it is reasonable to accelerate the first process and retard or impede the second one.

The specific surface area of a porous body or a loose powder is the surface area of the pores,  $S$ , divided by the volume,  $V_m$ :  $s_s = S/V_m$  (where  $s_s$  is in  $\text{cm}^2/\text{cm}^3$ ). Thus,  $s_s$  is proportional to the ratio  $A/L$ , where  $A$  is a constant ( $3 \div 4$ ) and  $L$  is a structural parameter (mean particle size of the powder, or the average pore size in a porous body, for cylinder-shaped pores,  $L = 2R_{\text{cyl}}$ ). If the volume of a body  $V$  and  $L$  are independent variables, the full differential of  $s_s$  can be written [40] as

$$ds_s = \frac{\partial s_s}{\partial V} \Big|_{L=\text{const}} dV + \frac{\partial s_s}{\partial L} \Big|_{V=\text{const}} dL \quad (35)$$

In accordance with the rheological theory of sintering, which uses the statistical model of a porous body, the second addend can be omitted if we suppose that the only shrinkage affect variation is in the surface area. This assumption is reliable if the grain size is larger than  $10^{-3}$  cm. In the case of ensemble of nanosized particles, the surface area changes at the initial sintering stage because of variation in the structural parameter (coalescence). Shrinkage and coalescence make a combined contribution to the reduction of the surface area at the intermediate sintering stage.

#### 4.1. Coalescence of Pores and Inclusions

The initial stage of volume shrinkage occurs because of mechanisms with low activation energies. According to different assumptions, mutual particle rotation and sliding leading to rearrangement of particles, accommodation of facets in adjacent particles, and other modes correspond to this requirement. First, such assumptions and mechanisms were described by Geguzin and Thoelen in [21, 61], and today they are in the focus again. Particle rearrangement and accommodation, however, are restricted by package density.

The intermediate stage of shrinkage denotes the formation of a peculiar structure, namely, channel-like porosity, due to simultaneous action of grain boundary and surface diffusion mechanisms. This structure evolves specifically through changes in pore diameter, while their length remains unchanged. Pinching off the channel pores occurs locally, in those places where pore diameter becomes smaller than the critical value, defined from the ratio of Raleigh. The fragmentation of channels results in pore isolation and formation of close porosity, which is usually localized on grain boundaries or in triple junctions. Elimination of such porosity depends on grain boundary mobility, temperature, and sintering duration.

Both initial and intermediate stages can be attributed to low-activation-energy mechanisms. Comparative characteristics of nanograined and conventional micrograined ceramics are presented in Table 4. However, all of these parameters are rather close to the activation energy of surface diffusion obtained for coarse-grained materials.

Mayo suggested that such a low activation energy can be explained by the mechanism of facet accommodation. In [62], a contact formation mechanism was proposed for the initial stage of sintering if the diffusion coefficient is a function of the contact geometry and decreases surface diffusion coefficient to grain boundary diffusion one.

**Table 4.** Effective sintering activation energies for nanocrystalline powders and corresponding activation parameters of diffusion in some substances.

Substance	$E_a$ (experiment) (kJ/mol)	$E_a$ (grain bound.) (kJ/mol)	$E_a$ (surface) (kJ/mol)	$E_a$ (volume) (kJ/mol)

At low and moderate temperatures, sintering of nanoparticles is controlled by the mechanism of surface self-diffusion. In this case, the kinetic equation is easily derived for isothermal variation of a structural parameter with the modified equation of diffusion coalescence [53]:

$$L^4 = L_0^4 + \frac{32\sigma D_s \delta^4}{kT} t \quad (36)$$

where  $D_s$  is the coefficient of surface self-diffusion,  $\sigma$  is the surface tension,  $\delta$  is the thickness of a surface layer,  $L_0$  is the initial value of the structural parameter,  $k$  is the Boltzmann constant, and  $T$  is the temperature. Equation (36) is valid for a description of coalescence in nanostructured systems, such as ensembles of pores. Relaxation of the pore surface occurs when pores coalesce, making the microstructure coarser. At the same time, the surface area decreases simultaneously with porosity reduction and decreasing mean pore size. The competition between shrinkage and coalescence as a function of the heating rate is represented in Figure 2.

For nanocrystalline powders, which tend toward coarsening through the mechanism of surface self-diffusion, Eq. (36) is correct and the assumption of linear viscous flow accompanied by interparticle sliding under the action of capillary forces becomes reasonable [21, 63]. In this case, the viscosity of the system is reversely proportional to the third power of the linear size of the structural element [21, 63]:

$$\frac{1}{\eta} = 100 \frac{\Omega b D_b}{kTL^3} \quad (37)$$

where  $\Omega$  is the atomic volume,  $D_b$  is the grain boundary diffusivity, and  $b$  is the width of the grain boundary.

To build this graph, the coalescence of pores (the region between curves 2 and 3) and densification (curves 4 and 5) was calculated and compared with experimental data (curve 1) [4]. At low heating rates (curves 3 and 5), there is a temperature interval (300–500 °C) in which the coalescence prevails over densification, that is, it makes the main contribution to the reduction of surface area. The higher the

heating rate, the smaller is the contribution of pore coalescence to the surface area reduction. At high heating rates, densification prevails over coalescence in the whole temperature interval, and pore growth is impeded. Thus, during sintering of nanosized powders there exists the dependence of structure on heating rate, which influences the driving forces of sintering.

It was experimentally shown that the coarsening of pores and grains at the initial stage of sintering proceeds simultaneously. Actually, if a small particle is located inside a pore and is surrounded by coarser particles, it divides the pore into several small ones and porosimetry shows a small pore size. During heating, the particle gradually coalesces, with the coarser particles redistributing substance all over the surface and filling the contact necks between the coarse particles. At the same time, the pore becomes larger. In this case, coarse particles and large pores increase in size while small particles and pores disappear. The process of coarsening is shown in Figure 3.

**Figure 2.** Temperature dependence of specific pore surface for nano-sized Ni. Rates of heating: 1, 2, 4, 0.44 °C/c; 3, 5, 0.18 °C/c. 1, experimental data; 2–5, calculated data; 2, 3, for coalescence; 4, 5, for compaction. Reprinted with permission from [4], V. V. **Figure 3.** Schematic drawing of coalescence increase of pores and grains at the initial stage of sintering when shrinkage is absent. Reprinted with permission from [4], V. V. Skorokhod et al., "Physicochemical Kinetics in Nanostructured Systems." Academperiodica, Kiev, 2001 (in Ukrainian). © 2001, Academperiodica.

Particles of sizes  $R1$  and  $R2$  increase to  $R3$  and  $R4$ , respectively, owing to coalescence with small particles (shown in black). The pore inside the agglomerate also increases: a pore of the maximum size  $r1$  is transformed into a pore of size  $r2$  after coalescence. At this stage of sintering, the pores change in size and shape, which reduces the free surface energy as well. Figure 4 presents the results of calculations and experiments, both for coalescence growth, which takes place under nonisothermal conditions. The only coalescence provides a rapid growth, but it cannot be observed in practice because of the competitive contribution of shrinkage.

When the porosity is large and the structure of the pores is well developed, the intensive densification of the porous body is the reason for the suppression of grain growth. As shown, the maximum contribution of coalescence to coarsening microstructure doubles the mean linear size of the structural element. A correctly selected heating regime at the initial stage of sintering, however, and a homogeneous green microstructure as a result of the optimal scheme of compaction can minimize the effect of coalescence coarsening the microstructure at the initial stage of sintering.

**Figure 4.** Temperature dependence of coalescence growth of grains and pores of nanopowder at constant initial rate of sintering. Reprinted with permission from [4], V. V. Skorokhod et al., "Physicochemical Kinetics in Nanostructured Systems." Academperiodica, Kiev, 2001 (in Ukrainian). © 2001, Academperiodica.

General theoretical calculations allowed the following equations to be deduced:

$$f(\theta) \frac{d\theta}{dt} \approx \frac{A\sigma D}{a^n kT} \quad (38)$$

$$a^n = a_0^n + \frac{B\sigma D'}{kT} t \quad (39)$$

where  $t$  is time,  $m$  and  $n$  are indexes of power,  $a$  is the middle grain size, and  $D$  and  $D'$  are the effective diffusion coefficients, corresponding to densification and grain growth, respectively. A detailed analysis of the two competitive processes can be carried out. First of all, it is necessary to note that densification does not depend on the heating rate if  $m = n$ . If grain boundary diffusion prevails over bulk diffusion at the initial and intermediate stages of sintering, the index of densification is equal to  $m = 4$ . At the same time, the index of grain growth is equal to  $n = 4$ , provided either the nanoparticles coalesce from the beginning of sintering by means of surface mass transport or grain growth is restricted by porosity and inclusions of the second phase. Thus, the case of  $n = 4$  can be suitable for the nonisothermal stage of densification as a whole. Actually, the heating rate independence of the temperature derivative of density remains unchanged in many experiments. For nanocrystalline titanium nitride, nickel, barium titanate, and composition  $B_4C-TiB_2$  this was confirmed in [64]. If  $m > n$ , the temperature derivative of density (or porosity) is directly proportional to the heating rate, and, vice versa, for  $m < n$  it is reversely proportional to the heating rate. Both cases were revealed experimentally at the late stage of sintering at high temperatures, where the contribution of volume diffusion is much higher than that of grain boundary diffusion and the contribution of surface mass transfer is negligibly small. There is an interval of heating rate (about 1) where densification does not depend on the ratio  $m/n$ . Since the contribution of different mechanisms of mass transport to the kinetics of total densification changes synchronously, the ratio  $m/n$  is variable. Thus, the heating rate must be variable to optimize the densification process as a whole and instantaneous density in particular. This statement is the basis for rate-controlled sintering, which is the most profitable in the manufacture of dense nanostructured materials.

## 4.2. Recrystallization and Grain Growth

New ideology and experimental achievements of rate-controlled thermally activated processes of synthesis and sintering are very useful in the manufacture of nanosized powders and nanograined materials. The rate-controlled processes differ strikingly from the conventional synthesis and sintering due to back-coupling established between transformation degree (completeness of chemical reaction or shrinkage) and instantaneous temperature. During the process, the transformation degree is a dependent parameter, whereas the temperature is an independent parameter. sintering, chemical synthesis, and phase transformations proceed through the competition between densification and grain growth or new phase nucleation and nuclei growth. This competition results in the possibility of controlling particle and grain size within the nanoscale range, where a useful "size effect" takes place.

The size effect is the most attractive fundamental problem in nanocrystalline materials since it directly answers the question of whether these extremely fine-grained materials are worth producing. Variations in properties with size and shape of structural element occur in all solids, because the relative contributions from surface and volume energies are both size- and shape-dependent and are different for particles, fibers, films, and polycrystals.

The final stage of sintering is characterized by fast reducing densification and an intensive grain growth. At this stage, the process of shrinkage of nanocrystal material and an intensive grain growth are both complete. In a number of cases, fully dense and nanostructured materials cannot be produced. At the intermediate stage, the two processes can keep in balance. However, at the final stage it is difficult to restrain grain growth because of the essential decrease in the driving force of sintering. To clear up the question of whether this is the result of imperfections of procedures used to produce a nanostructured material or it is an inherent trait of the latter, the evolution of the structure during sintering of ideally packed powders with different dispersities was investigated [4]. It was found that the grain growth at the final stage could be described by the following exponential expression:

$$a^m = a_0^m + K_0 \exp(-Q/RT) \quad (40)$$

where  $a$ ,  $a_0$  are the current and initial sizes of a grain,  $Q$  is the energy of grain growth activation, and  $m$  is an index of the level of grain growth. The index  $m$  is defined by the mechanism of grain growth and changes from 1 to 4, but in some cases it can reach 20. When a grain growth is abnormal,  $m = 1$ ; for normal growth,  $m = 2$ ; in the case of deceleration of the grain growth caused by impurities or of sintering of powders of solid solutions,  $m = 3$ . For dense nanostructured metals, the index  $m$ , however, is equal to 20 at low temperatures and, under heating, decreases to 2. As for normal grain growth, it is seldom observed in nanostructured materials.

The "classical" curve of the grain growth against the density, the so-called trajectory of sintering, has three distinct regions corresponding to three stages of sintering. At the initial (where coalescence is dominant) and intermediate (where deceleration of grain growth takes place) stages, the grain growth changes very slowly. When the density reaches 0.84 of its theoretical value, a very sharp increase in grain size (by 2 times) begins.

The most attractive process from the point of view of the possibility of controlling the evolution of microstructure under nonisothermal sintering is deceleration of the grain growth by pores and inclusions.

Gupta et al. [65] summed up experimental data for different polycrystalline materials by drawing density dependences of the grain size. The increase in grain size proved to be linear in the density range from the initial value to 90% of the theoretical one. With increasing density, a more intensive (by 2–3 times) grain growth was observed. Other investigators obtained similar results.

In the common case, the mechanisms of densification and grain growth have different dependences on the scale. In practice, a change in grain growth leads to a change in the

temperature of isothermic sintering, which, in its turn, influences the trajectory of sintering. Thus, the following two cases can be distinguished:

- Activation energies for densification and size growth are equal.
- Activation energy for densification is higher than that for size growth (coarsening the microstructure).

In the first case, the influence of temperature and heating rate is minimal or absent. In the second case, a great heating rate can confer essential advantages because at high temperatures shrinkage is accelerated more than grain growth.

An algorithm for the calculation of the trajectory of sintering was proposed in [66] on the basis of the suggestion that deceleration caused by pores and internal grain boundary diffusion can be interpreted as mechanisms of densification during sintering. The slope of the trajectory of sintering is described by the expression

$$\frac{dg}{d\rho} = \frac{\dot{G}}{G_0 \dot{\rho}} \quad (41)$$

where  $g = G/G_0$ ,  $\rho$  is the density, and the symbols with dots denote derivatives with respect to time. If grain growth is reduced by pores, the expression can be transformed as follows:

$$\frac{dg}{d\rho} = g \frac{\delta_s D_s^0}{\delta_b D_b^0} \exp\left(-\frac{Q_s - Q_b}{kT}\right) \rho^{-1} K_1(\psi) \quad (42)$$

If the mobility of grain boundaries is responsible for grain growth,

$$\frac{dg}{d\rho} = g^3 G_0^2 \frac{M_b^0}{\Omega \delta_b D_b^0} kT \exp\left(-\frac{Q_M - Q_b}{kT}\right) \rho^{-1} K_2(\psi) \quad (43)$$

where  $K_2(\psi)$ ,  $K_1(\psi)$  are functions describing the contact geometry and dihedral angle, and  $M_b$  and  $Q_M$  are a preexponent and the energy of grain boundary mobility activation, respectively. Equation (42) corresponds to the intermediate stage of shrinkage, where the competition between shrinkage and coalescence is changed by the competition between shrinkage and grain growth limited by channel porosity and independent of the initial grain size. The final stage of sintering proceeds under conditions when pores do not prevent grain growth. However, they are dependent on the initial grain size, and Eq. (43) defines the conditions of competitions of the mechanisms at this stage. It is worth noticing that the only competition between shrinkage and grain growth limited by boundary migration can lead to a poreless material. In addition, in this case the process becomes sensitive to the heating rate and, as in the initial stage, optimization of heating conditions is actual. In practice, this is taken into account in the method for sintering with the controlled rate of shrinkage.

Thus, by taking into account the competition between the rates of nucleation and nuclei growth in heterogeneous or solid-state reactions and the competition between the rates of densification and the grain growth, it can be possible to create nanosized powders and nanostructured sintered materials.

## GLOSSARY

**Coagulation** A process of reducing free surface energy in the system followed by coarsening of nanoparticles and maintaining the interfaces.

**Coalescence** A process of reducing free surface energy in the system followed by coarsening of nanoparticles and disappearance of interfaces between them.

**Genesis** Genesis of nanostructured systems is a structural heredity of powders from precursors and nanograined materials from powders.

**Kinetics** Kinetics in nanostructured systems is a complex of characteristics determining the change of properties in solids during a process.

**Sintering** A process of reducing free surface energy in the system of nanoparticles and pores resulting in healing of pores, transformation of particles into grains and grain growth.
