**Figure 26.** Infrared emission integrated intensity recorded under excitation of 514.5 and 457.9 nm for the (a)  $U(900)_nEu(CF_3SO_3)_3$ ,  $n = 10, 40$ , and 100,  $\Delta$  and  $\blacktriangle$ , respectively, and (b)  $U(2000)_nEu(CF_3SO_3)_3$ ,  $n = 10, 40$ , and 100,  $\circ$  and  $\bullet$ , respectively. The lines are guides to the eyes.

Section 4.2, the band in the PLE spectra monitored around the cations lines (essentially,  $Eu^{3+}$ ) (Figs. 14B, 15B, and 16B) was assigned to a transition occurring within the ligand levels. The efficiency of energy transfer in this hybrid type was demonstrated both by the lack of emission arising from the ligands/host in the PL spectra and by the lower intensity of the intra- $4f^6$  transitions, relative to the ligand excitation band, in the PLE spectra monitored around the  $Eu^{3+}$  emission lines.

Franville et al. compared the luminescence intensity of the  $EuH_i$  ( $i = 1-4$ ) hybrids, and found the following decreasing order:  $EuH_2 > EuH_3 > EuH_1 > EuH_4$  [155]. The main factor considered to be responsible for this result was attributed to the efficiency of the energy-transfer mechanisms between the ligand and the  $Eu^{3+}$  cation, which depend on the relative positions between the intra- $4f^6$  levels and the excited states of the ligands, namely, the singlet ( $S_1$ ) and triplet ( $T_1$ ) states [155]. The  $S_1$  and  $T_1$  energies were determined by measuring the absorption/emission spectra of the corresponding  $GdH_i$  ( $i = 1-4$ ) materials (see Fig. 28). The emission intensity differences were attributed to the resonant condition between the  $Eu^{3+}$   $^5D_1$  level and the ligand excited state  $T_1$  since it is known that the most efficient energy transfer occurs from the ligands to the intra- $4f^6$  level [155]. As Figure 28 shows,

**Figure 27.** Schematic illustration of the energy diagram for (a)  $U(2000)_nEu(CF_3SO_3)_3$ ,  $40 \leq n \leq 200$ , and (b)  $U(2000)_{20}Eu(CF_3SO_3)_3$ . For the hybrid levels, the black and gray lines correspond to the siliceous nanodomain and NH group emitting levels, respectively. The solid and dotted lines indicate radiative and nonradiative processes, respectively. The dashed lines exemplify possible energy-transfer paths between the host and the  $Eu^{3+}$  ions and between the LMCT states and the intra- $4f^6$  levels. Reprinted with permission from [170], R. the state  $T_1$  is closer to the  $^5D_1$  level for the  $\text{EuH}_2$  and  $\text{EuH}_3$  hybrids, contributing to a more efficient energy transfer (a); the low intensity of the  $\text{EuH}_2$  regarding that of the  $\text{EuH}_3$  was attributed to the possible back transfer from the  $^5D_2$  level to the ligand excited level (b). For the remaining samples, two major factors were considered as responsible for their low relative emission intensity: (1) the higher energetic  $T_1$  triplet state, and (2) back transfer from intra- $4f^6$  levels (c) and (d), namely,  $^5L_6$  and  $^5D_3$  [155].

## 8. $\text{Eu}^{3+}$ LOCAL COORDINATION

The  $\text{Eu}^{3+}$  local coordination was investigated in great detail for the di-ureasils,  $\text{U}(\text{Y})_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $\text{Y} = 600$  and  $2000$ , and  $\text{U}(600)_n\text{Eu}(\text{Cl}_4\text{O})_3$ , [166, 170, 171, 177, 180, 181], and for the  $\text{Eu}^{3+}$ -activated hybrids with four different dicarboxylic acids, designated as  $\text{EuH}_i$  ( $i = 1-4$ ) [153, 155].

The typical  $\text{Eu}^{3+}$  emission lines for the di-ureasil hybrids were already presented in Figure 7. The number of components clearly identified for the  $^7F_{0-2}$  levels is one, three, and five, respectively. While for the  $^7F_1$  level it is possible to discern unequivocally the three components, in the  $^7F_2$  level, there is some uncertainty in the assignment of the lower energetic component [166]. The  $\text{Eu}^{3+}$  luminescence features, namely, the number of Stark components and respective energy, do not vary either with the excitation wavelength or the ion content, except in the case of highly concentrated  $\text{U}(600)_n\text{Eu}(\text{Cl}_4\text{O})_3$  ( $n > 62$ ) and  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  ( $n > 40$ ) [170, 171, 181]. For these samples, a variation of the energetic position of the emission lines with the variation of the excitation wavelength was observed, namely, in the energy of the nondegenerated  $^5D_0 \rightarrow ^7F_0$  transition (see Fig. 7B and C). The number of local-field splitting  $^7F_{1,2}$  Stark components detected and the presence of the  $^5D_0 \rightarrow ^7F_{0,3}$  transitions indicate a low-symmetry environment for the  $\text{Eu}^{3+}$  ions in the di-ureasil's host. Generally, the  $\text{Eu}^{3+}$  ions are accommodated in a continuous distribution of closely similar network sites in the di-ureasils, excluding the  $\text{U}(600)_n\text{Eu}(\text{Cl}_4\text{O})_3$  ( $n > 62$ ) and  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  ( $n > 40$ ) hybrids, where two different local environments were discerned. This is also suggested by the high values found for the FWHM of the  $^5D_0 \rightarrow ^7F_0$  transition, between 17 and  $31 \text{ cm}^{-1}$  [166].

The chemical nature of the  $\text{Eu}^{3+}$  local sites can be discussed in greater detail through the analysis of the energy of the  $^5D_0 \rightarrow ^7F_0$  transition in a given sample  $E_{\text{complex}}$  relative to the value calculated for gaseous  $\text{Eu}^{3+}$  ions ( $E_{\text{gaseous}} = 17374 \text{ cm}^{-1}$  [166, 168, 205]). This shift  $\Delta E$  was related to the nature of the  $\text{Eu}^{3+}$  first coordination shell through the following phenomenological equation [166, 168, 205]:

$$\Delta E = E_{\text{complex}} - E_{\text{gaseous}} = C_N [n_1 \delta_1 + \dots + n_j \delta_j] \quad (15)$$

where  $C_N$  is a nephelauxetic parameter adjustment related to the total number of first-ligand atoms,  $n_j$  is the number of atoms of type  $j$  in the first coordination shell, and  $\delta_j$  is an adjusted parameter that measures the tendency of a particular atom to bond covalently to the  $\text{Eu}^{3+}$  ion [166, 168, 205]. Frey et al. gathered the energy of the  $^5D_0 \rightarrow ^7F_0$  transition of several  $\text{Eu}^{3+}$ -based materials whose local structures were known, and determined the typical  $\delta_j$  parameters for

several ligands, ordering the ligand types in terms of their tendency to produce the *nephelauxetic* effect [205]:  $\text{Cl} > \text{OT} > \text{O} > \text{O}\beta > \text{ON} > \text{NT} > \text{OH} > \text{OE} > \text{OW}$ , where OT, O,  $\text{O}\beta$ , ON, NT, OH, OE, and OW represent oxygen atoms that belong to charged carboxylate, amide carbonyl,  $\beta$ -diketonate, nitrate, hydroxyl, ether groups, and  $\text{H}_2\text{O}$  molecules, respectively [205]. This ordination suggests that the oxygen atoms that belong to the polyether chain (OE) have a lower tendency to establish covalent bonds to  $\text{Eu}^{3+}$  than the oxygen atoms of the carbonyl groups (OT) of the urea cross linkages.

An ordinal scale of covalency for lanthanide compounds based on the overlap polarizability of a chemical bond was recently proposed by Malta et al. [214], showing a good correlation with the *nephelauxetic* effect, observed from the red shift of the  $^5D_0 \rightarrow ^7F_0$  transition in the  $\text{Eu}^{3+}$  complexes, relatively to the value reported for free ion. This corroborates the conclusion reached in [205] and [215] stressing the importance of covalency in the mechanism that governs the red shift in the energy of certain transitions when the ions are incorporated into solid structures, relatively to the value found for free ions.

Considering the structural information supplied by EXAFS and FTIR (see Section 3), Eq. (15) was used to simulate the first coordination shell of the  $\text{U}(2000)_n \cdot \text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $n = 40, 60$ , and  $80$ , di-ureasils. An 11-fold coordination was considered in all cases. FTIR results suggested that one of the three-triflate anions does not belong to the first coordination shell. Therefore, five (or four) oxygen atoms of the  $\text{SO}_3$  end groups of the remaining triflate anions establish a tri- and a bidentate (monodentate) coordination to the  $\text{Eu}^{3+}$  [164, 166, 168]. If the  $\text{Eu}^{3+}$  concentration is expressed in terms of the number of available oxygen atoms of the carbonyl group per  $\text{Eu}^{3+}$  cation, then there are four, three, and two oxygen atoms of that type for the di-ureasils with  $n = 80, 60$ , and  $40$ , respectively. The 11-fold coordination is thus completed with two, three, and four  $\text{H}_2\text{O}$  molecules, respectively. As expressed in Table 6, the predicted energy shift  $\Delta E$  agrees well (within the correlation uncertainty reported for the  $C_N$  and  $\delta_j$  coefficients,  $\pm 3 \text{ cm}^{-1}$ ) with the experimental values  $\Delta E_{\text{exp}}$ . These calculations were performed using the  $C_N$  and  $\delta_j$  coefficients present in [205, Table 2]. Note that, since the  $\delta_j$  coefficient was not reported for the  $\text{SO}_3$  group, the value proposed for the nitrate group was used. We should stress that this assumption seems to be correct, as the predicted and

**Table 6.** Energy of the  $^5D_0 \rightarrow ^7F_0$  transition for the  $\text{U}(2000)_n \cdot \text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $n = 40, 60$ , and  $80$ ,  $E_{\text{complex}}$ . The experimental ( $\Delta E_{\text{exp}}$ ) and simulated ( $\Delta E$ ) energetic shifts and the type and number of  $\text{Eu}^{3+}$  first ligands, denoted according to the notation of [205], are also presented.

	$\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$

experimental values coincide, within the referred correlation uncertainty.

The decrease of  $\Delta E$  when increasing the  $\text{Eu}^{3+}$  content suggests that the covalence degree of the lanthanide first coordination shell decreases with the increase in the amount of incorporated  $\text{Eu}^{3+}$ . This occurs due to the replacement of oxygen atoms of the carbonyl group by  $\text{H}_2\text{O}$  molecules in the  $\text{Eu}^{3+}$  first ligands, whose  $\delta_j$  coefficient is inferior to that of the oxygen atoms of the carbonyl groups [166, 168].

As already noted in Section 3, the local coordination of the  $\text{Eu}^{3+}$  ion depends on the length of the polymer chain. In fact, for the U(2000)-based hybrids ( $40 \leq n \leq 400$ ), the lanthanide ions are mainly coordinated to the oxygen atoms of the carbonyl group of the urea linkages, whereas for the U(600)-based di-ureasils ( $n \geq 60$ ), the preferential coordination sites are the ether-type oxygens of the polymer chains. As ether-oxygen atoms are characterized by a lower  $\delta_j$  coefficient than that of the oxygen atoms of the carbonyl groups, it is expected that the  $\text{Eu}^{3+}$  first coordination shell in the latter case presents a lower degree of covalence.

In fact, the PLE spectra monitored around the  $\text{Eu}^{3+}$  emission lines (Section 4.2) confirm this suggestion. The LMCT states are more energetic in the U(600)-based hybrids than in the U(2000)-based di-ureasils. As the energy of these states is related to the covalence degree of the  $\text{Eu}^{3+}$  local environment in such a way that a decrease in the LMCT state's energy is related to an increase in the covalence of the  $\text{Eu}^{3+}$  coordination shell [see Eq. (5)], the PL data are in perfect agreement with the different local coordination sites suggested by the structural results.

The covalency and polarizability degree of the  $\text{Eu}^{3+}$  first coordination shell may also be inferred from the calculus of the intensity parameters,  $\Omega_\lambda$  ( $\lambda = 2, 4, 6$ ) [129, 168, 170, 216, 217]. The  $\Omega_{2,4,6}$  parameters are determined from the RT emission spectra by expressing the emission intensity of the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_{0-6}$  transitions  $I_{i \rightarrow j}$  in terms of the surface of their emission curves  $S_{i \rightarrow j}$ :

$$I_{i \rightarrow j} = \hbar\omega_{i \rightarrow j} A_{i \rightarrow j} N_i \equiv S_{i \rightarrow j} \quad (16)$$

where  $i$  and  $j$  represent the initial ( ${}^5\text{D}_0$ ) and final ( ${}^7\text{F}_{0-6}$ ) levels, respectively,  $\hbar\omega_{i \rightarrow j}$  is the transition energy,  $A_{i \rightarrow j}$  is the corresponding Einstein's coefficient of spontaneous emission, and  $N_i$  is the population of the emitting level ( ${}^5\text{D}_0$ ) [106–108, 129, 158, 168, 170, 216, 217]. The radiative transition probability  $k_{\text{rad}}$  from the  ${}^5\text{D}_0$  to the  ${}^7\text{F}_{0-6}$  levels may be expressed from the Einstein's spontaneous emission probability between levels  $i$  and  $j$ :

$$A_{i \rightarrow j} = k_{\text{rad}} = \sum_{j=0}^6 A_{0 \rightarrow j} \quad (17)$$

Usually, the  $\Omega_\lambda$  intensity parameters are obtained from absorption data. However, for the  $\text{Eu}^{3+}$  ion, the pure magnetic dipole character of the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_1$  transition enables the determination of such parameters from the emission spectra. Since this transition does not depend on the local ligand field seen by the  $\text{Eu}^{3+}$  cations, it may be used as a reference for the entire spectrum,  $A({}^5\text{D}_0 \rightarrow {}^7\text{F}_1) \approx 50 \text{ s}^{-1}$

[218]. In that way, it is possible to express the radiative transition probability  $k_{\text{rad}}$  between the first excited state  ${}^5\text{D}_0$  and the  ${}^7\text{F}_{0-6}$  levels as

$$k_{\text{rad}} = \frac{A_{0 \rightarrow 1} \hbar\omega_{0 \rightarrow 1}}{S_{0 \rightarrow 1}} \times \sum_{j=0}^6 \frac{S_{0 \rightarrow j}}{\hbar\omega_j} \quad (18)$$

Moreover, the electric dipolar  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_{2,4,6}$  transitions depend only on the  $U^{(2)}$ ,  $U^{(4)}$ , and  $U^{(6)}$  reduced matrix elements, respectively, which allows the evaluation of the  $\Omega_\lambda$  intensity parameters directly from the RT emission spectra. It is important to note that theoretical calculations indicate the contribution to the values of the  $\Omega_\lambda$  intensity parameters of two different mechanisms: forced electric dipole and dynamic coupling [216, 217, 219]. Jørgensen and Judd first reported the dynamic coupling mechanism in 1945 [220]. In a simple way, the dynamic coupling mechanism can be described assuming that the electric field of the incident radiation induced the formation of oscillating dipoles on the atoms in the neighborhood of the  $\text{Eu}^{3+}$  cations, producing an additional oscillating electric field. An interesting aspect of two such mechanisms, forced electric dipole and dynamic coupling, is that they contribute with opposite signs to the value of the  $\Omega_\lambda$  intensity parameters, so that when such parameters are phenomenologically evaluated, it is not possible to individually identify each contribution. Nevertheless, there are some empirical evidences that make relevant the phenomenological evaluation of the  $\Omega_\lambda$  intensity parameters. The major contribution to the  $\Omega_2$  intensity parameter comes from the hypersensitivity electric dipole  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_2$  transition. It was empirically observed that, in complexes where a higher degree of covalence in the  $\text{Eu}^{3+}$  first coordination shell should be expected, a higher value for the respective  $\Omega_2$  intensity parameter was also observed [212]. Another correlation was reported between the  $\Omega_{4,6}$  intensity parameters and the local vibrational modes involving the  $\text{Eu}^{3+}$  ions, suggesting that a greater rigidity of the material is observed at higher values of such intensity parameters [212]. The  $\Omega_6$  intensity parameter is not usually calculated due to the low relative intensity of the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_6$  transition, regarding the remaining intra- $4f^6$  transitions.

Summarizing, the expressions used in the calculus of the Einstein spontaneous emission coefficients  $A_{0 \rightarrow 2}$  and  $A_{0 \rightarrow 4}$  are, respectively,

$$\frac{\hbar\omega_{0 \rightarrow 2} A_{0 \rightarrow 2}}{\hbar\omega_{0 \rightarrow 1} A_{0 \rightarrow 1}} = \frac{S_{0 \rightarrow 2}}{S_{0 \rightarrow 1}} \quad (19)$$

and

$$\frac{\hbar\omega_{0 \rightarrow 4} A_{0 \rightarrow 4}}{\hbar\omega_{0 \rightarrow 1} A_{0 \rightarrow 1}} = \frac{S_{0 \rightarrow 4}}{S_{0 \rightarrow 1}} \quad (20)$$

where  $\hbar\omega_{0 \rightarrow j}$  and  $S_{0 \rightarrow j}$  ( $j = 1, 2,$  and  $4$ ) are the energies of the center of gravity and the integrated intensities of the emission curves of the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_{1,2,4}$  transitions, respectively. Finally, the expressions used for the calculus of the  $\Omega_{2,4}$  intensity parameters are

$$A_{0 \rightarrow 2} = \frac{4e^2}{3\hbar^4 c^3} (\hbar\omega_{0 \rightarrow 2})^3 \frac{n_0(n_0^2 + 2)}{9} \Omega_2 \left( {}^5\text{D}_0 \| U^{(2)} \| {}^7\text{F}_2 \right)^2 \quad (21)$$

and

$$A_{0 \rightarrow 4} = \frac{4e^2}{3\hbar^4 c^3} (\hbar\omega_{0 \rightarrow 4})^3 \frac{n_0(n_0+2)}{9} \Omega_4 \left\langle {}^5D_0 \parallel U^{(4)} \parallel {}^7F_4 \right\rangle^2 \quad (22)$$

where  $e$  is the electron charge (in these equations, an undimensional number equal to  $1.16140 \times 10^{-3}$ ),  $\hbar$  is the Planck constant (units  $\text{cm}^{-1} \cdot \text{s}$ ),  $c$  is the velocity of the light (in  $\text{cm} \cdot \text{s}^{-1}$ ),  $n_0$  is the refractive index of the medium, and  $U^{(2)}$  and  $U^{(4)}$  are reduced matrix elements (values of 0.0032 and 0.0023, respectively [221]). In the case of the di-ureasils,  $n_0$  was set to 1.5, a value very close to that measured for similar organic–inorganic hybrids [55, 72, 74].

The  $\Omega_{2,4}$  intensity parameters calculated for the  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $400 \geq n \geq 20$  [168] and  $\text{U}(2000)_n \cdot \text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $200 \geq n \geq 40$  di-ureasils are listed in Table 7. The  $\Omega_2$  and  $\Omega_4$  intensity parameters found for the precursor salt  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$  were 0.6 and 5.8, respectively [168]. The high-molecular-weight di-ureasils exhibit higher values for the  $\Omega_{2,4}$  intensity parameters than those of the  $\text{U}(600)$ -based hybrids within the entire  $\text{Eu}^{3+}$  concentration range examined. This result unequivocally states that the  $\text{Eu}^{3+}$  experiences a more covalent first coordination shell in the former hybrids. This is exactly the same conclusion already derived from the analysis of the energy observed for the LMCT states detected in the PLE spectra monitored around the  $\text{Eu}^{3+}$  lines.

The relatively high values found for the  $\Omega_2$  intensity parameters indicate that the local environment around the  $\text{Eu}^{3+}$  cations is highly polarizable, suggesting an improvement of the di-ureasil luminescence when compared with that of the  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$  [168]. Increasing the concentration in the  $\text{U}(2000)$ -based series results in a decrease of the  $\Omega_2$  values, except for the  $\text{U}(2000)_{80}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  hybrid, which presents the highest value of the  $\Omega_2$  intensity parameter, indicating a higher degree of covalence for the  $\text{Eu}^{3+}$  first coordination shell. This conclusion was independently suggested by the lower energy observed for the LMCT states of the remaining  $\text{Eu}^{3+}$  concentrations, and is in perfect agreement with the suggestion of the maximum number (four) of carbonyl-type oxygen atoms in the  $\text{Eu}^{3+}$  first coordination shell [168, 170]. For the  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasils, the variation of the  $\Omega_{2,4}$  intensity parameters with the increase of the concentration from  $n = 200$  to  $n = 80$  does not present the same trend observed for the high-molecular-weight hybrids. In fact, the values of the  $\Omega_{2,4}$  intensity parameters oscillate between 5.6 ( $n = 60$ ) and 7.6 ( $n = 40$ ). A detailed interpretation of these results is hard to realize since, as no EXAFS measurements were performed in these di-ureasils, we do not know how the number of  $\text{Eu}^{3+}$  first neighbors changes with the increase

of the  $\text{Eu}^{3+}$  content. However, the slight variation of the  $\Omega_{2,4}$  intensity parameters between  $n = 200$  and  $n = 40$  suggests that possible changes in the  $\text{Eu}^{3+}$  coordination shell are not as noteworthy as in the case of the  $\text{U}(2000)$ -based hybrids.

Franville et al. carried out a detailed study of the  ${}^5D_0 \rightarrow {}^7F_0$   $\text{Eu}^{3+}$  excitation spectra for the  $\text{EuH}_i$  ( $i = 1-4$ ) organic–inorganic hybrids [155]. These spectra were recorded at 15 K by monitoring the  ${}^5D_0 \rightarrow {}^7F_2$  transition of the four hybrids. For all of the samples, the measured excitation spectra revealed the presence of two contributions in the profile of the  ${}^5D_0 \rightarrow {}^7F_0$  transition [155]. This observation clearly established the presence of two distinct local  $\text{Eu}^{3+}$  coordination sites as this transition occurs between nondegenerated levels. Assuming a sum of two Gaussian functions, the spectra of the  ${}^5D_0 \rightarrow {}^7F_0$  transition were fitted, and the peak energy, FWHM, and relative intensity between the two contributions were estimated [155]. The low and high energetic  ${}^5D_0 \rightarrow {}^7F_0$  transitions were related to two local  $\text{Eu}^{3+}$  environments, designated as *A* and *B*, respectively. For the  $\text{EuH}_i$  ( $i = 1-3$ ) hybrids, the  ${}^5D_0 \rightarrow {}^7F_0$  energy of the two contributions *A* and *B* was detected around 17212–17218 and 17238–17240  $\text{cm}^{-1}$ , and present an FWHM of 11.1–12.4 and 21.2–22.1  $\text{cm}^{-1}$ , respectively. For the  $\text{EuH}_4$  hybrid, a blue shift of both *A* and *B*  ${}^5D_0 \rightarrow {}^7F_0$  transitions (17248 and 17262  $\text{cm}^{-1}$ ) and an increase in the respective FWHM values (13.5 and 24.3  $\text{cm}^{-1}$ ) were observed [155].

Taking into account that the energy of the  ${}^5D_0 \rightarrow {}^7F_0$  transition can be correlated with the number and type of the  $\text{Eu}^{3+}$  first neighbors [Eq. (15)] [205], Franville et al. related the aforementioned results with the structural data known for each hybrid. The  $\text{EuH}_i$  ( $i = 1-3$ ) materials presented a similar coordination mode for the lanthanide ion involving a ninefold coordination, while the  $\text{EuH}_4$  sample exhibited a fivefold coordination that was completed by nitrogen atoms. The blue shift observed for the  ${}^5D_0 \rightarrow {}^7F_0$  transition of the latter hybrid was attributed to the presence of N atoms, from  $\text{NO}_3$  groups, that are known to have a lower tendency to establish covalent bonds with  $\text{Eu}^{3+}$  compared with carbonyl-type oxygen atoms [155, 205].

The presence of two singular  $\text{Eu}^{3+}$  environments was further demonstrated by recording the  ${}^5D_0 \rightarrow {}^7F_0$  excitation spectra at selective monitoring wavelengths that correspond to each contribution (*A* and *B*) and under different delay times after the laser pulse. Although no change was observed in the shape of the spectra, the fitting procedure revealed changes in the intensity ratio of the *A/B*  $\text{Eu}^{3+}$  distributions [155].

**Table 7.**  $\Omega_2$  and  $\Omega_4$  intensity parameters [ $10^{-20} \text{ cm}^2$ ] for the  $\text{U}(Y)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $Y = 2000$ ,  $400 \leq n \leq 40$  and  $Y = 600$ ,  $200 \leq n \leq 40$ .

## 9. LUMINESCENT UNDOPED NANOHYBRIDS

The hybrid concept also has been employed to synthesize stable and efficient white-light photoluminescent amine-functionalized hybrids lacking metal activator ions, such as these obtained from APTES and 3-glycidoxypropyltrimethoxysilane (GPTES) with carboxylic acids, and from urea and urethane precursors (di-ureasils and di-urethanesils; Schemes 9 and 10) [163, 177, 186, 191–195, 198, 222–230]. The APTES–formic acid hybrid is one of the most efficient phosphors known among those lacking activator metal ions as it exhibits an external PL quantum yield of  $0.35 \pm 0.01$  [222]. For APTES–acetic acid phosphors, lower limits of 0.21 and 0.12 were estimated for the quantum yields of the two distinct emissions reported [223, 224]. Similar values were found for the di-ureasils and di-urethanesils [194].

Comparing the PL efficiencies of these amine-functionalized cross-linked hybrids with the characteristic values of other materials used in solid-state luminescent displays (e.g., amorphous porous silicon, *p*-Si, and conjugated conducting polymers), we note that the RT quantum yield for these amine-based hybrids is higher than that reported for *p*-Si [231], and similar to the typical values of the most efficient conjugated polymers [232]. Nevertheless, the PL features of the latter materials present substantial intensity degradation under laboratory ambient conditions, with the consequent drastic decrease in the quantum yield.

In spite of the potential technological relevance of the amine-functionalized hybrids, the origin of their efficient white-light intrinsic PL is not completely clarified [194–196, 228–230]. The identification of the nature of the emitting centers and the characterization of the recombination mechanisms subjacent to the intrinsic emission of these amine-functionalized cross-linked hybrids will certainly open new directions for developing other siloxane-based hybrids with similar or even greater light emission efficiency. Moreover, as we have described in the previous sections, most of the research on organic–inorganic frameworks has been focused on the PL features of lanthanide-based hybrid matrices, seeking essentially to take advantage of the high chromaticity and long excited lifetime characteristic of the metal ions, and of the improvement in the emission features and mechanical stability of the samples (compared to those of conventional silica gel hosts).

This section reviews the synthesis and the PL features of sol-gel-derived APTES-based hybrids (classed as aminosils; Scheme 11) and urea and urethane cross-linked organic–inorganic xerogels (Schemes 9 and 10). The nature of the white-light emission and the characterization of the recombination mechanisms subjacent to this intrinsic emission are also discussed. A detailed review on this subject was recently published [195]. The conclusions may be easily generalized to the di-ureasil precursor compounds (e.g., the diamines) and to other amine-functionalized hybrids, such as those based on GPTES and APTES incorporating carboxylic acids such as formic (HCOOH), lactic (CH<sub>3</sub>CHOHCOOH), acetic (CH<sub>3</sub>COOH), and valeric (CH<sub>3</sub>(CH<sub>2</sub>)<sub>3</sub>COOH) [222–224, 228–230].

**Scheme 11.** Molecular structure of the aminosils.

### 9.1. Synthesis

The synthetic procedure of the white-light phosphors proposed by Green et al. [222], which involves the reaction of the TEOS and tetramethoxyortosilane (TMOS) precursors with an excess of an organic carboxylic acid (formic, lactic, acetic, trifluoroacetic, cyclopropanoic, malonic, citric, tartaric, glyoxylic, or oxalic acids) at RT and under nitrogen atmosphere, leads to the formation of gels at times ranging from a few minutes to several days [222]. Solid acids were dissolved in a minimum of anhydrous methanol, whereas most acids were used as neat liquids. Thermal treatment performed in air between 200 and 500 °C gave rise to white or yellowish solid materials that underwent PL. The reaction of APTES with some of the carboxylic acids listed above (performed also by other groups all over the world [223, 224, 229, 230]) yielded a clear water-soluble material that could be drawn into fibers from a melt or cast into films or monolithic structures without any shrinking or cracking [222, 223, 229, 230].

The nondoped di-ureasil d-U(Y) and di-urethanesil d-Ut(Y') hybrids were synthesized using the procedure described in Section 2.2.2, dealing with the detailed description of the synthesis of Class II RE-doped hybrids. The three diamines used were Jeffamine ED-2001® (with  $a + c = 2.5$  and  $b = 40.5$ ), Jeffamine ED-900® (with  $a + c = 2.5$  and  $b = 15.5$ ), and Jeffamine ED-600® (with  $a + c = 2.5$  and  $b = 8.5$ ) (Scheme 9). The PEGs employed have average molecular weights of 300 and 2000 g/mol (PEG(300) and PEG(2000)), with  $m = 6$  and 45, respectively; Scheme 10). A slightly different synthesis procedure was proposed for the di-ureasil hybrids using HCl or NH<sub>4</sub>F for acid- or base-catalyzed hydrolysis, respectively [177, 186, 233]. Recently, the synthesis of di-ureasil hybrids by a completely distinct method involving acetic acid solvolysis in the absence of water was introduced [230].

The aminosil hybrids discussed here (Scheme 11) were prepared using the same procedure employed by Rousseau et al. [234]. APTES was mixed, at RT, with H<sub>2</sub>O and

methanol (molar ratio 1 Si:9.6 CH<sub>3</sub>CH<sub>2</sub>OH:1.5 H<sub>2</sub>O). This procedure is substantially different from that reported previously for similar hybrids in which APTES reacts with carboxylic acids [222–224, 229, 230].

## 9.2. Photoluminescence

Figure 29 displays the PL spectra of representative amine-based functionalities, the nonhydrolyzed precursors, and the di-ureasil, di-urethanesil, and aminosil hybrids. Apart from minor shifts in energy and in relative intensities, the emission of the other two diamines (Jeffamine-ED-900® and Jeffamine-ED-600®), nonhydrolyzed precursors, di-ureasils, and di-urethanesils are quite similar. The spectra also resemble those reported for APTES-derived hybrids with HCOOH, CH<sub>3</sub>CHOHCOOH, and CH<sub>3</sub>COOH carboxylic acids [222–224, 226, 230]. Furthermore, both the di-ureasils prepared with HCl or NH<sub>4</sub>F catalysts [177, 186] and by means of acetic acid solvolysis (a procedure carried out in the absence of water) [230] show identical PL features. The hypothesis that these PLs might arise from any contaminant present in the starting commercial products used in the synthesis was readily discarded [194–196]. Moreover, based on the molecular structure of ICPTES and APTES and on the fact that pure PEG (the organic precursor of the di-urethanesils) is not luminescent, a suggestion relating that emission with the lone pair of electrons of the NH-related groups existent in all of these amine-functionalized materials was previously pointed out in several works dealing with the PL features of amine-based hybrids [191–196, 222, 223, 230].

The PL features of a series of solutions of Jeffamine ED-2001®, using H<sub>2</sub>O and THF as solvents, provides other

Mater.* 2, 111 (2001). © 2001, Wiley–VCH.

experimental evidence indicating that the NH-related groups must be involved in the PL features of these materials [195, 196]. The supralinear decrease of the PL intensity with the decrease of the diamine concentration in the solutions was related to the increase of the average distance between NH<sub>2</sub> groups (belonging to different chains) induced by the dilution. A similar suggestion was recently pointed out, stressing that the emission properties of amine-functionalized hybrids are connected to the existence of clusters involving both the organic and inorganic components [186, 230]. In di-ureasils and di-urethanesils, SAXS data [178, 181–183] and fluorescence probing [225, 227] were used to study these clusters.

The difference between the PL features of the hybrids and those of their respective precursors was well established by time-resolved spectroscopy [194–196]. As previously reported for di-ureasils and di-urethanesils, for SDs between  $0.08 \times 10^{-3}$  and  $5.00 \times 10^{-3}$  s, two components are clearly observed in the hybrids’ spectra, namely, in the blue ( $\approx 2.50$  eV) and in the purplish–blue ( $\approx 2.92$  eV) spectral regions. In contrast, the diamines’ time-resolved spectra display only one component, peaking at  $\approx 2.50$  eV [194]. Upon increasing the time delay beyond  $5.00 \times 10^{-3}$  s, the time-resolved emissions of the hybrids and the related diamines became similar, as the more energetic purplish–blue emission in the hybrids’ spectra disappeared, and only the longer lived component remained [194]. Besides having dissimilar recombination time scales, the two bands also behaved differently when the excitation wavelength was varied from 330 to 420 nm (2.95 to 3.76 eV). While the blue band was visible in the entire excitation range, the purplish–blue component could only be detected within the interval between 350 and 375 nm (3.31 and 3.54 eV) [194]. Furthermore, the less energetic band energy strongly depended on the excitation wavelength, displaying a red shift as the excitation wavelength increased, contrary to the purplish–blue emission that presented no significant variation of its energetic position [194, 195].

These results showed that another emission component appeared after gelation, establishing the unequivocal presence of two distinct emissions in the bulk organic–inorganic

hybrids. These two emissions bands should arise from different chemical–physical origins since the recombination mechanisms subjacent to each one occur in distinct time scales [191, 194, 195] and present different behaviors when the excitation wavelength changes.

The PL decay profiles of each di-ureasil emission component and of Jeffamine ED-2001® emission could be described by an exponential behavior, and were detected at the maximum intensity position of each emission band under an excitation of 365 nm (3.40 eV). The 14 K di-ureasil's lifetimes were 160.0 and 3.5 ms (errors within 3–5%) for the blue and purplish–blue emissions, respectively [194, 195]. Raising the temperature up to 220 K led to no changes in the lifetime of the longer lived emission, whereas the purplish–blue band displayed a typical Arrhenius behavior [194, 195]. Above approximately 220 K, an abrupt decrease of both lifetimes was observed. This was well illustrated by a set of real time frames, extracted from a video film that recorded the white-light emission after the excitation source was turned off (Fig. 31). For temperatures higher than 220 K, the lifetimes were in a time scale smaller than  $10^{-5}$  s, being ca.  $10^{-8}$  s at RT [223], disabling the chance to record the emission with the aforementioned experimental setup.

The 14 K lifetime of the diamine emission was  $\approx 120.0$  ms, and thus of the same order of magnitude as the U(2000) blue band lifetime. Upon raising the temperature, the Jeffamine ED-2001® lifetime remained constant until 200 K, and for temperatures higher than 220 K, the value belonged to a time scale smaller than  $10^{-5}$  s, thus resembling the characteristic behavior of the hybrid's less energetic band [194].

The PL characterization of the Jeffamines®, non-hydrolyzed precursors, di-ureasils, di-urethanesils, and APTES-based hybrids supported persuasive arguments that the full color emission (namely, the blue band) might involve the NH groups of the cross linkages [186, 191, 194–196, 222, 227, 230]. For instance, the white-light emission of the APTES hybrids with a variety of organic carboxylic acids

was explicitly related to the presence of amide functionalities [222]. Furthermore, in di-ureasils and di-urethanesils, the grafting of  $\text{NH}_2$  or OH to the isocyanate group—with the subsequent formation of urea or urethane groups, respectively—did not significantly alter the emission properties of the diamines [191, 194, 195]. Nevertheless, a new band with completely distinct features was detected after polycondensation and building up of the inorganic network [191, 194, 195]. According to SAXS results, the di-ureasil and di-urethanesil morphology has a diphasic structure made of spatially correlated siliceous nanoclusters dispersed and located at the ends of the organic chains [178–183, 191]. Consequently, the purplish–blue component present in the emission spectra of the final xerogels must be related to the existence of these siliceous nanodomains. This was further confirmed by altering the conditions at which the hydrolysis and condensation reactions occurred, thus modifying the local structures of those siliceous nanoregions. A new U(600) di-ureasil sample was synthesized using a different ICPTES: ethanol: water ratio, which altered both the condensation degree and the relative proportions between the two local Si surroundings, as confirmed by  $^{29}\text{Si}$  MAS NMR results. The 14 K time-resolved spectra for that hybrid displayed a long-lived blue band similar to the one observed in all of the other samples. However, a new short-lived band, centered at  $\approx 450$  nm, was detected in the purplish–blue region, supporting the suggested influence of the siliceous nanoclusters on the full color emission detected, particularly in the purplish–blue band [194, 195].

The emission of these classes of amine-functionalized hybrids depended noticeably on the excitation wavelength [186, 191–195, 222–224, 227]. Figure 31 exemplifies the situation found for the RT emission of the aminosil, the U(2000) di-ureasil and the Ut(2000) di-urethanesil. When the excitation wavelength increases, the maximum intensity of the spectra moves to lower energies. The emission tuning by choosing an appropriate excitation wavelength was also observed for the sol–gel-derived APTES– $\text{CH}_3\text{COOH}$  phosphors, both in fresh samples and in the gels aged for 30–60 days at 50 °C [223, 224]. The excitation wavelengths were varied between 340 and 470 nm, and the corresponding emission spectra were detected from the blue to the orange–red spectral ranges. This is also reported for di-ureasils obtained by carboxylic acid solvolysis [230].

In order to quantify the energy of those two distinct emissions, a deconvolution fitting procedure was applied to the emission spectra [191, 192, 194]. The procedure used to fit the experimental emission spectra to the Gaussian parameters (peak energy, integrated intensity, and FWHM) was described previously for the  $\text{Eu}^{3+}$ -based samples (Section 4.1).

For excitation wavelengths between 300 and 400 nm (3.10–4.00 eV), the curve-fitting method revealed the presence of two Gaussian bands in the blue ( $\approx 2.50$ – $2.60$  eV) and in the purplish–blue (2.80–3.10 eV) spectral regions [191–196]. Only the former component could be accounted for in the 400–420 nm excitation wavelength range (2.95–3.10 eV). The FWHM reached approximately 0.40 and 0.35 eV for the blue and purplish–blue bands, respectively. The Gaussian peak energies resulting from the fitting procedure clearly show that it is the purplish–blue

**Figure 31.** RT PL spectra of (A) the Ut(2000) di-urethanesil, (B) the U(2000) di-ureasil, and (C) the aminosil under different excitation wavelengths, (a) 330 nm, (b) 350 nm, (c) 375 nm, (d) 395 nm, and (e) 420 nm.

component that originates the shift of the emission spectra as the excitation wavelength is varied. In the range of excitation wavelengths used, the luminescence position of the blue band remains approximately constant, around 2.50 eV. The purplish–blue band shifts linearly as the excitation wavelength increases from 350 to 400 nm (3.54–3.10 eV). For excitation wavelengths between 330 and 300 nm (3.76 and 4.13 eV), the emission is invariably peaked between 415 and 400 nm (3.00 and 3.10 eV) [191–195].

This strong dependence of the emission energy the excitation wavelength is characteristic of all of the materials under analysis (diamines, nonhydrolyzed precursors and final di-ureasil, di-urethanesil, and APTES-based xerogels), providing strong evidence of disorder-related processes generally associated with transitions occurring within localized states in noncrystalline structures (e.g., *p*-Si [235], hydrogenated amorphous Si, *a*-Si:H [236], and As<sub>2</sub>Se<sub>3</sub> glasses [237]). An identical dependence was also reported for a nonhydrolyzed di-ureasil precursor [186] and for APTES-based hybrids with carboxylic acids [230].

Although no significant changes were detected in the energy of the blue component, the energy of the purplish–blue band depends on the sample. In fact, in silicon-based nanostructured materials, the dimensional hierarchy of the backbone determines the energy in such a way that an increase in the siliceous network corresponds to a decrease in the respective energy gap [238–241]. Figure 32 shows the dependence of the di-ureasil emission energy on the respective domain sizes determined by SAXS [178, 181, 182] and by XRD [191], designated as  $R_p$  and  $L_p$ , respectively. We notice that the energy range of the emitting siliceous nanodomains depends on the polymer chain length in such a way that an increase in the domain size results in a decrease of the corresponding energy gap. For each excitation wavelength used, the emission energy follows approximately the same trend presented in Figure 32. The different values found for  $R_p$  and  $L_p$  are due to the fact that these parameters were calculated from different experimental data and different structural models. However, the crucial point is

**Figure 32.** Relation between the emission energy, excited at 365 nm, of the di-ureasils, ( $\blacktriangle$ ,  $\triangle$ ) U(600), ( $\bullet$ ,  $\circ$ ) U(900), and ( $\blacksquare$ ,  $\square$ ) U(2000), and the respective size domain determined by SAXS (solid symbols) and XRD (open symbols) measurements. The dashed lines are a guide to the eyes.

that, independently of the absolute value found for  $R_p$  and  $L_p$ , we observe that greater nanodomain sizes correspond to smaller emission energies. A similar behavior was reported for other materials like, for example, nanocrystals of oxidized silicon [242] and hydrogenated silicon clusters [243]. There are also other reports referring to the theoretical calculation of the emission energy as a function of the nanodomain size [238, 240, 242, 243].

### 9.3. Recombination Mechanisms

In order to enlighten the nature of the white-light emission detected in amine-functionalized hybrids, our following discussion will be based on the recombination mechanisms known for crystalline semiconductors, *c*-SC, with relevance to amorphous materials. In *c*-SC, there are two types of transitions, recognized as near band-edge and deep transitions [199, 244, 245]. The former type involves either intrinsic states or donor–acceptor levels, whereas the latter type is related to defects or deep impurities, usually oxygen or metal transitions. The near band-edge transitions can be divided into four main classes: (1) free exciton, (2) bound exciton, (3) free carrier to neutral acceptor–donor, and (4) donor–acceptor, *D*–*A*, pairs. The distinction between the various near band-edge transitions can be made through the analysis of the behavior of the emission intensity as the excitation power is varied [244, 246]. The emission intensity  $I$  depends on the excitation power  $L$  according to the power law  $I \propto L^k$ . When  $1 < k < 2$ , we are in the presence of exciton-like transitions;  $k \leq 1$  is characteristic of free-to-bound and donor–acceptor pairs [244, 246]. Deviations from this behavior were observed either when  $L$  was varied more than two orders of magnitude or when the selected excitation energy was resonant with the semiconductor band gap [244].

Figure 33 represents the integrated intensity of the U(2000) di-ureasil steady-state emission calculated for different magnitudes of the excitation power [196]. A curve-fitting

**Figure 33.** RT integrated intensity of the di-ureasil U(2000) emission components, ( $\circ$ ) blue and ( $\blacksquare$ ) purplish–blue and of the ( $\blacktriangle$ ) Jeffamine ED-2001® excited with an He–Cd laser (325 nm) at different power excitations. The lines correspond to the data linear fit ( $r > 0.99$ ).

procedure was applied to all of the emission spectra in order to access the energy and integrated intensity values of both components independently [191]. The integrated intensity depends sublinearly on the power excitation, with a  $k$  value of  $0.91 \pm 0.07$  and  $0.89 \pm 0.06$  for the blue and purplish–blue components, respectively (Fig. 33). This is a clear indication that both emissions revealed a recombination mechanism typical of  $D$ – $A$  pairs, mediated by some localized centers [244, 246]. Similar dependence on the power excitation  $k = 0.98 \pm 0.03$  was detected for the integrated emission intensity of Jeffamine ED-2001® (Fig. 33).

Relevant additional experimental evidence allowing the identification of  $D$ – $A$  transitions can be obtained from time-resolved spectroscopy [247, 248]. For longer delay times, a red shift is expected in the spectrum because distant pairs have a smaller recombination probability. The respective energy levels therefore have larger lifetimes, a situation that is favored with the increasing delay time. As a consequence, the recombination takes place at lower energies [199, 245–248].

The results obtained for the energetic shift ( $\Delta E$ ) between the energy of the maximum intensity of the time-resolved spectra, measured for SD between  $8 \times 10^{-5}$  and  $10^{-1}$  s, and the corresponding value measured under continuous excitation for the two components of the di-ureasil emission are consistent with  $D$ – $A$  pair recombination [195, 196].

The paragraphs that follow deal with several comments regarding the possible chemical nature and the recombination mechanisms that induce the blue and the purplish–blue  $D$ – $A$  pair-related emissions. Let us start with the discussion of the former component.

It has been clearly evidenced that the existence of oppositely charged defects in  $c$ – $SC$  [248], amorphous semiconductors  $a$ – $SC$ , [246, 249], and organic compounds [250–252] provides a good method for radiative electron–hole recombinations. In the 1970s, it was reported that urea [ $OC(NH_2)_2$ ] and thiourea [ $SC(NH_2)_2$ ] crystals exhibited luminescence in the blue and green spectral regions (400–500 nm), induced by X-ray radiation [250, 251]. It was proposed that the defects responsible for the emission were related to the rupture of intermolecular hydrogen bonds established between packed urea molecules. The oxygen atom of each urea molecule binds four hydrogen atoms of two adjacent molecules, forming weak hydrogen-type bonds ( $N-H \cdots O=C$ ). When the urea crystals were irradiated, proton transfer was induced, and two defects with opposite charges,  $NH_3^+$  and  $NH^-$ , were formed. These two defects can act as electron and hole traps, respectively, recombine radiatively, and account for the observed emission. Photoinduced proton transfer has been also reported in many other materials, for example, organic systems involving amine groups [252], semiconducting polymers [253], and microporous zeolites [254–256].

We have proposed the same type of defects as the chemical species responsible for the PL blue component of diamines, aminosils, di-ureasils, and di-urethanesils, that is,  $NH_3^+/NH^-$ , for the diamines and aminosils, and  $NH_2^+/N^-$  for the urea and urethane-based hybrids [195, 196]. Furthermore, similar defects could also be responsible for the PL of GPTES- and APTES-based hybrids with carboxylic acids, that is,  $NH_3^+$  and  $RCOO^-$ ,  $R = H, CH_3, CH_3CHOH$ , or  $CH_3(CH_2)_3$  for  $HCOOH, CH_3CHOHCOOH, CH_3COOH,$

and  $CH_3(CH_2)_3COOH$ , respectively. It is interesting to note that the presence of  $NH_3^+/CH_3COO^-$  defects was recently proposed in xerogels formed by reactions of APTES, TEOS, and  $CH_3COOH$  [229].

The above suggestion is consistent with the observed behavior of the emission intensity of Jeffamine ED-2001® solutions in  $H_2O$  and THF. The two solvents differ in the polarity of their molecules. The  $H_2O$  molecules are more polar than those of the THF. Therefore,  $H_2O$  behaves as a more efficient vehicle for proton transport than THF, thus contributing to a more efficient luminescent mechanism. As a consequence, the PL intensity of the aqueous solutions is higher than that of the THF solutions [195, 196]. Moreover, the observed red shift of the PL spectra of the aqueous solutions, with respect to those of THF (characteristic of emission-size-dependent) [195, 196] may also be explained on the basis of the differences in the polarity between the molecules of the two solvents. Considering the photoinduced proton-transfer model,  $D$ – $A$  pairs are formed in distinct  $NH_2$  groups, and the distance between them determines the emission energy in such a way that distant pairs emit at longer wavelengths. For the aqueous solutions, the emission arising from more distant  $NH_2$  groups is then favored due to the presence of a much more efficient proton transfer vehicle (greater polarity), resulting in a spectra blue shift with respect to the emission measured for the THF solutions. Another experimental result that supports the previous suggestion is the variation of the emission quantum yield of the blue component with the length of the polymeric chain [196]. For the di-ureasil with shorter polymer chains, U(600), strong hydrogen bonds are formed [198] that localize the proton and render difficult the induced proton transfer between  $NH$  groups, leading to the corresponding decrease of the quantum yield. For di-ureasils containing longer polymer chains, U(900) and U(2000), there is no evidence of interactions via hydrogen bonds [198]. Therefore, in spite of the larger distance between the  $NH$  groups, the protons have a greater degree of mobility, a situation that favors higher quantum yields.

The existence of mobile (free) protons in the hybrids and in the diamines is further demonstrated by complex impedance measurements. At RT, the ionic conductivity of U(2000), U(900), U(600), and Jeffamine ED-2001® is about  $3.4 \times 10^{-8}$ ,  $5.0 \times 10^{-9}$ ,  $9.2 \times 10^{-10}$ , and  $3.9 \times 10^{-9}$  S/cm, respectively. These results show that the mobility of the protons decreases from U(2000) to U(600), confirming the conclusions drawn from quantum yield analysis.

The explanation of the siliceous nanodomain-related emission is less straightforward since, for silicon-based materials, several mechanisms and chemical origins have been proposed as responsible for the luminescence features [242, 257–263].

One hypothesis for the observed RT emission invokes the presence of Si nanoparticles or Si quantum wires that, due to quantum confinement effects, are responsible for the visible emission [258]. The quantum confinement of the carriers in the Si nanowires leads to a significant widening of the band gap and to an enhancement of the oscillator strength, thereby inducing efficient radiative recombination. An alternative mechanism suggested for the emission of amorphous or disordered silicon-based structures is the existence of

delocalized states induced by the lack of long-range order or by the presence of impurities or defects [235–237]. It is known that the radiative recombination arising from localized states depends on the excitation wavelength [235–237], and also that it is a thermally activated process.

Although the energy of the purplish–blue emission depends on the nanodomain size, the red shift observed in the emission spectra as the excitation wavelength decreases [191–194] and the typical Arrhenius behavior displayed by the respective lifetime [194] as the temperature increases from 14 to 300 K strongly suggest the presence of localized states probably created either by the amorphous properties of the siliceous domains or by the presence of defects.

In parallel with the discussion concerning the physical mechanisms under visible emission of silicon-based materials, several hypotheses concerning the chemical nature of the luminescent species were proposed, namely: (1) surface contamination due to luminescent organic solvents [257]; (2) the presence of an amorphous silicon, *a*-Si, phase [235]; (3) the existence of silicon-based structures, like siloxene ( $\text{Si}_6\text{O}_3\text{H}_6$ ) and siloxene derivatives, hydrides, and polysilane chains  $[(\text{SiH})_n]$  [249] and the silanone bond ( $\text{Si}=\text{O}$ ) [261]; and (4) oxygen-related defects [261].

The possible influence of oxygen defects in the emission features of APTES-based hybrids containing carboxylic acids [229] and TEOS- and MTEOS-based hybrids containing acetylacetonate (acac) and zirconium propoxide [228] was previously suggested. In the APTES-based hybrids case, it was observed that the luminescence intensity of such organic–inorganic hybrids increases with the increase of the heat treatment temperature between 20 and 200 °C. Furthermore, the luminescence intensity is greater in the xerogels treated under vacuum than in the hybrids treated in air [229]. This finding was interpreted as an indication that higher temperatures and vacuum conditions favor the creation of oxygen-related defects [229]. The TEOS- and MTEOS-based hybrids with doped with acac and zirconium propoxide [229] were studied by the electron paramagnetic resonance (EPR) technique, which demonstrated the existence of oxygen-related defects and silicon dangling bonds.

Another defect type associated with carbon impurities was proposed as being in the origin of the luminescence of sol–gel-derived silica gels based on TEOS and TMOS incorporating a variety of carboxylic acids [222]. Under adequate heat treatments, above 520 K, at least, a carbon impurity is created in the  $-\text{O}-\text{Si}-\text{O}-$  network forming  $-\text{O}-\text{C}-\text{O}-$  and/or  $-\text{Si}-\text{C}-$  bonds [222]. However, the carbon-related defects are only luminescently active after a heat treatment [222]. This situation contrasts with that found with oxygen-related defects, as the luminescent centers are active prior to any thermal treatment.

Since the di-ureasils and di-urethanesils discussed here are RT efficient emitters, without needing a prior heat treatment, we can rule out carbon-defect impurities as being responsible for the siliceous nanodomain emission features.

The PL results on amine-based hybrids related to the siliceous nanodomains undoubtedly show recombination mechanisms associated with disordered structures mediated by localized states, namely, the emission energy dependence on the excitation wavelength and the Arrhenius behavior characteristic of the respective lifetime. However, a detailed

description of the chemical–physical nature of such emission remains unsolved because, so far, we have not obtained experimental evidence that enables us to unequivocally identify the chemical nature of the *D*–*A* pairs responsible for the luminescent features described. However, we note that preliminary RT EPR studies performed on the di-ureasils demonstrated the existence of paramagnetic signals. This experimental evidence is in agreement with the possible existence of *D*–*A* pairs arising from nitrogen-, silicon-, and oxygen-related defects.

## 10. SUMMARY

The interest in organic–inorganic hybrids is basically associated with the extraordinary implications resulting from the tailoring of novel multifunctional advanced materials induced by the mixture in a single material and at the nanosize level of organic, inorganic, and even biological components. The synergy of that combination and the particular role of the inner interfaces open up exciting directions in materials science research and related technologies for the processing of novel multiuse advanced materials with innovative and unparalleled performances. Moreover, these hybrids present preeminent advantages in assisting the integration, miniaturization, and multifunctionalization of the devices, opening, therefore, a series of new opportunities for many applications.

The synthesis of such hybrids requires “soft” chemistry methods. The sol–gel process is probably the preeminent “soft” process allowing a “bottom-up” nanotechnology approach in the chemical design of organic–inorganic structures as an assembly of nano-building blocks. Furthermore, the sol–gel method clearly offers the flexibility necessary for implementing the chemical design strategies that are the basis of photonic hybrid materials, which are perhaps one of the first systems to take real advantage of the hybrid materials approach.

The PL features of the RE-based hybrid frameworks reviewed here illustrate nicely the impact on photonics that could result from the encapsulating of RE complexes in siloxane-based matrices through the simple embedding of the complexes within the sol–gel-derived matrix (generally Class I hybrid materials), or by using complexing ligands covalently grafted to the framework (Class II hybrid materials).

## GLOSSARY

**CIE color coordinates** Two chromaticity coordinates (*x*, *y*) that map the color with respect to hue and saturation on the two-dimensional CIE chromaticity diagram.

**CIE color system** Characterization of colors based on the spectral power distribution of the light emitted from a colored object and factored by sensitivity curves that have been measured for the human eye.

**Class I hybrid materials** Hybrids in which the organic and inorganic components are linked through weak interactions (van der Waals contacts, hydrogen bonding or electrostatic forces).

**Class II hybrid materials** Hybrids in which the organic and inorganic components are linked through strong chemical bonds (covalent, ionocovalent or acid-base bonds).

**Electroluminescence** Emission of radiation obtained by electric excitation.

**Electroluminescence external quantum efficiency** Fraction of generated photons that leave the light-emitting diode.

**Emission quantum yields** The ratio of photons absorbed to photons emitted through emission of radiation. The quantum yield gives, therefore, the probability of an excited state being deactivated by emission rather than by non-radiative mechanisms.

**Glass transition temperature** The glass transition temperature is the temperature at which the amorphous domains of a polymer take on the characteristic properties of the glassy state—brittleness, stiffness, and rigidity.

**Hydroxyl quenching** The luminescence efficiency of RE ions is quenched by nonradiative multiphonon relaxation of OH oscillators.

**Ligand-to-metal charge transfer transition** An electronic transition of a metal complex that corresponds to excitation populating an electronic state in which considerable electron transfer from a ligand to a metal center has occurred.

**Nephelauxetic effect (“could expanding” in Greek)** A slight shift of peak positions of f-f transitions depending on the matrix, relatively to the values found for the free ion. Electron–electron repulsion and spin-orbit coupling primarily determine the excited levels of transition bands. For covalent compounds the apparent values of the inter-electronic repulsion parameters are smaller than those in aqueous solutions, inducing a shift of the peak positions toward lower energy with increasing covalency of the surrounding media.

**Organic light-emitting diodes (OLEDs)** OLEDs are made from plastic compounds or small organic molecules that glow when a voltage is applied.

**Organic/inorganic hybrids** Materials combining organic and inorganic components at the nanosize level.

**Photoluminescence** Emission of radiation (usually in the visible or in the infrared regions of the electromagnetic spectrum) obtained by photon excitation (often in the ultraviolet).

**Quantum efficiency of emission** Ratio between the radiative transition probability and the experimental transition probability (sum of the radiative and non-radiative transition probabilities). The inverse of the experimental transition probability is the lifetime of the state.

**Recombination mechanisms** Recombination of electrons and holes is a process by which both carriers annihilate each other. The electrons occupy—through one or multiple steps—the empty state associated with a hole and both carriers eventually disappear in the process. The energy difference between the initial and final state of the electron is released in the process.

**Sol-gel method** Versatile “soft” chemical synthetic process that involves the hydrolysis and condensation of precursor molecules (often metal alkoxides) to yield gels with tunable shape and properties.

**Stark Effect** Splitting of a free ion electronic level in a series of Stark components due to the local charge distribution around a rare earth ion.

**White light emission** Emission of polychromatic radiation.

## 1. INTRODUCTION

Single-wall and multi-wall carbon nanotubes (SWNT, MWNT) have unique physical properties associated to their one-dimensional nanostructures. They are considered very promising materials for various applications [1–3]. For instance, thanks to their structure-dependent conducting or semi-conducting character, nano components such as diodes and transistors have already been made with nanotubes [4, 5]. Patterning nanotubes at the nanoscopic scale is thus a challenge for what might be the electronics of the future. But in this article, we focus rather on another challenge—obtaining nanotube materials with interesting macroscopic properties. For instance, nanotubes have remarkable mechanical properties, with Young modulus of the order of 1 TPa [6–9], and one may hope to obtain very strong materials with them. More precisely, in this article, we do not consider composite materials that include only a small fraction of nanotubes, generally embedded in polymeric matrices; rather we focus on materials comprised mostly of nanotubes. The physical properties of these one-dimensional objects being strongly anisotropic, aligned nanotubes materials are of particular interest. The topic is in strong development, as is illustrated in Figure 1 by the “exponential-type” of increase of the number of related

publications during the last few years. To obtain aligned nanotube materials, two different approaches are followed: (i) processing nanotubes, starting from an isotropic soot, and (ii) the direct synthesis of aligned nanotubes. The processing methods developed up to now are reviewed in Section 2. The degree of alignment of the nanotubes and the related properties of materials are also discussed. Section 3 is the counterpart of Section 2 for chemical vapor deposition, which is the most widely used method for synthesizing aligned nanotubes.

## 2. PROCESSING MATERIALS OF ALIGNED NANOTUBES

After the discovery of nanotubes in 1991 [10], an important step was the production of nanotubes in macroscopic quantities, in 1996 and 1997, using laser ablation [11] and electric arc [12] methods. As produced, nanotubes are under the form of a fragile and isotropic soot. This soot is rather difficult to use. Processing nanotubes on macroscopic scales to obtain materials of more practical use was, and is still now, a major challenge. In most cases, the nanotubes are initially dispersed in liquid media. Dispersing nanotubes is also widely used for filtrations and purifications of raw materials [13]. To be dispersed in a given medium, carbon nanotubes generally have to be either chemically modified [14, 15] or coated by adsorbed amphiphilic molecules [16]. Detailed discussion of the phase behavior of these suspensions is beyond the scope of this article, but we want to emphasize that it is of critical importance.

In this introduction, we briefly discuss the methods used to quantify the degree of alignment of nanotubes. For single-wall nanotubes, it can be deduced from electron and X-ray scattering or from polarized Raman spectroscopy. Single-wall nanotubes are usually assembled in bundles, forming a two-dimensional hexagonal array perpendicular to

**Figure 1.** Evolution of the number of articles with “align” and “nano-tube” in the title, after ISI web of science

the bundle axis. The crystalline nature of the bundles has been used to quantitatively probe their degree of alignment using electron and X-ray diffraction. Mosaic distributions are obtained from the angular intensity distributions of the first diffraction peak of their hexagonal lattice (Fig. 2). In most cases, it can be fitted by a Gaussian function with a full width at half maximum (FWHM) related to the angular distribution of nanotube axes in direct space. The smaller it is, the better the nanotube alignment. For a two-dimensional distribution of nanotube orientations within a plane, the width of the intensity distribution directly gives that of the distribution of orientations in direct space. For a given FWHM, 76% of the nanotubes long axes lie within  $\pm\text{FWHM}/2^\circ$  from the mean direction of alignment. For a three-dimensional distribution around an axis, the width of the distribution in direct space is equal to that in reciprocal space for  $\text{FWHM} < 40^\circ$ , and then becomes slightly smaller: it is for instance equal to  $70^\circ$  for  $75^\circ$  in reciprocal

**Figure 2.** X-ray scattering study [18] of the orientation of the nanotubes along the axis of a fiber obtained by the spinning process described in [16]. The angular distribution of the scattered intensity from a nanotube fiber at constant Q value of  $0.4 \text{ \AA}^{-1}$ , which corresponds to the (1, 0) peak position of nanotube hexagonal array, is reported. The orientation of the nanotubes with respect to the fiber axis can be deduced from the width of this angular distribution.

space [17]. For  $\text{FWHM} = 30^\circ$  ( $75^\circ$ ),  $\sim 50\%$  of the nanotube axes lie inside a cone of angle  $15^\circ$  ( $35^\circ$ ). In this article, we will refer to widths in reciprocal space, as was done in quoted publications. A “two-phase” model can be considered with partially aligned nanotubes, characterized by the Gaussian distribution, plus a fraction of nonaligned nanotubes [18, 19]. The nonaligned fraction may be sample dependent for a given method [20] and is not always discussed in quoted references. Some information about tubes not assembled, or poorly crystallized in bundles, may be obtained from the analysis of the diffuse intensity distribution outside of the Bragg peaks [19]. The nanotube alignment can also be deduced from polarized Raman measurements. Indeed, Raman line intensities depend on the angles made by the polarization of the laser excitation and that of the scattered light with the nanotubes long axes (Fig. 3). This is explained within a resonant model for highly anisotropic tube absorption. All nanotubes assembled in bundles or not, are probed in the same way with this method. An advantage of the X-ray scattering method, with respect to electron scattering or Raman spectroscopy, is that the volume investigated is much larger. Moreover, the interpretation of X-ray scattering experiments is more direct than that of Raman experiments. On the other hand, Raman spectroscopy probes all nanotubes, and not preferentially those organized in crystalline bundles. Finally, for multi-wall nanotubes, the method used to study their orientation is X-ray (or electron) diffraction, the analysis of

**Figure 3.** Raman scattering spectra (excitation wave-length = 647.1 nm) of a SWNT fiber obtained by electrophoresis (H. H. Gommans et al.). The analyzer polarization direction is parallel to the incident polarization. The angle between the fiber axis and the excitation polarization—indicated at the right of the curves—varies from  $0^\circ$  to  $90^\circ$  direction. The intensity of the nanotube lines decreases with increasing angle. Reprinted with permission from [36], H. H. Gommans et al., *J Appl. Phys.* 88, 2509 (2000). © 2000, American Institute of Physics.

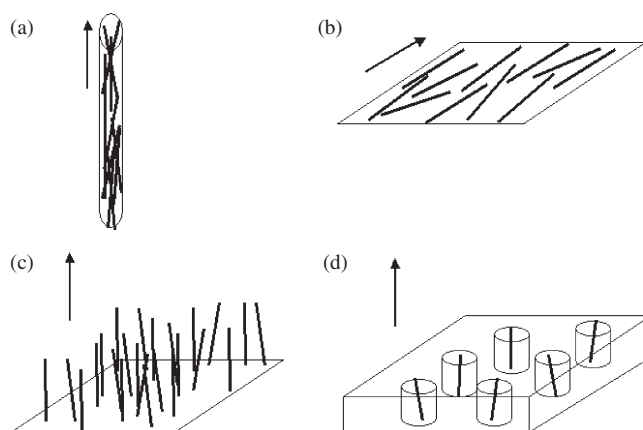

the intensity distribution being made on the diffraction peak corresponding to the interwalls distance ( $\sim 3.4$  Å). Other methods are also reported in the literature, but they are not quantitative. Under a scanning electron microscope (SEM), the nanotubes can be visualized and thereby their alignment roughly estimated. However, it is a rather local and only two-dimensional probe. If the material is sufficiently transparent (not too thick), it can be placed between crossed vertical and horizontal polarizers: due to nanotube birefringence, a bright transmitted light is seen when the nanotubes axes make an angle of  $45^\circ$  with respect to the polarizers axes.

A variety of different methods have been developed during the last few years to achieve films or fibers of nanotubes with a marked preferential orientation, as shown in the following (first results have been reviewed in [21]).

## 2.1. Films of Magnetically Aligned Nanotubes

Classical films of buckypaper [13] are made by deposition from suspensions of single-wall carbon nanotubes onto a membrane filter. The nanotubes lie preferentially in the plane of the film but they are randomly oriented within this plane. Moreover, the in-plane orientation is far from being perfect: the upper limit for the FWHM of the Gaussian distribution of nanotubes orientations with respect to the plane of the paper is  $56^\circ$ , as deduced from X-ray scattering experiments [19, 22]. One may notice that much better in-plane orientation (FWHM  $\approx 4^\circ$ ) has been obtained very recently by pressing a raw nanotube powder up to a pressure of 10 kbars [23]. Despite their relatively poor two-dimensional alignment, buckypapers obtained by deposition already present interesting properties. Indeed, electromechanical actuators based on such papers were shown to generate higher stresses than natural muscles and higher strains than high-modulus ferroelectrics [24]. As a reference for measurements on aligned nanotubes materials, we also give here the Young modulus of buckypaper  $Y \sim 1.2$  GPa [24].

By filtering the nanotube suspension in a strong magnetic field Walters et al. [25] have achieved a preferential orientation of the nanotubes in the plane of the film, as schematically drawn in Figure 4(b). The film thickness typically ranges between 1 and 5  $\mu\text{m}$ . The obtained materials are denser than classical films of buckypaper because of the higher compactness of oriented nanotubes. According to Smith et al. [22], the empty volume in magnetically aligned nanotubes is about 30%, whereas it is between 70% and 90% in ordinary buckypaper, and of about 95% as produced materials. The films cleave along a direction in parallel to that of the applied magnetic field  $H$ , which indicates anisotropic strength of the film, maximal along the  $H$ -direction (Fig. 5(a)). The degree of alignment within the plane of the film has been measured using electron and X-ray scattering [19, 22, 26], and with polarized Raman experiments [19]. The FWHM deduced from Gaussian fits typically ranges between  $25^\circ$  and  $45^\circ$ . The first results were obtained under high magnetic field (26 T) at the National High Magnetic Field Laboratory in Florida. But it was shown recently that similar values of FWHM  $\approx 35^\circ$  are obtained with  $H = 7$  T [19]. This last result is very

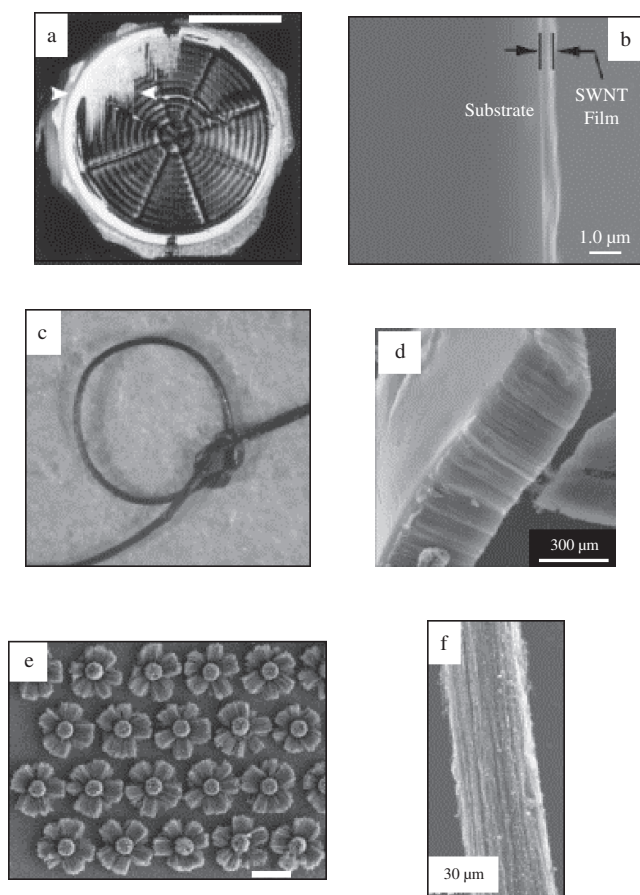

**Figure 4.** Schematic representation of the real materials of aligned nanotubes obtained up till now. Nanotubes are represented by the thick sticks; their direction of preferential orientation is indicated by an arrow. (a) A fiber where the nanotubes are preferentially oriented along the fiber axis, (b) a film where nanotubes have a preferential orientation along a direction within the film, (c) array of nanotubes perpendicular to a surface, and (d) nanotubes inside meso or nanoporous materials.

interesting because seven Tesla fields can be reached in many laboratories using superconducting solenoids. It also allows the authors to conclude that further enhancements in anisotropic properties of the films may require optimizing the filter deposition process rather than large magnetic fields. The degree of alignment of nanotubes with respect to the plane of the film should be higher than within the plane, due to conjugated deposition and magnetic field effects. However, no value for it has been given yet.

Hone et al. [27] have reported quantitative measurements of the anisotropic electrical and thermal transport properties of magnetically aligned nanotubes. Both electrical and thermal conductivities are found to be higher in the  $H$ -alignment axis. The ratios between the parallel and perpendicular components of the conductivity vary between 6 and 24 for different samples, the highest value corresponding to the best nanotube alignment. Good correlation between resistivity and texture parameters is found within a simple geometrical model [19]. For annealed samples, where electronic “doping” effects are minimized, the order of magnitude of resistivity is  $\sim 10^{-5}$   $\Omega\text{m}$  in the  $H$ -direction at room temperature, to be compared with  $\sim 10^{-6}$   $\Omega\text{m}$  for a single bundle [28] and to  $\sim 1.7 \cdot 10^{-5}$   $\Omega\text{m}$  for buckypaper [13]. Thermal transport properties have been shown to be different in aligned and nonaligned materials. At room temperature, the conductivity is about 230 W/mK in aligned materials along the applied field axis and about 30 W/mK in nonaligned materials. We note that the thermal conductivity of aligned materials is within an order of magnitude of that of graphite, parallel to the layers. Liu et al. [26] have performed momentum-dependent electron energy-loss studies, taking advantage of the macroscopic alignment of the nanotubes. They have shown that the  $\pi$  plasmon is strongly anisotropic, confirming experimentally its previously postulated polarization dependent momentum dependence.

**Figure 5.** Examples of oriented assemblies of nanotubes from the literature. (a) In plane-aligned assembly of SWNTs, obtained by filtration, under a magnetic field (reprinted with permission from [25], D. A. Walters et al., *Chem. Phys. Lett.* 338, 14 (2001). © 2001, Elsevier Science). Scale bar = 1 cm. The membrane was partially removed from the filter: cleavage is found to occur parallel to the field axis. (b) Membrane of self-organized SWNTs on a Si substrate: an edge-on SEM image (reprinted with permission from [30], H. Shimoda et al., *Adv. Mat.* 14, 899 (2002). © 2002, Wiley-VCH). The nanotubes have a preferred orientation within the membrane plane. (c) Optical micrograph of a SWNT fiber obtained after a spinning process (typical fibers diameters: 10–100  $\mu\text{m}$  [16]). The nanotubes are preferentially aligned along the fiber axis. The knot reveals the high flexibility of the fiber. (d) Flake of aligned MWNTs collected on quartz tube walls, after pyrolysis of homogeneously dispersed, toluene-ferrocene aerosols (from Martine Mayne-L’Hermite, DSM/DRECAM/SPAM/LFP, URA-CNRS 2453, CEA-Saclay and Luc Belin, DEN/DMN/SEMI, CEA-Saclay; image credit: CEA-Saclay). (e) Repeating patterns containing mutually orthogonal MWNTs arrays obtained by CVD on 5- $\mu\text{m}$  deep silica cylinders machined on silicon substrates (reprinted with permission from [79], B. Q. Wei et al., *Nature* 416, 495 (2002). © 2002, Nature). Scale bar-50  $\mu\text{m}$ . (f) SEM image of a long SWNT fiber obtained by CVD (reprinted with permission from [80], H. W. Zhu et al., *Science* 296, 884 (2002). © 2002, American Association for Advancement of Science). The nanotubes are preferentially aligned along the fiber axis.

In summary, the thermal and electrical properties of magnetically aligned nanotubes are strongly anisotropic and significantly improved when compared to that of traditional buckypaper. Moreover, alignment of nanotubes at a macroscopic scale has made possible the experimental study of some electronic properties of nanotubes.

## 2.2. Films of Mechanically Aligned Nanotubes

As was said in the introduction, we do not consider in this article composite materials that include only a small fraction of nanotubes. However, let us mention the work of Jin et al. [29], which will allow us to illustrate the effect of mechanical stretching at still relatively high nanotube weight fraction. Multi-wall nanotubes are mixed with a thermoplastic polymer (polyhydroxyaminoether), and in this case, the amount of nanotubes is rather large (50 wt % of raw carbon nanotube materials incorporated). The obtained composite films are uniaxially stretched at 100° C and are found to remain elongated after removal of the load at room temperature (final length  $L$  greater than initial length  $L_0$ ). For  $L/L_0 = 330\%$ , 58% of the nanotubes are partially aligned along the stress direction, this alignment being characterized by a FWHM = 46°, showing the efficiency of the process.

## 2.3. Films of Self-Assembled Nanotubes

Self-assembly of preformed single-wall carbon nanotubes was reported in 2002 by Shimoda et al. [30]. Nanotubes lengths were reduced to  $\sim 1 \mu\text{m}$  by chemical etching. A homogeneous suspension of such nanotubes could be obtained in deionized water, probably because of the presence of sidewall defects terminated by polar groups due to chemical etching. A hydrophilic glass slide was immersed in the solution. When the water gradually evaporated, a continuous nanotubes film is formed at the surface of the glass (Fig. 5(b)). The process invoked for the film formation is heterogeneous nucleation. The film thickness ranges between 0.1 and 1  $\mu\text{m}$ , depending on the nanotube concentration in the suspension. Shimoda et al. also demonstrated that they could obtain a great variety of two-dimensional structures by using hydrophobic surfaces patterned with hydrophilic regions. The above-mentioned sidewall defects on nanotubes can finally be removed after annealing at 400 °C in  $10^{-6}$  torr vacuum. Transmission electron microscopy (TEM), polarized Raman spectroscopy, and optical measurements between crossed polarizers revealed that the nanotubes exhibit a preferential orientation within the film (Fig. 4(b)). The ordering may be attributed to the interactions between nanotubes and to surface tension effects at the interface between water and the hydrophilic surface. These promising results are very recent: quantitative studies of nanotube alignment or of the film properties are much awaited.

## 2.4. Ribbons of Self-Assembled Nanotubes

Li et al. [31] reported in 2002 the self-organization of aligned multi-wall nanotubes in ribbons. After adequate treatment, in particular with concentrated nitric acid and hydrofluoric acid, the nanotubes are put in solution in deionized water. While the solution is annealed at 373 K in vacuum for 12 h, long ribbons form on the wall of the container. The ribbons are about 50–100  $\mu\text{m}$  wide, 4–12  $\mu\text{m}$  thick, and 100 mm long, with a very clear rectangular cross-section. Scanning electron microscopy shows that the nanotubes are preferentially aligned along the long axis of the ribbon. The oxidation with acid has introduced many functional groups at

the surface of the nanotubes, which play a major role in the self-organization phenomenon (no ribbons form when nanotubes are not refluxed with acid). It is suggested that polycondensation may take place through the functional groups [32].

The Young modulus of as-grown ribbon is  $Y \sim 24$  GPa. However, this is much below the Young modulus value of a single nanotube [6–8], which can be attributed to too weak interactions between the nanotubes. After thermal treatment at 2200 °C under argon atmosphere, the Young modulus of ribbons increases to 60 GPa (Fig. 6(a)) [32]. This is attributed to graphitization between nanotubes, which would lead to stronger intertube cohesion.

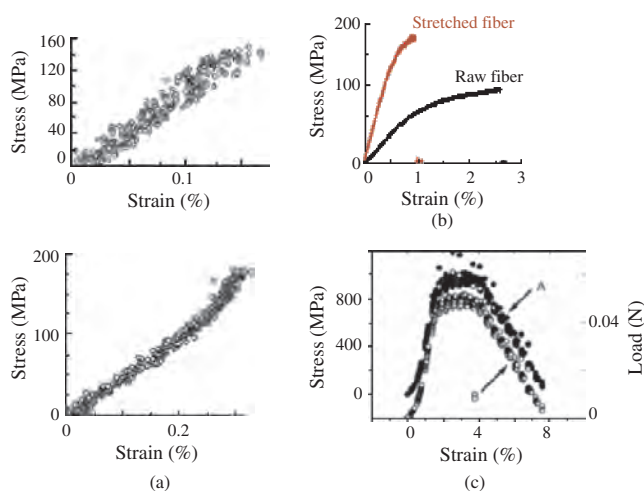

## 2.5. Langmuir–Blodgett Films of Nanotubes

The Langmuir–Blodgett (LB) technique has been developed for depositing molecularly ordered ultra-thin films with controlled thickness and orientation [33]. In the case of nanotubes, a main impediment with respect to this method was their poor dispersibility in aqueous solutions. In 2002, Guo et al. [34, 35] reported the elaboration of homogeneous films of single-wall carbon nanotubes with preferential orientation within the film by this method. The nanotubes are chemically modified: solubility of nanotubes in chloroform is brought by the attachment of octadecylamine groups to the tubes. They are then mixed with an amphiphilic polymer matrix

of poly(N-dodecylacrylamide) (PDDA). The SWNT/PDDA mixtures are deposited on the water surface and condensed mixed films are obtained, as in the case of pure PDDA. They can thus be transferred vertically on glass, quartz, and silicon substrates. Multilayer LB films have been successfully realized. Their homogeneity is controlled by light absorption and mass measurements. Scanning electron microscopy and polarized Raman spectroscopy show that the nanotubes are preferentially aligned along the dipping direction of the substrate (but the extent to which they are aligned has not been quantified yet). Guo et al. underline that the realization of these thin films of oriented SWNTs with controlled thickness and optical transparency may be a useful tool for a better understanding of some electronic and optoelectronic properties of nanotubes.

## 2.6. Fibers Made By an Electrophoretic Method

In 2000 Gommans et al. [36] have developed a method for making fibers of SWNTs possessing substantial alignment along the fiber axis (cf. the schematic drawing in Fig. 4(a)). The first step of the method consists of dispersing nanotubes in N,N-dimethylformamide. A commercially available carbon fiber is attached to a conducting wire coupled to a motor-driven translation stage. The carbon fiber is translated along its axis down in the nanotube suspension to a depth of few mm. The set-up is designed so that a voltage can be applied between the carbon fiber and the suspension. When a voltage is applied with the carbon fiber as the positive electrode, the nanotubes are attracted and form a cloud around the carbon fiber. Then the carbon fiber is slowly withdrawn from the suspension. As it pulls out of the liquid, another fiber attached to its end, forms spontaneously from the nanotube cloud. The formation of SWNTs cloud around a positive electrode indicates that nanotubes are negatively charged when dispersed in N,N-dimethylformamide; they migrate electrophoretically towards the positively charged carbon fiber. The fibers are several centimeters long and their diameters typically range between 2 and 10 microns depending on the preparation conditions. Selected area electron diffraction has been used to characterize the structure of the fibers. The results qualitatively evidence a substantial alignment of the nanotubes along the fiber axis. However, this probe was restricted to the side of the fibers to allow transmission of the electron beam. More detailed analysis has been achieved using polarized Raman spectroscopy by Gommans et al. and Hwang et al. [36, 37]. This study was the first of this type. The authors have developed a model to interpret the change of the Raman intensities depending on polarization (Fig. 3) by considering that absorption phenomena induce an angle-dependent resonance enhancement. The intensities have been fitted within a Lorentzian model for the distribution of nanotubes orientations. The FWHM of the distribution was found to be 23°, showing a rather good alignment of nanotubes. Since the above-mentioned publications [36, 37] in 2000, no new result has been published on these fibers. Their mechanical, electrical, and thermal properties are still to be analyzed.

**Figure 6.** The Young modulus ( $Y$ ) is deduced from the slope of stress versus strain curve at the origin. Stress-strain measurements: (a) For an as-grown, self-organized ribbon of MWNTs (upper curve)— $Y \approx 24$  GPa—and for a graphitized ribbon (lower curve)— $Y \approx 60$  GPa (reprinted with permission from [32], Y.-H. Li et al., *Chem. Phys. Lett.* 365, 95 (2002). © 2002, Elsevier), (b) For a raw SWNT fiber obtained by a spinning process— $Y \approx 10$  GPa—and for a fiber stretched by 145% in water— $Y \approx 40$  GPa (reprinted with permission from [20], B. Vigolo et al., *Appl. Phys. Lett.* 81, 1210 (2002). © 2002, American Institute of Physics); (c) For a SWNT fiber synthesized by CVD— $Y \approx 77$  GPa (reprinted with permission from [80], H. W. Zhu et al., *Science* 296, 884 (2002). © 2002, American Association for Advancement of Science). The authors have plotted true stress versus strain curve (A) and the load versus engineering strain curve (B) because of the possible variation of the diameter of the fiber during deformation. They present almost the same slope.

## 2.7. Ribbons and Fibers made by a Spinning Process

Vigolo et al. [16] reported in 2000 a simple method to assemble single-wall carbon nanotubes into long ribbons and fibers. Their process is reminiscent of the flow-induced alignment processes already used for rigid polymers [38] or anisotropic colloids [39]. The nanotube bundles are dispersed in water with the help of a commercially available surfactant molecule—sodium dodecyl sulfate (SDS). A detailed study of the phase diagram of the surfactant stabilized nanotube dispersions has been performed, to determine the optimized concentrations in surfactant and nanotubes. The aim was to obtain a homogeneous suspension with a relatively large concentration in nanotubes (an optimum was found for 0.35 wt % of SWNTs and 1 wt % of SDS). The SWNTs dispersion was injected in the co-flowing stream of a polymer solution that contains between 2 and 6 wt % of polyvinylalcohol (PVA), an amphiphilic polymer. The PVA adsorbs onto the tubes and provides a strong bridging attraction [40] between the bundles. This process leads to the formation of long ribbons that remain stable in the absence of flow. In [16], the nanotubes used were single-wall nanotubes obtained by the electric arc method [12]. Since then, the same process was successfully applied to single-wall nanotubes obtained from the laser vaporization method [11] or by using the more recent HiPCO process [41], and to multi-wall nanotubes [42]. The alignment of nanotubes in the ribbons has been studied by SEM and by optical observations between crossed polarizers [16]. The nanotubes have a clear preferential orientation along the long axis of the ribbons. However, no quantitative measurements of this orientation have been published yet.

In order to make systems that are more compact, rinsed ribbons are vertically drawn out of water [16]. Capillary forces, water drainage, and evaporation cause the ribbon to collapse into a dense fiber (density  $\sim (1.4 \pm 0.3) \text{ g/cm}^3$  for electric arc raw material) with a diameter ranging from a few micrometers to 100 micrometers when dry. This simple method leads to several tens of centimeter long fibers. Such a fiber is shown in Figure 5(c). A knot was intentionally made with it, to reveal its high flexibility. The amount of nanotubes with respect to that of PVA is about 60% as determined by thermogravimetric experiments [43]. Moreover, PVA can be completely removed by annealing the fibers at high temperature [18]. Nanotube alignment in electric arc nanotube fibers has been studied using X-ray scattering [18] and polarized Raman spectroscopy [44]. The FWHM within a Gaussian model is found to be  $\sim 75 \pm 5^\circ$  using X-ray scattering (Fig. 2). It remains the same if PVA is burnt. Surprisingly, Raman measurements indicate much better alignment; this apparent discrepancy is under study. The value of FWHM, as determined by X-ray scattering, is strongly dependent on the raw material used. FWHMs  $\sim 45^\circ$  are found for fibers made from HiPCO single-wall nanotubes [45]. Different hypotheses can be put forward to account for the better nanotube alignment in HiPCO nanotube fibers. The lower amount of impurities in the as-produced material is one of them: HiPCO samples contain less amorphous carbon [41]. Others include the shorter length of HiPCO nanotubes and the fact that HiPCO nanotubes may be less entangled.

A procedure has been recently developed to improve nanotube alignment in the fibers [20]. The fibers are rewetted, swollen in a solvent of the polymer, and redried vertically under tensile load with a weight attached to their end. Even in a solvent in which the polymer is highly soluble, they do not disassemble (this amazing result is attributed to the fact that the networks of nanotubes and adsorbed polymers form cross-linked assemblies). The reader can refer to [20] for a more detailed discussion on the role of the fibers wetting agent. The fibers can be stretched up to  $\sim 160\%$ , the improvement of the nanotube alignment being significant: FWHMs, determined by X-ray scattering [20], are reduced by 40%, that is, to about  $45^\circ$  for arc discharge nanotubes. Full width at half maximum as low as  $30^\circ$  are reached for stretched fibers of HiPCO nanotubes [45].

Let us emphasize that the spinning process, as well as the post-synthesis one developed to improve the nanotube alignment, are very simple and could be easily scaled up for industrial developments.

Mechanical measurements show that the mixed nanotube-PVA fibers exhibit an elastic behavior followed by a plastic one before they break (when PVA is removed, the plastic region disappears and the Young's modulus is slightly reduced). The Young's modulus of nonannealed fibers, deduced from the slope of the curve stress versus strain in the elastic region, varies between 10 and 20 GPa for arc discharge nanotubes raw fibers [16]. It is one order of magnitude greater than the modulus of high-quality buckypaper [24]. After fiber stretching, Young moduli of  $\sim 40$  GPa can be found (Fig. 6(b)) [20]. Globally, the Young modulus increases when the nanotube alignment gets better. A similar trend was found for fibers made of HiPCO single-wall nanotubes or of multi-wall nanotubes. One should notice that the mechanical properties of nanotube fibers are still far away from those of individual nanotube bundles [9], or from those of carbon fibers (mechanical properties of carbon fibers are summarized in [2]). This is probably to be attributed to too weak intertube interactions, as was already discussed in Section 2.4. Further improvements are expected if strong covalent bonding between nanotubes could be established by functionalization, for instance. The study of the electrical and thermal properties of the fibers is in progress [46]. For such studies, insulating PVA is removed by annealing. Room temperature electrical resistivities as low as  $6 \cdot 10^{-5} \Omega\text{m}$  could be obtained for purified HiPCO nanotube fibers. Finally, the fibers can be used as electromechanical actuators (Fig. 7) [47]. Stress generation and work per cycle are higher than that of buckypaper.

**Figure 7.** Electromechanical actuation of a HiPCO SWNT spun fiber in an electrolyte solution (NaCl 1 M) when an alternative voltage of 1 V is applied at a frequency of 1 Hz. It exhibits a periodic motion as shown in the pictures.

At the end of this section about nanotube processing, it is interesting to compare the main results. They are also summarized in Table 1.

Processing of SWNTs or MWNTs can be performed after solubilization of the raw soot obtained by usual synthesis methods. Films, ribbons, and fibers have been successfully realized, using very different processes: alignment of nanotubes under magnetic field, in the flow of a polymer solution, by electrophoretic migration, or because of their (self-) interactions. It is even possible to obtain two-dimensional patterned arrays of these aligned nanotubes, or to precisely control the film deposit width by the LB technique. In fibers, the nanotubes are preferentially aligned along the fibers long axes, as is schematically drawn in Figure 4(a). In films and ribbons, the nanotubes are preferentially aligned within the plane of the film or of the ribbon (Fig. 4(b)), with possibly some additional out-of-plane misalignment. Typical FWHMs, characteristic of the degree of alignment of nanotubes in fibers or films, are about  $30^\circ$ .

The mechanical properties of aligned nanotube assemblies are better than those of buckypapers with Young moduli up to 60 GPa to be compared to  $\sim 1$  GPa. The Young modulus increases with the nanotube alignment. Further improvement, to approach properties of individual tubes or of carbon fibers, would need stronger interactions between nanotubes inside the materials. Anisotropic electrical, thermal, and optical properties are measured and found to be correlated with the degree of alignment of nanotubes. Moreover, electrical resistivities of  $\sim 10^{-5}$ – $5 \cdot 10^{-5}$   $\Omega\text{m}$ , to be compared with  $10^{-6}$   $\Omega\text{m}$  for individual SWNTs bundles, indicate rather good contacts between nanotubes.

### 3. DIRECT SYNTHESIS OF MACROSCOPICALLY ALIGNED NANOTUBES BY CHEMICAL VAPOR DEPOSITION

Primary synthesis methods for producing carbon nanotubes include arc-discharge [10, 12], laser ablation [11, 13], and chemical vapor deposition (CVD) from hydrocarbons [48–51]. These methods classically lead to the production of entangled and disoriented nanotubes, and for CVD, to nanotubes whose structure is often not perfectly graphitic, as noted by Dai in his review article on nanotube growth [2]. However, improved CVD methods have allowed one to synthesize large arrays of aligned nanotubes with controlled diameters and lengths (as an exception, let us cite Liu et al. [52], who reported the synthesis of macroscopically long ropes of well-aligned, single-walled carbon nanotubes along plasma flow direction using an electric arc technique). In this article, we focus on CVD results. First, we briefly review the main approaches developed to make arrays and films of aligned nanotubes (the literature on the subject is very abundant; our aim here is only to give an overview of the different realizations via a few examples). Then, we discuss more recent works showing the direct synthesis of long macroscopic nanotube fibers by CVD methods. These fibers are reminiscent of the ones described in Section 2.7. However, the fibers described in this section result from a direct or quasi-direct synthesis instead of being produced by post-synthesis spinning process.

**Table 1.** Illustrates the variety of materials formed with aligned, single-wall nanotubes (SWNTs) and multi-wall nanotubes (MWNTs). FWHM is a measure of nanotube alignment, as explained in the text. Given here are the smallest FWHMs reported for different methods used to obtain aligned nanotubes materials, corresponding to the best alignments.

Geometry	Sort of nanotubes	Nanotube alignment	Method used	Some properties
One-dimensional fibers	SWNTs	FWHM $\sim 30^\circ$ [45]	Processing (spinning [16], electrophoretic process [36]) and CVD [80]	Young modulus increases with the degree of alignment [20]; electromechanical actuation [47]
	MWNTs		Processing from a powder: spinning [16]; spinning from a CVD film [81]	
Two-dimensional films (or ribbons): nanotubes preferred orientation within the plane of the film	SWNTs	FWHM $\sim 25$ – $35^\circ$ (magnetic field [22])	Processing (spinning [16], magnetic field [25], self-organization [30], LB method [34])	Anisotropic strength [25], anisotropy of electrical and thermal conductivities [27], anisotropic optical properties [30], $\pi$ plasmon anisotropy [26]
	MWNTs		Processing (mechanical constraint [29], self-organization [31])	
Two dimensional films: nanotubes preferred orientation perpendicular to the plane of the film	MWNTs	FWHM $\sim 16^\circ$ [73]	CVD [63, 65, 66, 71–73]. (Elaborated patterns such as pillows of aligned nanotubes: [77, 79])	Field emission [66], ultrahydrophobic materials [78]
Nanotubes inside meso or nanoporous materials	MWNTs	FWHM $\sim 34^\circ$ [56]	CVD [53, 55, 57]	Membranes for lithium-ion batteries [54]
	SWNTs	FWHM $< 1^\circ$ [60]	CVD [58]	Superconductivity [62]

### 3.1. Growth Inside Templates

Nanotubes can be obtained by CVD of different precursors inside nanoporous materials (Fig. 4(d)). The main advantage of the method is that the orientation and diameter of nanotubes may be controlled by the pores inside which they grow.

As an example, we mention here the results obtained by Che et al. [53, 54] inside alumina template membranes (200 nm diameter pores, 60  $\mu\text{m}$  thick). Ethylene or pyrene were used as precursors and heated to 900 °C. Nanotubes formed inside alumina pores. Their outer diameter was the same as that of the pores, and they formed a highly ordered assembly [53]. After further removal of the template, the authors obtained freestanding nanoporous carbon membranes. The tubes being electrochemically active for intercalation of lithium ion, they suggested possible applications of the membranes for lithium-ion batteries [54]. The use of templates to grow nanotubes can also allow one to obtain more elaborate nanotube assemblies than parallel nanotubes with the same outer diameter. For instance, Suh et al. have recently made brushes of linearly joined nanotubes of 60- and 30-nm diameter, respectively [55]. The location and shapes of the junctions are controlled by a multistep anodization and pore-widening process of alumina membranes. Acetylene was used as a precursor and decomposed at 700 °C. Only a few quantitative measurements of the degree of nanotube alignment inside templates are reported in the literature. We mention here the X-ray scattering experiments of Dore et al. [56] on multi-wall nanotubes obtained by CVD in microporous alumina [57]: the angular intensity distribution is characterized by a FWHM  $\approx 34^\circ$ .

The synthesis of aligned single-wall nanotubes by CVD methods is much less developed than that of aligned MWNTs. However, a few examples are shown in this article: aligned SWNTs suspended between electrodes (Section 3.2), SWNTs fibers (Section 3.3), and SWNTs inside zeolite crystals. In this last case, the use of templates has allowed the synthesis of one of the smallest diameter single-wall carbon nanotubes observed so far. The template is single crystal zeolite  $\text{AlPO}_4\text{-5}$ , with very narrow parallel pores. In 1998, Tang et al. [58] reported the formation of parallel-aligned single-wall carbon nanotubes in the channels of single-crystal zeolite by pyrolysis of tripropylamine. The nanotube diameter, as determined for instance by X-ray scattering [59], is about 4 Å. Their orientation is nearly perfect (FWHM  $< 1^\circ$ ) [60]. The above-mentioned nanoporous materials were amorphous, while zeolite is crystalline. Thus one might hope that interactions with the zeolite during nanotube formation could have led to the selection of only one helicity, but recent Raman results [61] contradict this hypothesis. However, a very interesting effect could be observed on these 4 Å diameter nanotubes: they exhibit superconducting behavior below 20 K [62]. Evidence for anisotropic Meissner effect was made possible thanks to the nanotubes alignment.

### 3.2. Growth on Substrates

Chemical vapor deposition techniques have been developed to grow controlled arrays of aligned nanotubes at the surface of a template. In 1996, Li et al. [63] achieved the large-scale

synthesis of aligned carbon nanotubes by a CVD method, with iron nanoparticles embedded in mesoporous silica. The nanotubes, obtained from decomposition of acetylene at 700 °C, are multi-walled with their inner diameter at about 4 nm and their outer diameter at about 30 nm. They are on average perpendicular to the surface of the substrate and the spacing between the tubes is about 100 nm. The alignment may be attributed to the constraint of the vertically aligned pores from which the nanotubes grow out. In 1997 Terrones et al. [64] obtained arrays of MWNTs aligned with nanotracks of cobalt particles deposited on a silica substrate by laser etching, by pyrolysis of 2-amino-4,6-dichloro-*s*-triazine. The method allowed the control of the length, up to 50 microns, and a diameter between 30 and 50 nm of the tubes. In 1998, Ren et al. [65] proposed a plasma-enhanced, hot filament CVD method that allowed them to work below the strain point of glass ( $\sim 650^\circ\text{C}$ ), which is of interest for display device fabrication. Acetylene gas was used as the carbon source and aligned MWNTs were grown on nickel-coated glass. Their external diameters range from 20 to 400 nanometers, depending on the nickel layer thickness. Lengths from 0.1 to 50  $\mu\text{m}$  are obtained. In 1999, Fan et al. [66] obtained similar MWNTs arrays, but on silicone substrates, with the promising possibility to develop nanotube devices integrated into the existing semiconductor technology. Multi-wall carbon nanotubes form after catalytic decomposition of acetylene on iron oxide particles. Their alignment, perpendicular to the silicon film, is attributed to van der Waals interactions between their outermost walls. Their length, from  $\sim 35$  to 240  $\mu\text{m}$ , can be controlled by tuning the CVD reaction time. The sample properties with respect to field emission appear interesting, with low-operating voltage and high-current stability. For a review on “carbon films as electron field emitters,” the reader can refer to [67]. The ideal cathode would be formed of well-spaced nanotubes aligned in the electrical field direction. However, no better results have yet been obtained for aligned nanotube materials with respect to nonaligned ones [68]. One has to improve in particular the nanotube crystallinity and to control the spacing between them.

We have listed above some of the earliest contributions dealing with the synthesis of arrays of nanotubes using CVD methods. These methods have been largely developed and improved by several other groups in the last few years. Among the improvements we emphasize, through several examples, the recently shown possibilities to grow aligned nanotubes in high yields, as well as very long nanotubes, and to achieve a higher degree of control using external fields.

After Rao et al. showed that aligned nanotube bundles can be obtained in copious quantities from ferrocene pyrolysis [69], progress was made toward important production through catalytic decomposition of a ferrocene-xylene mixture [70]. In 2001 Mayne et al. [71] synthesized aligned MWNTs by pyrolyzing aerosols generated from benzene/ferrocene mixtures at 800° or 950 °C. Syntheses from toluene/ferrocene mixtures are also currently performed (Fig. 5(d)). The nanotubes form on quartz tube walls and show good alignment. They are 10–200 nm outer diameter and are partially filled with metal [71]. The method opens up new avenues in carbon nanotube synthesis using liquid hydrocarbon and catalyst precursor. Due to the continuous

feeding of the reactor, high yields of nanotubes can be produced. The nanowires inside tubes could also be of strong interest. Furthermore, in 2002, Zhang et al. [72] have grown arrays of very long MWNTs by catalytic decomposition of a ferrocene-xylene mixture at 850 °C on a quartz substrate. The nanotubes grow perpendicularly to the quartz surface at a very high rate of 50  $\mu\text{m}/\text{min}$  and reach 1.5 mm length in about 30 mm. Their outer diameter ranges from 30 to 60 nm. They are also partially filled with iron.

Controlled structures have been even achieved by CVD of acetylene on contoured surfaces, instead of flat films, using a plasma-induced alignment method [73]. Bower et al. have grown uniform nanotube films on substrates of different geometries. The MWNTs always grow perpendicular to the local substrate surface. The alignment is primarily induced by the electric self-bias field imposed on the surface from the plasma environment. For flat silicon surfaces, FWHM  $\sim 16^\circ$  has been deduced from X-ray diffraction studies, regardless of the substrate orientation in the growth chamber. Radially grown nanotubes could even be obtained on the highly curved surface of a 125- $\mu\text{m}$  diameter optical fiber. Moreover, the growth rate in these experiments is rather high ( $\sim 6 \mu\text{m}/\text{min}$ ). The influence of an electrical field on the nanotube synthesis was also expertly illustrated by Zhang et al. [74] who have shown electric field-directed CVD growth of single-wall nanotubes. They were able to grow aligned, suspended SWNTs between silicon electrodes, by applying an electric field during CVD of methane mixed with hydrogen at 900 °C. These results appear promising for directed growth of ordered molecular-wire architectures and networks on surfaces.

Finally, attempts to obtain elaborated assemblies of aligned nanotube patterns have been recently reported. The growth of a single crystal of single-walled nanotubes formed by self-assembly, using thermolysis of nano-patterned precursors, was reported in 2001 [75]. However, it was shown recently that the majority of the structures formed are compounds of molybdenum, carbon, and oxygen [76]. Wang et al. [77] have synthesized pillars of bamboo-like MWNTs by pyrolysis of iron(II) phthalocyanine. The growth mechanism of these patterns is yet to be clarified. Recent results indicate that such nanotube arrays are good candidates for ultra-hydrophobic materials [78]. Wei et al. [79] were able to grow aligned MWNTs in several directions at once in a single process: the pyrolysis of xylene-ferrocene at 800 °C over lithographically machined substrates of silica over silicon. Indeed, nanotubes grow selectively on and normal to silica surfaces. A beautiful pattern of “nanotube flowers” obtained by the authors is shown in Figure 5(e).

In brief, MWNTs can be grown by CVD at the surface of porous templates and of plain plates of quartz, silicon, silica, glass, etc. In most cases, nanotubes are aligned perpendicularly to substrates [63, 65, 66, 71, 72], as drawn in Figure 4(c). The precursors are hydrocarbons or metal-organic compounds. With hydrocarbons as precursors, metal catalysts (Fe, Ni, Co, etc.) should be added on the surface. Aligned MWNTs and SWNTs can also be obtained on highly curved surfaces [73] or between electrodes [74], under the action of an electric field along which nanotubes grow. More elaborated patterns, such as pillows or flowers of aligned MWNTs, have also been recently made [77, 79].

Chemical vapor deposition methods are now rather well controlled (Table 1). Their versatility makes them promising processes for a variety of future applications ranging from field emission devices to nanoelectronics through more specific domains such as biomimetic ultra-hydrophobic surfaces.

### 3.3. Direct or Quasi-Direct Synthesis of Fibers by CVD Methods

The synthesis of films and arrays by CVD methods is not particularly suitable for the production of macroscopic 3-dimensional materials containing aligned nanotubes. The limitation of being attached to a template or a patterned substrate has been recently overcome with two examples of synthesis of nanotube fibers [80, 81]. Unlike previous methods that are reviewed in Section 2, the fibers are directly grown or spun from nanotubes synthesized by CVD. The first method consists in the direct growth by a CVD method in a vertical furnace [80]. The second one consists in drawing out nanotube yarns from aligned arrays of nanotubes [81]. We describe in the next section the main features of these two methods and of the obtained fibers.

#### 3.3.1. Direct Synthesis of Single-Wall Nanotube Strands

Zhu et al. [80] have optimized a floating catalyst method in a vertical furnace, where *n*-hexane is catalytically pyrolyzed. The *n*-hexane solution, which contains some amount of ferrocene and thiophene, was introduced into the reactor at a rate of 0.5 ml/min with hydrogen as the carrier gas flowing at a rate of 250 ml/min. Single-wall nanotubes formed during this continuous process with yields of  $\sim 0.5 \text{ g/h}$ . The formation of very long SWNT strands is a unique characteristic of this vertical floating process.

The obtained strands generally have a diameter of  $\sim 0.3 \text{ mm}$ . Scanning electron microscopy images showed the preferential alignment of the tubes (Fig. 5(f)). Raman spectroscopy measurements suggest that both metallic and semiconducting single-wall nanotubes coexist with a wide distribution of diameters, ranging from 1.1 to 1.7 nm with a dominant diameter of 1.1 nm. Additional structural characterizations were achieved using X-ray diffraction [82]: the angular distribution is characterized by FWHM  $\sim 44^\circ$ . This value is of the same order as that measured on raw HiPCO nanotube fibers obtained by a spinning process, but it is larger than that of  $\sim 30^\circ$  obtained after fiber stretching [45].

The SWNT strands exhibit a metallic behavior above 90 K, with an electrical resistivity of about  $7 \times 10^{-6} \Omega \text{ m}$  at room temperature. Such a low value of the resistivity suggests that there are macroscopic lengths of continuous conducting paths in the strands. Young's modulus was measured and found to range from 49 to 77 GPa (Fig. 6(c)). This is far from Young's modulus of individual nanotubes, but among the best present results for fibers or ribbons of aligned nanotubes.

The synthesis of nanotube strands by this improved CVD method leads to promising materials with high electrical conductivity and reasonable mechanical strength.

### 3.3.2. Spinning From Nanotube Films

Jiang et al. [81] have shown that carbon nanotubes can be self-assembled into yarns of up to 30 cm in length, simply by being drawn out from aligned arrays of carbon nanotubes. While pulling out carbon nanotubes from an array several hundred micrometers high and grown on a silicon substrate, the authors obtained a continuous yarn of pure nanotubes. They estimate that an array of about 1 cm<sup>2</sup> can generate about 10 m of yarn. The authors could make optical polarizers by parallel alignment of their nanotube yarns. When a beam of light passes through the nanotube polarizer, photons having a polarization direction parallel to the axis of the tubes are absorbed, whereas those that are perpendicularly polarized pass through it. The authors have also submitted their fibers to a strong voltage under vacuum. After 3 h at 70 V, the conductivity of the filament slightly increases and the tensile strength changes from 1 mN to 6.4 mN. These results indicate that some welding effect may be occurring at the weak connection points, because these points have a higher resistivity and, as a result, a higher temperature when a current is applied. Therefore it seems that the properties of the fibers can be improved using this method. Nevertheless, the comparison with the properties of other materials remains difficult because the data reported by Jiang et al. are not normalized with respect to the mass or section of the fibers.

In summary, the CVD synthesis of nanotubes aligned perpendicularly to a substrate (Fig. 4(c)), or inside a mesoporous template (Fig. 4(d)), has been the subject of numerous studies during the last few years. Within this method, mostly MWNTs are synthesized. Possible applications of these materials as field emitter screens, as membranes for batteries or as ultra-hydrophobic surfaces are evoked. Moreover, fibers of SWNTs have been recently synthesized by CVD. The first results reported on these fibers appear very promising: the Young modulus is slightly higher than that of the fibers obtained by spinning, and electrical conductivity is low. Nanotube alignment is given by FWHM  $\sim 45^\circ$ , to be compared to  $30^\circ$  for the best-aligned fibers obtained by spinning and stretching.

## 4. CONCLUSION

For a few years, great progresses have been made in the elaboration of aligned nanotube-based macroscopic assemblies. Substantial alignments can now be obtained (with typically FWHM  $\approx 30^\circ$ ). It concerns both single-wall and multi-walls nanotubes. Nanotubes can be aligned (i) within fibers by post-synthesis processing or CVD methods, (ii) parallel to two-dimensional planes via processing, or (ii) perpendicular to two-dimensional films, and within meso- or nano-porous materials, by CVD (Fig. 4, Table 1). Nanotube processing can be realized by different methods: under the action of a magnetic field, using a spinning process, by an electrophoretic method, by a LB technique; or nanotubes can even self-assemble under appropriate conditions. Via CVD methods, one can vary the precursor, the catalyst, and the substrate, and even control the alignment by applying an electrical field.

The obtained materials present anisotropic optical, mechanical, electrical, and thermal properties. Their field

emission properties or their electrochemical activity are also particularly exciting. Fiber mechanical properties still have to be improved but are progressing (Young modulus multiplied by 3–4 within the last year). Aligned nanotube materials may thus find industrial applications in the future. In this respect, let us underline that spinning processes and CVD methods developed to produce nanotube fibers could be scaled-up for large-scale production.

In this article, we have mentioned examples of fundamental studies on electronic properties of nanotubes, by electron energy loss spectroscopy on films of magnetically aligned nanotubes, or on superconductivity and Meissner effect for nanotubes inside zeolite crystals. We emphasize that the alignment of nanotubes on a macroscopic scale is also of critical importance for the understanding of their fundamental properties.

## GLOSSARY

**Carbon multi-wall nanotube (MWNT)** Nanotube formed of concentric single-wall nanotubes.

**Carbon single-wall nanotube (SWNT)** Cylinder at the surface of which carbon atoms are organized in a honeycomb lattice.

**Chemical vapor deposition (CVD) method** A method to deposit solid films via chemical reaction of gases.

**Nanotube (NT)** Tube with a very small diameter (less than 10 nm).

**Process** A series of actions that bring about a particular result (in this article, the result is the alignment of nanotubes).

**Self-assembly** Spontaneous organization (in this article: spontaneous organization of nanotubes).

## 1. INTRODUCTION

Rechargeable batteries are used in modern communications, computers, and electric vehicles. The Ni-MH battery is one of the key competitors in the rechargeable battery market, especially for commercial electric powered vehicles, which constitute a rapidly expanding market. Rechargeable batteries made from nickel–metal hydride are a better choice for rechargeable batteries than those made from nickel–cadmium in terms of environmental benefits and performance.

For most commercial Ni-MH batteries, their negative electrodes are of rare-earth system alloys, which have low theoretical discharge capacities (LaNi<sub>5</sub> alloy has a theoretical discharge capacity of 370 mAh/g). The capacities of the negative alloy electrodes restrict the further improvement of the capacities of nickel–metal hydride batteries. In order to increase the energy density of the Ni-MH battery, it is necessary to improve the negative (metal hydride) electrode properties.

Mg and Mg-based hydrogen storage alloys are promising energy conversion and storage materials because they possess very high theoretical hydrogen storage capacities; for example, the theoretical discharge capacity of Mg<sub>2</sub>Ni alloy is 999 mAh/g [1]. Magnesium is also abundant in nature, light in weight, and relatively low in cost. However, the absorption and desorption of hydrogen in Mg-based hydrogen storage alloys require high temperatures (over 250 °C for Mg<sub>2</sub>Ni) at

around atmospheric pressure [2], and therefore many efforts have been made to lower the hydrogen-absorbing temperature of Mg alloys for practical application in Ni-MH batteries [3–5].

A large number of investigations have shown that amorphous and nanocrystalline metals and alloys have the features of new alloy compositions and new atomic configurations, which are different from those of crystalline alloys. There also appear to be some possibilities of achieving high discharge capacities with amorphous and nanocrystalline Mg-based alloys.

### 1.1. Amorphous Alloys

The distinctive feature of the amorphous state for a single-phase solid alloy is that it has no crystal lattice, no grain boundaries, and no dislocations. However, it does have a structure that is dependent on the way its atoms are arranged, and this structure is important in determining the properties described in some metallic glass structural models, such as the dense random-packed hard sphere model [6], local-coordination model [7], and so on.

#### 1.1.1. Methods for Achieving Amorphous Alloys

Amorphous metals and alloys can be made using rapid quenching from the liquid and the vapor phase [8], mechanical alloying [9], mechanical milling [9], evaporation deposition [10], sputtering deposition [11], ion-implantation [12], and electrodeposition [13]. The amorphous metals and alloys prepared by rapid solidification processing have features that enable various kinds of characteristics to be achieved, such as excellent mechanical properties, useful physical properties, and unique chemical properties, which have not been obtained for conventional crystalline alloys [14]. Solid-state amorphization by mechanical alloying (MA) and mechanical milling (MM) has become the most effective method for obtaining amorphous alloys [9].

### 1.1.2. Rapid Quenching (RQ) from Melt

This is one of the most commonly used methods in preparing amorphous alloys. Amorphous alloys formed by RQ are also named metallic glasses because they are formed when liquids are cooled but fail to crystallize and instead continuously and uniformly congeal into solids [8]. The basic principle of obtaining amorphous alloys by RQ from the melt is that the liquid must be converted very rapidly from a droplet or jet into a thin layer or wire in contact with a highly thermally conductive metal to produce thin plates, ribbons, or wires.

### 1.1.3. Mechanical Alloying (MA) and Mechanical Milling (MM)

For a large-scale production of amorphous alloys, MA/MM is the most commonly used method. Mechanical alloying/milling is usually carried out in high-energy mills such as vibratory mills, planetary mills, and attrition mills. The energy transfer to the powder particles in these mills takes place by a shearing action or impact of the high-velocity balls with the powder. In addition to the above mills, several other types of mills such as the rod mill, modified rod mill, and other specially designed mills have been used for mechanical alloying/milling.

During MA/MM processes, the kinetics of alloying and other phase transformations depend on the energy transferred to the powder from the balls. The energy transfer is governed by many parameters such as the type of mill, milling speed, type and size of the balls, ball/powder weight ratio, choice of dry or wet milling, atmosphere in the mill, and the duration of milling.

The ball-milling sequence consists primarily of collision, shearing, wearing, and cold-welding. The formation of amorphous phase by MA/MM is a very complicated process, which not only depends on the alloy system but is also affected by many ball-milling parameters. The MA process synthesizes amorphous alloy powders by reacting elemental crystalline powders through solid-state chemical diffusion, being often accompanied by a negative heat of formation. In the MM process, however, crystalline alloy or compound powders are transformed into amorphous solid powders by destroying the periodic long-range order of atomic arrangement without any changes of chemical composition due to long-distance solid-state diffusion.

MA is a chemical reaction of  $mA$  (crystal) +  $nB$  (crystal)  $\rightarrow A_mB_n$  (amorphous) proceeding from a higher free-energy state to a lower one, providing a continuous evolution in the local chemical composition through long-range solid-state chemical diffusion.

MM is a phase transformation of  $A_mB_n$  (crystal)  $\rightarrow A_mB_n$  (amorphous) going from the ground state to an excited state caused by destroying the long-range order of atomic arrangement, without any changes of chemical composition [15].

## 1.2. Nanocrystalline Materials

A novel way of transforming a material to a metastable state is to reduce its grain size to very small values of a few nanometers where the proportion of atoms lying on grain

boundaries is equivalent to or higher than that of those in the interior of the grains. Materials with such small grain sizes are referred to as nanocrystalline materials, which are defined as single or multiphase polycrystals, with a crystal size typically within the range 1–100 nm. Because of their ultrafine grain sizes, nanocrystalline materials exhibit a variety of properties that are different from and often considerably better than those of conventional coarse-grained polycrystalline materials [16]. These include higher catalytic activity [17], more uniform corrosion [18] and superior localized corrosion resistance [19], improved strength/hardness [20], enhanced diffusivity [21], higher electrical resistivity [22], increased specific heat [23], higher thermal expansion coefficient [24], and better magnetic properties [25] compared with conventional coarser-grained materials.

### 1.2.1. Structure of Nanocrystalline Materials

The structures of nanocrystalline materials are dominated by their ultrafine grain sizes and their large number of grain boundaries. Much research has been done to determine the structure of nanocrystalline materials. Most of the results have been interpreted according to a two-components microstructure: perfect long-range ordered atomic arrangement within the grains and a random interfacial atomic arrangement [16, 24, 26, 27]. Because of their ultrafine grain size, nanocrystalline materials have a significant fraction of their atoms in grain boundary environments, where they occupy positions relaxed from their normal lattice sites. For conventional high-angle grain boundaries, these relaxations extend over about two atomic planes on either side of the boundary, with the greatest relaxation occurring in the first plane [28, 29]. The percentage of atoms in grain boundaries (including grain boundary junctions) of a nanocrystalline material is a function of grain diameter [30], assuming that the average grain boundary thickness ranges from 0.5 to 1.0 nm, about 2 to 4 atomic planes. Assuming that grains are spherical, the volume fraction of nanocrystalline materials associated with the boundaries can be calculated [31].

### 1.2.2. Synthesis and Processing of Nanocrystalline Materials

In principle, any method capable of producing very fine grain size polycrystalline materials can be used to produce nanocrystalline materials. If a phase transformation is involved, for example, liquid to solid or vapor to solid, then steps have to be taken to increase the nucleation rate and decrease the growth rate during formation of the product phase. The methods include inert gas condensation [32], mechanical milling [33], chemical vapor deposition [34], sputtering [35], spray conversion processing [36], electrodeposition [37], sol–gel processing [38], spark erosion [39], plasma processing [40], and quenching a melt under high pressure [41]. Among these, gas condensation and mechanical milling methods are the most commonly used. A typical apparatus [16, 42] for gas condensation is widely used for synthesis of nanocrystalline materials by the *in-situ* consolidation of gas-condensed clusters.

Mechanical milling (MM) is a popular method for making nanocrystalline materials because of its simplicity,

the relatively inexpensive equipment needed, and the applicability to essentially all classes of materials. MM produces nanostructures not by cluster assembly but by the structural decomposition of coarser-grained structures as the result of severe plastic deformation. The major advantage often quoted is the possibility for easily scaling up to tonnage quantities of material for various applications [43]. This process consists of repeated welding, fracturing, and rewelding of powder particles in a dry high-energy ball mill. In this process, a metal, an alloy, or mixtures of elemental or pre-alloyed powder are subjected to grinding under a protective atmosphere in equipment such as attrition mills, vibrating ball mills, and shaker mills. A majority of the work on nano-crystalline materials has been carried out in highly energetic small shaker mills, and it has been shown that nanometer-sized grains can be obtained for almost any material after sufficient milling time. The grain sizes were found to decrease with milling time down to a minimum value, which appeared to scale inversely with the melting temperature. Further, mechanical alloying of immiscible metals can be achieved with very large metastable solid solutions, presumably related to solute segregation at the nanocrystalline grain boundaries [33].

## 2. MAGNESIUM–NICKEL ALLOYS FOR HYDROGEN STORAGE

In the early 1970s, the interest in metal hydrides and the development of their applications started with the discovery of hydrogen absorption by  $\text{LaNi}_5$  [44] at Philips Research Laboratories in Holland and  $\text{FeTi}$  [45] at the Brookhaven National Laboratory in the United States. Since then, many metals, intermetallics, and alloys that react reversibly with hydrogen to form hydrides have been observed. In the 1970s and 1980s, the practical applications for these new materials included hydrogen storage, hydrogen compression and purification, heat pumping, refrigeration, and thermal storage [46]. Later in the 1980s, utilizing hydrogen storage alloys instead of cadmium as an anode material in alkaline rechargeable batteries had brought about a revolution in power sources. By 1990, the first Ni-MH batteries reached the marketing stage [47]. In late 1997, a hybrid electric vehicle power-assisted by a high-power Ni-MH battery was commercialized in Japan by Toyota [48]. More recently, attention has been paid to the investigation and development of various new hydrogen storage alloys with high hydrogen absorption capacities and low costs.

### 2.1. Types of Hydrogen Storage Alloys

The hydrogen storage alloys in common use are classified in terms of their stoichiometric composition into four categories:  $\text{AB}_5$ ,  $\text{AB}_2$ ,  $\text{AB}$ , and  $\text{A}_2\text{B}$  types [49]. Here are some examples of hydrogen storage alloys studied by researchers around the world:

- $\text{AB}_5$ -type ( $\text{LaNi}_5$ ; La is often replaced by mischmetal (Mm), which is a commercial mixture of rare earths, predominated by Ce, La, Nd, and Pr. Ni is partially substituted by Al, Si, Fe, Mn, Sn, etc.)

- $\text{AB}_2$ -type ( $\text{MgNi}_2$ ,  $\text{ZrV}_2$ ,  $\text{ZrCr}_2$ ,  $\text{TiV}_2$ ,  $\text{TiMn}_2$ ,  $\text{TiCr}_2$ ,  $\text{ZrNi}_2$ ,  $\text{ZrMn}_2$ , etc.)
- $\text{AB}$ -type ( $\text{TiNi}$ ,  $\text{MgNi}$ ,  $\text{CaNi}$ ,  $\text{TiFe}$ , etc.)
- $\text{A}_2\text{B}$ -type ( $\text{Ti}_2\text{Ni}$ ,  $\text{Mg}_2\text{Ni}$ ,  $\text{Mg}_2\text{Cu}$ , etc.)

In these alloys, it is the A component which forms the stable hydride. The B component performs several functions [50]: (i) playing a catalytic role in enhancing the hydriding/dehydriding characteristics; (ii) altering the equilibrium pressures for the hydrogen absorption/desorption and raising it or lowering it to a desired level, and (iii) stabilizing the alloys. The last function is important because some of the A components can be readily oxidized. The hydriding/dehydriding characteristics of these alloys can be altered by a partial substitution or a small addition of other elements. Anani and co-workers [50] summarized the roles of some substitutes or additives as follows: (i) to increase or decrease the crystal lattice constants, thereby changing the equilibrium pressure for hydrogen absorption/desorption; (ii) to decrease the hysteresis during hydrogen absorption/desorption; (iii) to catalyze hydriding/dehydriding reactions; and (iv) to improve the stability of these alloys, thus preventing oxide formation on one or more of the components.

### 2.2. Magnesium-Based Alloys for Hydrogen Storage

Magnesium is the lightest of the commercial structural materials and is the sixth most abundant element on the earth. Magnesium can also reversibly store about 7.65 wt.% hydrogen according to the reaction ( $\text{Mg} + \text{H}_2 \rightarrow \text{MgH}_2$ ).  $\text{MgH}_2$  contains much more hydrogen than other metal hydrides. Unfortunately, the reaction is generally difficult to nucleate because the surface is usually contaminated by magnesium oxide ( $\text{MgO}$ ), or magnesium hydroxide ( $\text{Mg}(\text{OH})_2$ ) which either inhibits the dissociative adsorption of hydrogen or the transfer of hydrogen from the surface to bulk.

In order to eliminate the limitations of using Mg alone, studies of numerous metal additions to Mg (binary, ternary, and multicomponent) were carried out in order to find the optimum alloy for hydrogen storage. Reilly and Wiswall [51, 52] reported a fairly rapid reaction of  $\text{Mg}_2\text{Ni}$  and  $\text{Mg}_2\text{Cu}$  with hydrogen at about 300 °C. They concluded that the presence of Ni or Cu has a catalytic effect on the hydrogenation of Mg. The catalytic effect of these elements is probably due to the formation of oxide-free penetration sites on the surface of Mg particles, as reported for the Mg- $\text{Mg}_2\text{Cu}$  system [53–55].

### 2.3. Mg–Ni Based Alloys for Hydrogen Storage

It is known that in the phase diagram of the Mg-Ni system, two intermetallic compounds are formed:  $\text{Mg}_2\text{Ni}$  and  $\text{MgNi}_2$ . The latter does not react with hydrogen at pressures up to 540 atm in the temperature range –196 to 300 °C. However,  $\text{Mg}_2\text{Ni}$  reacts with hydrogen to form a ternary hydride  $\text{Mg}_2\text{NiH}_4$  even at room temperature, and it will react rapidly at 200 °C and a pressure of 14 atm [51]. The hydrogen content in  $\text{Mg}_2\text{NiH}_4$  is about 3.6 wt.%, which is

still a very good value compared to other hydrogen storage materials, but it is less than one-half the amount of hydrogen in  $\text{MgH}_2$  (7.65 wt%).

Substitution is one of the most widely used methods to control or improve the hydrogenation properties of the hydrogen storage alloys. Many substituted  $\text{Mg}_2\text{Ni}$  alloys have been investigated with a view to improving their hydrogenation properties. In the early 1980s, Oesterricher et al. [56] suggested that the partial substitution of Mg in  $\text{Mg}_2\text{Ni}$  by an element with a more exothermic heat of hydride formation, such as Ca, Sc, or Y, might result in a rise of equilibrium pressure for the substituted  $\text{Mg}_2\text{Ni}$ . This would bring  $\text{Mg}_2\text{Ni}$  into the range of reversible room temperature hydrogen sorption. Yvon et al. [57] suggested that the maximum hydrogen concentration of this compound is mainly limited by electronic factors and that structurally related compounds having more than four hydrogen atoms per formula unit could possibly be stabilized by partially replacing Ni with a transition metal of lower valence, or Mg by a non-transition metal of higher valence.

The compounds prepared by partially replacing Ni by 3d elements [58–62], and Mg by non-transition elements [61], in the binary phase of  $\text{Mg}_2\text{Ni}$  show that the alloys prepared could not form to hydrides having more than four H atoms per formula unit. On the other hand, they show some interesting properties with respect to hydriding and dehydriding kinetics as well as the dissociation temperature of the hydride. It was also reported [63–65] that the partial substitution of Mg by 3d metals on Mg-rich, rare-earth intermetallic compounds resulted in improved dehydriding kinetics.

In order to achieve partial substitution of Ni atoms in  $\text{Mg}_2\text{Ni}$  by iron or cobalt, some experiments were performed by Mintz et al. [58]. However, no significant amount of substitution occurred in the  $\text{Mg}_2\text{Ni}_{1-x}\text{M}_x$  ( $\text{M} = \text{Fe}$  or  $\text{Co}$ ) systems. The highest substituent concentrations of about 2 at.% were obtained for Co. The effects of these low-concentration additives on the stability of the corresponding hydrides were negligible. The same observation was reported by Darnaudery et al. [60] for the addition of Mn or Ti, but they did observe the substitution of other elements such as V, Cr, Fe, Co, Cu, and Zn. On the contrary, Lupu et al. [62] reported that there was no substitution of Ni by Fe in  $\text{Mg}_2\text{Ni}_{1-x}\text{Fe}_x$  ( $x \leq 0.37$ ) alloys. This was explained on the basis of Extended X-ray Absorption Fine Structure (EXAFS) measurements with Mössbauer spectral results. In this range of composition multiphase alloys were obtained containing  $\text{Mg}_2\text{Ni}$ , Mg, and more or less finely dispersed Fe in the form of isolated atoms or small clusters as proved by the EXAFS technique and Mössbauer spectroscopy. Thus they confirmed that there is no significant substitution of Ni by Fe atoms in the  $\text{Mg}_2\text{Ni}$  lattice, which is in agreement with the observation of Mintz et al. [58].

A study of the action of hydrogen on  $\text{Mg}_2\text{Ni}_{1-x}\text{M}_x$  ( $\text{M} = \text{V}$ , Cr, Fe, Co, Cu, or Zn;  $x = 0.25$ ) alloys has been carried out [60]. Hydriding of the alloys resulted in the formation of quaternary hydrides. The hydriding process leads to ternary alloys, except in the case of the Cu-containing alloy. This behavior of  $\text{Mg}_2\text{Ni}_{0.75}\text{Cu}_{0.25}$  seems to be similar to that of  $\text{Mg}_2\text{Cu}$  due to the decomposition of the alloy during the hydriding reaction [52]. The thermal stabilities of these

compounds are close to that of  $\text{Mg}_2\text{NiH}_4$ . In each case the hydrogen/alloy mole ratio is lower than for  $\text{Mg}_2\text{NiH}_4$ .

The replacement of Ni in  $\text{Mg}_2\text{Ni}$  by the 3d elements alters the dissociation temperature markedly. For example, the dissociation temperature in 1 atm pressure for the Cu-containing alloy drops significantly from 250 °C to 227 °C, whereas for the Co-containing alloy this temperature increases to 267 °C. The absorption and desorption rates for  $\text{Mg}_2\text{Ni}_{1-x}\text{M}_x$  alloys are close to those obtained with  $\text{Mg}_2\text{Ni}$  except for the Co-containing alloy. Because of the encouraging results obtained with the  $\text{Mg}_2\text{Ni}_{1-x}\text{Cu}_x$  system, Darnaudery et al. [66] continued their work on the same system by varying the  $x$  values from 0 to 0.85 in order to optimize the composition. The absorption and desorption rates for these alloys are close to those obtained with  $\text{Mg}_2\text{Ni}$ .

Au and co-workers [67] have investigated the hydrogen storage properties of multi-component Mg-based alloys and found that  $\text{Mg}_{0.833}\text{Ni}_{0.066}\text{Cu}_{0.095}\text{Ml}_{0.006}$  (Ml stands for La-rich mischmetal) has good hydriding/dehydriding properties. It can absorb 4.75 wt.% hydrogen at 330 °C under 0.1 MPa pressure in 0.5 h. The alloying elements Ni, Cu, and Re (rare-earth metal) are identified as having positive effects on the kinetic properties of Mg-based alloys. The intermetallic compound of Mg with Ni, Cu (and Re), namely  $\text{Mg}_2(\text{Cu}, \text{Ni})$ , plays the key role in improving the kinetic properties of the multicomponent Mg-based alloy.

Iwakura et al. [68] investigated the effect of partial substitution of Mg in MgNi with both Ti and V and found that subsequent surface modification with graphite greatly enhanced the hydrogen desorbability of the MgNi alloy compared with either the partial substitution or the surface modification.

## 2.4. Hydrogenation Properties of Nanocrystalline and Amorphous MgNi Alloys

As Mg and Mg-based alloys are some of the most promising hydrogen storage alloys, there has been extensive work on Mg-based hydrogen storage alloys for more than three decades, from both fundamental and applications points of view. In recent years, it has been found that ball milling is a highly effective method of improving the hydriding/dehydriding kinetics and hydrogenation characteristics of Mg-based alloys. In the late 1980s, Khrussanova et al. reported that ball milling a 90 wt.% Mg and 10 wt.%  $\text{TiO}_2$  mixture in a planetary mill results in improvement of the absorption and desorption characteristics of magnesium [69] and that ball milling is favorable to the appearance of a clean Mg surface without the usual thin oxide film [70]. Ball-milled 90 wt.% Mg and 10 wt.%  $\text{V}_2\text{O}_5$  mixture is activated quickly and has a high hydrogen capacity which is preserved after prolonged cycling. It also has good desorption characteristics [71]. Ball milling can also greatly improve the hydrogen absorption rate of  $\text{Mg}_2\text{Ni}$  intermetallic compound [72]. Song [73–75] investigated the hydriding and dehydriding characteristics of mechanically milled Mg and mechanically alloyed mixtures with the compositions Mg- $x$  wt.% Ni ( $x = 5, 10, 25$ , and 55) using a planetary mill. The results indicated that the Mg- $x$  wt.% Ni and Mg-25 wt.%

Ni mixtures are easily activated with the activation accelerated within 5 min, and also show much larger hydrogen storage capacities and much higher hydriding rates, and higher dehydriding rates, than other magnesium-based alloys or mixtures. Mechanically milled Mg-based composites, Mg-G (graphite) and Mg-Pd-G (graphite), were extremely active with respect to hydrogen absorption even at 27 °C and showed good reversibility for hydriding/dehydriding [76–79]. The ball-milled MgNi alloy with graphite can also absorb hydrogen at 30 °C in much larger quantities than that prepared by induction melting [80]. Considerable work has also been done on ball milling ternary hydrogen storage alloys, such as  $Mg_2Ni_{1-x}Zr_x$  ( $0 < x \leq 0.3$ ) [81], and Mg-based composite [82–85], which has led to better hydriding/dehydriding kinetics and/or larger hydrogen absorption abilities of the materials.

Ball milling is the most effective and simplest method to manufacture nanocrystalline and amorphous MgNi alloys. The activation of nanocrystalline  $Mg_2Ni$  is much easier, or even unnecessary. At high temperatures (about 300 °C), the hydrogen absorption rate is very high, even for as-made nanocrystalline samples. The absorption rate can be further improved by applying one hydrogenation cycle as a pretreatment. Nanocrystalline  $Mg_2Ni$  also exhibits hydrogen absorption at lower temperatures (for instance at 200 °C, i.e., below the temperature of structural transformation of the  $Mg_2NiH_4$  hydride) without any activation [86]. Tanaka et al. investigated the hydrogen absorbing rates and pressure–composition isotherms ( $P$ - $C$ - $T$ ) of nanocrystalline MgNi and MgNi-Re (Re = La, Nd) alloys prepared by a melt-spinning and crystallization method. These nanocrystallized alloys, particularly of the MgNi-Re systems, exhibit excellent hydrogen absorbing kinetics and  $P$ - $C$ - $T$  characteristics in comparison with those of the corresponding as-cast alloys with coarse eutectic structure [87].

Orimo et al. investigated the hydrogenation properties of amorphous MgNi alloys prepared by ball milling under a hydrogen atmosphere [88, 89]. The hydrogen pressure–composition isotherms in dehydriding processes of amorphous MgNi alloy show that the dehydriding reaction proceeds below 0.1 MPa even at 160°C. The pressure dependence of the hydrogen content is small, compared to the other amorphous alloys with a broad site energy distribution for hydrogen atoms, such as the FeTi system [90, 91]. This suggests that the energy distribution is narrower in amorphous MgNi alloy. Funaki et al. [92] synthesized amorphous  $MgNiC_x$  ( $x = 0$ –1.31) by mechanical alloying of amorphous MgNi and graphite as starting materials. Upon hydrogenation of  $MgNiC_x$ , the atomic ratio of hydrogen plus carbon to metal ( $(H + C)/M$ ) remained at a constant value of about 0.9.

Tsushio and co-workers investigated the effect of elemental substitutions on the hydrogenation properties of amorphous  $Mg_2Ni_{0.86}M_{0.03}$  ( $M = Cr, Fe, Co, Mn$ ) alloys prepared by ball milling [93]. Most of the  $P$ - $C$ - $T$  curves were completely different from those of the crystalline  $Mg_2Ni-H_2$ ,  $Mg-H_2$  systems, and even amorphous MgNi alloy [89]. They show a monotonic increase of hydrogen content with the logarithm of applied pressure with no plateau. The synthesis and hydriding/dehydriding properties of  $Mg_2Ni_{1.9}M_{0.1}$  ( $M =$  none, Ni, Ca, La, Y, Al, Si, Cu, and Mn) alloys mechanically alloyed from  $Mg_2Ni_{1.9}M_{0.1}$  and Ni powder were also

reported [94]. The pressure–composition isotherms of amorphous  $Mg_2Ni_{1.9}M_{0.1}$  ( $M =$  none, Ca, and Cu) indicate that elemental substitutions of amorphous MgNi alloys can effectively change their hydriding/dehydriding properties [94]. The formation of amorphous or nanocrystalline Mg-based hydrogen storage alloys produced by ball milling results in dramatic changes in hydrogen sorption properties, especially by elimination of the need for activation and improvement of hydriding/dehydriding kinetics. Yang et al. have successfully synthesized  $Mg_2Ni_{0.75}M_{0.25}$  ( $M = Ti, Cr, Mn, Fe, Co, Ni, Cu,$  and  $Zn$ ) alloys by the ball-milling diffusion method [95]. Results show that the alloys after treatment have the best performance: the hydrogen desorption capacity reaches the highest value after only two adsorption/desorption cycles. The ratio of H/M is about 1.18 (approx. 3.3 wt.%) under the STP conditions for each alloy. After substitution for Ni in  $Mg_2Ni$  (Fig. 1), there are three results: Cr, Mn, and Co all lower the decomposition plateau pressure of  $Mg_2Ni$ ; Ti and Cu have the opposite effect on  $Mg_2Ni$  from Cr, Mn, and Co; Fe and Zn have little effect. The preparation and hydrogen absorption/desorption capacities of the alloys reported by various researchers are shown in Table 1.

### 3. MAGNESIUM–NICKEL ALLOYS ELECTRODES FOR Ni-MH BATTERIES

After the invention of the Pb-acid battery in 1859 and the Ni-Cd battery in 1899, no successful rechargeable battery appeared for 90 years. The Ni-MH battery is the third practical secondary battery and is now a key component not only for advanced information and telecommunication systems, but also for the next generation of vehicles in which energy can be used efficiently with low emissions to the environment. The key materials for this high-tech battery are the hydrogen storage alloys [48].

**Figure 1.**  $P$ - $C$  desorption isotherms of the ternary  $Mg_2Ni_{0.75}M_{0.25}$  alloys. Reprinted with permission from [95], H. B. Yang et al., *J. Alloys Comp.* 330, 640 (2002). © 2002, Elsevier Science.

**Table 1.** Preparation method and hydrogen absorption/desorption capacity of the alloys reported by various researchers.

Alloys	Preparation	Hydrogen absorption/desorption capacity of the alloy	Ref.
MgNi MgNi <sub>1.5</sub> MgNi <sub>2</sub>	MgNi <sub>x</sub> alloys were prepared by ball milling mixtures of metallic Mg and Ni	2.0 wt.% 1.1 wt.% 0.7 wt.%	[130]
MgNi	MgNi alloy was prepared from Mg and Ni mixed powders by mechanical alloying under Ar for seven days	An amount of absorbed hydrogen saturated at H/M ratios of ca. 1.0 and 0.58 for the alloys prepared by MA and induction melting respectively	[80]
Mg <sub>2</sub> Ni <sub>0.75</sub> M <sub>0.25</sub> (M = Ti, Cr, Mn, Fe, Co, Ni, Cu and Zn)	Mg, Ni, and M powders were mixed, ball-milled under Ar for 2 h, pressed to pellets, and sintered in Ar	H/M = 1.3, ≈3.3 wt.%	[95]
Mg <sub>2</sub> Ni Mg <sub>2</sub> Ni <sub>0.9</sub> Cu <sub>0.1</sub>	Mixing of Mg and Ni powders, then mechanical alloying 120 h Mechanical alloying 120 h	At 200 °C, 2.6 wt.% (abs.) at 5 MPa At 300 °C, 3.75 wt.% (abs.) at 5 MPa At 200 °C, 3. wt.% (abs.) at 0.01 MPa	[128]
Mg <sub>2-x</sub> Ni (x = 0) Mg <sub>2-x</sub> Ni (x = 0.25) Mg <sub>2-x</sub> Ni (x = 0.5) (Nanostructured)	Mg flakes and Ni powders were premixed and poured into a die cavity. The mixture of powders was repeatedly extruded and compressed using a high-speed forging machine	H/M = 0.11 H/M = 0.23 H/M = 0.26  Alloys were immersed in 6 M KOH solution for 44 h	[117]
Mg <sub>2</sub> Ni Mg <sub>2</sub> Ni <sub>1-x</sub> Zr <sub>x</sub>	Mg, Ni, and Zr powders were mixed, ball-milled under Ar for 2 h, pressed to pellets, and sintered in Ar	3.3 wt.% for Mg <sub>2</sub> Ni <sub>0.7</sub> Zr <sub>0.3</sub> , which is a little higher than that of Mg <sub>2</sub> Ni	[131]
Mg <sub>2</sub> Ni + Ni Mg <sub>1.9</sub> Mn <sub>0.1</sub> Ni (M = Al, Mn)	Alloys were prepared in an induction furnace under inert gas, pulverized, then mechanically ground (MG) for 100 h	H/M = 0.1 for Mg <sub>1.9</sub> Al <sub>0.1</sub> Ni (80 °C), Mg <sub>1.9</sub> Mn <sub>0.1</sub> Ni (125 °C), and Mg <sub>2</sub> Ni (150 °C)	[110]
MG-Mg <sub>2</sub> Ni + Ni		H/M = 1.2 (80 °C)	
Mg <sub>2</sub> Ni-Ni composite Crystalline Mg <sub>2</sub> Ni	Ingot of Mg <sub>2</sub> Ni alloy was prepared by induction melting, pulverized, mixed with Ni powder	H/M = 1.02, ≈4.0 wt.% for Mg <sub>2</sub> Ni and 2.4 wt.% for Mg <sub>2</sub> Ni-Ni  Theoretical value 3.6 wt.% on basis of Mg <sub>2</sub> NiH <sub>4</sub>	[132]
Mg <sub>1.8</sub> Ag <sub>0.2</sub> Ni	Pure Mg, Ni, and Ag metal powders were mixed, ground, and ball-milled under Ar; pressed into pellets under Ar and heated for 4 h	Hydriding and dehydriding process can take place at 150 °C. Hydrogen storage capacity reached 2.2 wt.% at 150 °C	[139]

In 1969, Zijlstra and Westendorp accidentally found during research on rare-earth magnets (SmCo<sub>5</sub>) that rare-earth intermetallic compounds absorbed large amounts of hydrogen [96], opening a new scientific and technical field—hydrogen storage alloys. Soon after the discovery of hydrogen storage alloys, intermetallic compounds were applied as “hydrogen storage alloy electrodes,” for instance, TiNi-Ti<sub>2</sub>Ni [96], LaNi<sub>5</sub> [97, 98], and LaNi<sub>5-x</sub>M<sub>x</sub> (M = Al, Cr, Cu, Mn) [99–101]. Markin et al. constructed and evaluated the rechargeable nickel–metal hydride (Ni-MH) batteries composed of nickel hydroxide positive electrodes and metal hydride negative electrodes using LaNi<sub>5</sub> [102, 103].

Since 1985, a tremendous research and development effort has been conducted on MH electrodes and the Ni-MH

battery, leading to outstanding progress in every area of performance. The good combination of both metal hydride technology and Ni-Cd technology resulted in the rapid commercialization of the sealed Ni-MH battery by the end of 1990 [104]. The hydrogen storage alloys used for the negative electrode materials of Ni-MH batteries must satisfy the following requirements [7, 105, 106]:

- Large electrochemical hydrogen storage capacity.
- High electrochemical catalytic activity.
- High durability against oxidation in concentrated alkaline solution.
- Good electrochemical hydriding-dehydriding kinetics.
- Low cost.

**Table 2.** Capacity of MgNi-based alloy electrodes.

Alloy	Discharge current density (mA/g)	Discharge capacity (mAh/g)	Ref.

### 3.1. Capacities of Mg-Ni-Based Alloy Electrodes

In recent years, some research has shown that the MgNi-type alloys are promising materials for increasing the negative electrode capacity of Ni-MH batteries.

By sintering Mg and Ni powders in their required proportions under an argon atmosphere, crystalline Mg<sub>2</sub>Ni alloys can be prepared. The sintered crystalline Mg<sub>2</sub>Ni alloys have extremely low discharge capacities of only 15 or 18 mAh/g at a discharge current density of 50 mA/g, which is negligibly small in comparison with their theoretical discharge capacity. Thus, common crystalline Mg<sub>2</sub>Ni alloy is not suitable for use as a rechargeable anode material in an alkaline solution at room temperature.

Orimo and Fujii [107] reported that by ball milling Mg<sub>2</sub>Ni with Ni powder, the resulting MgNi alloy absorbed hydrogen more easily than the initial crystalline Mg<sub>2</sub>Ni alloy. Iwakura et al. [108] have also improved the discharge capacity of MA Mg-based alloy with graphite surface modification by ball milling (BM). Kohno et al. reported that by mechanical grinding of Mg<sub>2</sub>Ni alloys with Ni powders, a discharge capacity of 750 mAh/g (Mg<sub>2</sub>Ni) was obtained at a discharge current density of 20 mA/g [109, 110]. Iwakura et al. reported that the calculated discharge capacity of the Mg<sub>2</sub>Ni-Ni composite is ~1090 mAh/g(Mg<sub>2</sub>Ni) [112], while a Mg<sub>2</sub>Ni-70 wt.% Ni (Mg<sub>2</sub>Ni/Ni = 1/1.28 in mole ratio) composite had a homogeneous amorphous structure and exhibited a maximum discharge capacity of ca. 1082 mAh/g(Mg<sub>2</sub>Ni) (636 mAh/g(Mg<sub>2</sub>Ni + Ni)) at 30 °C [111, 112]. However, the capacity decay of the Mg-based alloy electrode is still serious, which makes it difficult to use as an electrode material in practice.

Table 2 lists the capacity of MgNi-based alloy electrodes reported by various researchers. It is seen from Table 2 that the addition of other elements can increase the discharge capacities of Mg<sub>2</sub>Ni electrodes. Cui and co-workers reported a discharge capacity of 150 mAh/g for Mg<sub>1.9</sub>Al<sub>0.1</sub>Ni<sub>0.9</sub>Y<sub>0.1</sub> alloy [114, 115] and 90 mAh/g for Mg<sub>1.8</sub>Ti<sub>0.2</sub>Ni<sub>0.75</sub>Fe<sub>0.25</sub> alloy [116] compared with only 8 mAh/g for Mg<sub>2</sub>Ni alloy at a discharge current density of 5 mA/g.

### 3.2. Cycle Lives of Mg-Ni-Based Alloy Electrodes

When Mg is immersed in an alkaline solution, hydrogen gas generation and Mg(OH)<sub>2</sub> formation take place, but these reactions terminate soon after immersion because the Mg surface is coated with Mg(OH)<sub>2</sub>. Mg(OH)<sub>2</sub> could thus also form on the Mg<sub>2-x</sub>Ni alloy surfaces. Kuji et al. found that during the first charging–discharging cycle, the alloys were severely corroded. Especially during the discharging process, the alloys were anodically polarized, so that the maximum hydrogen concentration obtained by the second charging process was markedly reduced and as a result only a small discharge capacity was obtained [117].

Microencapsulation of Mg<sub>2</sub>Ni-type alloys by metal and alloy coatings can improve the electrode performance. Luo and Cui [118] increased the discharge capacity of Mg<sub>1.9</sub>Al<sub>0.1</sub>Ni<sub>0.9</sub>Y<sub>0.1</sub> alloy to about 175, 200, and 230 mAh/g at a current density of 10 mA/g by microencapsulation with Ni-B, Ni-P, and Ni-Pd-P, respectively. The discharge capacity of the bare Mg<sub>1.9</sub>Al<sub>0.1</sub>Ni<sub>0.9</sub>Y<sub>0.1</sub> alloy was only 140 mAh/g at the same discharge current density. Lei et al. prepared MgNi alloy by mechanical alloying (MA) and demonstrated discharge capacities of around 500 mAh/g at a current density of 20 mA/g [119, 120]. Mg<sub>1.9</sub>Al<sub>0.1</sub>Ni<sub>0.8</sub>Co<sub>0.1</sub>Mn<sub>0.1</sub> alloy fabricated by ball milling with Ni powder for 50 h showed good discharge capacity at a discharge current density of 50 mA/g [121].

Zhang et al. [113] reported that the cycle performance of MgNi<sub>x</sub> alloys can be significantly enhanced by increasing the  $x$  value. The X-ray patterns of the MgNi<sub>x</sub> alloys show that only broad peaks at around 40–45° were observed, indicating that amorphous MgNi<sub>x</sub> phases were formed for the MgNi, MgNi<sub>1.5</sub>, and MgNi<sub>2.0</sub> alloys shown in Figure 2. The charge–discharge capacities of MgNi<sub>x</sub> alloys as a function of the cycle number are shown in Figure 3.

The electrode containing the nickel ball-milled Mg<sub>1.8</sub>Ti<sub>0.2</sub>Ni alloy gave a discharge capacity of 720 mAh/g at a discharge current density of 50 mA/g and over 42 cycles to a specific capacity of 100 mAh/g [122]. A discharge capacity of 780 mAh/g was achieved at a discharge current

**Figure 2.** X-ray diffraction patterns of  $\text{MgNi}_x$  alloys ( $x = 1, 1.5$  and  $2.0$ ). Reprinted with permission from [113], S. G. Zhang et al., *J. Alloys Comp.* 293–295, 552 (1999). © 1999, Elsevier Science.

density of 50 mAh/g for Ni-coated  $\text{Mg}_2\text{Ni}_{0.9}\text{Mn}_{0.1}$  electrodes [123]. Figure 4 shows the discharge capacities of the bare, nickel ball-milled, and nickel coated  $\text{Mg}_2\text{Ni}_{0.9}\text{Mn}_{0.1}$  alloy electrodes as a function of cycle number. Figure 5 shows the discharge capacity as a function of the cycle number for  $\text{Mg}_2\text{Ni}$  alloy, ball-milled  $\text{Mg}_2\text{Ni}$  alloy, and  $\text{Mg}_2\text{Ni}$ -Ni composite. The  $\text{Mg}_2\text{Ni}$ -Ni composite exhibited a longer cycle life than the ball-milled  $\text{Mg}_2\text{Ni}$  alloy and  $\text{Mg}_2\text{Ni}$  alloy.

$\text{Mg}_{0.9}\text{Ti}_{0.06}\text{V}_{0.04}\text{Ni}$  alloy prepared by mechanical alloying showed better performance than either  $\text{Mg}_{0.9}\text{Ti}_{0.1}\text{Ni}$  or  $\text{Mg}_{0.9}\text{V}_{0.1}\text{Ni}$  alloy [124]. Figure 6 shows that the discharge capacity of  $\text{MgNi}$  alloy decreases greatly with increasing discharge current density, which may be due to the low electrochemical reactivity of the alloy surface and poor diffusivity of hydrogen into the alloy bulk [68]. In charge-discharge cycle tests, the partial substitution of Mg with Ti and V or surface modification with graphite suppressed the decay of discharge capacity with increasing cycle number.  $\text{Mg}_{0.9}\text{Ti}_{0.06}\text{V}_{0.04}\text{Ni}$  alloy modified with graphite exhibited further improved cycle performance as compared with either unmodified  $\text{Mg}_{0.9}\text{Ti}_{0.06}\text{V}_{0.04}\text{Ni}$  or  $\text{MgNi}$  alloy modified

with graphite [125]. The partial substitution of Ti for Ni in Mg<sub>50</sub>Ni<sub>50</sub> increases both the discharge capacity and the degradation rate. The substitution of Zn for Ni shows no effect on the discharge capacity but increases the deterioration rate. The substitution of Fe, W, Cu, Al, or C for Ni decreases both the deterioration rate and the discharge capacity, while the substitution of Se, Sb, Co, or Si decreases both the discharge capacity and the cycle life [126, 127]. Woo and Lee reported that the discharge capacity of a nanostructured Mg<sub>2</sub>Ni electrode is much higher than that of a polycrystalline one, while the partial substitution of Cu for Ni increased the hydrogen desorption of the nanostructured Mg<sub>2</sub>Ni electrode at 30 °C [128]. All the investigation suggests that the amorphous Mg-based alloys differ greatly

in nature from the crystalline ones, and Ni may play an extremely important role in facilitating the absorption and desorption of hydrogen.

Table 3 lists the discharge capacity and cycle life of the Mg-based alloy electrodes at different discharge current densities. The best performance in discharge capacity and cycle life is found with Ti-containing alloys. It is clearly seen that the discharge capacity, high-rate discharge capability, and cycle life of these Mg-based alloy electrodes were greatly improved by the ball-milling and nickel-coating processes. For example, the discharge capacities of the bare Mg<sub>2</sub>Ni<sub>0.9</sub>Mn<sub>0.1</sub> alloy electrode at 50 mA/g and 100 mA/g were only 118 mAh/g and 5 mAh/g, respectively, and the corresponding discharge capacities of the nickel-coated

**Table 4.** Comparison of LaNi<sub>5</sub>, ZrV<sub>2</sub>, and Mg<sub>2</sub>Ni hydrogen storage alloys as the negative electrode of Ni-MH batteries.

Type of alloys	AB <sub>5</sub>	AB <sub>2</sub>	A <sub>2</sub> B
Example of alloys	LaNi <sub>5</sub> MmNi <sub>3.55</sub> Co <sub>0.75</sub> Mn <sub>0.4</sub> Al <sub>0.3</sub>	ZrV <sub>2</sub> Cubic or hexagonal [137] C15, Zr <sub>3</sub> V <sub>3</sub> O, BCC [138]	Mg <sub>2</sub> Ni Hexagonal

Commercial price (\$/Kg)	15	22.5	7.5
Advantages	Environment acceptable Higher specific energy Higher charge-rate capability compared with Ni/Cd batteries	Environment acceptable Higher specific energy Higher charge-rate capability compared with Ni/Cd batteries	High capacity Light weight Relative abundance Lower cost
Disadvantages	Low capacity Expensive Poisonous element Co Deterioration and disintegration of electrodes	Low capacity Expensive Poisonous element V Slow electrode activation Poor high rate discharge Low charging efficiency	Serious capacity decay  Poor hydriding/dihydriding kinetics
Present use	MmNi <sub>3.55</sub> Co <sub>0.75</sub> Mn <sub>0.4</sub> Al <sub>0.3</sub> is commercialized and mostly used in Ni-MH battery.	Used by several companies	Under development

Mg<sub>2</sub>Ni<sub>0.9</sub>Mn<sub>0.1</sub> electrodes at 50 mA/g and 100 mA/g were 780 mAh/g and 546 mAh/g.

The reasons for the short cycle life of MgNi-based alloy electrode are that (1) magnesium oxide easily forms on the alloy surface exposed to air and the MgO layer prevents hydrogen molecules from penetrating into the bulk; (2) Mg on the surface of MgNi-based alloy is easily corroded to Mg(OH)<sub>2</sub> in alkaline solutions, and the insoluble Mg(OH)<sub>2</sub> layer may prevent the diffusion of hydrogen into the alloy bulk to form the hydride. So for improving

the anticorrosion properties and overcoming the kinetic limitations of MgNi-based alloys, it is necessary to suppress the oxidation of the alloys. Yang et al. [133] reported that the electrochemical properties of the ternary alloys Mg<sub>2-x</sub>Mm<sub>x</sub>Ni ( $x < 0.2$ ) show that the substitution of Mm for Mg reduces the reaction resistances and improves the absorption/desorption properties. Zhang et al. reported that the loss of the active hydrogen-absorbing element Mg is definitely the main cause for cycling capacity deterioration [134]. Han et al. have reported that Ni and graphite can

protect the Mg from oxidation in nanocrystalline and amorphous Mg<sub>2</sub>Ni-based alloys for Ni-MH batteries: after 50 cycles, the degradation of the bare electrode was 94% of maximum capacity, but that of coated electrode with Ni and graphite was 45 and 76% of maximum capacity [135]. Han et al. reported from electrochemical impedance spectroscopy analysis that the charge transfer resistance between the Mg<sub>0.7</sub>Ti<sub>0.3</sub>Ni alloy and the electrolyte does not increase during charge–discharge cycles. They also reported from auger electron spectroscopy that the thickness of the surface oxide layer on the Mg<sub>0.7</sub>Ti<sub>0.3</sub>Ni alloy is thinner than that of the oxide layer on the MgNi alloy and from X-ray photoelectron spectroscopy that the magnesium in the Mg<sub>0.7</sub>Ti<sub>0.3</sub>Ni alloy exists in a metallic state while the titanium forms an oxide layer, indicating that the titanium oxide layer not only prevents further oxidation of magnesium, but also induces a nickel-enriched layer on the alloy surface [136].

Table 4 is the basic information on comparison of the magnesium–nickel hydride alloys with two current battery materials. It is clear that the practical capacity is nearly double the current one while the cost is about one-half to one-third of the current cost. The capacity has been reached 750–780 mAh/g (Mg<sub>2</sub>Ni), the remarkable value for Mg-based hydrogen storage alloys [109–112, 123]. The capacity decay of the nickel-coated alloy electrode was 10% after 50 cycles [123] at high-rate charge–discharge (50 mA/g). This breakthrough has a real commercial potential.

#### 4. CONCLUSIONS

The MgNi-based alloys are promising hydrogen storage materials because of their high storage capacities and the abundance of the constituent elements in nature. However, they are inadequate for practical use in hydrogen storage applications because of their poor hydriding and dehydriding properties at ambient temperature and easy corrosion in alkaline solutions. The kinetics of the hydriding/dehydriding reactions of Mg-based alloy electrodes can be greatly improved by the processes of ball milling with Ni (or graphite) and chemical coating. The amorphous Mg-based alloys differ greatly from the crystalline ones, and Ni (or graphite) may play an extremely important role in facilitating the absorption and desorption of hydrogen. A surface modification to protect MgNi alloys from corrosion is very effective in improving hydrogen desorbability and charge–discharge cycle performance of the alloys for practical applications. From the encouraging results, it is expected that Mg-based alloys will be excellent negative electrode materials of the third generation for nickel–metal hydride batteries.

#### GLOSSARY

**Amorphous alloy** For a single-phase solid alloy at amorphous state, it has no crystal lattice, no grain boundaries, and no dislocations.

**C rate** The discharge or charge current, in milliamperes (mA), expressed as a multiple of the rated capacity in milliampere-hours (mAh).

**Capacity** The total number of milliampere-hours that can be withdrawn from a fully charged battery under specified conditions of discharge.

**Cycle** Set of charge and discharge steps for a secondary battery.

**Cycle life** The number of cycles that can be delivered by a secondary battery before it fails to meet specified performance criteria.

**Electrode** The conductor and associated active materials at which an electrochemical reaction occurs.

**Nanocrystalline alloys** They are defined as single- or multiphase polycrystals with a crystal size typically within the range 1–100 nm.

**Ni-MH battery** It is composed of nickel hydroxide positive electrodes and metal hydride negative electrodes using LaNi<sub>5</sub>.

**Rechargeable battery** A cell which may be restored to a fully charged state by passage of an electric current through the cell (opposite direction to that used in discharging the cell.)

**Specific capacity or capacity density** Ah/kg (ampere hour per kilogram) or mAh/g (milliampere per gram).

#### ACKNOWLEDGMENTS

Financial support by the Australian Research Council/Department of Education, Training and Youth Affairs, the Strategic Partnerships with Industry–Research and Training (SPIRT) Scheme Grant (File Number: C00001879) is gratefully acknowledged. Thanks are given to Drs. B. Luan, N. Cui, J. Chen, and L. Sun for their valuable research work during their time at the University of Wollongong. The author also thanks Dr. T. Silver for valuable suggestions for improving the manuscript.

## 1. INTRODUCTION

In recent years, there has been renewed interest in the problem of motion of charge carriers in nanostructured systems, perturbed by external magnetic fields. The principal tool for their study has been the so-called “effective mass approximation” or “envelope function approximation,” which replaces the effect of the periodic field by a mass tensor, the elements of which are determined by the unperturbed band structures.

We can consider the crystal as a quantum system formed by two subsystems, a gas of electrons and a gas of phonons. All the phenomena or elementary excitations that take place in a solid are given by one of these two subsystems or by their interaction, which is known as electron–phonon coupling, or also for the answer that each one of them separately, or together, gives to an external perturbation, which can be represented by a impurity potential, an electric field, a wave of light or acoustics, a thermal source, a barrier potential, or finally a magnetic field.

Between the elementary excitations and quasi-particles more well known in the solids we can mention the following: excitons, polarons, plasmons, polaritons, magnons, Cooper pairs, etc. The definition of a solid as a mixture of electrons and phonons is implicit to the consideration of the electron as a quasi-particle and of the phonon as an elementary excitation.

When a crystal undergoes to the presence of a magnetic field, a series of phenomena can occur that involves the electron as much as the phonon and their interaction or coupling. We can distinguish four types of phenomena or fundamental effects, such as:

- (i) The interaction of the orbital angular moment of the electron with the magnetic field. In the semiconductors and the metals this phenomenon gives rise to Landau levels.
- (ii) The interaction of the angular moment of spin of the electron with the magnetic field. In the semiconductors this phenomenon gives rise to splitting of each Landau level in two.
- (iii) The interaction of the orbital angular moment of the electron with the phonon and both with the magnetic field. This is known as the electron–magnetophonon resonance phenomenon.
- (iv) The interaction of the angular moment of spin of the electron with the phonon and both with the magnetic field. This is known as the spin–magnetophonon resonance phenomenon.

These four phenomena are shown in Figure 1.

The polar semiconductors are artificially created compounds, uniting two or three elements of the periodic table. The binary polar semiconductors generally are formed by III–V, II–V, and III–VII chemical elements, although the most abundant and exploited in the technological applications are the first two. The ternary compounds are semiconductors binary doped with a metal. When this metal is of magnetic origin such as Mn, Fe, Zn, and Ni, then they are called diluted magnetic semiconductors.

One of the most significant movements in semiconductor physics has been the progressive miniaturization of devices. On the one hand, this led to explosive growth in computer technology; on the other hand, the opportunity to fabricate devices with characteristic dimensions significantly below

**Figure 1.** Schematic view of the magnetic field effect on the energy bands of semiconductors.

1  $\mu\text{m}$  led to the investigation of a whole range of novel physical phenomena. In turn, these new physical phenomena promise to give rise to new generations of devices working on completely different physical principles than their predecessors.

The nanostructured systems are real solids built artificially with polar semiconductors, binary and ternary. In this way the quasi-particles and elementary excitations in them feel a potential barrier that limits their movement to a determined space of mesoscopic dimensions, giving rise to a set of energy discrete states, which it makes these solids very attractive systems for their novel properties.

In the past three decades, nanostructured semiconductors have been studied extensively both theoretically and experimentally and applied to various electronic and photonic devices. The interest in the quantum size effects present in the low dimensional structures has been primarily motivated by the fact that the optical and electronic properties of these structures are modified and improved by the reduction of dimensionality. It is expected that the same properties will be further improved by the reduction of dimensionality. The fabrication of quantum structures by methods such as molecular-beam epitaxy, metal-organic chemical vapor deposition, lithography and others allows one to obtain high-quality samples which are required in investigations with experimental techniques, including optical studies such as photoluminescence spectroscopy and photoluminescence excitation spectroscopy [1–6]. In addition, theoretical properties have been reported [7–14], such as electronic structure [15–26], impurity levels [27–42] and excitonic states [43–52].

Experiments in magnetic fields are of particular interest in order to understand the basic physical properties of

nanostructures, because the magnetic confinement potentials compete with the geometric confinement potentials depending on the strength and orientation of magnetic field. The magnetic length can be varied from values which are larger than the typical lateral dimensions of quantum wires and quantum dots to values that are smaller than these dimensions. This information about the geometric confinement potentials can be obtained in a very direct way by magnetic field studies.

A number of magneto-optical studies on interband transitions in GaAs based quantum wires and dots have been performed previously [53–59]. An anisotropy of the photoluminescence of GaAs wires for different orientations of the magnetic field relative to the wire axis was observed [57]. For  $\text{In}_{0.13}\text{Ga}_{0.87}\text{As}/\text{GaAs}$  wires [58] and  $\text{GaAs}/\text{Al}_{0.36}\text{Ga}_{0.64}\text{As}$  wires [59] a transformation from quasi-one-dimensional quantum wire states to quasi-zero-dimensional, fully quantized states was observed with increasing magnetic field normal to the wire axis. However, all these studies were performed on wire patterns that contained only wires of one fixed lateral width. Other work on the magnetic field effect in nanostructures can be found in [60–76].

## 2. EFFECT OF STATIC EXTERNAL MAGNETIC FIELD ON THE QUASI-PARTICLE ENERGY LEVELS IN THE LOW DIMENSIONAL STRUCTURES

### 2.1. Magnetic Field Effect in the Quasi-Two-Dimensional System

The study of the magnetic field effects (Landau quantization) gives access to fine characterization methods of conducting in the quasi-two-dimensional structures through cyclotron resonance or Shubnikov–de Haas experiments [79]. At the same time, they prove to be difficult to understand. As we shall see, a magnetic field  $\vec{B}$  completely reorganizes the energy spectrum of quasi-two-dimensional electrons by splitting the continuum of the low dimensional structure density of states ( $B = 0$ ) into highly degenerate levels which are separated by finite bandgaps ( $B \neq 0$ ). Thus, what was a metallic system at  $B = 0$  is now either metallic or insulating at finite  $B$  depending on whether the Fermi level sits in the gaps or in the levels. The existence of finite bandgaps is responsible for the quantization of the Hall conductivity into multiples of the fundamental constant  $e^2/\hbar$ . The quantized Hall effect has become one of the most spectacular experimental effects discovered in solid state physics these last three decades.

In the following discussions band structure effects are ignored. The carriers are characterized by an isotropic effective mass, which is assumed to be position independent.

In this topic we consider the motion of a quasi-two-dimensional electron under the action of a static and uniform magnetic field  $\vec{B}$ , which forms an angle  $\theta$  with respect to the growth  $z$  axis of the structure (see Fig. 2). Thus  $\vec{B}$  is given by

$$\vec{B} = (0, B \sin \theta, B \cos \theta) \quad (1)$$

It can be shown that the Lorentz force  $(q/c)\vec{v} \times \vec{B}$  acting on a particle of charge  $q$  can be derived using the Hamilton equations

$$\frac{d\vec{r}}{dt} = \frac{\partial H}{\partial \vec{p}} \quad \frac{d\vec{p}}{dt} = -\frac{\partial H}{\partial \vec{r}} \quad (2)$$

provided the particle momentum  $\vec{p}$  is replaced by  $\Pi$  in the classical Hamiltonian. The vector  $\Pi$  is equal to

$$\Pi = \vec{p} - \frac{q}{c}\vec{A} \quad (3)$$

where  $\vec{A}$  is the vector potential of the magnetic field  $\vec{B}$  which is related as

$$\vec{B} = \nabla \times \vec{A} \quad (4)$$

and  $q$  is the algebraic charge of the carrier ( $q = -e$  for electrons). Unfortunately  $\vec{A}$  is only a mathematical tool which is in fact not very convenient since, if  $\vec{A}$  is replaced by  $\vec{A}' = \vec{A} + \nabla f$  where  $f$  is an arbitrary differentiable scalar function, the magnetic field  $\vec{B}' = \nabla \times \vec{A}'$  coincides with  $\vec{B}$ . Thus, there is a large ambiguity in the choice of the vector potential which corresponds to a given field  $\vec{B}$ . Since only  $\vec{B}$  retains a physical significance, the results should only depend on  $\vec{B}$  and not on the precise choice of  $\vec{A}$  (i.e., should be gauge invariant). In the following we will use

$$\vec{A} = (Bz \sin \theta, Bx \cos \theta, 0) \quad (5)$$

as well as the notations

$$B \sin \theta = B_{\perp} \quad B \cos \theta = B_{\parallel} \quad (6)$$

$$\omega_{c\perp} = \frac{eB_{\perp}}{m_e^*c} \quad \omega_{c\parallel} = \frac{eB_{\parallel}}{m_e^*c} \quad (7)$$

The electron spin  $\sigma$  interacts with the field adding to the particle energy the quantity

$$g^* \mu_B \sigma \cdot \vec{B} \quad (8)$$

where  $\mu_B = e\hbar/2m_0c$  is the Bohr magneton and  $g^*$  is the effective Landé  $g$  factor of the quasi-particle ( $g^* = 2$  for electrons in the vacuum,  $g^* > 0$  or  $g^* < 0$  in the semiconductors). The operator  $\sigma$  has the eigenvalues  $\pm 1/2$ . The electron Hamiltonian is expressed by

$$\begin{aligned} \hat{H} = & \frac{1}{2m_e^*} \left( -i\hbar \frac{\partial}{\partial x} + \frac{e}{c} B_{\perp} z \right)^2 + \frac{1}{2m_e^*} \left( -i\hbar \frac{\partial}{\partial y} + \frac{e}{c} B_{\parallel} x \right)^2 \\ & + \frac{\hat{p}_z^2}{2m_e^*} + V_b(z) + g^* \mu_B \sigma \cdot \vec{B} \end{aligned} \quad (9)$$

Figure 2.

Thus, the envelope wave function for  $\hat{H}$  can be written as a product of functions depending on separated orbital and spin variables

$$f(\vec{r}, \sigma) = f(\vec{r})\alpha(\sigma) \quad (10)$$

Suppose  $\sigma$  is quantized along  $\vec{B}$ . Let us denote by  $|\uparrow\rangle$  and  $|\downarrow\rangle$  the two eigenvectors of  $\sigma_z$  and by  $|\nu\rangle$  the eigenstates of the orbital part of  $\hat{H}$ , associated with the eigenvalues  $\varepsilon_{\nu}$ . The eigenstates and eigenenergies of Eq. (9) are obtained in the following form:

$$f(\vec{r}, \sigma) = \langle \vec{r} | \nu \rangle \otimes |\uparrow\rangle \quad \varepsilon_{\nu} + \frac{1}{2} g^* \mu_B B \quad (11)$$

$$f(\vec{r}, \sigma) = \langle \vec{r} | \nu \rangle \otimes |\downarrow\rangle \quad \varepsilon_{\nu} - \frac{1}{2} g^* \mu_B B \quad (12)$$

The spin term is rotationally invariant. Therefore, if  $\sigma$  is quantized along a fixed direction (say  $z$ ), which is not necessarily colinear to  $\vec{B}$ , we will obtain (after diagonalizing  $g^* \mu_B \sigma \cdot \vec{B}$ ) the same spin eigenvalues  $\pm(1/2)g^* \mu_B B$ . Thus the spin splitting  $g^* \mu_B B$  depends on the modulus of  $\vec{B}$ , not on its direction.

Since the spin effects are now well known, let us put our attention on the search for the eigenvalues  $\varepsilon_{\nu}$ . The spin effects, however, will have to be taken into account when evaluating the carrier density of states.

The enveloped wave function for the orbital part of  $\hat{H}$ , considering that the motion in  $y$  is independent, can be written as

$$f_{\nu}(\vec{r}) = \frac{1}{\sqrt{L_y}} \exp(ik_y y) \varphi_{\mu}(x, z) \quad (13)$$

Generally [ $\theta \neq 0$ ,  $V_b(z)$  arbitrary],  $x$  and  $z$  variables cannot be separated. However, except when  $\theta$  is close to  $\pi/2$ , the separability between  $x$  and  $z$  motions appears to be a good zero order approximation. In fact, let us rewrite  $\hat{H}$  in the form

$$\hat{H} = \hat{H}_{\parallel} + \hat{H}_{\perp} + \delta\hat{H} \quad (14)$$

where

$$\hat{H}_{\parallel} = \frac{\hat{p}_z^2}{2m_e^*} + V_b(z) \quad (15)$$

$$\hat{H}_{\perp} = \frac{\hat{p}_x^2}{2m_e^*} + \frac{1}{2m_e^*} \left( \hbar k_y + \frac{e}{c} B_{\parallel} x \right)^2 \quad (16)$$

$$\delta\hat{H} = \delta\hat{H}_1 + \delta\hat{H}_2 = \frac{1}{2m_e^*c^2} e^2 B_{\perp}^2 z^2 + \hat{p}_x z \frac{eB_{\perp}}{m_e^*c} \quad (17)$$

and where Eq. (13) was used. If the splitting of our original Hamiltonian proves to be correct, the zero order energies (i.e., those of  $\hat{H}_{\parallel} + \hat{H}_{\perp}$ ) will only depend on  $B_{\parallel}$  and not on  $B_{\perp}$ . This means that, in contrast to the spin term, the eigenvalues  $\varepsilon_{\nu}$  will depend on the component of  $\vec{B}$  parallel to the growth axis.

An immediate experimental check of this property for a given heterostructure is to rotate the sample with respect to

$B$  and to see whether the physical property (of orbital origin) which is under study depends on  $B_{\parallel}$  (i.e., on the angle  $\theta$ ). For a three-dimensional isotropic system with vanishing  $V_b(z)$ , it is very easy to show that the eigenvalues of  $\hat{H}$  only depend on the modulus of  $\vec{B}$  and not on its direction. Thus, provided the decoupling of  $\hat{H}$  into a main separable term and a small nonseparable one is valid, a clear proof of the existence of quasi-two-dimensional electron gas in a given heterostructure is obtained by studying the angular dependence of magnetic field dependent properties.

Let us then examine the validity of the decoupling procedure. First we investigate the eigenstates of  $\hat{H}_{\parallel} + \hat{H}_{\perp}$ . The wave functions  $\varphi_{\mu}(x, z)$  factorize into

$$\varphi_{\mu}(x, z) = \chi_m(z)\varphi_n(x) \quad (18)$$

where

$$\hat{H}_{\parallel}\chi_m(z) = \xi_m\chi_m(z) \quad (19)$$

and

$$\begin{aligned} \hat{H}_{\perp}\varphi_n(x) &= \left\{ \frac{\hat{p}_x^2}{2m_e^*} + \frac{1}{2m_e^*} \left( \hbar k_y + \frac{eB_{\parallel}}{c} x \right)^2 \right\} \varphi_n(x) \\ &= \varepsilon_n \varphi_n(x) \end{aligned} \quad (20)$$

$\chi_m(z)$  are the wave functions for the  $z$  motion, which correspond to the  $m$ th state (bound or unbound) of energy  $\xi_m$  for the heterostructure Hamiltonian at zero magnetic field. The functions  $\varphi_n(x)$  are the eigensolutions of a harmonic oscillator problem (frequency  $\omega_q$ ) centered at

$$x_0 = -\frac{\lambda^2 k_y}{\cos \theta} \quad (21)$$

where  $\lambda$  is the magnetic length

$$\lambda = \sqrt{\frac{\hbar c}{eB}} \quad (22)$$

The eigenvalues of Eq. (20) are  $k_y$  independent and evenly spaced in  $\hbar\omega_q$ . They are the celebrated Landau levels:

$$\varepsilon_n(k_y) = \left( n + \frac{1}{2} \right) \hbar\omega_q \quad n = 0, 1, 2, \dots \quad (23)$$

The eigenfunctions of Eq. (15) which correspond to the eigenvalue  $(n + 1/2)\hbar\omega_q$  can be expressed in terms of the Hermite polynomials

$$\begin{aligned} \varphi_n(x) &= \frac{\cos \theta^{1/4}}{\sqrt{\lambda}} \frac{1}{\sqrt{2^n n! \sqrt{\pi}}} \exp \left[ -\frac{\cos \theta}{2\lambda^2} (x - x_0)^2 \right] \\ &\times H_n \left[ \left( \frac{x - x_0}{\lambda} \right) \sqrt{\cos \theta} \right] \end{aligned} \quad (24)$$

where

$$H_n(x) = (-1)^n \exp(x^2) \frac{d^n}{dx^n} \exp(-x^2) \quad (25)$$

It can be verified that

$$\langle n-1|x|n \rangle = \int_{-\infty}^{\infty} \varphi_{n-1}(x)x\varphi_n(x) dx = \frac{\lambda}{\sqrt{\cos \theta}} \sqrt{\frac{n}{2}} \quad (26)$$

$$\langle n|x|n \rangle = x_0 \quad (27)$$

$$\left\langle n-1 \left| \frac{\partial}{\partial x} \right| n \right\rangle = \frac{\sqrt{\cos \theta}}{\lambda} \sqrt{\frac{n}{2}} \quad (28)$$

We have thus succeeded in classifying the eigenstates of  $\hat{H}_{\parallel} + \hat{H}_{\perp}$ . These eigenstates consist of Landau level ladders, which are attached to each of the zero field heterostructures bound (or unbound) states. Each of the levels is degenerate with respect to  $k_y$  or to  $x_0$ , the center of the  $n$ th harmonic oscillator function. Thus, apart from the spin quantum number we may write

$$|\nu\rangle = |m, n, k_y\rangle \quad (29)$$

which corresponds to the energy

$$\varepsilon_{\nu} = \xi_m + \left( n + \frac{1}{2} \right) \hbar\omega_{c\parallel} \quad (30)$$

The remarkable point is that the carrier motion is entirely quantized;  $V_b(z)$  has quantized the  $z$  component of the carrier motion, while the  $B_{\parallel}$  component, which is parallel to the growth axis, has quantized the in plane motion.

Each of the eigenvalues  $\varepsilon_{\nu}$  is, however, enormously degenerate. This orbital degeneracy  $g_{\text{orb}}$  can be calculated as follows: the center of the harmonic oscillator function has to be in the crystal. Thus

$$-\frac{L_x}{2} < x_0 < \frac{L_x}{2} \quad (31)$$

where the dimension  $L_x$  is so large that the crystal boundaries were justifiably ignored in Eqs. (14)–(17).

The allowed  $k_y$  values are uniformly distributed and separated by the interval  $2\pi/L_y$  (periodic boundary condition applied to the  $y$  axis). Thus, the degeneracy of the eigenvalue  $\varepsilon_{\nu}$  is equal to

$$g_{\text{orb}} = \frac{L_x L_y}{2\pi\lambda^2} \cos \theta \quad (32)$$

Notice that  $g_{\text{orb}}$  is exact at  $\theta = 0$  ( $\delta\hat{H}_1 = \delta\hat{H}_2 = 0$  in this case) but only approximate at  $\theta \neq 0$  since the effects of  $\delta\hat{H}_1$ ,  $\delta\hat{H}_2$  have not yet been evaluated.

We now have to investigate the effects of  $\delta\hat{H}$  on the zeroth order eigenstates  $|m, n, k_y\rangle$ . The first term  $\delta\hat{H}_1$  does not affect the separability between  $x$  and  $z$  (as a matter of fact  $\delta\hat{H}_1$  could have been included into  $\hat{H}_{\parallel}$ ). The only effect is that the different quantum states of the  $z$  motion are admixed. For a state  $|m\rangle$ , which is sufficiently energy separated from the others (e.g., the ground state),  $\delta\hat{H}_1$  can be treated by first order perturbation calculus. Thus  $\xi_m$  is changed by  $\delta\xi_m$  where

$$\delta\xi_m = \frac{e^2}{2m_e^*c^2} B_{\perp}^2 \langle \chi_m | z^2 | \chi_m \rangle \quad (33)$$

To ensure the convergence of our perturbative scheme  $\langle \chi_n | \delta \hat{H}_1 | \chi_m \rangle$  should remain much smaller than the level spacing  $\xi_n - \xi_m$ . For the states of a confined particle by a potential well of range  $\approx L$ ,  $\xi_n \approx \hbar^2 \pi^2 n^2 / 2m_e^* L^2$  whereas  $\langle \chi_n | z^2 | \chi_m \rangle \approx L^2$ . Thus,  $\langle \chi_1 | \delta \hat{H}_1 | \chi_2 \rangle / (\xi_2 - \xi_1) \approx L^4 \sin^2 \theta / 3\pi^2 \lambda^4$  and the perturbative approach will be justified for the ground state if the Landau quantization along the  $z$  direction remains much smaller than the size quantization arising from  $V_b(z)$ .

Suppose, for instance, that the heterostructure consists of a quantum well of thickness  $L$ , clad between impenetrable barriers. For the ground state we obtain

$$\delta \xi_1 = \frac{e^2 B^2}{4m_e^* c^2} \sin^2 \theta L^2 \left( \frac{1}{6} - \frac{1}{\pi^2} \right) \quad (34)$$

If  $B = 10$  T,  $\theta = \pi/4$ ,  $L = 100$  Å,  $m_e^* = 0.067m_0$ , we obtain  $\delta \xi_1 \approx 0.2$  meV, which is much smaller than  $\xi_2 - \xi_1 \approx 168$  meV. Note, however, that  $\delta \xi_1 \approx \xi_2 - \xi_1$  if  $L \geq 500$  Å. In the latter situation, the first order perturbation becomes insufficient. A better approach would have been to include  $\delta \hat{H}_1$  into  $\hat{H}_\parallel$  from the very beginning. However, the failure of the perturbative approach indicates that the whole decoupling procedure underlying Eqs. (14) and (15) becomes dubious. This is what happens when the system is weakly two-dimensional, either because the bound states supported by  $V_b(z)$  are too dense or [when  $V_b(z)$  is finite] too close to the continuum. A better zero order Hamiltonian is the whole magnetic field dependent term (bulklike). The perturbation becomes  $V_b(z)$  and, if  $B$  is large enough, the effects associated with  $V_b(z)$  can be treated within the subspace which is spanned by all the states of a given  $n$ . For more complete treatments of tilted magnetic effects in superlattices, see [80, 81].

The second kind of perturbing term,  $\delta \hat{H}_2$ , can be rewritten as  $z \hat{p}_x \omega_{c\perp}$ .  $\delta \hat{H}_2$  has no nonvanishing diagonal elements in the  $|m, n, k_y\rangle$  basis since  $\langle n | \hat{p}_z | n \rangle = 0$ . To the second order of perturbation theory we obtain

$$\delta(\xi_m + \varepsilon_n) = \sum_{m', n' \neq m, n} \frac{\omega_{c\perp}^2 |\langle \chi_m | z | \chi_{m'} \rangle|^2 |\langle \varphi_n | \hat{p}_x | \varphi_{n'} \rangle|^2}{\xi_m - \xi_{m'} + (n - n') \hbar \omega_q} \quad (35)$$

Thus,  $\delta \hat{H}_2$  couples Landau levels of different subbands whose indexes  $n'$ ,  $n$  differ by one. In addition, if  $V_b(z)$  is even in  $z$ , only subbands of opposite parities are coupled by  $\delta \hat{H}_2$ . Note that  $\delta[\xi_m + \varepsilon_n]$  can become very large (but cannot be described by means of perturbative treatments) when the energy denominators in Eq. (35) vanish. Practically, this means that two consecutive Landau levels, which belong to two adjacent subbands, intersect. For the sake of definiteness, let us assume that the involved levels and subbands are  $n = 0$ ,  $n = 1$ , and  $m = 1$ ,  $m = 2$  respectively. Notice that at  $\theta = 0$  the two levels  $|1, 1, k_y\rangle$  and  $|2, 0, k_y\rangle$  can cross since  $\delta \hat{H}_2$  vanishes. Let us denote by  $B_c$  the crossing fields at  $\theta = 0$ :  $B_c = (\xi_2 - \xi_1) m_e^* c / \hbar e$ . At finite  $\theta$ , the crossing field would take place at  $B_c / \cos \theta$ . However, the  $\delta \hat{H}_2$  matrix element which connects the two levels is now nonvanishing and increases with  $\theta$ . Thus, the crossing is suppressed and

replaced by an anticrossing (see Fig. 3). Retaining the dominant  $\delta \hat{H}_2$  contributions and neglecting  $\delta \hat{H}_1$ , we can write

$$|f\rangle \approx \alpha |1, 1, k_y\rangle + \beta |2, 0, k_y\rangle \quad B \approx B_c / \cos \theta \quad (36)$$

The eigenvalues are the solutions of

$$\begin{vmatrix} \xi_1 + \frac{3}{2} \hbar \omega_q - \varepsilon & \langle 2, 0, k_y | \delta \hat{H}_2 | 1, 1, k_y \rangle \\ \langle 1, 1, k_y | \delta \hat{H}_2 | 2, 0, k_y \rangle & \xi_2 + \frac{1}{2} \hbar \omega_q - \varepsilon \end{vmatrix} = 0 \quad (37)$$

or

$$\varepsilon_{\pm} = \frac{\xi_1 + \xi_2}{2} + \hbar \omega_q \pm \sqrt{\left( \frac{\xi_2 - \xi_1 - \hbar \omega_q}{2} \right)^2 + |\langle 2, 0, k_y | \delta \hat{H}_2 | 1, 1, k_y \rangle|^2} \quad (38)$$

The magnitude of the anticrossing (which is the energy difference  $\delta \varepsilon = \varepsilon_+ - \varepsilon_-$  evaluated at  $B = B_c / \cos \theta$ ) is

$$|\delta \varepsilon| = \frac{1}{\lambda(B_c)} \langle \chi_1 | z | \chi_2 \rangle \frac{\hbar e B_c}{m_e^* c} \tan \theta \sqrt{2} \quad (39)$$

which varies like  $B_c^{3/2}$ . At the anticrossing the mixing between the two interacting levels is complete:  $|\alpha| = |\beta| = 1/\sqrt{2}$ . Note finally the close formal analogy between this type of anticrossing and those that arise when the cyclotron energy  $\hbar \omega_q$  becomes equal to the energy of the longitudinal optical phonon energy  $\hbar \omega_{LO}$  (magnetopolaron [82]).

### 2.1.1. Magnetic Field Density of States

Since the effects of  $\delta \hat{H}_1$  are only approximately known, our attention in this section will be restricted to the case of  $\theta = 0$ , taking into account the spin splitting effect. As the  $z$  and  $(x, y)$  motions are separable, we can decompose the

**Figure 3.** Schematic fan charts of Landau levels attached to two subbands 1 and 2 with confinement energies  $\xi_1$  and  $\xi_2$  respectively. The dashed lines represent the effect of the anticrossing induced by  $\delta \hat{H}_2$ . Reprinted with permission from [186], J. L. Marín et al., "Handbook of Advanced Electronic and Photonic Materials and Devices" (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

total density of states into contributions which arise from different subbands  $m$ ,

$$\rho(\varepsilon) = \sum_m \rho_m(\varepsilon) \quad (40)$$

where

$$\rho_m(\varepsilon) = \sum_{\sigma_z, k_y, n} \delta \left\{ \varepsilon - \xi_m - \left( n + \frac{1}{2} \right) \hbar \omega_q - g^* \mu_B \sigma_z \right\} \quad (41)$$

$$\sigma_z = \pm \frac{1}{2}$$

Since the eigenenergies are  $k_y$  independent, the summation over  $k_y$  can immediately be performed. This results in the appearance of the orbital degeneracy factor  $g_{\text{orb}}$ . Thus

$$\rho_m(\varepsilon) = \frac{S}{2\pi\lambda^2} \sum_{n, \sigma_z} \delta \left\{ \varepsilon - \xi_m - \left( n + \frac{1}{2} \right) \hbar \omega_q - g^* \mu_B B \sigma_z \right\} \quad (42)$$

As the carrier motion is entirely quantized, the density of states is zero except at the discrete energies

$$\varepsilon_{m\sigma_z} = \xi_m + \left( n + \frac{1}{2} \right) \hbar \omega_q + g^* \mu_B B \sigma_z \quad (43)$$

where it is infinite. The results of Eqs. (41)–(43) are quite remarkable when compared with the zero field situation:

$$\rho_{m\sigma_z}^{B=0}(\varepsilon) = \frac{m_e^* S}{2\pi \hbar^2} Y(\varepsilon - \xi_m) \quad (44)$$

At zero field the quasi-two-dimensional electron gas is metallic, with a gapless density of states for  $\varepsilon > \xi_1$ . A finite magnetic field dramatically alters this situation, replacing the continuum Eq. (44) by pointlike singularities [Eq. (42)] separated by gaps. Thus, depending on the respective locations of the characteristic electron energy  $\eta$  (the Fermi energy for a degenerate electron gas at  $T = 0$  K) and  $\varepsilon_{m\sigma_z}$ , the electron gas will behave either like an insulator ( $\eta \neq \varepsilon_{m\sigma_z}$ ) or a metal ( $\eta = \varepsilon_{m\sigma_z}$ ). Notice that similar effects cannot be found in bulk materials: the carrier-free motion along the field prevents the density of states from vanishing at any energy larger than  $\hbar \omega_c / 2 - |g_c^*| \mu_B B / 2$ .

Of course, we know that imperfections (impurities, interface defects, etc.) will alter the deltalike singularities of  $\rho_m(\varepsilon)$ , rounding off the peaks, adding states into the gaps. However, it remains generally accepted that, if  $B$  is large enough (i.e.,  $B \geq$  few Teslas in good GaAs–Ga<sub>1-x</sub>Al<sub>x</sub>As heterostructures at low temperature), the previous conclusions retain their validity, at least for the following meaning: for energies belonging to a certain bandwidth of finite (yet undefined) extension, the density of states is large and corresponds to conducting states, whereas for other energy segments, the states are localized (i.e., at  $T = 0$  K are unable to contribute to the electrical conduction at vanishingly small electric fields).

Some words have to be added concerning the broadening effects. The present state of the art is far from being satisfactory. First, there is, to the authors' knowledge, no general consensus on the microscopic origin of these effects.

Most likely it is sample dependent: in some samples, charged impurities play a dominant part. In others, interface roughness or alloy scattering (if it exists) may dominate. Second, even if we assume that the disorder potential has a simple algebraic form (e.g., uncorrelated deltalike scatterers), it proves difficult, if not impossible, to obtain precise information on  $\rho_m(\varepsilon)$  by any method other than by numerical simulation. The complications are twofold:

- The unperturbed density of states is highly singular. This precludes the use of non-self-consistent perturbative treatments of the disorder potential.
- When the required self-consistency is included, calculations are performed up to a finite order in the perturbation approach. By doing so, the nature of the states which occur in the tails of the broadened delta function are ill-treated: a localized level requires an inclusion of the electron disorder potential to an infinite order.

## 2.2. Magnetic Effect in Quasi-One-Dimensional Systems

The energy spectrum of a particle confined within a circle in the presence of an external magnetic field perpendicular to the plane of confinement is studied both exactly and approximately by the quasi-classical formalism (WKB). For pure spatial confinement (without magnetic field) the energy spectrum for states other than the ground state is twofold degenerate, while in the case of pure magnetic confinement the spectrum shows infinite-fold degeneration, typical of Landau states. For both types of confinement, the latter infinite-fold degeneration is lifted due to spatial confinement. Interestingly enough, for a given ratio between spatial and magnetic confining lengths, the magnetic flux is quantized. The conditions for the quantization of the flux are established; the nature and peculiarity of the energy spectrum are also discussed.

Basically, the physical properties are implicitly contained in the wavefunction; it is clear that this function is modified whenever the system is restricted on its available space either by its size (spatial confinement) or by an external perturbation (field confinement).

In this context, the first attempt at the study of these kind of systems will be the solution of the Schrödinger equation in which the corresponding Hamiltonian addresses in one way or another some of the characteristics of the spatial restrictions [83].

If the boundary which encloses the system is impenetrable, its energy increases as the confinement region decreases in agreement with the uncertainty principle; that is, more localization in space means an increase in the moment and consequently in the energy. If the latter boundary is penetrable then there is a probability of the system to escape and thus if the surroundings possess available states the system can occupy those which will be consistent with its energy and selection rules.

One of the simplest systems of this kind is a single particle confined by impenetrable boundaries and perturbed by an external magnetic field. This system was first studied by Stransky [52] to show how the energy spectrum transforms

smoothly to that of a free particle spectrum as the magnetic field strength goes to zero.

In this context we shall study a similar system but we further analyze the situations raised whenever the typical length introduced by both types of confinement are far apart or nearly equal.

### 2.2.1. Spatial Confinement

Let us consider the two-dimensional confinement of a particle within a circle of radius  $r_0$  and  $k_z = 0$ . The Hamiltonian in this case can be written as

$$\hat{H}_0 = \frac{\hat{p}^2}{2m^*} + V_b(r) \quad (45)$$

where the confining potential is given by

$$V_b(r) = \begin{cases} 0 & 0 \leq r \leq r_0 \\ \infty & r > r_0 \end{cases} \quad (46)$$

In polar coordinates  $(r, \varphi)$ , the corresponding Schrödinger equation for  $\hat{H}_0$  is given by

$$\left\{ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2}{\partial \varphi^2} + \frac{2m^*}{\hbar^2} [\varepsilon_0 - V_b(r)] \right\} f_0(r, \varphi) = 0 \quad (47)$$

where  $\varepsilon_0$  is the energy of the particle and  $f_0(r, \varphi)$  is its envelope wavefunction that must satisfy

$$f_0(r_0, \varphi) = 0 \quad (48)$$

due to the form of the confining potential  $V_b$ . The solutions of Eq. (47) have already been studied previously; thus, considering the condition for the wavefunction given by Eq. (48) the energy spectrum is obtained as

$$\varepsilon_0^{n, |m|} = \frac{\hbar^2 \alpha_{n, |m|}^2}{2m^* r_0^2} \quad (49)$$

Here,  $\alpha_{n, |m|}$  denotes the  $n$ th zero of  $J_{|m|}$ .

Note that for  $m \neq 0$ , the energy levels are twofold degenerate with eigenfunctions

$$f_0^{n, m} = \frac{1}{\sqrt{2\pi}} A_{n, |m|} J_{|m|} \exp(im\varphi) \quad (50)$$

and

$$f_0^{n, -m} = \frac{1}{\sqrt{2\pi}} A_{n, |m|} J_{|m|} \exp(-im\varphi) = (f_0^{n, m})^* \quad (51)$$

Due to the properties of the zeroes of  $J_{|m|}$ , the energy levels satisfy

$$\varepsilon_0^{1, |m|} < \varepsilon_0^{1, |m|+1} < \varepsilon_0^{2, |m|} < \varepsilon_0^{2, |m|+1} < \varepsilon_0^{3, |m|} \dots \quad (52)$$

The dependence of the lowest energy levels on the confinement radius  $r_0$  is displayed in Figure 4.

Two main features emerge from this figure: (i) as the confinement radius decreases the energy of each level increases. This fact is consistent with the uncertainty principle (i.e., more localization of the particle implies an increase

**Figure 4.** Energy  $\varepsilon_0^{n, |m|}$  as a function of confinement radius  $r_0$ . From bottom to top, the states with  $(n, |m|) = (1,0), (1,1), (1,2),$  and  $(1,3)$  are displayed. Academic Press, San Diego, 2001. © 2001, Academic Press.

of its momentum and consequently a greater energy). (ii) As the confinement radius is increased, the energy level separation decreases and they coalesce smoothly into a single one, the free particle spectrum. The latter is consistent with the results of Rensink [52], as expected.

### 2.2.2. Magnetic Confinement

Let us now consider the case of a charged particle moving in the plane  $(x, y)$  in the presence of a homogeneous magnetic field  $\vec{B} = B_0 \hat{e}_z$ , without spatial confinement [i.e.,  $V_b(r) = 0$ ]. The Hamiltonian for this system can be written as

$$\hat{H} = \frac{\hat{P}^2}{2m^*} \quad (53)$$

where

$$\hat{P}^2 = \left( \hat{p} - \frac{q}{c} \vec{A} \right)^2 = \hat{p}^2 - \frac{q}{c} \hat{p} \cdot \vec{A} - \frac{q}{c} \vec{A} \cdot \hat{p} + \frac{q^2}{c^2} \vec{A}^2 \quad (54)$$

Now, for any state vector  $\Phi$

$$\begin{aligned} (\hat{p} \cdot \vec{A})\Phi &= -i\hbar \nabla \cdot (\vec{A}\Phi) = -i\hbar [(\nabla \cdot \vec{A})\Phi + \vec{A} \cdot (\nabla\Phi)] \\ &= [-i\hbar(\nabla \cdot \vec{A}) + \vec{A} \cdot \hat{p}]\Phi \end{aligned} \quad (55)$$

Then, when the gauge  $\nabla \cdot \vec{A} = 0$  is chosen,  $\hat{p} \cdot \vec{A} = \vec{A} \cdot \hat{p}$ ; that is,  $\vec{A}$  and  $\hat{p}$  commute and  $\hat{H}$  can be written as

$$\hat{H} = \frac{\hat{p}^2}{2m^*} - \frac{q}{m^*c} \vec{A} \cdot \hat{p} + \frac{q^2}{2m^*c^2} \vec{A}^2 \quad (56)$$

As a consequence of the symmetric gauge  $\nabla \cdot \vec{A} = 0$ ,  $\vec{A}$  is of the form

$$\vec{A} = \frac{1}{2} \vec{B} \times \vec{r} = \frac{1}{2} B_0 (-\hat{e}_x y + \hat{e}_y x) = \frac{1}{2} B_0 r \hat{e}_\varphi \quad (57)$$

This choice leads to

$$\vec{A} \cdot \hat{p} = -\frac{1}{2}i\hbar B_0 \left( x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right) = -\frac{1}{2}i\hbar B_0 \frac{\partial}{\partial \varphi} = \frac{1}{2}B_0 \hat{L}_z \quad (58)$$

where  $\hat{L}_z$  is the z-component of the angular momentum  $\vec{L}$ . If we define the cyclotron frequency  $\omega_c = -qB_0/m^*c$ ,  $\hat{H}$  is now given by

$$\hat{H} = -\frac{\hbar^2}{2m^*} \nabla^2 + \frac{1}{2}\omega_c \hat{L}_z + \frac{1}{8}m^* \omega_c^2 r^2 \quad (59)$$

This Hamiltonian can be envisioned as that of a two-dimensional oscillator (first and third terms in  $\hat{H}$ ) with oscillating frequency  $\omega = \omega_c/2$ , perturbed by the “potential”  $\omega_c \hat{L}_z/2 = \omega \hat{L}_z$ . That is,

$$\hat{H} = \hat{H}_{\text{osc}} + \hat{H}' \quad (60)$$

with  $\hat{H}_{\text{osc}} = -(\hbar^2/2m^*)\nabla^2 + (1/2)m^*\omega^2 r^2$  and  $\hat{H}' = \omega \hat{L}_z$ .

Moreover, it can be easily shown that  $[\hat{H}, \hat{H}'] = [\hat{H}_{\text{osc}}, \hat{H}']$ , a property that allows one to establish that  $\hat{H}$ ,  $\hat{H}_{\text{osc}}$ , and  $\hat{H}'$  possess common eigenfunctions. In view of the latter, if  $f_{lm}(r, \varphi)$  is the complete set of eigenfunctions of  $\hat{H}$ , then

$$\hat{H}_{\text{osc}} f_{lm}(r, \varphi) = \varepsilon_{\text{osc}} f_{lm}(r, \varphi) \quad (61)$$

and

$$\hat{H}' f_{lm}(r, \varphi) = \varepsilon' f_{lm}(r, \varphi) = \hbar \omega m f_{lm}(r, \varphi) \quad (62)$$

Here  $\varepsilon_{\text{osc}}$  is the energy of a two-dimensional isotropic harmonic oscillator, which can be found by separating the corresponding Schrödinger equation in polar coordinates, to give

$$\varepsilon_{\text{osc}} = \hbar \omega (2l + |m| + 1) \quad l = 0, 1, 2, \dots \quad (63)$$

The total energy for this system is then given by

$$\begin{aligned} \varepsilon_{lm} &= \varepsilon_{\text{osc}} + \varepsilon' = \hbar \omega (2l + |m| + m + 1) \\ &= \frac{1}{2} \hbar \omega_c (2l + |m| + m + 1) \end{aligned} \quad (64)$$

and the wavefunctions

$$\begin{aligned} f_{lm}(r, \varphi) &= \frac{N_{lm}}{\sqrt{2\pi}} r^{|m|} \exp\left(-\frac{1}{2}\alpha r^2\right) \\ &\times F(-l, |m| + 1, \alpha r^2) \exp(im\varphi) \end{aligned} \quad (65)$$

where  $\alpha = m^* \omega_c / 2\hbar$ ,  $N_{lm}$  is a normalization constant, and  $F$  is the confluent hypergeometric function [52, 78]. As can be immediately seen, the energy levels for a given  $l$  and  $m$  negative or zero are infinitely degenerate since  $|m| + m = 0$  in such a case. The levels given by Eq. (64) are the well-known Landau levels [84].

Moreover, as  $\omega_c \rightarrow 0$  (i.e., when the field is vanishingly small), the levels coalesce into a single level corresponding to the free particle, analogous to the previous section. Figure 5 shows the behavior of the energy levels as a function of the strength of the magnetic field  $B_0$ .

**Figure 5.** Energy  $\varepsilon_0^{n,|m|}$  as a function of magnetic field strength  $B_0$ . From bottom to top, the states with  $(l, m) = (0,0)$ ,  $(0,1)$ ,  $(0,2)$ , and  $(0,3)$  are displayed. Note that the states  $(l, 0) = (l, m)$  with  $m = 0$  or negative are infinitely degenerate, while the states  $(l, 0) = (0, m)$  with  $m$  positive are twofold degenerate. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

### 2.2.3. Spatial and Magnetic Confinement

In this context we shall study the case of a charged particle with both types of confinement considered in the previous cases. In this context, the Hamiltonian can be written as

$$\hat{H}_{bc} = -\frac{\hbar^2}{2m^*} \nabla^2 + \frac{1}{2}\omega_c \hat{L}_z + \frac{1}{8}m^* \omega_c^2 r^2 + V_b(r) \quad (66)$$

As can be seen, the inclusion of the term  $V_b(r)$  requires that the wavefunction satisfy the boundary condition given by Eq. (48) and this fact prevents  $l$  [Eq. (63)] from being a good quantum number as in the previous section. Instead, the boundary condition is now satisfied if [see Eq. (65)]

$$F(-\beta_{nm}, |m| + 1, \alpha r^2) = 0 \quad (67)$$

where now  $\beta_{nm}$  represents the  $n$ th zero of  $F$ . Then the energy for the system can be written as

$$\varepsilon_{nm} = \frac{1}{2} \hbar \omega_c (2\beta_{nm} + |m| + m + 1) \quad (68)$$

an expression similar to Eq. (64), but the infinite degeneracy of the levels for a given  $n$  and  $m$  negative is lifted by the spatial confinement because, in spite of the fact that  $m$  is still a good quantum number, the zeroes of  $F$  depend on its value, in contrast with the case of the preceding section. Hence, the problem can be solved if we find the zeroes of  $F$  as a function of  $r_0$  for a given value  $m$  and  $\omega_c$ .

Alternatively, it is interesting to note that  $\hat{L}_z$  commutes with all operators appearing in Eq. (66) and then the states of the new situation have a definite value of  $m$ . The latter

property allows one to construct the total wavefunction as the expansion

$$\begin{aligned} f_{bc}^m(r, \varphi) &= \sum_{n=0}^{\infty} a_n f_0^{n,m}(r, \varphi) \\ &= \frac{1}{\sqrt{2\pi}} \exp(im\varphi) \sum_{n=0}^{\infty} a_n J_{|m|} \left( \frac{\alpha_{n,|m|} r}{r_0} \right) \\ &= \sum_{n=0}^{\infty} a_n |nm\rangle \end{aligned} \quad (69)$$

Here we have exploited the fact that radial functions found in Section 2.2.1 represent a complete set of orthogonal functions satisfying the proper boundary condition. Of course this is not the only basis in which the total wavefunction can be expanded, but it would represent an alternative representation of  $F$  in terms of  $J_{|m|}(\alpha_{n,|m|} r/r_0)$  to that of [78].

As can be noted, in the Dirac notation,

$$\langle nm|n'm'\rangle = \delta_{nn'} \delta_{mm'} \quad (70)$$

Hence, to find the energy levels for a given value of  $m$ , we must diagonalize the matrix with elements

$$A_{nn'} = \left[ \varepsilon_0^{n,|m|} + \frac{1}{2} \hbar m \omega_c \right] \delta_{nn'} + \frac{1}{8} m^* \omega_c^2 \langle n|r^2|n'\rangle \quad (71)$$

Strictly speaking, the involved matrix is infinite, but in practice we can use one large enough, but finite, depending on the precision required to find the eigenvalues. In the present case we have used a (256,256) matrix, a choice that leads to a precision of about six decimal places.

The diagonalization procedure will render the eigenvalues as well as the eigenvectors  $\{a_n\}$  and thus we have the complete solution of this problem. In Figure 6, the energy of the lowest states is displayed as a function of the strength of

**Figure 6.** Energy of the lowest states for a particle confined within a circle of radius  $r_0 = 2.0$  Bohrs, as a function of magnetic field strength. From bottom to top, the states with  $(n, m) = (1, 0)$ ,  $(1, 1)$ ,  $(1, 2)$ , and  $(1, 3)$  are displayed. Note the energy scales introduced by the selected confinement regime. **Figure 7.** Energy of the lowest states for a particle confined within a magnetic field  $B_0 = 1$  Tesla, as a function of confining radius  $r_0$ . From bottom to top, the states with  $(n, m) = (1, 0)$ ,  $(1, 1)$ ,  $(1, 2)$ , and  $(1, 3)$  are displayed. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

the field for  $r_0 = 2.0$  Bohrs, while Figure 7 shows the same levels as a function of  $r_0$  for  $B_0 = 1$  Tesla.

Before closing this case we can mention three main points: (i) the spatial confinement lifts the degeneracy on the Landau levels (see Fig. 6). (ii) The magnetic confinement lifts the degeneracy of levels with positive and negative values of  $m$  (see Fig. 7). (iii) Each kind of confinement introduces a typical length; namely, the spatial confinement length is of the order of  $r_0$  while the magnetic confinement length is of the order of  $l_m \approx \sqrt{\hbar c/|q|B_0} \cong 484.52 B_0^{-1/2}$  (Bohrs), when  $|q| = |e|$  and  $B_0$  is given in Teslas.

In this sense, we can talk about a competition between the two kinds of confinement depending on the ratio of  $r_0/l_m$ , a fact that will be discussed in the next section.

## 2.2.4. WKB Approximation for Energy Levels

Now we shall study approximately a variety of situations raised depending on the relative size of confining region  $a$  and the characteristic length introduced by the magnetic field  $l_m$ . To do the latter we shall follow the WKB formalism as developed in the book of Morse and Feshbach [85]. In the first place, we note that the extension of one-dimensional WKB formalism to the two- or three-dimensional radial Schrödinger equation is accompanied by the change

$$\begin{aligned} m^2 - \frac{1}{4} &\rightarrow m^2 \quad (\text{two-dimensional}) \quad \text{or} \\ l(l+1) &\rightarrow \left(l + \frac{1}{2}\right)^2 \quad (\text{three-dimensional}) \end{aligned} \quad (72)$$

in the centrifugal barrier. Once the latter is recognized, the formalism can be applied in exactly the same way as in the one-dimensional case.

The effective potential in our case is of the form

$$V_{\text{eff}}(r) = \beta^2 r^2 + \frac{m^2}{r^2} \quad (73)$$

For illustrative purposes, this potential is displayed in Figure 8 from which two different situations merge, depending on the size of spatial confinement as compared with magnetic confinement, namely, when the energy is smaller or greater than  $V_{\text{eff}}(a) = \beta^2 r_0^2 + m^2/r_0^2$ . This fact is important since we are interested in analyzing approximately the solution of this problem, say by the quasi-classical method or more precisely by the WKB method.

Notice that when the energy is smaller than  $V_{\text{eff}}(r_0)$  there are two classical turning points whereas when it is greater there is only one, and hence the application of the WKB approximation is different for each case.

When only one turning point exists, the approximate wavefunction can be written as

$$F(r) \approx A \cos\left(\int_{r_1}^r q_r dr - \frac{1}{4}\right) \quad (74)$$

where  $A$  is a normalization constant and  $r_1$  is the turning point (lowest zero of  $q_r$ ), where

$$q_r = \sqrt{\alpha^2 - V_{\text{eff}}} \quad (75)$$

and

$$\alpha^2 = \frac{2m^* \varepsilon}{\hbar^2} - \frac{m^* \omega_c}{\hbar} m \quad (76)$$

Additionally, the boundary condition demands that  $F(r_0) = 0$ , which implies that

$$\int_{r_1}^a q_r dr - \frac{1}{4}\pi = \left(N + \frac{1}{2}\right)\pi \quad (77)$$

or

$$\int_{r_1}^a q_r dr = \left(N + \frac{3}{4}\right)\pi \quad (78)$$

which represents the quantization condition as a function of  $r_0$  and the magnetic field through  $r_1$  (lowest zero of  $q_r$ ).

**Figure 8.** Qualitative drawing of  $V_{\text{eff}}(r)$  used to illustrate its turning points and minimum.

Performing the integral of  $q_r$ , the eigenvalues satisfy the following transcendental equation:

$$\sqrt{\alpha^2 r_0^2 - \beta^2 r_0^4 - m^2} + \left(\frac{\alpha^2}{2\beta}\right) \left(\frac{\pi}{2} - \arcsin\left[\frac{\alpha^2 - 2\beta^2 r_0^2}{\sqrt{\alpha^4 - 4m^2\beta^2}}\right]\right) - |m| \left(\frac{\pi}{2} + \arcsin\left[\frac{\alpha^2 r_0^2 - 2m^2}{r_0^2 \sqrt{\alpha^4 - 4m^2\beta^2}}\right]\right) = 2\pi \left(N + \frac{3}{4}\right) \quad (79)$$

In the case when  $r_0 \cong r_2$  (greatest zero of  $q_r$ ) it can be easily shown that

$$\varepsilon_{Nm} \cong \frac{1}{2} \hbar \omega_c \left(2N + |m| + m + \frac{3}{2}\right) \quad (80)$$

an expression which is similar to that of the Landau levels [see Eq. (64)], except that the level spacing is slightly different because of the boundary condition on the wavefunction at  $r = r_0 \cong r_2$ . Thus in the case when the greatest turning point is equal to the radius of the confining region, the corresponding spectrum is Landau-like and represents an extreme situation because in this case

$$r_0 \cong r_2 = \frac{\alpha}{\sqrt{2\beta}} \left(1 + \sqrt{1 - \frac{4m^2\beta^2}{\alpha^4}}\right)^{\frac{1}{2}} \quad (81)$$

from which one can see that

$$\alpha^2 = \beta^2 r_0^2 + \frac{m^2}{r_0^2} = V_{\text{eff}}(r_0) \quad (82)$$

Then when  $\alpha^2 \geq V_{\text{eff}}(r_0)$ , only one turning point can exist and the energy spectrum of the system is of Landau type. However, when  $\alpha^2 \leq V_{\text{eff}}(r_0)$  two turning points merge and the quantization rule, in the standard WKB approximation, would be

$$\int_{r_1}^a q_r dr = \left(N + \frac{1}{2}\right)\pi \quad (83)$$

but this result will only be valid for  $r_2 \ll r_0$  because the corresponding WKB function in the region  $r_2 < r < r_0$  is exponentially decaying and does not satisfy the boundary condition at  $r = r_0$ . Hence only when  $r_2 \ll r_0$  will the latter function approximately be consistent with this boundary condition and will the energy spectrum of the system behave Landau-like [i.e., as that given by Eq. (80)]. Whenever the condition  $r_2 \ll r_0$  is not fulfilled, the standard WKB approximation cannot be used.

Another interesting situation corresponds to the case when there is only one turning point but  $r_0 \cong a$  (see Fig. 8). At this point  $V_{\text{eff}}$  has a minimum when  $a = \sqrt{|m|/\beta}$ . Then inserting this value into Eq. (79), we obtain

$$\sqrt{V^-} r_0 + \frac{\pi V^-}{4\beta} - \frac{V^+}{2\beta} \arcsin\left(\frac{\sqrt{V^-}}{\sqrt{V^+}}\right) = 2\pi \left(N + \frac{3}{4}\right) \quad (84)$$

where

$$V^- = \alpha^2 - 2|m|\beta \quad (85)$$

and

$$V^+ = \alpha^2 + 2|m|\beta \quad (86)$$

Moreover, when  $\alpha^2 \gg 2|m|\beta$ ,

$$\frac{\sqrt{V^-}}{\sqrt{V^+}} \cong 1 - \frac{2|m|\beta}{\alpha^2} \quad (87)$$

and the approximation

$$\arcsin(1-z) \cong \frac{\pi}{2} - (2z)^{1/2} \quad z \ll 1 \quad (88)$$

can be used to obtain

$$\varepsilon_{Nm} = \frac{\hbar^2 \pi^2 [N + \frac{1}{2}(|m| + \frac{3}{2})]^2}{2m_0 r_0^2} + \frac{1}{2} m \hbar \omega_c \quad (89)$$

which clearly resembles the energy of a particle in a box “perturbed” by a term related with the eigenvalues of  $\widehat{L}_z$ . Since the minimum of  $V_{\text{eff}}$  depends on  $m$  and the strength of the field, we note also that the infinite degeneration is removed for the level whose value of  $m$  is “tuned” by the field strength to satisfy  $r_0 = \sqrt{|m|/\beta}$ . The latter property could not be applied to the ground state since in such a case  $r_0 = 0$  and the system would behave as a confined oscillator whose energy levels would be similar to those studied in [86]. Interestingly enough, if we analyze more closely the situation when  $r_0 = a = \sqrt{|m|/\beta}$  it can be seen that

$$r_0^2 = \frac{|m|}{\beta} = |m| \frac{2\hbar}{m^* \omega_c} = 2|m| \frac{\hbar c}{|e| B_0} \quad (90)$$

or

$$B_0 \pi r_0^2 = |m| \frac{hc}{|e|} \quad (91)$$

The term of the left is just the magnetic flux across the confining circle while the term of the right represents an integer number of times  $|m|$  the quantum flux  $\hbar c/|e|$ . The latter means that in this situation the magnetic flux is quantized; thus by changing the field strength, the system can be tuned into states in which the magnetic flux is quantized. It also must be noted that when  $r_0 = a$ ,  $r_0 = \sqrt{2}|m|l_m$ , where  $l_m$  is the magnetic length defined in the previous case.

The results obtained in Sections 2.2.1, 2.2.2, and 2.2.3, which are summarized in Figures 4–7, show the same trends as those obtained by Rensink [52]; that is, when the spatial confining radius is much greater than the magnetic length the spectrum approaches smoothly the free particle spectrum, while when it is much less the energy spectrum is a sort of Landau-like spectrum. In between, the spectrum is very rich because the typical infinite-folded degeneration of the Landau-like spectrum is lifted by the spatial confinement.

Special attention is necessary for the energy spectrum for which the spatial confining radius coincides with the minimum of the effective potential, since in this case three main features merge:

- (i) The magnetic flux is quantized for field strengths which are an integer multiple of the inverse of the cross-sectional area of spatial confining [see Eq. (91)].

- (ii) The nature of these states is quite different from those of Landau-like or pure spatial confining-like states, since they can only be observed when the spatial confining length is an integer multiple of the magnetic length. In this sense, they may be called “surface states.”

- (iii) These special or “surface states” are nondegenerate [see Eq. (89)] and their energies are greater than those of the “bulk” states [87] [compare Eq. (68) and (89)].

The aforementioned properties make this system attractive for further study and characterization. It would be interesting to study its energy spectrum and/or some important physical properties when, for instance, the confining potential is finite. The latter would also motivate new experiments, which would lead to some insight on the overall physical properties of these kinds of systems.

### 2.3. Two-Dimensional Quantum Dot in an External Magnetic Field

In the last few years the properties of the fundamental quantum systems, quantum dots, defined in two-dimensional electron gases in semiconductor heterostructures, have become the subject of intensive research because these systems are widely used in many fields of modern technology [88]. In this connection, the problem of creation of quantum computers [89–91], memory devices and electronics (see [92] and references therein), new types of lasers [93–95], and other problems connected with the ultrafast switching and quantum information processing should be mentioned. Quantum dots are the most promising candidates for this kind of technology because they have a discrete atomiclike density of states, due to the strong quantum confinement. Many important results on quantum dot can be found in a great number of review articles (see for example [96, 97]).

For all the applications mentioned, the feature of bigger importance is the flexibility of the electronic structure of quantum dot, which is controlled by magnetic and electric external fields, so it is of particular interest to investigate the structure of the states in more detail for different external conditions.

Here we discuss the one-electron energy spectra in a two-dimensional quantum dot with magnetic confinement. The spectra are calculated under the assumption of two different types of the boundary conditions. In the first case, there is only the spatial confinement due to a nonmagnetic finite potential barrier (we will call spatial confinement); in the second case the spatial confinement is combined with the magnetic spatial confinement.

#### 2.3.1. Equations

The Hamiltonian for an electron confined by the finite potential  $V(\vec{r})$  within a magnetic field  $\vec{B}$  in a two-dimensional quantum dot is given by

$$H = -\frac{\hbar^2}{2m^*} \nabla^2 + \frac{\omega_c}{2} L_z + \frac{1}{8} m^* \omega_c^2 r^2 + V(\vec{r}) \quad (92)$$

where  $r$  and  $\nabla$  are defined in the plane. We have used the same symmetric gauge as that used by Rosas et al. [83].

In this work we begin with a more realistic shape of the potential  $V(\vec{r})$  instead of that used in [83]. Namely, let the potential be described by the following expression:

$$V(\vec{r}) = \begin{cases} 0 & 0 \leq r \leq a \\ V_c & r > a \end{cases} \quad (93)$$

In this case the Schrödinger equation can be rewritten in polar coordinates,

$$\left\{ \frac{\hbar^2}{2m^*} \left[ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2}{\partial \varphi^2} \right] + i\hbar\omega \frac{\partial}{\partial \varphi} - \frac{m^*}{2} \omega^2 r^2 + E - V_c \right\} \Psi = 0 \quad (94)$$

where the frequency  $\omega = \omega_c/2$  was introduced.

### 2.3.2. Quantum Dot without Magnetic Field

If the magnetic field is not included, Eq. (94) can be rewritten as

$$\frac{\hbar^2}{2m^*} \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial}{\partial r} \right) \right) \psi + \frac{\hbar^2}{2m^*} \frac{1}{r^2} \frac{\partial^2}{\partial \varphi^2} \psi + (E - V_c) \Psi = 0 \quad (95)$$

In this equation  $E$  is the energy of the particle and the wave function  $\psi$  must satisfy the boundary condition at  $r = a$ :

$$\frac{\psi'_-(r, \varphi)}{\psi_-(r, \varphi)} = \frac{\psi'_+(r, \varphi)}{\psi_+(r, \varphi)} \quad (96)$$

Here  $\psi_-$  is the solution of Eq. (95) for the region  $0 \leq r \leq a$  and  $\psi_+$  for  $r > a$  and the derivatives are taken with respect to  $r$ . However, for the region  $0 \leq r \leq a$  we should take the solution of the Schrödinger equation with the magnetic field instead of  $\psi_-$ . Let us consider Eq. (95) in the region  $r > a$ . In this case the variables are separable and the substitution  $\psi = R(r)\Phi(\varphi)$  yields the set of well-known equations

$$r(rR)' - (r^2|k|^2 + m^2)R = 0 \quad (97)$$

$$\Phi'' + m^2\Phi = 0 \quad (98)$$

where  $m$  is a separation constant and

$$|k|^2 = \frac{2m^*}{\hbar^2} (E - V) < 0 \quad \text{for } r > a$$

The solution of this equation set is

$$\Psi_+ = AK_m(kr)e^{im\varphi} \quad (99)$$

where  $K_m$  is the modified Bessel functions (or Macdonald functions), and  $A$  is a constant.

The solution of Eq. (95) in the region  $0 \leq r \leq a$  as well as the energy spectrum have been discussed earlier [83]. For this reason we do not need consider it here again (in this region of  $r$  we are interested in the wavefunction that corresponds to the case with magnetic field).

### 2.3.3. Quantum Dot with Magnetic Confinement

The case of a charged particle moving in the homogeneous magnetic field  $B_0$  without a spatial confinement was discussed in a previous work [83]. Here we would only like to mention that in this case the Schrödinger equation for a particle of mass  $m^*$  is

$$\left\{ \frac{\hbar^2}{2m^*} \left[ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2}{\partial \varphi^2} \right] + i\hbar\omega \frac{\partial}{\partial \varphi} - \frac{m^*}{2} \omega^2 r^2 + E \right\} \psi = 0 \quad (100)$$

which has the solution

$$\psi_m = Ae^{im\varphi} e^{-\frac{x}{2}} x^{\frac{|m|}{2}} F \left( -\frac{\varepsilon - m - |m| - 1}{2}, |m| + 1; x \right) \quad (101)$$

where

$$\begin{aligned} x &= \frac{r^2}{2l_m^2} & l_m^2 &= \frac{\hbar}{m^* \omega_c} = \frac{c\hbar}{eB_0} \\ \omega &= \frac{\omega_c}{2} & \varepsilon &= \frac{E}{\hbar\omega} \end{aligned} \quad (102)$$

In the case when we need to take in consideration the spin of the electron we should change the energy  $E$  by  $(E + \mu_s \frac{\omega_c}{s} B_0)$  in the last expression, and the corresponding degeneracy will be lifted.

The energy levels that can be obtained with the boundary condition at  $r = a$  for the wavefunctions corresponding to the regions  $0 \leq r \leq a$  and  $r > a$  are [see Eq. (96)]

$$\frac{1}{m^*} \frac{\Psi'_m(r^2)}{\Psi_m(r^2)} = \frac{1}{m^*} \frac{K'_m(r)}{K_m(r)} \quad (103)$$

where  $\Psi_m(r^2)$  is the solution of Eq. (101) in the region  $0 \leq r \leq a$ ,  $r^2 = 2xl_m^2$ , and  $K_m(r)$  is the Macdonald function which is the solution of Eq. (100) for the region  $r > a$ .

### 2.3.4. A More Realistic Potential

It is clear that the energy levels obtained from condition (103) are approximations. More strictly speaking, we should substitute in this equation the solution of Eq. (100) for the region  $r > a$  with an additional constant  $-V$ , the height of the potential barrier, instead of the function  $K_m(r)$  [the potential in this case becomes  $((m^*/2)\omega^2 r^2 + V)$ ]. In this case Eq. (100) takes the form

$$\psi'' + \frac{1}{x} \Psi' - \frac{m^2}{4x^2} \Psi + \frac{\varepsilon - V - m}{2x} \Psi + \frac{1}{4} \psi = 0 \quad (104)$$

and its solutions can be written as

$$\Psi_m^{(+)} = Ae^{im\varphi} e^{-\frac{x}{2}} x_1^{\frac{|m|}{2}} F_1 \left( -\frac{\varepsilon - V - m - |m| - 1}{2}, |m| + 1; x \right) \quad (105)$$

for the region  $r > a$  (in this case we have the relation  $E - V < 0$ ), and for the internal region the solution is equal to (101),

$$\Psi_m^{(-)} = A e^{im\varphi} e^{-\frac{x}{2}} x_1^{\frac{|m|}{2}} F_1\left(-\frac{\varepsilon - m - |m| - 1}{2}, |m| + 1; x\right) \quad (106)$$

where all variables are the same as in Eq. (105), and  $\varepsilon = (E + \mu_s \frac{\sigma}{s} B) \frac{1}{\hbar\omega}$ . In this case the boundary condition is

$$\frac{\Psi_m'(-)}{\Psi_m(-)} = \frac{\Psi_m'(+) }{\Psi_m(+)} \quad (107)$$

which leads to the transcendental equation for energy:

$$\begin{aligned} & (\alpha - V)_1 F_1\left(-\alpha + \frac{V}{2} + 1, |m| + 2; x\right)_1 F_1(-\alpha, |m| + 1; x) \\ & - \alpha_1 F_1(-\alpha + 1, |m| + 2; x)_1 \\ & \times F_1\left(-\alpha + \frac{V}{2}, |m| + 1; x\right) = 0 \end{aligned} \quad (108)$$

The results of calculations of the energy spectra that correspond to the boundary conditions of Eq. (107) are presented in Figure 9. The energies are plotted as functions of the parameters of the problem—the magnetic field and the height of the rectangular potential barriers—and all values are shown in relative units. In this figure it can also be observed that for the size of the potential barrier ( $V_c/\hbar\omega = 1$ ) there are no energy states when the spatial confinement and magnetic confinement are almost the same. The energy states exist when  $a > l_m$ , and for the case when  $a < l_m$  the intensity of the magnetic field is such that the electron energy levels are located above the potential barrier and electrons escape from the interior of the quantum dot. Under these conditions the magnetic field can be used in order to tune the electronic states inside the quantum

**Figure 9.** The one-electron energy spectrum for a QD, with the magnetic field only in the inner part of the QD where the confinement potential is  $V(r)$ . The energy is calculated under assumption of boundary condition (107) as a function of the width of the confinement potential  $a/l_m$  for constant value  $V_c/\hbar\omega = 1$ . Reprinted with permission from [88], A. Lipovka et al., *Phys. Low-Dim. Struct.* 9/10, 97 (2002). © 2002, VSV.

dot. As should be expected, these results are similar to those calculated in [83], but our results are thought to be more realistic ones.

In Figure 10 one can see a more detailed comparison of the one-electron energy spectra for the two cases which correspond to different potentials [boundary conditions (103) and (107)]. The corresponding one-electron energy spectra are presented as functions of external magnetic field. It also is observed that for a potential barrier bigger than the potential barrier of Figure 9 there only exist energy states with  $a < l_m$  for  $m = 0$  since the state with  $m = 1$  only exists with  $a > l_m$ ; this only happens for magnetic fields inside the quantum dot. However, with the magnetic fields inside or outside the quantum dot the energy level with  $m = 0$  extends to  $a/l_m = 1.7$  approximately (i.e., from the region with  $a < l_m$  to the region  $a > l_m$ ). Thus, with a magnetic field in the exterior of the quantum dot the energy states inside the quantum dot can be manipulated. We can also conclude that the choice of a diamagnetic or paramagnetic material in the exterior of the quantum dot can be used to manipulate or tune the electronic states in the quantum dot for a fixed  $a$  and  $B$ .

In Figures 11, 12, and 13 the variation of state with  $m = 0$  with respect to the potential barrier  $V(r)$  for several values of  $a/l_m$ , which characterize the relation between the spatial and the magnetic confinements, is shown. In Figure 11,  $a = 0.5l_m$ , in Figure 12  $a = l_m$ , and in Figure 13  $a = 2l_m$ . The variation of the curves means that when the spatial confinement increases the energy states due to magnetic confinement appear for a lower potential barrier  $V(r)$ ; on the other hand, if the magnetic confinement decreases the energy states tend to disappear, as one can expect. Also plotted in Figure 13 is the state with  $m = 1$  and we can observe that for barriers lower than that of Figure 11 this state goes out to the exterior of the quantum dot because

**Figure 10.** Solid lines are the same as in Figure 9, but for  $V_c/\hbar\omega = 5$ . Dashed line is the one-electron energy spectrum for the QD, with the magnetic field inside and outside the QD where the confinement potential is  $V(r)$ . The energy is calculated under the assumption of boundary condition (107) as a function of the width of the confinement potential  $a/l_m$  for constant value  $V_c/\hbar\omega = 5$ . Reprinted with permission from [88], A. Lipovka et al., *Phys. Low-Dim. Struct.* 9/10, 97 (2002). © 2002, VSV.

**Figure 11.** The one-electron energy spectrum in the QD with the magnetic field only in the inner part of the QD with the confinement potential given by  $V(r)$ . The energy is calculated under the assumption of boundary condition (107) as a function of the depth of the confinement potential  $V_c/\hbar\omega$  for a constant value  $a/l_m = 0.5$ . Reprinted with permission from [88], A. Lipovka et al., *Phys. Low-Dim. Struct.* 9/10, 97 (2002). © 2002, VSV.

it has a larger energy than for  $m = 0$ . Thus, the existence of this energy state inside the quantum dot requires bigger potential barriers  $V(r)$ .

#### 2.4. Exciton Binding Energy in a Quantum Wire in the Presence of a Magnetic Field

A calculation of the ground state energy of an exciton confined in a cylindrical quantum wire in the presence of a uniform magnetic field as a function of wire radius is made using a variational approach. It is assumed that the magnetic field is applied parallel to the axis of the wire. The calculations have been performed using a suitable variational wavefunction taken as a product of the appropriate confining confluent hypergeometric functions and a hydrogenic

**Figure 12.** The same as in Figure 11 but for  $a/l_m = 1$ . Reprinted with permission from [88], A. Lipovka et al., *Phys. Low-Dim. Struct.* 9/10, 97 (2002). © 2002, VSV.

**Figure 13.** The same as in Figure 11 but for  $a/l_m = 2$ . Reprinted with permission from [88], A. Lipovka et al., *Phys. Low-Dim. Struct.* 9/10, 97 (2002). © 2002, VSV.

function for infinite and finite confining potentials [98]. For a given value of the magnetic field, the binding energy is found to be larger than the zero field case. This behavior is explained in terms of an average electron–hole separation, which depends on the wire radius and the magnetic field strength.

##### 2.4.1. Infinite Potential Barrier Case

The Hamiltonian for the interacting electron–hole pair inside a cylindrical wire of radius  $r_0$ , with infinite potential barrier at the surface, in the presence of a magnetic field applied parallel to wire axis, is given by

$$\hat{H} = \frac{1}{2m_e^*} \left( \hat{p}_e + \frac{e}{c} \vec{A}_e \right)^2 + \frac{1}{2m_h^*} \left( \hat{p}_h - \frac{e}{c} \vec{A}_h \right)^2 - \frac{e^2}{\kappa |\vec{r}_e - \vec{r}_h|} + V_e(\rho_e, \phi_e) + V_h(\rho_h, \phi_h) \quad (109)$$

where

$$|\vec{r}_e - \vec{r}_h| = [\rho_e^2 + \rho_h^2 - 2\rho_e\rho_h \cos(\phi_e - \phi_h) + z^2]^{1/2} \quad (110)$$

and

$$V_{e(h)}(\rho_{e(h)}, \phi_{e(h)}) = \begin{cases} 0 & 0 \leq \rho_e \text{ and } \rho_h \leq r_0 \\ \infty & \rho_e \text{ or } \rho_h > r_0 \end{cases} \quad (111)$$

For a uniform magnetic field we can write

$$\vec{A}_{e(h)}(\vec{r}_{e(h)}) = \frac{\vec{B} \times \vec{r}_{e(h)}}{2} \quad (112)$$

where  $\vec{B} = B\vec{e}_z$ . In cylindrical coordinates the magnetic field potential becomes  $A_\rho = A_z = 0$ ,  $A_\phi[e(h)] = B\rho_{e(h)}/2$ . The inclusion of the Coulombic potential leads to a nonseparable differential equation which cannot be solved analytically. Therefore, it is necessary to use a variational approach to calculate the eigenfunctions and eigenvalues of the Hamiltonian.

Following Brown and Spector [46] we take into account the cylindrical confining symmetry, the presence of the magnetic field, and the electron-hole Coulombic potential, by choosing a trial wavefunction for the ground state, which can be written as product of a hydrogenic part and the radial solutions of an electron and a hole in a cylindrical wire in the presence of magnetic field, applied parallel to the wire axis:

$$f(\vec{r}) = \begin{cases} N \exp\left[-\frac{(\xi_e + \xi_h)}{2}\right] F(-a_{01e}, 1; \xi_e) \\ \quad \times F(-a_{01h}, 1; \xi_h) \exp[-\lambda|\vec{r}_e - \vec{r}_h|] & 0 \leq \rho_e \text{ and } \rho_h \leq r_0 \\ 0 & \rho_e \text{ or } \rho_h > r_0 \end{cases} \quad (113)$$

In Eq. (113) the variable

$$\xi_{e(h)} = \frac{\rho_{e(h)}^2}{2\alpha_{c[e(h)]}^2} = \frac{eB\rho_{e(h)}^2}{2\hbar c} \quad \alpha_{c[e(h)]} = \left( \frac{\hbar}{m_{e(h)}^* \omega_{c[e(h)]}} \right) \quad (114)$$

is the cyclotron radius,  $\omega_{c[e(h)]} = eB/m_{e(h)}^*c$  is the cyclotron frequency,  $N$  is the normalization constant, and  $\lambda$  is a variational parameter. Equation (113) satisfies the boundary condition that  $f(\rho_{e(h)} = r_0) = 0$ , while  $a_{01[e(h)]}$  is the eigenvalue for the electron (hole) in a wire in a magnetic field, calculated numerically from the boundary condition eigenvalue equation.  $N$  is given by

$$N^{-2} = -2\pi \frac{dG}{d\lambda} \quad (115)$$

with

$$G = \int_0^{r_0} \rho_e d\rho_e \int_0^{r_0} \rho_h d\rho_h \exp\left(-\frac{\rho_e^2}{2\alpha_{c(e)}^2}\right) \\ \times F^2\left(-a_{01(e)}, 1; \frac{\rho_e^2}{2\alpha_{c(e)}^2}\right) \exp\left(-\frac{\rho_h^2}{2\alpha_{c(h)}^2}\right) \\ \times F^2\left(-a_{01(h)}, 1; \frac{\rho_h^2}{2\alpha_{c(h)}^2}\right) I_0(2\lambda\rho_{<}) K_0(2\lambda\rho_{>}) \quad (116)$$

where  $\rho_{<}(\rho_{>})$  is the lesser (greater) of  $\rho_e$  and  $\rho_h$ ; the particular values for  $\rho_{<}$  and  $\rho_{>}$  are determined by electron and hole locations and the integration limits. In Eq. (116),  $I_0$  and  $K_0$  are the modified Bessel functions of the second kind of order zero.

The binding energy  $\varepsilon_b(r_0, B)$  for the exciton is defined as the ground state energy of a system without Coulombic interaction, minus the ground state energy  $\varepsilon_0(r_0, B) = \langle \hat{H}(r_0, B) \rangle$  in the presence of electron-hole interaction. That is,

$$\varepsilon_b(r_0, B) = \hbar\omega_{c(e)}\left(a_{01(e)} + \frac{1}{2}\right) + \hbar\omega_{c(h)}\left(a_{01(h)} + \frac{1}{2}\right) \\ - \varepsilon_0(r_0, B) \quad (117)$$

The binding energy defined in this way is a positive quantity.

The ground state energy  $\langle \hat{H}(r_0, B) \rangle = \langle T \rangle + \langle V \rangle$  is found after tedious algebra,

$$\langle T \rangle = \hbar\omega_{c(e)}\left(a_{01(e)} + \frac{1}{2}\right) + \hbar\omega_{c(h)}\left(a_{01(h)} + \frac{1}{2}\right) + \frac{\hbar^2}{2\mu^*}\lambda^2 \quad (118)$$

where  $\mu^*$  is the effective reduced mass and

$$\langle V \rangle = -\frac{4\pi e^2}{\kappa} N^2 G \quad (119)$$

Therefore,

$$\varepsilon_b(r_0, B) = -\frac{\hbar^2}{2\mu^*}\lambda^2 - \frac{2e^2}{\kappa} \frac{G}{dG/d\lambda} \quad (120)$$

For computational purposes, we normalize the expression for the binding energy  $\varepsilon_b(r_0, B)$  [Eq. (120)] in Rydberg units and define  $\gamma_{e(h)} = \hbar\omega_{c[e(h)]}/2R_{y, \text{exc}}^*$ . In addition, we transform the integral for  $G$  in a dimensionless form by letting  $\rho = tr_0$ ; the expressions for  $\langle \hat{H}(r_0, B) \rangle$  and  $\varepsilon_b(r_0, B)$  are then written as

$$\langle \hat{H}(r_0, B) \rangle = \gamma_e(1 + 2a_{01(e)}) + \gamma_h(1 + 2a_{01(h)}) \\ + (\lambda a_B^*)^2 + 4a_B^* \frac{G_1}{dG_1/d\lambda} \quad (121)$$

$$\varepsilon_b(r_0, B) = -(\lambda a_B^*)^2 - 2a_B^* \frac{G_1}{dG_1/d\lambda} \quad (122)$$

where

$$G_1 = \int_0^1 t_e dt_e \int_0^1 t_h dt_h \exp(-t_e^2 \xi_{r_0(e)}) F^2(-a_{01(e)}, 1; t_e^2 \xi_{r_0(e)}) \\ \times \exp(-t_h^2 \xi_{r_0(h)}) F^2(-a_{01(h)}, 1; t_h^2 \xi_{r_0(h)}) \\ \times I_0(2\lambda r_0 t_{<}) K_0(2\lambda r_0 t_{>}) \quad (123)$$

and  $\xi_{r_0[e(h)]} = r_0^2/2\alpha_{c[e(h)]}^2$ .

In order to find the minimum of  $\langle \hat{H}(r_0, B) \rangle$  with respect to  $\lambda$  and thus to obtain a lower bound to the ground state the variational method is used. The radial double integration in  $G_1$  is performed numerically since there is no analytical method to evaluate it.

#### 2.4.2. Finite Potential Barrier Case

For the finite potential barrier case, the potential in the Hamiltonian [Eq. (109)] is taken as zero for  $\rho_{e(h)} < r_0$  and  $V_0$  for  $\rho_{e(h)} > r_0$ . All the other assumptions remain the same. Furthermore, we assume that the electron and hole masses are constant (at their values in GaAs) across the barrier. Again, following Brown and Spector [46] we take into account the cylindrical confining symmetry, the presence of the magnetic field, and the Coulomb potential by choosing a trial wavefunction for the ground state, which can be written as a product of a hydrogenic part and the radial solutions of

an electron and a hole in a cylindrical wire in the presence of a magnetic field, parallel to the wire axis,

$$f(\vec{r}_e, \vec{r}_h) = \begin{cases} N \exp\left(-\frac{\xi_e + \xi_h}{2}\right) F(-a_{01(e)}, 1; \xi_e) \\ \times F(-a_{01(h)}, 1; \xi_h) \exp(-\lambda|\vec{r}_e - \vec{r}_h|) & 0 \leq \rho_e \text{ and } \rho_h \leq r_0 \\ N \frac{F(-a_{01(e)}, 1; \xi_{r_0e})}{U(-a'_{01(e)}, 1; \xi_{r_0e})} \exp\left(-\frac{\xi_e + \xi_h}{2}\right) \\ \times U(-a'_{01(e)}, 1; \xi_e) F(-a_{01(h)}, 1; \xi_h) \\ \times \exp(-\lambda|\vec{r}_e - \vec{r}_h|) & \rho_e > r_0 \text{ and } \rho_h \leq r_0 \\ N \frac{F(-a_{01(h)}, 1; \xi_{r_0h})}{U(-a'_{01(h)}, 1; \xi_{r_0h})} \exp\left(-\frac{\xi_e + \xi_h}{2}\right) \\ \times F(-a_{01(e)}, 1; \xi_e) U(-a'_{01(h)}, 1; \xi_h) \\ \times \exp(-\lambda|\vec{r}_e - \vec{r}_h|) & \rho_e \leq r_0 \text{ and } \rho_h > r_0 \\ N \frac{F(-a_{01(e)}, 1; \xi_{r_0e})}{U(-a'_{01(e)}, 1; \xi_{r_0e})} \frac{F(-a_{01(h)}, 1; \xi_{r_0h})}{U(-a'_{01(h)}, 1; \xi_{r_0h})} \\ \times \exp\left(-\frac{\xi_e + \xi_h}{2}\right) U(-a'_{01(e)}, 1; \xi_e) \\ \times U(-a'_{01(h)}, 1; \xi_h) \exp(-\lambda|\vec{r}_e - \vec{r}_h|) & \rho_e \text{ and } \rho_h > r_0 \end{cases} \quad (124)$$

where  $\xi_{e(h)} = \rho_{e(h)}^2 / 2\alpha_{e(h)}^2$ . Equation (124) satisfies the boundary condition

$$\frac{1}{m_i^*} \frac{\partial f_i}{\partial \rho_{e(h)}} = \frac{1}{m_o^*} \frac{\partial f_o}{\partial \rho_{e(h)}} \quad \text{at } \rho_{e(h)} = r_0 \quad (125)$$

while  $a_{01e(h)}$  and  $a'_{01e(h)}$  are the eigenvalues for the ground state of the problem inside and outside the wire for an electron and a hole, respectively.  $N$  is given by

$$N^{-2} = -4\pi^2 \frac{d}{d\lambda} (I_K + I_L + I_M + I_N) \quad (126)$$

with

$$I_K = \int_0^{r_0} \rho_e d\rho_e \int_0^{r_0} \rho_h d\rho_h \exp[-(\xi_e + \xi_h)] F^2(-a_{01(e)}, 1; \xi_e) \\ \times F^2(-a_{01(h)}, 1; \xi_h) I_0(2\lambda\rho_<) K_0(2\lambda\rho_>) \quad (127)$$

$$I_L = \frac{F^2(-a_{01(e)}, 1; \xi_{r_0e})}{U^2(-a'_{01(e)}, 1; \xi_{r_0e})} \int_0^\infty \rho_e d\rho_e \exp(-\xi_e) \\ \times U^2(-a'_{01(e)}, 1; \xi_e) K_0(2\lambda\rho_e) \int_0^{r_0} \rho_h d\rho_h \exp(-\xi_h) \\ \times F^2(-a_{01(h)}, 1; \xi_h) I_0(2\lambda\rho_h) \quad (128)$$

$$I_M = \frac{F^2(-a_{01(h)}, 1; \xi_{r_0h})}{U^2(-a'_{01(h)}, 1; \xi_{r_0h})} \int_0^{r_0} \rho_e d\rho_e \exp(-\xi_e) \\ \times F^2(-a_{01(e)}, 1; \xi_e) I_0(2\lambda\rho_e) \int_{r_0}^\infty \rho_h d\rho_h \exp(-\xi_h) \\ \times U^2(-a'_{01(h)}, 1; \xi_h) K_0(2\lambda\rho_h) \quad (129)$$

and

$$I_N = \frac{F^2(-a_{01(e)}, 1; \xi_{r_0e})}{U^2(-a'_{01(e)}, 1; \xi_{r_0e})} \frac{F^2(-a_{01(h)}, 1; \xi_{r_0h})}{U^2(-a'_{01(h)}, 1; \xi_{r_0h})} \\ \times \int_{r_0}^\infty \rho_e d\rho_e \int_{r_0}^\infty \rho_h d\rho_h \exp[-(\xi_e + \xi_h)] \\ \times U^2(-a'_{01(e)}, 1; \xi_e) U^2(-a'_{01(h)}, 1; \xi_h) \\ \times I_0(2r_0 t_<) K_0(2\lambda r_0 t_>) \quad (130)$$

The binding energy  $\varepsilon_b(r_0, B)$  is calculated as in the infinite potential barrier case, leading to the following expression:

$$\varepsilon_b(r_0, B) = -\frac{\hbar^2}{2\mu^*} \lambda^2 - \frac{2e^2}{\kappa} \frac{(I_K + I_L + I_M + I_N)}{d(I_K + I_L + I_M + I_N)/d\lambda} \quad (131)$$

We normalize the expression for the binding energy  $\varepsilon_b(r_0, B)$ , in units of exciton Rydberg  $R_{y, \text{exc}}^*$ ,

$$\varepsilon_b(r_0, B) = -(\lambda a_B^*)^2 - 4a_B^* \frac{(I_{KK} + I_{LL} + I_{MM} + I_{NN})}{d(I_{KK} + I_{LL} + I_{MM} + I_{NN})/d\lambda} \quad (132)$$

where

$$I_{KK} = \int_0^1 t_e dt_e \int_0^1 t_h dt_h \exp(-t_e^2 \xi_{r_0e}) \\ \times F^2(-a_{01(e)}, 1; t_e^2 \xi_{r_0e}) \exp(-t_h^2 \xi_{r_0h}) \\ \times F^2(-a_{01(h)}, 1; t_h^2 \xi_{r_0h}) I_0(2\lambda r_0 t_<) K_0(2\lambda r_0 t_>) \quad (133)$$

$$I_{LL} = \frac{F^2(-a_{01(e)}, 1; \xi_{r_0e})}{U^2(-a'_{01(e)}, 1; \xi_{r_0e})} \int_1^\infty t_e dt_e \exp(-t_e^2 \xi_{r_0e}) \\ \times U^2(-a'_{01(e)}, 1; t_e^2 \xi_{r_0e}) K_0(2\lambda r_0 t_e) \int_0^1 t_h dt_h \\ \times \exp(-t_h^2 \xi_{r_0h}) F^2(-a_{01(h)}, 1; t_h^2 \xi_{r_0h}) I_0(2\lambda r_0 t_h) \quad (134)$$

$$I_{MM} = \frac{F^2(-a_{01(h)}, 1; \xi_{r_0h})}{U^2(-a'_{01(h)}, 1; \xi_{r_0h})} \int_0^1 t_e dt_e \exp(-t_e^2 \xi_{r_0e}) \\ \times F^2(-a_{01(e)}, 1; t_e^2 \xi_{r_0e}) I_0(2\lambda r_0 t_e) \\ \times \int_1^\infty t_h dt_h \exp(-t_h^2 \xi_{r_0h}) U^2(-a'_{01(h)}, 1; t_h^2 \xi_{r_0h}) \\ \times K_0(2\lambda r_0 t_h) \quad (135)$$

and

$$I_{NN} = \frac{F^2(-a_{01(e)}, 1; \xi_{r_0e})}{U^2(-a'_{01(e)}, 1; \xi_{r_0e})} \frac{F^2(-a_{01(h)}, 1; \xi_{r_0h})}{U^2(-a'_{01(h)}, 1; \xi_{r_0h})} \\ \times \int_1^\infty t_e dt_e \int_1^\infty t_h dt_h \exp[-(t_e^2 \xi_{r_0e} + t_h^2 \xi_{r_0h})] \\ \times U^2(-a'_{01(e)}, 1; t_e^2 \xi_{r_0e}) U^2(-a'_{01(h)}, 1; t_h^2 \xi_{r_0h}) \\ \times I_0(2\lambda r_0 t_<) K_0(2\lambda r_0 t_>) \quad (136)$$

The values of the physical parameters pertaining to the material GaAs used in the calculations are given in Table 1 [77].

**Table 1.** Physical parameters pertaining to the material GaAs.

	$m_e^*$	$\kappa$	$\gamma_1$	$\gamma_2$	$m_{hh}^*(x, y)$	$m_{hh}^*(z)$	$m_h^*(x, y)$	$m_h^*(z)$
GaAs	$0.067m_0$	12.5	7.36	2.57	$0.10m_0$	$0.45m_0$	$0.21m_0$	$0.08m_0$

For mathematical convenience and without any loss of physical insight, isotropic hole mass is assumed and, therefore, we can write an expression for an isotropic hole mass:

$$(m_h^*)^{-1} = \frac{2}{3}(m_h^*(x, y))^{-1} + \frac{1}{3}(m_h^*(z))^{-1} \quad (137)$$

The reduced mass for the heavy hole exciton is  $0.0447m_0$  and that for the light hole exciton is  $0.0449m_0$ . Since both heavy and light hole exciton masses are close to each other, for the rest of the topic we present results for the heavy exciton.

In Figure 14 the variation of the exciton binding energy  $\varepsilon_b$  as a function of wire radius  $r_0$  for several values of the magnetic field in the infinite potential barrier case is shown. For a given value of the magnetic field the binding energy increases as the wire radius is reduced and diverges as  $r_0 \rightarrow 0$ . For small values of the wire radii ( $r_0 \leq a_B$ ) and for values of the magnetic field considered in this work, the exciton binding energy is relatively insensitive to the variation of the magnetic field, since the confinement effect due to the potential barrier is more significant than that due to the application of the magnetic field. For large values of the wire radii ( $r_0 \geq 3a_B^*$ ) the binding energy for  $B = 0$  approaches its value in the bulk GaAs (i.e., the exciton Rydberg) and

**Figure 14.** Variations of the binding energy of a heavy hole exciton  $\varepsilon_b$ , expressed in terms of an exciton Rydberg  $R_{y,exc}^*$  in GaAs ( $\approx 3.9$  meV) as a function of the radius of the wire  $r_0$  expressed in terms of Bohr radius  $a_B$  in GaAs ( $\approx 148$  Å) for  $B_0 = 0$  kG (solid line), 50 kG (dotted line), 100 kG (short dashed line), and 200 kG (long dashed line). Academic Press, San Diego, 2001. © 2001, Academic Press.

varies with the magnetic field essentially in the same fashion as calculated by Aldrich and Greene [99].

In Figure 15 the variation of the exciton binding energy  $\varepsilon_b$  as a function of magnetic field for several values of the wire radii in the infinite potential barrier case is plotted. Again, for small values of the wire radii ( $r_0 \leq a_B^*$ ) the binding energy is relatively insensitive to the variations of the magnetic field; however, for large values of the wire radii ( $r_0 \geq 3a_B^*$ ) the variation of  $\varepsilon_b$  with magnetic field is much more pronounced due to the strong confinement effect of the magnetic field.

In Figure 16 the variation of the exciton binding energy  $\varepsilon_b$  as a function of the radius of the wire for several values of the magnetic field for a finite potential barrier is plotted. The Al concentration in the barrier material is assumed to be  $x = 0.3$ . For a given value of the magnetic field the binding energy increases from its bulk value in GaAs as the wire radius is reduced, reaches a maximum value, and then drops to the bulk value characteristic of the barrier material as the wire radius goes to zero. This is due to the fact that as the wire radius is decreased the electron wavefunction is compressed thus leading to the enhancement of the binding energy. However, below a certain value of  $r_0$  the leakage of the wavefunction into the barrier region becomes more important and, thus, the binding energy starts decreasing until it reaches a value that is characteristic of the barrier material as  $r_0 \rightarrow 0$ . For a given value of  $r_0$  the binding energy increases as a function of the magnetic field due to the increasing compression of the wavefunction with magnetic field.

In Figure 17 the variation of the exciton binding energy as a function of the magnetic field for several values of the wire radius is shown. It is found that for small values of  $r_0/a_B^*$  ( $< 1$ ) the change in the binding energy with magnetic

field is similar to that in the case of bulk GaAs, since most of the wavefunction resides in the barrier. For intermediate values of  $r_0/a_B^*$  ( $\approx 1.0$ ) the variation of the binding energy with magnetic field is considerably smaller since the electron wavefunction is highly confined by the barrier potential. For larger values of  $r_0/a_B^*$  ( $\geq 3.0$ ) the exciton binding energy varies with magnetic field essentially the same way as it does in bulk GaAs.

## 2.5. Magnetoconductivity of a Quasi-Two-Dimensional Electron Gas

### 2.5.1. Macroscopic Derivation

Let us consider a quasi-two-dimensional electron gas subjected to a strong magnetic field. We are interested in its linear response to a weak static electric field  $\vec{E} \perp \hat{e}_z$  (i.e., applied in the layer plane of the heterostructure). The electron gas responds to this external disturbance with an electrical current which, since  $E$  is assumed to be small, will be proportional to  $\vec{E}$ . Thus, we may write that the  $x, y$  components of the areal current density  $\vec{J}$  are related to  $\vec{E}$  by

$$J_x = \sigma_{xx}E_x + \sigma_{xy}E_y \quad J_y = \sigma_{yx}E_x + \sigma_{yy}E_y \quad (138)$$

As we are dealing with cubic host materials  $\sigma_{xx} = \sigma_{yy}$  and the Onsager relationships [101, 102] show that

$$\sigma_{xy} = -\sigma_{yx} \quad (139)$$

The conductivity tensor  $\vec{\sigma}$  is the quantity that is most naturally calculated. Practically, however, the resistivity tensor

$$\vec{\rho} = \vec{\sigma}^{-1} \quad (140)$$

is the most accessible to the experiments. If we invert Eq. (138), we obtain

$$\rho_{xx} = \rho_{yy} = \frac{\sigma_{xx}}{\sigma_{xx}^2 + \sigma_{xy}^2} \quad \rho_{yx} = -\rho_{xy} = \frac{\sigma_{xy}}{\sigma_{xx}^2 + \sigma_{xy}^2} \quad (141)$$

Let us consider a sample with “spider” geometry. It consists of a long bar ( $L_x \gg L_y$ ) with side contacts (see Fig. 18). The voltage  $V_x$  is imposed via a battery and the voltage  $V_H$  is measured across the small dimension of the bar. Since  $J_y$  vanishes we have

$$E_x = \rho_{xx}J_x \quad E_y = \rho_{yx}J_x \quad (142)$$

If one assumes that the current densities  $J_x, J_y$  are uniform in the sample (the spatial variation of  $\vec{J}$  is still a matter of controversy) we may write

$$J_x = \frac{I_x}{L_y} \quad V_H = E_y L_y \quad V_x = E_x L_x \quad (143)$$

Thus

$$V_x = \frac{\rho_{xx}}{L_y} L_x I_x = R_{xx} I_x \quad V_H = \rho_{yx} I_x = R_{yx} I_x \quad (144)$$

**Figure 18.** Sample geometry used to measure the resistivity tensor  $\vec{\rho}(B)$ . Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

where  $V_z, V_H$  are expressed in volts,  $I_x$  in amperes, and  $R_{xx}, R_{yx}$  in ohms. Finally

$$R_{xx} = \frac{L_x}{L_y} \frac{\sigma_{xx}}{\sigma_{xx}^2 + \sigma_{yy}^2} \quad R_{yx} = \frac{\sigma_{xy}}{\sigma_{xx}^2 + \sigma_{yy}^2} \quad (145)$$

The resistance  $R_{xx}$  involves the geometrical factor  $L_x/L_y$  and thus is sample dependent. In literature, people often get rid of this inconvenience by quoting the resistance which would be measured in samples with a square shape but which are otherwise identical to their investigated samples. Thus, to recall this feature,  $R_{xx}$  measurements are given in units of square ohms ( $\Omega_0$ ).

On the other hand, the Hall resistance  $R_{yx}$  is independent of the sample shape. This explains why several Bureaux of Standards, in the hope of defining a new resistance standard, are interested in accurate  $R_{yx}$  data [103]. The former will be independent of sample size and thus free of dilata-tion effects, which often plague the usual ohm standards, which are presently based on resistance of platinum rods. Finally let us stress once more that both  $R_{xx}, R_{yx}$  as well as  $\rho_{xx}, \rho_{xy}$  are expressed in ohms. Nothing is wrong with the latter property. Only the resistivities  $\rho_{xx}, \rho_{xy}$  are two-dimensional resistivities. We know that in the dimension equation

$$\rho = \frac{m_e^*}{\eta_e e^2 \tau} \quad (146)$$

As in bulk materials  $\tau$  has the dimension of a relaxation time. However, in Eq. (146)  $\eta_e$  is an areal electron concentration instead of a volumetric concentration as usually found in bulk materials.

### 2.5.2. Microscopic Discussion

The linear response theory, originally derived by Kubo et al., has been used to evaluate the components  $\sigma_{xx}$  and  $\sigma_{yx}$  of the static magnetoconductivity tensor in the independent electron approximation [104]. We found that at  $T = 0$  K

$$\sigma_{xx} = \frac{\pi \hbar e^2}{(m_e^*)^2 S} \text{Trace} \left\{ \delta(\varepsilon_F - \hat{H}) \Pi_x \delta(\varepsilon_F - \hat{H}) \Pi_x \right\} \quad (147)$$

$$\sigma_{yx} = \frac{-ie^2 \hbar}{(m_e^*)^2 S} \int_{-\infty}^{+\infty} f(\varepsilon) d\varepsilon \times \text{Trace} \left\{ \delta(\varepsilon - \hat{H}) \left[ \Pi_y \frac{1}{(\varepsilon - \hat{H})^2} \Pi_x - \Pi_x \frac{1}{(\varepsilon - \hat{H})^2} \Pi_y \right] \right\} \quad (148)$$

where  $f(\varepsilon)$  is the Fermi–Dirac distribution function which, at zero temperature, is a step function of the argument  $\varepsilon_F - \varepsilon$  where  $\varepsilon_F$  is the Fermi level. In Eqs. (147) and (148)  $\Pi$  is  $\hat{p} + (e/c)\vec{A}$  and  $\hat{H}$  is the quasi-two-dimensional Hamiltonian which includes disorder,

$$\begin{aligned} \hat{H} &= \frac{\hat{p}_x^2}{2m_e^*} + \frac{1}{2m_e^*} \left( \hat{p}_y + \frac{e}{c} Bx \right)^2 \\ &\quad + \varepsilon_1 + g^* \mu_B B \sigma_z + V_{\text{disorder}}(\vec{\rho}) \\ \hat{H} &= \hat{H}_0 + V_{\text{disorder}}(\vec{\rho}) \end{aligned} \quad (149)$$

where

$$V_{\text{disorder}}(\vec{\rho}) = \int dz \chi_1^2(z) V_{\text{disorder}}(\vec{r}) \quad (150)$$

and  $\varepsilon_1$  is the confinement energy of the ground subband (wavefunction  $\chi_1$ ) which arises from the size quantization along the growth axis of the heterostructures. In Eqs. (149) and (150)  $\vec{\rho}(x, y), \vec{r} = (x, y, z)$ . To make sense, Eq. (149) requires a pronounced two-dimensionality of the electron gas; that is, the excited subbands  $\varepsilon_2, \dots$  must be far enough away from  $\varepsilon_1$  to allow a factorization of the carrier wavefunction  $\psi(\vec{r})$  in  $\chi_1(z)\varphi(\vec{\rho})$ . The assumed strong two-dimensionality also allows us to treat the case of the tilted magnetic fields with respect to the growth axis. Only the magnetic field  $B$ , which appears in Eq. (149), has to be understood as the projection of  $B$  along the  $z$  axis. The matrix elements of  $\Pi_x, \Pi_y$  on the Landau level basis (eigenstates of  $\hat{H}_0$ ) are

$$\begin{aligned} \langle n, k_y, \sigma_z | \Pi_x | n', k'_y, \sigma'_z \rangle &= \frac{i\hbar}{\lambda\sqrt{2}} [\sqrt{n}\delta_{n', n-1} - \sqrt{n+1}\delta_{n', n+1}] \\ &\quad \times \delta_{k'_y, k_y} \delta_{\sigma'_z, \sigma_z} \end{aligned} \quad (151)$$

$$\begin{aligned} \langle n, k_y, \sigma_z | \Pi_y | n', k'_y, \sigma'_z \rangle &= \frac{\hbar}{\lambda\sqrt{2}} [\sqrt{n}\delta_{n', n-1} + \sqrt{n+1}\delta_{n', n+1}] \\ &\quad \times \delta_{k'_y, k_y} \delta_{\sigma'_z, \sigma_z} \end{aligned} \quad (152)$$

In a perfect heterostructure  $V_{\text{disorder}}(\vec{\rho})$  vanishes. Thus the states  $|n, k_y, \sigma_z\rangle$  are eigenstates of  $\hat{H}$ . Consequently the matrix elements

$$\langle n, k_y, \sigma_z | \delta(\varepsilon - \hat{H}) | n', k'_y, \sigma'_z \rangle \quad (153)$$

are equal to

$$\begin{aligned} \langle n, k_y, \sigma_z | \delta(\varepsilon - \hat{H}) | n', k'_y, \sigma'_z \rangle \\ = \delta(\varepsilon - \varepsilon_{n\sigma_z}) \delta_{nn'} \delta_{k'_y, k_y} \delta_{\sigma'_z, \sigma_z} \end{aligned} \quad (154)$$

Equations (152)–(154) immediately lead to

$$\sigma_{xx} = 0 \quad \sigma_{yx} = \frac{\eta_e e^2}{m_e^* \omega_c} \quad (155)$$

Thus, for a perfect system the microscopic evaluation of the conductivity tensor leads to the same result as the classical Drude type of calculations.

Equation (155) is not surprising but merely serves as a reminder that, in the absence of scattering, a carrier subjected to crossed electric and magnetic fields actually drifts along a direction perpendicular to these two fields. The electrical transport along the electric field is entirely due to collisions, that is, to a nonvanishing  $V_{\text{disorder}}(\vec{\rho})$ .

We have already stated that very little is known about the exact shape of  $V_{\text{disorder}}(\vec{\rho})$ . Its spatial average over a macroscopic area should, however, vanish. Thus, in the  $(x, y)$  plane,  $V_{\text{disorder}}(\vec{\rho})$  shows uncorrelated fluctuations, which are either repulsive or attractive for electrons. (Notice that for very large magnetic fields both kinds of fluctuations, when considered as isolated, are capable of supporting bound states.) Taking the randomness of the disorder potential into account implies that Eqs. (147) and (148) should be completed by a spatial average over  $V_{\text{disorder}}(\vec{\rho})$ , and by taking the limit  $S \rightarrow \infty$ . If  $V_{\text{disorder}}(\vec{\rho})$  can be written as the sum of one-defect potentials centered at  $\vec{\rho}_i$

$$V_{\text{disorder}}(\vec{\rho}) = \sum_{\rho_i} W(\vec{\rho} - \vec{\rho}_i) \quad (156)$$

The spatial average signifies an average over the positions  $\vec{\rho}_i$  of the defects, which are assumed to be uncorrelated.

**Magnetic Field Dependence of  $\sigma_{xx}$  (Shubnikov–de Haas Effect)** Let us evaluate  $\sigma_{xx}$  by taking the eigenstates  $|\nu\rangle$  of  $\hat{H}$  as the basis vectors:

$$\sigma_{xx} = \frac{\pi e^2 \hbar}{(m_e^*)^2 S} \sum_{\mu, \nu} \delta(\varepsilon_F - \varepsilon_\mu) \delta(\varepsilon_F - \varepsilon_\nu) |\langle \nu | \Pi_x | \mu \rangle|^2 \quad (157)$$

Equation (157) shows that the zero temperature conductivity  $\sigma_{xx}$  is proportional to the number of pairs of states which have exactly the Fermi energy ( $\varepsilon_F = \varepsilon_\mu = \varepsilon_\nu$ ), weighted by the square of the  $\Pi_x$  matrix element between them.

Let us now suppose that we adopt the scheme of broadened Landau levels whose tail states are localized. Then, if the Fermi energy stays within the tail states, the matrix element  $\langle \nu | \Pi_x | \mu \rangle$  will decay (say exponentially) with  $|\vec{\rho}_\mu - \vec{\rho}_\nu|$  which is the distance separating the two localized states  $|\mu\rangle, |\nu\rangle$ . In addition, due to the randomness of  $V_{\text{disorder}}(\vec{\rho})$  the number of states with exactly the same energy  $\varepsilon_\mu = \varepsilon_\nu$  is extremely small. All these facts lead us to the conclusion that  $\sigma_{xx}$  is a very small at  $T = 0$  K. More sophisticated analysis [105] shows that  $\sigma_{xx}$  does indeed vanish when the limit of infinite  $S$  is taken. The previous argument does not hold for extended states of the broadened Landau levels at least because  $\langle \nu | \Pi_x | \mu \rangle \approx 1/\lambda$  for those states. Thus, when the magnetic field is swept and the Fermi energy passes through the consecutive Landau levels,  $\sigma_{xx}$  undergoes oscillations and is zero when  $\varepsilon_F$  is in the localized levels (or in a region where the density of states vanishes) and positive when  $\varepsilon_F$  coincides with the extended states of the spectrum.

Such behavior is analytically derived within the framework of the self-consistent Born approximation. In such a model, one obtains [106]

$$\sigma_{xx} = 0 \quad \text{if} \quad \left| \varepsilon_F - \left( n + \frac{1}{2} \right) \hbar \omega_c - \varepsilon_1 - g^* \mu_B B \sigma_z \right| > \Gamma_n \quad (158)$$

$$\sigma_{xx} = \frac{e^2}{\pi^2 \hbar} \left( n + \frac{1}{2} \right) \times \left\{ 1 - \left[ \frac{\varepsilon_F - \left( n + \frac{1}{2} \right) \hbar \omega_c - \varepsilon_1 - g^* \mu_B B \sigma_z}{\Gamma_n} \right]^2 \right\} \quad (159)$$

elsewhere. Here  $2\Gamma_n$  is the width of the  $n$ th broadened Landau level whose density of states is given by Eq. (42). Despite the incorrect treatment of the tail states, the formula [Eq. (159)] is very helpful in explicitly showing the oscillatory behavior of  $\sigma_{xx}$  upon  $B$ .

These oscillations are well known (Shubnikov–de Haas effect) [79, 104] and have been observed in a variety of bulk materials and heterostructures. They are of quantum origin (being absent in a Drude-type analysis of the magnetoconductivity tensor) and evidence the magnetic field-induced singularities of the density of states.

The  $\sigma_{xx}$  maxima [or equivalently the  $\rho_{xx}$  maxima since  $\sigma_{xx} \ll \sigma_{xy}$  in the first of Eq. (141)] are evenly spaced in  $1/B$ . The fields  $B_{n\sigma_z}$  where  $\sigma_{xx}$  is maximum are such that

$$\varepsilon_F - \varepsilon_1 = \left[ n + \frac{1}{2} + \frac{g^* \mu_B \sigma_z m_e^*}{\hbar e} \right] \frac{\hbar e}{m_e^*} B_{n\sigma_z} \quad (160)$$

This means that a plot of  $B_{n\sigma_z}^{-1}$  versus integer  $n$  should be a straight line (Fig. 19) whose slope  $S_B$  yields direct

**Figure 19.** Oscillatory behavior displayed by  $\rho_{xx}(B)$  upon  $B$  (Shubnikov–de Haas effect) in a GaAs–Ga<sub>0.7</sub>Al<sub>0.3</sub>As heterojunction at  $T = 2$  K (upper panel). The inverses of the magnetic fields  $1/B_n$  corresponding to maxima of  $\rho_{xx}(B)$  are plotted versus consecutive integers  $n$  (lower panel). The slope of the straight line  $B_n^{-1}$  versus  $n$  directly yields the areal concentration of quasi-two-dimensional electrons  $n_c$ .  $\vec{B} \parallel \hat{e}_z$ ,  $\eta = 3.93 \times 10^{11} \text{ cm}^{-2}$ . Academic Press, San Diego, 2001. © 2001, Academic Press.

information on  $\varepsilon_F - \varepsilon_1$  or, equivalently, on the areal carrier concentration  $\eta_c$ , which is present in the heterostructure:

$$\eta_c = \frac{m_e^*}{\pi \hbar^2} (\varepsilon_F - \varepsilon_1) \quad (161)$$

$$S_B = \frac{\hbar e}{m_e^* (\varepsilon_F - \varepsilon_1)} = \frac{e}{\pi \hbar \eta_c} \quad (162)$$

The determinations of  $\eta_c$  by means of the Shubnikov–de Hass effect are very accurate. In addition they do not require any information concerning the sample geometrical details (shape, distance between contacts, etc.).

## 2.6. Magnetic Field Dependence of $\sigma_{xy}$ : The Quantized Hall Effect

In the self-consistent Born approximation, there should exist corrections to the perfect Hall effect ( $\sigma_{xy} = -\eta_c e^2 / m_e^* \omega_c$ ). However, it is not very interesting to discuss these corrections insofar as the most spectacular effects are completely missed by any theory, which neglects the localized states in the tails of the Landau levels.

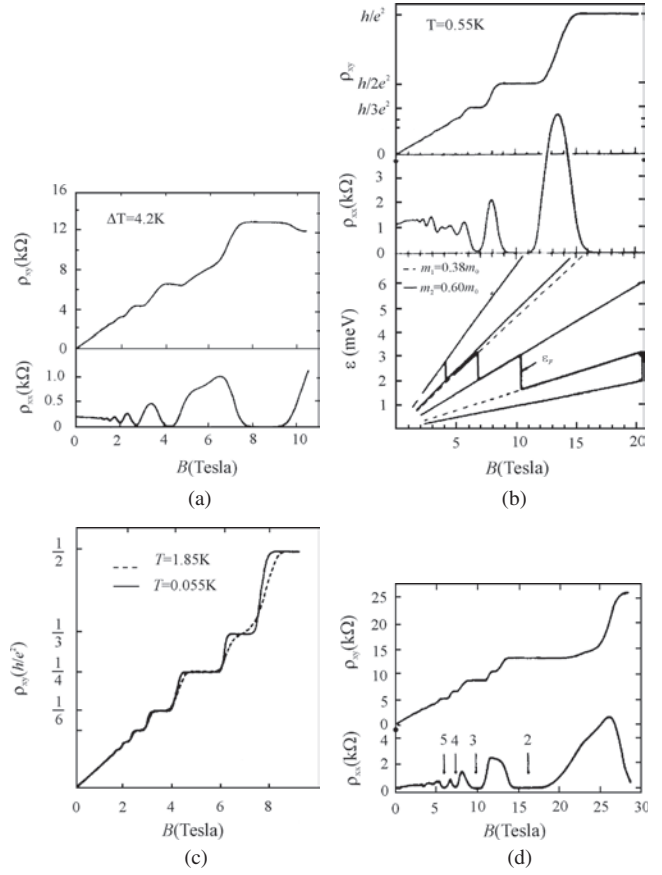

What was experimentally observed is the appearance of plateaus in the  $\rho_{xy}$  curves versus  $B$  (Fig. 20) at low temperatures ( $T \leq 4.2$  K). The  $\rho_{xy}$  plateaus are exactly (within at least one part per million) quantized, being subharmonics of  $\hbar/e^2$ . The so-called quantized Hall effect, discovered by von Klitzing et al. [107] in Si-MOSFETs, can be termed a universal effect. It has also been observed in other two-dimensional systems:  $\text{Ga}_{1-x}\text{Al}_x\text{As-GaAs}$  [108],  $\text{InP-Ga}_{0.47}\text{In}_{0.53}\text{As}$  [109],  $\text{AlSb-InAs}$  [110],  $\text{GaSb-InAs}$  [111]. Its occurrence is independent of the band structure of the host materials: the quantized Hall effect can be observed when the carriers are electrons belonging to a single conduction band ( $\text{Ga}_{1-x}\text{Al}_x\text{As-GaAs}$ ) [108] or to a multivalley conduction band (Si-MOSFET) [107]. It is also observed when the carriers are holes belonging to a degenerate valence band ( $\text{Ga}_{1-x}\text{Al}_x\text{As-GaAs}$ ) [112] and even when there is a mixed conduction ( $\text{GaSb-InAs}$ ) [111].

The width  $\Delta B$  of a given  $\rho_{xy}$  plateau increases as the temperature decreases, reaching an amplitude which is close to the maximum one at very low  $T$  (milli-Kelvin range) [113]. It appears established that  $\rho_{xy}$  develops plateaus when the Fermi level coincides with the localized states of the broadened Landau levels. In fact, in the plateau regimes for  $\rho_{xy}$ ,  $\rho_{xx}$  (and  $\sigma_{xx}$ ) are almost zero. The deviation from the zero resistance state exponentially decreases as temperature decreases. Such a feature evidences a hopping type of transport along the electric field. The details of the hopping processes remain uncertain: the hopping laws

$$\sigma_{xx}(T) \approx \exp \left[ - \left( \frac{T_0}{T} \right)^\alpha \right] \quad (163)$$

fit the data reasonably well but the exponent  $\alpha$  is sample dependent [111, 114, 115]. Perhaps the disorder potential responsible for the existence of localized states is markedly different in different types of heterostructures.

That  $\sigma_{xy}$  could be exactly quantized in units of a fundamental constant  $e^2/h$  irrespective of the band structure, defects, etc. clearly called for a theoretical explanation

**Figure 20.** The quantized Hall effect in III-V heterostructures. The  $\rho_{xy}$  curves plotted versus  $B$  are shown for: (a)  $n\text{-Ga}_{1-x}\text{Al}_x\text{As-GaAs}$ , (b)  $p\text{-Ga}_{1-x}\text{Al}_x\text{As-GaAs}$ , (c)  $p\text{-Ga}_{1-x}\text{Al}_x\text{As-GaAs}$ , and  $n\text{-GaSb-InAs-GaSb}$ . which would go beyond the usual perturbative approaches of the magnetoconductivity tensor and which would exploit the genuine characteristic of two-dimensional magnetotransport, which is the existence of nonconducting states separating conducting ones.

It was Aoki and Ando [116] and Prange [117] who first pointed out that localized levels do not contribute to  $\sigma_{xy}$  and that, moreover, delocalized states, in the presence of localized ones, conduct more efficiently, thus ensuring the pinning of  $\sigma_{xy}$  to a multiple of  $e^2/h$ . The theoretical breakthrough was made by Laughlin [118] who showed that the gauge invariance of the electromagnetism implies the quantization of  $\sigma_{xy}$ , at  $T = 0$  K, provided that the Fermi level sits in the localized levels ( $\sigma_{xx} = 0$ ). For a detailed discussion of the theoretical aspects of the quantized Hall effect, see [119].

There is no available theory of the quantized Hall effect at finite temperature. Such a theory is, however, very desirable in order to ascertain the magnitude and temperature dependence of the corrections to the  $T = 0$  K value, and thus the accuracy of new resistance standards based on the quantized Hall effect.

### 2.6.1. Fractionally Quantized Hall Effect

When the Fermi level has passed the  $0^-$  Landau level, nothing is expected to occur. A wealth of extra features was in fact detected for fractional occupancies of the remaining  $0^+$  sublevel (Fig. 21) [120, 121]. These features are only seen in samples with very high zero-field mobilities. Like the “normal” quantized Hall effect, the fractionally quantized Hall effect does not depend on the band structure of the host materials. It has been observed in both electrons [120–122] and holes [123] in quasi-two-dimensional systems. Of the fractional  $p/q$  defined by

$$\rho_{xy} = \frac{q}{p} \frac{h}{e^2} \quad (164)$$

only those with odd denominators have been unambiguously observed. The fractionally quantized Hall effect has been explained by Laughlin [124, 125] in terms of a condensation of the electron (or hole) system into a microscopic collective ground state due to electron–electron (or hole–hole) interaction. This ground state is separated from the excited one by  $\approx 0.03e^2/\lambda$ , where  $\lambda$  is the magnetic length defined in Eq. (22). That a repulsive interaction between carriers may give rise to a condensation is intimately linked to the quasi-two-dimensionality of the electron motion. In a bulk material two such electrons can never form a bound state, whereas the two-dimensional motion prevents the escape of the two electrons at infinite distance from each other. Laughlin’s wavefunction of the condensed ground state has been generalized by Halperin [126]. The exact microscopic nature of the ground state is still disputed [127].

### 2.6.2. Cyclotron Resonance

As can be shown, the frequency-dependent magnetoconductivity tensor  $\sigma_{\alpha\beta}(\omega)$  (which describes the linear response of the electron gas to a periodically varying electric field)

**Figure 21.** Fractionally quantized Hall effect in a  $n\text{-Ga}_{1-x}\text{Al}_x\text{As-GaAs}$  single heterojunction. The plateaus labeled  $2/3$  and  $1/3$  take place when the fractional occupation of the last ( $0^+$ ) Landau level is equal to  $2/3$  and  $1/3$  respectively.  $\eta = 1.48 \times 10^{11} \text{ cm}^{-2}$ . Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

exhibits singularities at  $\omega = \omega_c$ . Let us work in the Drude model (classical description) and assume that

$$\vec{E}(\vec{r}, t) = E \hat{e}_x \cos \omega t \quad (165)$$

The equation of motion of the complex velocity

$$\xi = v_x + i v_y \quad (166)$$

is

$$\frac{d\xi}{dt} = -\frac{\xi}{\tau} + i \omega_c \xi - \frac{eE}{m_e^*} \cos \omega t \quad (167)$$

where a viscous friction force  $-m_e^* v/\tau$  accounts for the scattering mechanisms. In the permanent regime,  $\xi$  oscillates at the frequency  $\omega$  and the  $\hat{e}_x$  component of the areal current density  $\vec{j} = -\eta_e e \vec{v}$  is found to behave like

$$j_x = \frac{\eta_e e^2 \tau}{2m_e^*} E \left\{ \frac{\cos \omega t + \tau(\omega - \omega_c) \sin \omega t}{1 + (\omega - \omega_c)^2 \tau^2} + \frac{\cos \omega t + \tau(\omega + \omega_c) \sin \omega t}{1 + (\omega + \omega_c)^2 \tau^2} \right\} \quad (168)$$

Over a period  $2\pi/\omega$ , the average power taken to the electric field is

$$\langle P \rangle = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} j_x E \cos \omega t dt \quad (169)$$

or

$$\langle P \rangle = \frac{\eta_e e^2 \tau}{4m_e^*} E^2 \left\{ \frac{1}{1 + (\omega - \omega_c)^2 \tau^2} + \frac{1}{1 + (\omega + \omega_c)^2 \tau^2} \right\} \quad (170)$$

There are two contributions to  $\langle P \rangle$ . The first one presents a resonance at  $\omega = \omega_c$ , while the second one is a decreasing function of  $\omega_c$  or  $\omega$ . The resonant term arises from the  $\exp(+i\omega t)/2$  part of the electric field. Indeed, the linear vibration [Eq. (165)] can be rewritten as the sum of two clockwise and counterclockwise circular vibrations:

$$E(t) = \begin{cases} E \cos \omega t \\ 0 \end{cases} = \begin{cases} \frac{1}{2} E \cos \omega t \\ \frac{1}{2} E \sin \omega t \end{cases} + \begin{cases} \frac{1}{2} E \cos(-\omega) t \\ \frac{1}{2} E \sin(-\omega) t \end{cases} \quad (171)$$

The first kind of circular vibration is, for  $\omega = \omega_c$ , constantly in phase with the electron motion. As a result, it transfers a finite amount of energy to the electron during a cyclotron period. On the other hand, the second type of circular vibration partly accelerates and partly decelerates the electron and, on average, does not transfer energy to the electron. Note that, ultimately, the carrier does not store the electromagnetic energy. Instead, this energy is given up to the lattice via the viscous friction force. In the limit  $\tau \rightarrow \infty$ ,  $\langle P \rangle$  would be zero unless  $\omega = \omega_c$ . Figure 22 shows a plot of  $\langle P \rangle$  versus  $\omega_c/\omega$  for three values of  $\omega\tau$ . Two features are remarkable:

- (i)  $\langle P \rangle$  displays an asymmetric lineshape at low  $\omega\tau$  and a rather symmetric one at large  $\omega\tau$ .
- (ii)  $\langle P \rangle$  gets narrower for larger  $\omega\tau$ .

**Figure 22.** The power absorbed by a classical electron gas from an electromagnetic wave (angular frequency  $\omega$ ), averaged over a period of the cyclotron motion, is plotted versus the dimensionless ratio  $\omega_c/\omega$  for  $\omega\tau = 2.1$  (1), 4.1 (2), 10.1 (3), respectively. Suppose we consider a heterostructure with a dc mobility of  $10^4$  cm<sup>2</sup>/V s. The condition  $\omega_c\tau \geq 1$ , which ensures that the electron has completed a revolution around  $\vec{B}$  without being scattered, is fulfilled as soon as  $B \geq 1$  Tesla. The cyclotron resonance absorption  $\omega = \omega_c$  is observed in the far infrared or millimeter parts of the electromagnetic spectrum for the actual masses of III–V heterostructures. Two experimental techniques are used: either sweep the magnetic field while keeping  $\omega$  fixed or work at fixed  $B$  by sweeping the frequency  $\omega$ . The first technique requires the use of far-infrared lasers or carcinotrons as monochromatic sources and a magnet to produce the field. It is more practical than the second one, which requires the use of Fourier interferometers combined with a magnet. By reporting the photon energies  $\hbar\omega_n$  versus the observed resonance fields  $B_n$  on a  $(B, \hbar\omega)$  diagram one gets a straight line (for parabolic band structures) whose slope  $\hbar e/m_e^*$  yields a very precise determination of the carrier effective mass  $m_e^*$ .

It is clear that the Drude model cannot describe very accurately all the experimental observations in quasi-two-dimensional electron gases. In particular, the quantity  $\tau$ , which accounts for the scattering effects, has, in practice, no reason to be  $\omega$ - and  $B$ -independent as postulated in the Drude model.

A better model of the cyclotron resonance absorption has been derived by Ando and is based on the microscopic calculation of  $\sigma_{\alpha\beta}(\omega)$  within the framework of the self-consistent Born approximation [128]. This model predicts resonance absorptions of the electromagnetic wave, not only at  $\omega = \omega_c$  but also at the harmonics  $\omega = n\omega_c$ . In addition, when the width  $\Delta B$  at half maximum of the main cyclotron resonance line ( $\langle P \rangle$  versus  $B$  at fixed  $\omega$ ) is large enough (i.e., when the dc mobility is not too high) to allow the Fermi level to be crossed by several Landau levels (i.e., when  $\eta_e$

is large enough), the cyclotron resonance lineshape is calculated to exhibit extra oscillations which are  $\omega$ -independent. These Ando oscillations are of the Shubnikov–de Hass type. They have been observed in Si-MOS structures [129], as well as in modulation-doped Ga<sub>1-x</sub>Al<sub>x</sub>As–GaAs heterostructures [130].

Apart from the Si-MOSFET’s the most complete study of the cyclotron absorption has been performed in Ga<sub>1-x</sub>Al<sub>x</sub>As–GaAs heterostructures [130–133]. The first output of these studies is the effective mass of the carrier in the GaAs channel. It has been found that this mass is slightly enhanced over the band edge conduction mass of bulk GaAs ( $0.067m_0$ ). The mass enhancement is, however, modest (few percent) and is in general attributed to the weak nonparabolicity of the GaAs conduction band. It has not yet been proved that part of the enhancement does not originate from the matching conditions for the wavefunction and its derivative at the interface between GaAs and Ga<sub>1-x</sub>Al<sub>x</sub>As.

The most striking results of cyclotron resonance experiments pertain to the cyclotron resonance linewidth and lineshape. If interference effects are carefully excluded from the experiments, the lineshape of the cyclotron absorption is rather symmetric in Ga<sub>1-x</sub>Al<sub>x</sub>As–GaAs heterostructures. For heterostructures with modest mobilities ( $\leq 10^5$  cm<sup>2</sup>/V s) the width at half maximum of the absorption curves follows the predictions of Ando’s model [128]. In high mobility heterostructures it has been shown [133] that the cyclotron resonance linewidth  $\Delta B$  plotted versus the resonance field displays oscillations, whereas Ando’s model (at least with pointlike scatterers) would rather predict a smooth increase of  $\Delta B$ . The carriers have tentatively correlated such oscillations with the oscillations of the screening of the scattering potentials.

In fact, if the resonance field corresponds to a situation where the Fermi level stays in the localized levels of a broadened Landau level or in the gap separating two such levels, the screening is inefficient, since the heterostructure is, for that particular field, an insulator. If, on the other hand, the resonance field is such that the Fermi level coincides with the extended states of a Landau level, the screening effects are very pronounced due to the large polarizability of the electron gas for that particular configuration. When the screening effects are weak, both the damping effects and the cyclotron resonance linewidth are large and vice versa.

When the host materials of the heterostructure are markedly nonparabolic (e.g., GaSb–InAs [134], InSb MOS structures [135]) many subbands are often populated (both effects arise from the smallness of the effective mass). These subbands have different cyclotron resonance effective masses and the ground subband displays the heavier mass. Thus, the cyclotron resonance absorption shows structures which can be associated with the cyclotron resonance absorption of each individual subband.

## 2.7. Magnetoconductivity of Quantum Wires with Elastic and Inelastic Scattering

In this section a Boltzmann equation is used to determine the magnetoconductivity of quantum wires, following Bruus et al. [136]. The presence of a confining potential in addition

to the magnetic field removes the degeneracy of the Landau levels and allows one to associate a group velocity with each single particle state. The distribution function describing the occupation of these single particle states satisfies a Boltzmann equation, which may be solved exactly in the case of impurity scattering. In the case where the electrons scatter against both phonons and impurities the integral equation for the distribution function is solved numerically, and in certain limits analytically, and is determined by the conductivity as a function of temperature and magnetic field. The magnetoconductivity exhibits a maximum at a temperature which depends on the relative strength of the impurity and electron–phonon scattering and shows oscillations when the Fermi energy or the magnetic field is varied.

The suppression of scattering between edge states, due to the presence of the magnetic field, was discussed by several authors [137–140]. The effects of impurity and boundary scattering on the Hall effect in quantum wires were treated by Akera and Ando [141] starting from a Boltzmann equation. The Kubo method [142] has been used for considering the effect of the coupling to optical phonons [143, 144] and the influence of impurity scattering [145] on the magnetotransport through quantum wires. Momentum and energy balance equations have been derived [146, 147] for a quasi-one-dimensional gas of electrons in a magnetic field. Other authors [148] have used the Keldysh method to discuss magnetotransport in the presence of impurity scattering, while the formalism due to Landauer [149] and Büttiker [150] was employed in [151] to treat the influence of disorder on the Hall effect in quantum wires.

Transport in strong magnetic fields has traditionally been treated within the Kubo formalism, since this allows one to fully take into account the quantization of the motion of an electron in a magnetic field. The resulting diagrammatic expansion of the conductivity requires the consideration of both self-energy effects and vertex corrections. It was demonstrated in [145] that it is essential to include vertex corrections in order to determine the effect of impurity scattering on the magnetoconductivity of a quantum wire. The physical reason for this is that only backscattering from the impurities contributes to the resistivity.

In this section a Boltzmann equation to determine the transport properties of quantum wires formed by additional confinement of the two-dimensional electron gas of, for example, a GaAs–GaAlAs heterojunction, is used. The presence of a confining potential in addition to the magnetic field removes the degeneracy of the Landau levels and allows one to associate a group velocity with each single particle state. The distribution function describing the occupation of these single particle states satisfies a Boltzmann equation, which we solve exactly in the case of impurity scattering. The resulting magnetoconductivity agrees with that obtained in [145] within the Kubo approach. In the case of electron–phonon scattering we solve numerically—and in certain cases analytically—the integral equation for the distribution function. The conductivity is determined as a function of temperature and magnetic field in the case when both impurities and phonons contribute to the scattering of the electrons.

Apart from its simplicity, the use of the Boltzmann equation has the additional advantage that it allows one to go

beyond linear response theory in a straightforward manner. Although this section treats in detail only the regime of linear response, the approach may readily be generalized to take nonlinear effects into account.

Since conduction in a quantum wire involves current transport in one dimension it is necessary to consider the role of localization. This was done in [152], where it was shown that weak localization in quantum wires is destroyed in a magnetic field greater than a critical value  $B_c$  where the critical magnetic field  $B_c$  apart from numerical factors is given by  $B_c \approx h\ell/eL_\phi W^2$ . Here  $\ell$  is the elastic scattering length,  $W$  is the width of the quantum wire, while  $L_\phi$  is the phase coherence length. In what follows we shall assume that the magnetic field is sufficiently strong that localization effects are always negligible. The transport properties of the quantum wires may then be obtained from a Boltzmann equation, in which the quantizing effect of the magnetic field is incorporated in the manner described. We shall also disregard Coulomb-blockade effects, which have been shown to be of importance in some systems [153].

### 2.7.1. Single Particle Energy Spectrum

We consider an electron moving in the  $xy$  plane under the influence of a constant magnetic field in the  $z$  direction. In addition a parabolic confinement potential limits its motion in the  $y$  direction whereby a wire is formed in the  $x$  direction. The Hamiltonian for such an electron is

$$\hat{H} = \frac{1}{2m^*} (\hat{p} + e\vec{A})^2 + \frac{1}{2}Ky^2 \quad (172)$$

with  $m^*$  being the effective (band) mass of the electron. For simplicity we have neglected the Zeeman splitting, since we shall be mainly concerned with quantum wires in GaAs based structures, where the Zeeman energy is a few percent of the cyclotron energy  $\hbar\omega_c$  to be defined. The electron spin therefore only enters as a factor of 2 in the expression for the current density. In the  $x$  direction we impose periodic boundary conditions, and for the vector potential  $\vec{A}$  we use the Landau gauge  $\vec{A} = B(-y, 0, 0)$ . Consequently the eigenfunctions of the Hamiltonian are products of plane waves and harmonic-oscillator functions involving Hermite polynomials  $H_n$ ,

$$\begin{aligned} \psi_{nk} = & \frac{1}{\sqrt{L}} \exp(ikx) \frac{1}{(\sqrt{\pi}2^n n! \ell_h)^{1/2}} H_n \left( \frac{y - y_k}{\ell_h} \right) \\ & \times \exp \left( -\frac{(y - y_k)^2}{2\ell_h^2} \right) \end{aligned} \quad (173)$$

with  $L$  being the length of the quantum wire. The center coordinate  $y_k$  and the characteristic length  $\ell_h$  of the harmonic oscillator are specified below. The wavefunction in the  $z$  direction is taken to be a  $\delta$  function.

In the case where  $K$  is zero and only the magnetic field is present the natural system of units is based on the cyclotron frequency  $\omega_c$  and the magnetic length  $\ell_c$ , given by

$$\omega_c = \frac{eB}{m^*} \quad \ell_c^2 = \frac{\hbar}{eB} \quad (174)$$

When  $K$  is different from zero, we define the quantity  $\gamma$ , which describes the relative strength of the confinement potential, by

$$\gamma \equiv \frac{K}{m_e^* \omega_c^2} \quad (175)$$

and the natural units are now based on the hybrid frequency  $\omega_h$  and the hybrid characteristic length  $\ell_h$  given by

$$\omega_h = (1 + \gamma)^{1/2} \omega_c \quad \ell_h = (1 + \gamma)^{-1/4} \ell_c \quad (176)$$

By inserting the function (173) in the Schrödinger equation

$$\hat{H} \psi_{n\bar{k}} = \varepsilon_{n\bar{k}} \psi_{n\bar{k}} \quad (177)$$

one finds that (177) is satisfied, provided that

$$\varepsilon_{n\bar{k}} = \hbar \omega_h \left( n + \frac{1}{2} \right) + \frac{\hbar^2 k^2}{2m^*} \quad n = 0, 1, 2, \dots \quad (178)$$

where  $m^*$  is a renormalized mass defined by

$$m^* = \frac{1 + \gamma}{\gamma} m_e^* \quad (179)$$

The center of the harmonic oscillator wavefunctions is given by

$$y_k = \frac{\omega_c \hbar k}{m_e^* \omega_h^2} = (1 + \gamma)^{-1/2} k \ell_h^2 \quad (180)$$

The confinement potential  $Ky^2/2$  removes the degeneracy of the Landau levels through the  $k$  dependence exhibited in Eq. (178). Note that the dispersion relation is that of a free particle with a renormalized mass  $m^*$ . When the strength of the confinement potential goes to zero, the renormalized mass  $m^*$  becomes infinite (corresponding to degenerate Landau levels), while in the opposite limit ( $\gamma \rightarrow \infty$ ), the renormalized mass becomes equal to the effective mass  $m_e^*$ .

In the following we shall describe conduction through the quantum wire on the basis of the Boltzmann equation for the distribution function of the excitations with energy  $\varepsilon_{nk}$ . The group velocity  $v$  of the excitations is seen to be

$$v_{nk} = \frac{1}{\hbar} \frac{\partial \varepsilon_{nk}}{\partial k} = \frac{\hbar k}{m} \quad (181)$$

If the confinement potential is not simply parabolic, the relation between  $v_{nk}$  and  $k$  becomes more complicated than Eq. (181), but the method described in the following is still applicable, provided one modifies the group velocity accordingly and incorporates the new wavefunctions into the matrix elements appearing in the collision probability.

## 2.7.2. Boltzmann Equation

We consider the distribution function  $f_{nk}$  for the excitations specified by the energy  $\varepsilon_{nk}$ , with group velocity  $v_{nk} = \hbar k/m$ . Unlike the usual semiclassical description of transport in a magnetic field, the magnetic field has here been taken into account from the very beginning, in defining the excitations with dispersion relation (178). The effect of an electric field  $E_x$  in the  $x$  direction is, however, included in the usual manner through the acceleration equation

$$\hbar \dot{k} = -eE_x \quad (182)$$

The Boltzmann equation [154] is

$$\frac{\partial f_{nk}}{\partial t} + \dot{k} \frac{\partial f_{nk}}{\partial k} = \left( \frac{\partial f_{nk}}{\partial t} \right)_{\text{coll}} \quad (183)$$

where the right-hand side of the equation contains the collision term. Since we are interested in the linear response to a static electric field, the time derivative  $\partial f/\partial t$  is equal to zero, while  $f_{nk}$  in the second term on the left-hand side may be replaced by the equilibrium function  $f_{nk}^0$ . Using Eq. (182) the Boltzmann equation then becomes an inhomogeneous integral equation of the form

$$\frac{eE_x}{k_B T} v_{nk} f_{nk}^0 (1 - f_{nk}^0) = \left( \frac{\partial f_{nk}}{\partial t} \right)_{\text{coll}} \quad (184)$$

with the integral term on the right-hand side the collision term to be specified.

Before we consider specific scattering mechanisms, let us write the conductivity  $\sigma$  in terms of the distribution function. We define  $\sigma$  as  $\sigma \equiv j_x/E_x$ ,  $j_x$  being the current density in the  $x$  direction. In terms of the two-dimensional resistivity tensors  $\rho$  we get  $\sigma = 1/\rho_{xx}$  because  $j_y = 0$ . However, in the presence of the magnetic field a current in the  $x$  direction will also induce an electric field in the  $y$  direction. For  $j_x$  we have

$$j_x = -2e \sum_n \int_{-\infty}^{\infty} \frac{dk}{2\pi} v_{nk} f_{nk} \quad (185)$$

We shall introduce the deviation function  $\psi_{nk}$  by the definition

$$f_{nk} \equiv f_{nk}^0 + f_{nk}^0 (1 - f_{nk}^0) \psi_{nk} \quad (186)$$

Then the current density becomes

$$j_x = -2e \sum_n \int_{-\infty}^{\infty} \frac{dk}{2\pi} v_{nk} f_{nk}^0 (1 - f_{nk}^0) \psi_{nk} \quad (187)$$

Since we shall be dealing with distribution functions that change sign upon  $k \rightarrow -k$ , we may restrict  $k$  to positive values and work instead with the distribution function as a function of energy:  $\psi_n(\varepsilon)$ . In this notation  $k$  is then a function of energy, and we denote the  $k$  value, which solves  $\varepsilon = \varepsilon_{nk}$  by  $k_n(\varepsilon)$ . Furthermore, by introducing the function  $\phi_n$  defined by

$$\phi_n \equiv \frac{k_B T}{eE_x} \psi_n \quad (188)$$

we may express the conductivity as

$$\sigma \equiv \frac{j_x}{E_x} = \frac{2e^2}{h} 2 \sum_n \int_0^\infty d\varepsilon \left( -\frac{\partial f^0(\varepsilon)}{\partial \varepsilon} \right) \phi_n(\varepsilon) \quad (189)$$

since  $dk = d\varepsilon/\hbar v$ . Note that  $\phi$  has dimension of length. The chemical potential entering the equilibrium distribution function  $f^0$  will be assumed to be independent of temperature, equal to  $\varepsilon_F$  since the quantum wire under typical experimental conditions is in contact with a large reservoir of electrons.

The Boltzmann equation considered in this section is an inhomogeneous integral equation of the form

$$X_{nk} = H\psi_{nk} \quad (190)$$

where

$$X_{nk} = -\frac{eE_x}{k_B T} v_{nk} f_{nk}^0 (1 - f_{nk}^0) \quad (191)$$

while the integral operator  $H$  is defined by

$$\left( \frac{\partial f_{nk}}{\partial t} \right)_{\text{coll}} = -H\psi_{nk} \quad (192)$$

with

$$H\psi_{nk} = \sum_{n'} \int_{-\infty}^\infty \frac{L}{2\pi} dk' K_{nn'}(k, k') (\psi_{nk} - \psi_{n'k'}) \quad (193)$$

Here  $K$  is an integral kernel specified in the previous section.

By introducing the scalar product  $(A, B)$  through the definition

$$(A, B) = \sum_n \int_{-\infty}^\infty \frac{dk}{2\pi} A_{nk} B_{nk} \quad (194)$$

the conductivity may be written as

$$\sigma = \frac{2k_B T}{E_x^2} (X, \psi) \quad (195)$$

In cases where we cannot solve explicitly for  $\psi$ , it is useful to employ a variational principle which yields a lower bound on  $\sigma$  by virtue of the Schwarz inequality

$$(\psi, H\psi)(U, HU) \geq (U, H\psi)^2 \quad (196)$$

where  $U$  is an arbitrary trial function. Since  $H\psi = X$ , this gives a lower bound on the conductivity

$$\sigma \geq \frac{2k_B T}{E_x^2} \frac{(X, U)^2}{(U, HU)} \quad (197)$$

This lower bound will be used to determine the low-temperature conductivity when the scattering is due to acoustic phonons, both with and without impurities, and the resulting analytic expressions are compared to the results of the numerical solution of the integral equation.

We shall always write our calculated values of the conductivity, as limited by the various scattering mechanisms to be considered in subsequent sections, in the form

$$\sigma = \frac{2e^2}{h} l \quad (198)$$

where  $l$  has the dimension of a length. As may be expected, in the presence of impurity scattering  $l$  tends to a finite value as  $T$  tends to zero, while it increases exponentially in the absence of impurity scattering, when the electrons are scattered only by phonons.

### 2.7.3. Impurity Scattering

In this section we consider the case of elastic impurity scattering. The collision integral is

$$\left( \frac{\partial f_{nk}}{\partial t} \right)_{\text{coll}} = -\sum_{n'} \int_{-\infty}^\infty \frac{L}{2\pi} dk' W_{nn'}(k, k') (f_{nk} - f_{n'k'}) \quad (199)$$

since the scattering is elastic. According to the golden rule we have

$$W_{nn'}(k, k') = \frac{2\pi}{\hbar} |\langle nk|V|n'k' \rangle|^2 \delta(\varepsilon_{nk} - \varepsilon_{n'k'}) \quad (200)$$

The square of the matrix element  $\langle nk|V|n'k' \rangle$  for scattering from impurities may be written as

$$|\langle nk|V|n'k' \rangle|^2 = \int d^2r \int d^2r' V(\vec{r})V(\vec{r}') \langle nk|\vec{r} \rangle \langle \vec{r}|n'k' \rangle \times \langle n'k'|\vec{r}' \rangle \langle \vec{r}'|nk \rangle \quad (201)$$

We shall perform an ensemble average over the distribution of impurities, corresponding to the replacement

$$V(\vec{r})V(\vec{r}') \rightarrow \langle V(\vec{r})V(\vec{r}') \rangle = F(\vec{r}, \vec{r}') \quad (202)$$

When the impurity potential may be approximated by a  $\delta$  function in space, the function  $F$  is proportional to the  $\delta$  function  $\delta(\vec{r} - \vec{r}')$ , corresponding to a “white-noise” model

$$F(\vec{r}, \vec{r}') = A^2 n_{\text{imp}} \delta(\vec{r} - \vec{r}') \quad (203)$$

Here we have introduced the number or impurities per unit area  $n_{\text{imp}}$  together with the constant  $A$ , which denotes the magnitude of the matrix element for scattering from a single impurity. The dimension of  $A$  is that of energy times area.

In order to distinguish between states of equal energy but opposite sign of  $k$ , we introduce the “branch index”  $s = \pm 1$ ,

$$k_{ns}(\varepsilon) \equiv sk_n(\varepsilon) = s \sqrt{\frac{2m}{\hbar^2} \left[ \varepsilon - \left( n + \frac{1}{2} \right) \hbar \omega_h \right]} \quad (204)$$

provided

$$\left( n + \frac{1}{2} \right) \hbar \omega_h \leq \varepsilon \quad (205)$$

The density of states at the Fermi energy  $\varepsilon_F$  is inversely proportional to the  $s$ -independent Fermi velocity  $v_n(\varepsilon_F) = \hbar k_n(\varepsilon)/m$ . Finally, since  $\phi_{ns}$  is odd in  $k$  and hence changes

sign with  $s$ , we may write  $\phi_{ns} = s\phi_n$ . The problem then becomes that of solving the matrix equation

$$s = \sum_{n's'} B_{ns}^{n's'} (s\phi_n - s'\phi_{n'}) \quad (206)$$

and calculating the conductivity according to Eq. (189). The matrix  $B_{ns}^{n's'}$  is positive and symmetric with respect to interchange of  $ns$  with  $n's'$ . Its elements are

$$B_{ns}^{n's'} = \frac{1}{\hbar^2} A^2 n_{\text{imp}} \frac{1}{v_n v_{n'}} \frac{1}{\ell_h \sqrt{2\pi}} F_{ns}^{n's'} \quad (207)$$

Here we have defined the following dimensionless quantities:

$$F_{ns}^{n's'} = \sqrt{2\pi} \ell_h \int_{-\infty}^{\infty} dy |u_n(y - y_{k_{ns}})|^2 |u_{n'}(y - y_{k_{n's'}})|^2 \quad (208)$$

where  $u_n(y)$  is the normalized  $y$ -dependent part of the wavefunction (173). The overlap integral  $F_{ns}^{n's'}$  has the form  $P_{ns}^{n's'}(z) \exp(-z)$ , where  $P_{ns}^{n's'}(z)$  is a polynomial in  $z$ , and where  $z = (y_{k_{ns}} - y_{k_{n's'}})^2 / 2l_h^2$ .

In Figure 23 we show the result of solving the matrix Eq. (206) and calculating the conductivity according to Eq. (189) as a function of the Fermi energy  $\varepsilon_F$ , for different choices of the parameter  $\gamma$  determining the strength of the confining potential. As can be seen in the figure the conductivity rises quickly as the Fermi level increases above

**Figure 23.** The conductivity for a quantum well wire with impurity scattering plotted versus the Fermi level for three different choices of the confinement potential corresponding to  $\gamma = 1, 0.5$  and  $0.25$ . The dashed line is the  $T = 0$  result and the solid lines correspond to  $k_B T = 0.05 \hbar \omega_h$ . The magnetic field is 9 T. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

$\hbar \omega_h / 2$ . This is due to the increasing separation between the two edge states, expressed by the overlap integral  $F_{0-}^{0+}$  of Eq. (208) which leads to the exponential factor in Eq. (209) below. When  $\varepsilon_F$  hits the next Landau level, the conductivity starts to decrease because a channel for backscattering is opened (i.e., the  $n = 0$  edge state can scatter to the opposite edge through the  $n = 1$  edge states). However, when the  $n = 1$  edge states become decoupled, the conductivity starts to increase again. This qualitative behavior is repeated each time a new Landau level crosses the Fermi level. The height of the conductance peak at  $3\hbar \omega_h / 2$  increases strongly with increasing channel width. At finite temperature these features are somewhat smeared, as evidenced by the figure, but still clearly visible.

Our calculation is relevant for the case where the scattering between different channels is so strong that the Boltzmann picture is valid; in other words, the calculated mean free path must be considerably shorter than the length of the wire. In the high magnetic field limit this means that the wire may not be so broad that the edge states become decoupled. Thus in practice we are dealing with wires only a few times  $l_h$  wide.

When  $\hbar \omega_h / 2 \leq \varepsilon_F \leq 3\hbar \omega_h / 2$  only the lowest Landau level is involved, corresponding to  $n = n' = 0$  in Eq. (206). Then the solution becomes particularly simple,  $\phi_0 = 1/2 B_{0+}^{0-}$ . By means of the Sommerfeld expansion we obtain the low-temperature expression for the conductivity  $\sigma = 2e^2/h B_{0+}^{0-}$ ,

$$\sigma = \frac{2e^2}{h} l_h \sqrt{2\pi} \frac{\hbar^2}{A^2 n_{\text{imp}}} \frac{\hbar^2 k_F^2}{m^{*2}} \exp\left(\frac{2k_F^2 l_h^2}{1 + \gamma}\right) \times \left\{ 1 + \frac{8\pi^2}{3\gamma^2} \left(1 + \frac{1 + \gamma}{k_F^2 l_h^2}\right) \left(\frac{k_B T}{\hbar \omega_h}\right)^2 \right\} \quad (209)$$

where  $k_F = k_{0+}(\varepsilon_F)$  is the Fermi momentum. The conductivity increases with temperature because electrons are excited into states, which have a smaller overlap with the states at the opposite branch. Consequently the electrons have a smaller backscattering probability. The result (209) is valid only to lowest order in  $k_B T / \hbar \omega_h$ . In obtaining our numerical results we do not use the Sommerfeld expansion but calculate directly the integral over energy according to expression (189).

As an illustration of the matrix inversion involved in the solution of the Boltzmann equation we shall also give the expression for the zero-temperature conductivity in the case when  $3\hbar \omega_h / 2 \leq \varepsilon_F \leq 5\hbar \omega_h / 2$ . By utilizing the symmetry  $\phi_{n+} = -\phi_{n-}$  the  $4 \times 4$  matrix equation becomes a  $2 \times 2$  equation which may readily be solved for  $\phi_{0+}$  and  $\phi_{1+}$ . The resulting conductivity  $\sigma = (2e^2/h) 2(\phi_{0+} + \phi_{1+})$  is at  $T = 0$  K given by

$$\sigma = \frac{2e^2}{h} \frac{2(2B_{0+}^{1+} + B_{1+}^{1-} + B_{0+}^{0-})}{2(B_{0+}^{1+} B_{0+}^{1-} + B_{0+}^{0-} B_{1+}^{1-}) + (B_{0+}^{1+} + B_{0+}^{0-})(B_{0+}^{0-} + B_{1+}^{1-})} \quad (210)$$

The result (210) yields the conductivity at zero temperature, when the Fermi energy  $\varepsilon_F$  satisfies the condition  $3\hbar \omega_h / 2 \leq \varepsilon_F \leq 5\hbar \omega_h / 2$ . The generalization to more Landau levels is straightforward. The  $B$  matrix in Eq. (206) is in general a

$2(n_0 + 1) \times (2n_0 + 1)$  matrix given by Eq. (207), where  $n_0$  is the quantum number associated with the highest occupied Landau level at  $T = 0$  K.

It is convenient to relate the conductivity calculated in the following two sections to the zero-temperature conductivity  $\sigma_{2D}$  associated with motion in two dimensions in the absence of a magnetic field and a confinement potential. The latter is given by

$$\sigma_{2D} = \frac{e^2 n_{2D}}{m_e^*} \tau_{\text{imp}} = e n_{2D} \mu_{\text{imp}} \quad (211)$$

where  $n_{2D}$  is the electron sheet density and  $\mu_{\text{imp}}$  is the zero-field, zero-temperature mobility,

$$\mu_{\text{imp}} = \frac{e \tau_{\text{imp}}}{m_e^*} \quad (212)$$

with

$$\frac{1}{\tau_{\text{imp}}} = \frac{m_e^* A^2 n_{\text{imp}}}{\hbar^3} \quad (213)$$

We shall thus express the calculated conductivity in units of  $(2e^2/h)l_{\text{imp}}$ , where

$$l_{\text{imp}} = \tau_{\text{imp}} \omega_c l_c \quad (214)$$

is a characteristic length which depends on the impurity content as well as the magnetic field.

#### 2.7.4. Electron–Phonon Scattering

Next we turn to the consideration of inelastic processes. The present section treats the case where the electrons are scattered by acoustical phonons due to the combined deformation potential and piezoelectric coupling, while the following section discusses the coupling of electrons to optical phonons.

Before specializing to a particular model let us write the contribution to the collision operator from the scattering against phonons. The phonons are assumed to be in thermal equilibrium. Then the integral operator  $\hat{H}$  is given by the following expression:

$$\begin{aligned} \hat{H} \psi_{nk} &= \frac{2\pi}{\hbar} \sum_{n'} \sum_{k'} \sum_{\vec{q}} |g_{\vec{q}}|^2 f^0(\varepsilon_{nk}) \\ &\times [1 - f^0(\varepsilon_{n'k'})] \delta_{k, k'+q_z} (\psi_{nk} - \psi_{n'k'}) \\ &\times \{ \delta(\varepsilon_{n'k'} - \varepsilon_{nk} + \hbar\omega_q) [1 + N^0(\omega_q)] \\ &+ \delta(\varepsilon_{n'k'} - \varepsilon_{nk} - \hbar\omega_q) N^0(\omega_q) \} \quad (215) \end{aligned}$$

Here  $g_{\vec{q}}$  is the electron–phonon coupling parameter, which will be specified, while  $N^0(\omega_q)$  is the equilibrium phonon distribution. For simplicity we have assumed that the phonon frequencies only depend on the magnitude of  $\vec{q}$ . In Eq. (215) we have explicitly written the factor  $\delta_{k, k'+q_z}$  discussed in Section 2.7.6.

Utilizing the relationship

$$\begin{aligned} f(\varepsilon) [1 - f(\varepsilon \pm \hbar\omega_q)] \\ = [f(\varepsilon) - f(\varepsilon \pm \hbar\omega_q)] [1 + N^0(\pm\omega_q)] \quad (216) \end{aligned}$$

the collision integral (215) can be written as

$$\begin{aligned} \hat{H} \psi_{nk} &= \frac{2\pi}{\hbar} \sum_{n' \vec{q} \sigma} |g_{\vec{q}}|^2 \frac{|f^0(\varepsilon_{nk}) - f^0(\varepsilon_{nk} + \sigma \hbar\omega_q)|}{4 \sinh^2(\hbar\omega_q/2k_B T)} \\ &\times (\psi_{nk} - \psi_{n'k-q_z}) \delta(\varepsilon_{n'k-q_z} - \varepsilon_{nk} - \sigma \hbar\omega_q) \quad (217) \end{aligned}$$

with  $\sigma$  assuming the two values  $+1$  and  $-1$  corresponding to phonon absorption and emission, respectively.

The calculations of  $g_{\vec{q}}$  are based on the standard electron–phonon interaction Hamiltonian, which disregarding umklapp processes takes the form

$$\hat{H}_{ep} = \sqrt{\frac{\hbar}{2V\rho\omega_q}} \sum_{\lambda, \vec{q}} M_{\lambda}(\vec{q}) \hat{\rho}(\vec{q}) (\hat{b}_{\vec{q}} + \hat{b}_{-\vec{q}}^+) \quad (218)$$

where  $\rho$  is the ion mass density,  $V$  is the normalization volume,  $\hat{\rho}(\vec{q})$  is the Fourier component of the electron density operator,  $\hat{b}_{-\vec{q}}^+$  is a phonon creation operator, and  $\lambda$  is the polarization index. The coupling function  $M$  is given by

$$M_{\lambda}(\vec{q}) = -V(\vec{q}) \vec{q} \cdot \vec{e}_{\lambda} \quad (219)$$

$V(\vec{q})$  being the electron–ion potential and  $\vec{e}_{\lambda}$  a unit vector describing the polarization  $\lambda$ . For a detailed treatment of electron–phonon coupling in semiconductors see, for example, [155]. The values of the GaAs parameters used in these calculations are listed in Table 2.

**Coupling to Acoustical Phonons** In GaAs heterostructures at low temperatures the electron–phonon scattering is mainly due to the combined piezoelectric coupling and the deformation potential coupling [100, 156–158]. We briefly sketch how these couplings are derived.

The deformation potential coupling only involves the longitudinal acoustical phonons. The coupling to the transverse acoustical phonons is suppressed by the square of the ratio between the speed of sound and the speed of light. In the long wavelength limit the coupling function  $M^{df}$  for the deformation potential coupling is written as

$$M^{df} = \Xi_{\vec{q}} \quad (220)$$

where  $\Xi$ , known as the deformation potential, is the zero wavevector limit of  $V(\vec{q})$ .

**Table 2.** The GaAs constants used in this section.

Parameter	Symbol	Value
Ion mass density	$\rho$	$5.3 \times 10^3 \text{ kg m}^{-3}$
Longitudinal sound velocity	$c$	$5.2 \times 10^3 \text{ m s}^{-1}$
Transverse sound velocity	$xc$	$3.0 \times 10^3 \text{ m s}^{-1}$
Sound velocity ratio	$x$	0.58
Static dielectric constant	$\kappa_0$	12.8
High-frequency dielectric constant	$\kappa_{\infty}$	10.6
Piezoelectric constant	$h_{14}$	$1.38 \times 10^9 \text{ V m}^{-1}$
Piezoelectric potential	$P$	$5.4 \times 10^{-20} \text{ J}^2 \text{ m}^{-2}$
Deformation potential	$\Xi$	$2.2 \times 10^{-18} \text{ J}$
Effective electron mass	$m_e^*$	$0.067 m_0$
Optical–phonon energy	$\hbar\omega_0$	36 meV

The electron-ion potential  $V$  for the piezoelectric coupling is found from the basic piezoelectric equations [155]. For GaAs (zinc blende structure) the only nonvanishing independent piezoelectric constant is  $h_{14}$  (reduced notation), and the coupling function  $M_\lambda^{pz}$  in this case becomes

$$M_\lambda^{pz} = i2eh_{14}(\hat{q}_x\hat{q}_y\hat{e}_{\lambda,z} + \hat{q}_y\hat{q}_z\hat{e}_{\lambda,x} + \hat{q}_z\hat{q}_x\hat{e}_{\lambda,y}) \quad (221)$$

where  $\hat{q}_i = (\vec{q}/q)_i$ . In the piezoelectric case  $\lambda$  is retained.

It is noted that  $M^{df}$  is real while  $M^{pz}$  is imaginary; thus to second order the two terms do not interfere, and the absolute square of the total coupling function  $M^{ac}$  is given by

$$|M^{ac}|^2 = |M^{df}|^2 + |M^{pz}|^2 \quad (222)$$

To obtain a more tractable form of the piezoelectric coupling we perform angular averages for the longitudinal and the (two) transverse modes separately and then add the terms [155, 159]. While this represents an approximation compared to retaining the full  $\vec{q}$  dependence of the coupling in the collision integral, we expect it to involve only minor quantitative differences. In adding the transverse and longitudinal contribution we must remember the different average sound velocities associated with each of the terms, originating in the factor  $1/\sqrt{\omega_q} = 1/\sqrt{cq}$  in Eq. (218). Expressing the transverse sound velocity as  $x$  times the longitudinal sound velocity we obtain the angular average of the absolute square of the piezoelectric coupling function  $M^{pz}$ ,

$$|M^{pz}|^2 = (eh_{14})^2 \left( \frac{12}{35} + \frac{1}{x} \frac{16}{35} \right) \equiv P \quad (223)$$

where we have introduced the constant  $P$ , and where it is understood that the only sound velocity appearing in the following is the longitudinal one.

The electron-phonon coupling parameter  $g_{\vec{q}}$  introduced in Eq. (215) now becomes

$$|g_{ac}(q)|^2 = \frac{\hbar}{2\rho Vc} \frac{1}{q} (\Xi^2 q^2 + P) |\langle nk | \exp(i\vec{q} \cdot \vec{r}) | n'k' \rangle|^2 \quad (224)$$

The matrix element appearing in this expression is treated in detail in the Section 2.7.6. In writing Eq. (224) we have taken the phonon frequency  $\omega_q$  to be given by

$$\omega_q = cq \quad (225)$$

**Coupling to Acoustical Phonons in the Low-Temperature Limit** In an analytical study of the low-temperature limit we use the variational principle discussed in Section 2.7.2 and choose a trial function given by

$$U = U_{nk} = \text{sgn}(k) \quad (226)$$

Thus  $U$  is 1 on the branches corresponding to  $k$  being positive, while it is  $-1$  on the branches corresponding to  $k$  being negative. This choice will lead to an expression for the conductivity which in the case of a single occupied Landau level and in the limit of low temperature agrees with a numerical solution of the integral equation. This suggests that the trial function is in fact the exact one under these conditions.

First we evaluate the scalar product  $(U, X)$  appearing in the general expression (197) for the lower bound on the conductivity. By changing the integration variable to the energy  $\varepsilon_{nk}$  we get

$$(X, U) = \frac{eE_x}{\hbar\pi} \sum_n f^0(\varepsilon_{n0}) \quad (227)$$

where  $\varepsilon_{n0}$  is the  $k = 0$  value of  $\varepsilon_{nk}$ . Because of the symmetry of the integral operator  $\hat{H}$  given in Eq. (217) the denominator occurring in Eq. (197) becomes

$$(U, HU) = \sum_n \int_{-\infty}^{\infty} \frac{dk}{2\pi} \int_{-\infty}^{\infty} \frac{dk'}{2\pi} \sum_{n'} K_{nn'}(k, k') \times \frac{1}{2} [1 - \text{sgn}(k)\text{sgn}(k')]^2 \quad (228)$$

As was discussed in Section 2.7.6  $k' = k - q_x$ . The occurrence of the factor  $[1 - \text{sgn}(k)\text{sgn}(k - q_x)]$  in the integrand of Eq. (228) implies that the summation over  $q_x$  becomes restricted by  $q_x > k$  for  $k > 0$ , while  $q_x < k$  for  $k < 0$ . Using the symmetry with respect to reversal of all momentum variables we may thus restrict the  $k$  integral to the interval 0 to  $\infty$ , which limits  $q_x$  to the region  $q_x > k$ . If  $\theta$  denotes the angle between  $\vec{q}$  and the  $x$  axis, the integration over  $\theta$  is therefore restricted by

$$\cos \theta > \frac{k}{q} \quad 0 < q < \infty \quad (229)$$

Thus we have to carry out three integrations (over  $q$ ,  $k$ , and  $\cos \theta$ ) as well as two sums (over  $n$  and  $n'$ ).

Let us consider the simplest case, in which  $n = n' = 0$ . If the sound velocity is much less than the Fermi velocity then the energy-conserving  $\delta$  functions are

$$\delta(\varepsilon_{n'k'} - \varepsilon_{nk} \pm \hbar\omega_q) \cong \delta\left(\frac{\hbar^2}{2m^*} (q^2 \cos^2 \theta - 2kq \cos \theta)\right) \quad (230)$$

The  $q$  integral is now restricted to the interval  $q > 2k$ , while  $k/q < \cos \theta < 1$ . This yields, after performing the  $\phi$  integral as shown in Section 2.7.6,

$$(U, \hat{H}U) = \frac{1}{4\pi^3 \hbar^2 c \rho} \int_0^\infty \frac{d\varepsilon}{v^2(\varepsilon)} \int_{2k}^\infty dq (\Xi^2 q^2 + P) \times I_{0,0} \left( q, 2\frac{k}{q} \right) \frac{|f^0(\varepsilon_{nk}) - f^0(\varepsilon_{nk} + \sigma \hbar\omega_q)|}{4 \sinh^2(\hbar\omega_q/2k_B T)} \quad (231)$$

where  $I_{0,0}(q, 2k/q)$  is given by Eq. (255) of Section 2.7.6. We may carry out the final integration over energy by expanding the difference of the Fermi functions in powers of  $\omega_q$ . Since the contribution due to terms involving higher order derivatives of the Fermi function is seen to vanish by the use of partial integration, we obtain

$$(U, \hat{H}U) = \frac{1}{2\pi^3 \hbar^2 c \rho} \int_0^\infty \frac{d\varepsilon}{v^2(\varepsilon)} \left( -\frac{\partial f^0}{\partial \varepsilon} \right) \int_{2k}^\infty dq \times \frac{(\Xi^2 q^2 + P) I_{0,0}(q, 2k/q) \hbar\omega_q}{4 \sinh^2(\hbar\omega_q/2k_B T)} \quad (232)$$

The remaining steps are standard. We assume that the temperature is much less than the Fermi temperature, so that the integral over  $\varepsilon$  yields  $1/v_F^2$ , while  $k$  may be replaced by the Fermi momentum  $k_F$ . Furthermore, we assume that the temperature is small compared to the characteristic temperature  $\Theta$  defined by

$$k_B \Theta = \hbar k_F c \quad (233)$$

Then we obtain

$$(U, \hat{H}U) = \frac{8}{\pi^2} \frac{m^{*2} k_F k_B T}{\rho c \hbar^4} \left( \Xi^2 + \frac{P}{4k_F^2} \right) \times \exp[-2k_F^2 \ell_h^2 / (1 + \gamma)] \exp(-2\Theta/T) \quad (234)$$

This results in the final conductivity expression

$$\sigma = \frac{2e^2}{h} l_\sigma \quad (235)$$

where the length  $l_\sigma$  is given by

$$l_\sigma = \frac{\pi c \hbar^3 \rho k_F}{m^{*2} (4k_F^2 \Xi^2 + P)} \exp[2k_F^2 \ell_h^2 / (1 + \gamma)] \exp(2\Theta/T) \quad (236)$$

At low temperatures the conductivity thus increases exponentially, in agreement with the result of the numerical calculation (see Fig. 24). In the presence of impurities, as we shall see in next section, the scattering against phonons yields a contribution to the inverse conductivity which is proportional to  $T^3$  rather than  $\exp(-2\Theta/T)$ , provided the temperature is sufficiently low that the impurities dominate the scattering.

### Scattering from Acoustical Phonons and Impurities

When the impurity scattering dominates we may use the variational principle with a trial function, which is proportional to the solution for impurity scattering alone. We shall consider the case where only the lowest Landau level  $n = 0$  is important. The trial function is thus chosen to be proportional to  $1/B_{0+}^0$ , as given by Eq. (207):

$$U(k) = k^2 \exp[2k^2 \ell_h^2 / (1 + \gamma)] \quad (237)$$

Since we have chosen the exact solution to the impurity problem as our trial function, the calculated upper bound on the contribution from electron-phonon scattering  $1/\sigma$  is exact, to lowest order in the magnitude of the electron-phonon coupling. At low temperatures we may make the approximation

$$[U(k) - U(k')]^2 \cong \left( \frac{dU(k)}{dk} \right)^2 (k - k')^2 \quad (238)$$

which is justified, since  $k - k' = q_x$  and the restriction to low temperatures implies that the phonon momentum is small. Furthermore, we may neglect the deformation potential coupling since the piezoelectric coupling dominates for small

**Figure 24.** Normalized conductivity in GaAs as a function of temperature for  $B = 9$  T,  $\gamma = 0.5$ ,  $\varepsilon_F = 0.6\hbar\omega_h$ . Dotted lines are used as reference ( $\sigma_1, \sigma_2, \sigma_3, \sigma_4, \sigma_5$ ),  $T = 0$  K,  $B = 0$  T,  $\mu_{\text{imp}}^0 = 7.5, 75, \mu_{\text{imp}}^0 = 7.5, 300, 3000, \text{ and } 30000$  m<sup>2</sup>/(V s). Full lines: ( $\sigma_{a4}, \sigma_{a5}$ ), only acoustical phonon scattering was considered (normalized to  $\sigma_4, \sigma_5$ ). ( $\sigma_i$ ), only impurity scattering was considered. ( $\sigma_{i4}, \sigma_{i5}$ ), assuming that the inverse conductivities for both mechanisms are additive. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

$q$  according to Eq. (224), and we also set the matrix element appearing in Eq. (224) equal to unity. By inserting  $U$  in Eq. (197) and carrying out the integrals we obtain

$$\sigma_{\text{ph}}^{-1} = \frac{h}{2e^2} l_{\text{ph}}^{-1} \frac{3s(3)}{8\pi} \frac{1 + \gamma}{\gamma \tilde{\varepsilon}_F^3} \left( 1 + \frac{4\tilde{\varepsilon}_F}{\gamma} \right)^2 \left( \frac{k_B T}{\hbar\omega_h} \right)^3 \quad (239)$$

where  $\tilde{\varepsilon}_F = \varepsilon_F / \hbar\omega_h$ , and

$$l_{\text{ph}}^{-1} = \frac{P m_e^*}{\rho c^2 \hbar^2} \quad (240)$$

This  $T^3$  behavior agrees well with our numerical calculations in the parameter range where it is expected to apply. In Figures 24 and 25 is shown the calculated conductivity, obtained by numerical solution of the integral equation, for samples with different amounts of impurities.

### 2.7.5. Scattering from Optical Phonons

Next we investigate the combined effects of scattering by longitudinal optical phonons [145] and impurities. The chief differences from the preceding section involve the  $q$  dependence of the electron-phonon matrix element and the absence of dispersion in the phonon frequencies. The conductivity is obtained by solving the Boltzmann equation in the limit where the temperature is much less than  $\hbar\omega_0/k_B$ .

**Figure 25.** Plots of the normalized conductivity versus temperature for a GaAs quantum well wire at the magnetic field  $B = 9$  T and the Fermi level  $\varepsilon_F = 0.6\hbar\omega_h$ . The confinement parameter in panel (a) is  $\gamma = 1.0$  and in (b) is  $\gamma = 0.5$ . The dashed curve in each panel is the case where only impurity scattering is taken into account. The four full curves in each panel are the result of combining impurity and acoustical-phonon scattering for each of the following values of the zero-field, zero-temperature mobility  $\mu_{\text{imp}} = 0.9, 9, 90,$  and  $900$   $\text{m}^2/(\text{V s})$ . Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Coupling to Optical Phonons** We shall use the simple model where the phonon frequency is independent of momentum,

$$\omega_q \cong \omega_0 \quad (241)$$

The electron-phonon matrix element [155] is given by

$$|g(nn', \vec{q})|^2 = \frac{1}{q^2} \frac{M_0^2}{V} M_n^{n'}(u) \quad (242)$$

where  $V$  is the normalization volume and where

$$M_0^2 = 2\pi \frac{e^2 \hbar \omega_0}{\varepsilon_0} \left( \frac{1}{\kappa_\infty} - \frac{1}{\kappa_0} \right) \quad (243)$$

The function  $M$  is given by

$$M_n^{n'}(u) = |\langle nk | \exp(i\vec{q} \cdot \vec{r}) | n' k' \rangle|^2 \quad (244)$$

which is calculated in Section 2.7.6, where also  $u$  is defined.

The approximation in Eq. (241) allows us to integrate over the  $y$  and  $z$  components of the phonon momentum. Using a  $\delta$  function for the wavefunction in the  $z$  direction, we get

$$\sum_{q_y, q_z} |g(nn', \vec{q})|^2 = \frac{M_0^2}{(2\pi)^2 L} K_n^{n'}(q_x) \quad (245)$$

where

$$K_n^{n'}(q_x) = \int_{-\infty}^{\infty} \frac{dq_y}{\sqrt{q_x^2 + q_y^2}} M_n^{n'}[u(q_x, q_y)] \quad (246)$$

**Scattering from Optical Phonons and Impurities** We now consider the case of impurity and optical-phonon scattering. The Boltzmann equation in this case reads

$$\frac{eE_x}{k_B T} v_{nk} f_{nk}^0 (1 - f_{nk}^0) = \left( \frac{\partial f_{nk}}{\partial t} \right)_{\text{coll}}^{\text{imp}} + \left( \frac{\partial f_{nk}}{\partial t} \right)_{\text{coll}}^{\text{op}} \quad (247)$$

The collision integral for the phonon scattering given in Eq. (217) simplifies in the case of optical phonons to

$$\begin{aligned} \left( \frac{\partial f_{nk}}{\partial t} \right)_{\text{coll}}^{\text{op}} &= -\frac{M_0^2}{\hbar 2\pi L} \frac{1}{4 \sinh^2(\hbar\omega_0/2k_B T)} \sum_{n'q_x} \sum_{\sigma} K_n^{n'}(q_x) \\ &\times |f^0(\varepsilon_{nk}) - f^0(\varepsilon_{nk} + \sigma\hbar\omega_0)| (\psi_{nk} - \psi_{n'k-q_x}) \\ &\times \delta(\varepsilon_{n'k-q_x} - \varepsilon_{nk} - \sigma\hbar\omega_0) \end{aligned} \quad (248)$$

with  $K_n^{n'}(q_x)$  given in Eq. (246). The argument of the energy-conserving  $\delta$  function is zero for

$$q_x = k \left[ 1 - s \sqrt{1 + \frac{\hbar\omega_h(n-n') + \sigma\hbar\omega_0}{\hbar^2 k^2 / 2m^*}} \right] \quad (249)$$

for each value of  $nk$ , provided the square root is real. The branch index  $s$  assumes the values  $+1$  and  $-1$  corresponding to forward and backward scattering. The Boltzmann equation now simplifies to

$$\begin{aligned} 1 &= \sum_{n's'} B_{n+}^{n's'}(\varepsilon) [\phi_n(\varepsilon) - s' \phi_{n'}(\varepsilon)] + \sum_{n's'} C_{n+}^{n's'}(\varepsilon, \sigma) \\ &\times [\phi_n(\varepsilon) - s' \phi_{n'}(\varepsilon + \sigma\hbar\omega_0)] \end{aligned} \quad (250)$$

where the matrix  $B$  is given by Eq. (207). The optical-phonon scattering gives rise to the matrix  $C$ , which is given by

$$\begin{aligned} C_{ns}^{n's'}(\varepsilon, \sigma) &= \frac{1}{f^0(\varepsilon)[1-f^0(\varepsilon)]} \frac{M_0^2}{\hbar^2 (2\pi)^2} \frac{1}{4 \sinh^2(\hbar\omega_0/2k_B T)} \\ &\times \sum_{\sigma} |f^0(\varepsilon) - f^0(\varepsilon + \sigma\hbar\omega_0)| \\ &\times \frac{K_n^{n'}[sk_n(\varepsilon) - s'k_{n'}(\varepsilon + \sigma\hbar\omega_0)]}{v_n(\varepsilon)v_{n'}(\varepsilon + \sigma\hbar\omega_0)} \end{aligned} \quad (251)$$

In GaAs the typical optical-phonon energies are about 36 meV. Furthermore, since the cyclotron energy  $\hbar\omega_c$  in GaAs is 1.5 meV  $B/T$ , the typical situation will be that the energy spacing between the Landau levels as modified by the confinement potential  $\hbar\omega_h$  is much smaller than the phonon energies  $\hbar\omega_0 \gg \hbar\omega_h$ . Since we are interested in temperatures that are small or comparable in magnitude to the energy spacing  $\hbar\omega_h$ , we are therefore always in a situation where  $k_B T$  is much less than  $\hbar\omega_0$ . Under these circumstances it is possible to simplify the Boltzmann equation for electrical transport by considering it to be a coupled system of equations for the functions  $\phi(\varepsilon \pm n\hbar\omega_0)$  with  $n$  integers. Since the current is mainly determined by the distribution of electrons  $\phi(\varepsilon)$  within a thermal layer of thickness comparable to  $k_B T$ , it is sufficiently accurate to neglect the contributions from  $\phi(\varepsilon \pm n\hbar\omega_0)$ , when  $n$  is different from zero. The collision integral may therefore be approximated by the

“scattering-out” term, corresponding to the neglect of vertex corrections in the Kubo approach.

In calculating the conductivity from Eq. (205) we thus neglect the “scattering-in” terms involving  $\phi_{n'}(\varepsilon + \sigma\hbar\omega_0)$  while retaining the full collision matrix for the impurities. We have then evaluated the solution of Eq. (250) numerically and inserted the solution in the conductivity formula, Eq. (189). Results are shown in Figure 26. The low-temperature behavior is dominated by the impurities, which give rise to an initial increase of the conductivity, in accordance with Eq. (209). The optical phonons come in at higher temperatures, yielding a maximum of the conductivity as a function of temperature. The position of the maximum is roughly proportional to the logarithm of the strength of the impurity scattering, since the phonon contribution depends exponentially on temperature. Note, however, that the acoustical phonons have reduced the conductivity for the high mobility cases rather strongly at the temperature range shown here; see Figure 25. The dashed line represents the conductivity without optical-phonon scattering.

**Figure 26.** The conductivity with combined impurity and optical-phonon scattering for a GaAs quantum well wire. The normalized conductivity is plotted versus temperature for different choices of confinement potential strengths, Fermi energies, and mobilities. The magnetic field is  $B = 9$  T. The confinement parameter is  $\gamma = 1.0$  for panels (a) and (c) and  $\gamma = 0.5$  for (b) and (d); the Fermi level is  $\varepsilon_F = 0.6\hbar\omega_h$  (i.e., close to the bottom of the first band) for (a) and (b), and panels (c) and (d) have  $\varepsilon_F = 1.3\hbar\omega_h$ . The conductivity is shown for each of the following values of the zero-field, zero-temperature mobility:  $\mu_{\text{imp}} = 0.9, 9, 90,$  and  $900$   $\text{m}^2/(\text{Vs})$ . The dashed curve in each panel is the case where only impurity scattering is taken into account. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

In comparing the curves in Figures 24–26 we observe that the optical-phonon scattering in clean systems tends to dominate the total scattering already at fairly low temperatures, around 50 K. This is in contrast to the situation in typical GaAs-based two-dimensional electron [100] gases, where the optical-phonon scattering begins to dominate around 100 K. This effect originates in the increased phase space for scattering in one dimension, caused by the fact that only the  $x$  component of the momentum is conserved in the scattering process, while Eq. (246) includes contributions from all perpendicular components  $q_y$ .

We have shown that the magnetoconductivity of quantum wires may be discussed in a simple and unified fashion within the framework of a Boltzmann equation, by taking into account the influence of the magnetic field on the electron group velocity and the matrix elements governing the transition probability. By treating in detail the scattering from acoustical as well as optical phonons in the presence of impurity scattering, we have determined the temperature dependence of the magnetoconductivity for realistic choices of parameters in GaAs-based structures. In particular, we have found that the magnetoconductivity exhibits a maximum as a function of temperature, depending on the relative strength of the impurity and electron-phonon scattering. The calculated magnetoconductivity oscillates when the Fermi energy or the magnetic field is varied. Our detailed calculations show that the scattering against optical phonons in quantum wires is significant at temperatures somewhat smaller than the corresponding temperatures for the two-dimensional case.

We have found that the inverse of the sum of the inverse conductivities (the Matthiessen conductivity) in general is not a good approximation to the total conductivity. If impurity scattering dominates, the temperature dependence of the electron-phonon contribution is changed from exponential to power law behavior; cf. Eqs. (236) and (239). If the different scattering contributions are of comparable magnitude the Matthiessen conductivity overestimates the total conductivity up to a factor of 2 dependent on parameter values. This overestimation is in accordance with the general resistivity theorem [154] for the Boltzmann equation:  $\rho_{\text{tot}} \geq \rho_1 + \rho_2$ . Only in the case where the phonon scattering dominates do we find a good agreement between the Matthiessen conductivity and the total conductivity; cf. Figure 24.

### 2.7.6. Matrix Element in Electron-Phonon Coupling Parameter

In this section we study the square of the matrix element  $\langle nk | \exp(i\vec{q} \cdot \vec{r}) | n'k' \rangle$ . Using the single-electron wavefunctions in Eq. (173) and performing the  $x$  and  $y$  integrals one obtains

$$\begin{aligned} & |\langle nk | \exp(i\vec{q} \cdot \vec{r}) | n'k' \rangle|^2 \\ &= \delta_{k, k'+q_x} \frac{n_{\min}!}{n_{\max}!} u^{|n-n'|} [L_{n_{\min}}^{|n-n'|}(u)]^2 \exp(-u) \end{aligned} \quad (252)$$

where  $n_{\min} = \min(n, n')$  and  $n_{\max} = \max(n, n')$ ;  $L_n^m(u)$  are the Laguerre polynomials while  $u$  is given by

$$u = \frac{1}{1+\gamma} \frac{1}{2} (q_x \ell_h)^2 + \frac{1}{2} (q_y \ell_h)^2 \quad (253)$$

The Kronecker  $\delta$  function appearing in Eq. (252), and which is written explicitly in the expression for the integral operator  $\hat{H}$  in Eq. (215), is a consequence of the translational invariance along the  $x$  direction.

In calculations involving acoustical phonons it is natural to use the polar coordinates  $(q, \theta, \varphi)$  with the  $x$  axis as the polar axis so that  $q_x = q \cos \theta$ ,  $q_y = q \sin \theta \cos \varphi$ , and  $q_z = q \sin \theta \sin \varphi$ . According to Eqs. (215) and (224) the only  $\varphi$  dependence is through  $u$  defined previously. It is therefore of interest to calculate the integral

$$I_{n,n'}(q, \cos \theta) \equiv \int_0^{2\pi} d\varphi u^{|n-n'|} [L_{n_{\min}}^{|n-n'|}(u)]^2 \exp(-u) \quad (254)$$

From Eq. (253) it follows that the  $\varphi$  dependence of  $u$  is of the form  $u = \beta + \alpha \cos^2 \varphi$ , so the integrand of  $I_{n,n'}$  therefore takes the form of a polynomial in  $\cos^2 \varphi$  times  $\exp(-\alpha \cos^2 \varphi)$ . The integral over  $\varphi$  may then be carried out explicitly in terms of the beta function and Gauss's hypergeometric function.

In the case where we consider only the lowest Landau level we just need to calculate  $I_{0,0}$ . Using the results quoted previously we find

$$I_{0,0}(q, q_x/q) = 2\pi \exp\left[-\frac{1}{2}(q_x \ell_h)^2 \frac{1}{1+\gamma} - \frac{1}{4}\ell_h^2(q^2 - q_x^2)\right] \times I_0\left(\frac{1}{4}\ell_h^2(q^2 - q_x^2)\right) \quad (255)$$

where  $I_0(x)$  is the modified Bessel function of order zero.

## 2.8. Hydrogenic Impurities in a Spherical Quantum Dot in the Presence of a Magnetic Field

The ground state and binding energies for a hydrogenic impurity in a spherical quantum dot in the presence of a uniform magnetic field are calculated by a variational method within the effective mass approximation [160]. The simple hydrogenic trial wavefunctions used in this calculation are flexible enough to treat on-center, off-center, and edge states of impurities in a quantum dot. Overall results are in reasonable agreement when compared to other calculations. Interestingly enough, in the case of an off-center impurity, a critical point from which bulk states change their nature (edge states) is also found.

Semiconductors composed of III-V materials usually have small effective masses, which means that the Bohr radius associated with the impurity is large compared to achievable quantum dot sizes. The binding energy of the impurity increases as the size of the confining region becomes of the order of Bohr radius, which makes possible, for instance, the fabrication of a low-threshold laser diode [161].

In this section a variational study about the effect of a magnetic field on the ground state and binding energies of a hydrogenic impurity within spherical quantum dot is made. The impurity can be located on (off) the center of symmetry to get a symmetric (asymmetric) situation, or near the boundary of quantum dot to get surfacelike states (edge states) of this system.

### 2.8.1. Theory and Model

Within the framework of the effective mass approximation, the Hamiltonian of a hydrogenic impurity located at the center of symmetry of a spherical quantum dots of radius  $r_0$ , in the presence of magnetic field, can be written as

$$\hat{H} = \frac{1}{2m_e^*} \left( \hat{p} - \frac{e}{c} \vec{A} \right)^2 - \frac{e^2}{\kappa r} + V_b(\vec{r}) \quad (256)$$

where  $\kappa$  is the dielectric constant of material inside the quantum dot,  $m_e^*$  is the electron effective mass,  $\vec{A}$  is the vector potential, and  $V_b(\vec{r})$  is the confining potential defined by

$$V_b(\vec{r}) = \begin{cases} 0 & 0 \leq r \leq r_0 \\ \infty & r > r_0 \end{cases} \quad (257)$$

For a uniform magnetic field,  $\vec{A}(\vec{r}) = \vec{B} \times \vec{r}/2$  if the Coulomb gauge  $\nabla \cdot \vec{A} = 0$  is chosen. In spherical coordinates, if the magnetic field is along the  $z$  direction,  $\vec{B} = B\hat{e}_z$ , the Hamiltonian can be expressed as

$$\hat{H} = -\frac{1}{2m_e^*} \nabla^2 - \frac{e^2}{\kappa r} - \frac{e}{2m_e^* c} B \hat{L}_z + \frac{e^2}{8m_e^* c^2} B^2 r^2 \sin^2 \theta \quad (258)$$

Here,  $\hat{L}_z$  is the  $z$  component of the angular momentum operator;  $\theta$  is the usual polar angle in these coordinates. The magnetic field preserves the azimuthal symmetry (i.e.,  $m$  is still a "good" quantum number). As only the ground state is studied, the value  $m = 0$  is required; thus the Hamiltonian [Eq. (258)] will retain the quadratic dependence on  $B$  only.

Because of confinement, the solution of Schrödinger equation associated with Eq. (258) must satisfy

$$\psi(r = r_0, \theta, \varphi) = 0 \quad (259)$$

In order to use the variational method, the trial wavefunction for the calculation of the ground state energy is chosen as

$$\begin{aligned} \psi(r) &= N \exp(-\alpha r) \exp\left(-\frac{1}{8} B r^2 \sin^2 \theta\right) (r_0 - r) \\ &= N \exp(-\alpha r) \exp\left(-\frac{1}{12} B r^2\right) (r_0 - r) \end{aligned} \quad (260)$$

where  $N$  is the normalization constant and  $\alpha$  is a variational parameter to be determined. The last term has been obtained considering that in absence of  $\vec{A}$  the system holds spherical symmetry. A similar choice of the trial wavefunction to calculate the ground state energy has widely been used in the case of hydrogenic impurities within spherical quantum dots [162] and cylindrical quantum wires [163] without magnetic field.

In the case of a hydrogenic impurity displaced a constant distance  $a$  from the center of symmetry of a quantum dot, the Hamiltonian of Eq. (256) is modified as

$$\hat{H} = \frac{1}{2m_e^*} \left( \hat{p} - \frac{e}{c} \vec{A} \right)^2 - \frac{e^2}{\kappa |\vec{r} - a\hat{e}_z|} + V_b(\vec{r}) \quad (261)$$

where the confining potential,  $V_b(\vec{r})$ , is still given by Eq. (257), and  $\hat{e}_z$  is a unit vector on  $z$  axis. Hence, the corresponding Hamiltonian and trial wavefunction, Eqs. (258) and (260), are given by

$$\hat{H} = -\frac{1}{2m_e^*} \nabla^2 - \frac{e^2}{\kappa|\vec{r} - a\hat{e}_z|} - \frac{e}{2m_e^*c} B \hat{L}_z + \frac{e^2}{8m_e^*c^2} B^2 r^2 \sin^2 \theta \quad (262)$$

and

$$\psi(r) = N \exp(-\alpha|\vec{r} - a\hat{e}_z|) \exp\left(-\frac{1}{8} B r^2 \sin^2 \theta\right) (r_0 - r) \quad (263)$$

respectively.

Notice that the wavefunction [Eq. (263)] satisfies the boundary condition imposed by Eq. (259). Again, since  $m = 0$  is chosen, the Hamiltonian [Eq. (262)] will not have linear dependence on magnetic field  $B$ , just like the symmetric case studied before.

As we shall see, the trial wavefunction [Eq. (263)] is flexible enough to describe the case when the radius of the confining sphere becomes infinite and the hydrogenic impurity is close to its boundary. The latter would correspond to the case of a hydrogenic impurity close a plane, which allows us to investigate the ground state edge level of the spherical quantum dot.

The binding energy ( $\varepsilon_b$ ) for the hydrogenic impurity is defined as the ground state energy of the system without Coulombic interaction ( $\varepsilon_w$ ) minus the ground state energy including the presence of the electron–nucleus interaction ( $\varepsilon_0$ ); that is,

$$\varepsilon_b = \varepsilon_w - \varepsilon_0 \quad (264)$$

The binding energy defined before is a positive quantity. The  $\varepsilon_w$  term of Eq. (264) is the ground state energy of an electron confined inside a spherical quantum dot of radius  $r_0$ ; that is

$$\varepsilon_w = \frac{\pi^2 \hbar^2}{2m_e^* r_0^2} \quad (265)$$

The values of the physical parameters pertaining to a GaAs quantum dot used in these calculations, for the sake of comparison, are  $m_e^* = 0.067m_0$  and  $\kappa = 12.5$ ; thus  $a_B^* = 98.7 \text{ \AA}$  and  $R_y^* = 5.83 \text{ meV}$ . Moreover, the linear dependence term on  $B$ , in Eq. (258), can be scaled down to

$$\gamma m = \frac{e\hbar}{2m_e^* c R_y^*} B m = \frac{m_0}{m_e^* R_y^*} \mu_0 B m \quad (266)$$

where  $\mu_0 = 5.78838263 \times 10^{-2} \text{ meV T}^{-1}$  is the Bohr magneton; then the value  $B = 6.75 \text{ T}$  corresponds to an effective Rydberg ( $\gamma = 1$ ).

The results for the symmetric case (on-center impurity) are displayed in Figure 27, in which the binding energy of the hydrogenic impurity is plotted as a function of the quantum dot radius for different magnetic field strengths. The qualitative and quantitative behavior of the results is in good agreement with those of Xiao et al. [164], and Branis et al.

**Figure 27.** The binding energy of an on-center hydrogenic impurity as a function of the quantum dot radius for different magnetic fields. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.), Academic Press, San Diego, 2001. © 2001, Academic Press.

[42], who studied the magnetic field dependence over the binding energies of hydrogenic impurities in quantum dots and quantum well wires, respectively. In the strong spatial confinement case ( $r_0 < a_B^*$ ), the binding energy is relatively insensitive to the magnetic field and diverges as the dot radius  $r_0 \rightarrow 0$ , as in the case of zero magnetic field. The latter reflects that the main contribution to the binding energy is due to electron spatial confinement, which prevails over magnetic field confinement. The latter can be estimated through the magnetic length defined as

$$l_B = \sqrt{\frac{\hbar c}{eB}} = 484.82 \times B^{-1/2} \quad (267)$$

where  $l_B$  is expressed in effective Bohrs, and  $B$  is given in Teslas. For dot radius  $r_0 \cong a_B^*$ , the different magnetic field curves deviate from each other reaching steady values as the dot radius increases. For weak spatial confinement ( $r_0 \gg a_B^*$ ), the binding energy converges asymptotically to the corresponding bulk values. In the limit of large dot radius, the binding energy for  $B = 0$  approaches its bulk value,  $\varepsilon_b = 1R_y^*$ , as expected. An increase of the field strength decreases the magnetic length as compared with the dot radius; thus in this case the binding energy increases due to magnetic confinement that compels the electron to move “closer” to the on-center impurity.

Figure 28 shows the behavior of binding energy as a function of field strength for different dot radii of an on-center impurity. The variation of binding energy as the field increases is less sensitive as dot radius decreases, thus enforcing the previous comment regarding Figure 27.

The results for the asymmetric case (off-center impurity) are plotted in Figures 29 and 30 with zero magnetic field. Figure 29 shows the ground state energy for different sizes of quantum dot versus the relative position of the off-center impurity ( $a/r_0$ ). The ground state energy increases from its on-center impurity value ( $a/r_0 = 0$ ) as the impurity is shifted off the center; this is a general behavior. For larger radii

**Figure 28.** The binding energy of an on-center hydrogenic impurity as a function of the magnetic field for different dot radii. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

the ground state energy becomes lower, and then, for closer distances to the wall, evolves from the  $1s$  “free” hydrogen ground state ( $-1/2$ -Hartree) to the  $2p_z$  “free” hydrogen first excited state ( $-1/8$ -Hartree). These results are in good agreement with those of Brownstein [165], Gorecki and Byers Brown [166], and Marín et al. [162]. It is clear now that the trial wavefunction as chosen is flexible enough to describe the case when the size of the quantum dot becomes infinite and the nucleus is close to the surface. The latter corresponds to the case of a hydrogenic impurity close to a plane. This situation will be discussed later when the effect of a magnetic field on the ground state of a hydrogenic impurity near the semiconductor surface will be considered.

In Figure 30, the binding energy for different sizes of quantum dot versus the relative position of the off-center

**Figure 29.** The ground state energy of an off-center hydrogenic impurity as a function of the relative position of the impurity for different dot radii. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Figure 30.** The binding state energy of an off-center hydrogenic impurity as a function of the relative position of the impurity for different dot radii. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

impurity ( $a/r_0$ ) has been plotted. The binding energy decreases as the impurity approaches to the boundary of the quantum dot. This behavior is due to the fact that wavefunctions vanish at the boundaries and thus their contributions to the binding energy of a quantum dot with an off-center impurity are smaller than a quantum dot with an on-center impurity. The results are similar to the case of a hydrogenic impurity placed in rectangular [167] or circular [163] cross-section quantum well wires, and in a spherical quantum dot [164].

The problem of a hydrogenic impurity near a crystal surface as a limit case of a hydrogenic impurity in a spherical quantum dot of very large radius will be considered next. In Figure 31, the ground state energy for different radii of quantum dot versus the relative position of the off-center impurity ( $a/r_0$ ) is shown. For very large quantum dot radii the Levine ground state energy of an atom located precisely on the surface of a semi-infinite medium is obtained; that is, the ground state energy changes gradually from its bulk value ( $-1$  Rydberg) into the Levine state ( $-1/4$  Rydberg) as the impurity reaches the surface.

In Figure 32, the ground state binding energy for different radii of quantum dot versus the relative position of the off-center impurity ( $a/r_0$ ) has been plotted. For the too large quantum dot radii considered here, binding energy curves cross one another and define a point from which the edge states begin to appear. This critical point corresponds to a hydrogenic impurity placed at the relative distance  $a/r_0 = 0.68$  from the center of the quantum dot. The associated binding energy with the quantum dot of largest radius ( $r_0 = 100$  effective Bohr) decreases from  $1R_y^*$  (effective Rydberg) for an impurity located far from a quantum dot surface to  $1/4R_y^*$  for an impurity located exactly at the surface of a quantum dot. The binding energy behavior is in reasonable agreement with that of Chen [168], who studied the problem of hydrogenic donors near semiconductor surfaces. Furthermore, starting from the critical point (near the quantum dot

**Figure 31.** The ground state energy of a hydrogenic impurity in a spherical quantum dot of very large radius. Note that the ground state changes gradually from its bulk value ( $-1R_0^*$ ) to the Levine state ( $-1/4R_0^*$ ). Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

surface), there is an inversion of binding energy for quantum dots of different radii. This occurs due to the fact that the boundary has a greater effect on binding energy when the quantum dot size increases, as a result of the strong spatial limitation due to the closeness of the impurity to the surface. When a magnetic field is applied, the critical point is removed and the binding energy curves cross one another at only one point. Moreover, crossing points are shifted away from the boundary as the magnetic field is increased; finally a moderate field strength causes them to vanish.

## 2.9. Energy States of Two Electrons in a Parabolic Quantum Dot in Magnetic Field

The energy spectra of two interacting electrons in a quantum dot confined by a parabolic potential in an applied magnetic field of arbitrary strength are obtained in this section. The shifted  $1/N$  expansion method is used to solve the effective mass Hamiltonian [68]. The influence of the electron–electron interaction on the ground state energy and its significant effect on the energy level crossings in states with different angular momenta are shown. The dependence of the ground state energy on the magnetic field strength for various confinement energies is presented.

The magnetic field dependence plays a useful role in identifying the absorption features. The effects of the magnetic field on the state of the impurity [169] and excitons [170–174] confined in quantum dot have been extensively studied. Kumar et al. [175] have self-consistently solved the Poisson and Schrödinger equations and obtained the electron states in GaAs–GaAlAs for both cases: in zero and for magnetic fields applied perpendicular to the heterojunctions. The results of their work [175] indicated that the confinement potential can be approximated by a simple one-parameter adjustable parabolic potential. Merkt et al. [176] have presented a study of quantum dots in which both the magnetic field and the electron–electron interaction terms were taken into account. Pfannkuche and Gerhardt [177] have devoted a theoretical study to the magneto-optical response to far-infrared radiation (FIR) of quantum dot helium, accounting for deviations from the parabolic confinement. More recently, De Groote et al. [178] have investigated the thermodynamic properties of quantum dots taking into consideration the spin effect, in addition to the electron–electron interaction and magnetic field terms. The purpose of this section is to show the effect of the electron–electron interaction on the spectra of the quantum dot states with nonvanishing azimuthal quantum numbers and the transitions in the ground state of the system as the magnetic field strength increases.

Here we shall use the shifted  $1/N$  expansion method to obtain an energy expression for the spectra of two confined electrons in a quantum dot by solving the effective mass Hamiltonian including the following terms: the electron–electron interaction, applied field, and the parabolic confinement potential.

### 2.9.1. Theory and Model

Within the effective mass approximation, the Hamiltonian for an interacting pair of electrons confined in a quantum dot by parabolic potential of the form  $m_e^* \omega_0 r^2 / 2$  in a magnetic field applied parallel to the  $z$ -axis (and perpendicular to the plane where the electrons are restricted to move) in the symmetric gauge is written as

$$\hat{H} = \sum_{i=1}^2 \left\{ -\frac{\hbar^2 \nabla_i^2}{2m_e^*} + \frac{1}{2} m_e^* \omega_0^2 r_i^2 + \frac{\hbar \omega_c}{2} L_i^z \right\} + \frac{e^2}{\kappa |\vec{r}_1 - \vec{r}_2|} \quad (268)$$

where the two-dimensional vectors  $\vec{r}_1$  and  $\vec{r}_2$  describe the positions of the first and the second electron in the  $(x, y)$

plane, respectively.  $L_i^z$  stands for the  $z$ -component of the orbital angular momentum for each electron and  $\omega_c = eB/m_e^*c$ ,  $m_e^*$ , and  $\kappa$  are the cyclotron frequency, effective mass, and dielectric constant of the medium, respectively. The frequency  $\omega$  depends on both the magnetic field  $B$  and the confinement frequency  $\omega_0$  and is given by

$$\omega = \left( \omega_0^2 + \frac{\omega_c^2}{4} \right)^{1/2} \quad (269)$$

The natural units of length and energy to be used are the effective Bohr radius  $a_b^* = \kappa \hbar^2 / m_e^* e^2$  and effective Rydberg  $R_y^* = \hbar^2 / 2m_e^* a_b^{*2}$ . The dimensionless constant  $\gamma = \hbar \omega_c / 2R_y^*$  plays the role of an effective magnetic field strength.

Upon introducing the center of mass  $\vec{R} = (\vec{r}_1 + \vec{r}_2) / \sqrt{2}$  and the relative coordinates  $\vec{r} = (\vec{r}_1 - \vec{r}_2) / \sqrt{2}$ , the Hamiltonian [178] in Eq. (268) can be written as a sum of two separable parts that represent the center of mass motion Hamiltonian,

$$\hat{H}_R = -\frac{\hbar^2}{2m_e^*} \nabla_R^2 + \frac{m_e^*}{2} \omega^2 R^2 + \frac{\hbar \omega_c}{2} L_z^R \quad (270)$$

and the relative motion Hamiltonian,

$$\hat{H}_r = -\frac{\hbar^2}{2m_e^*} \nabla_r^2 + \frac{m_e^*}{2} \omega^2 r^2 + \frac{\hbar \omega_c}{2} L_z^r + \frac{e^2}{r} \quad (271)$$

Equation (270) describes the Hamiltonian of the harmonic oscillator with the well-known eigenenergies

$$\varepsilon_{n_{cm}, m_{cm}} = (2n_{cm} + |m_{cm}| + 1) \hbar \omega + \frac{\hbar \omega_c}{2} m_{cm} \quad (272)$$

labeled by the radial ( $n_{cm} = 0, 1, 2, \dots$ ) and azimuthal ( $m_{cm} = 0, \pm 1, \pm 2, \pm 3, \dots$ ) quantum numbers. The problem is reduced to obtaining eigenenergies  $\varepsilon_{n_r, m}$  of the relative motion Hamiltonian. The energy states of the total Hamiltonian are labeled by  $CM$  and relative quantum numbers by  $|n_{cm} m_{cm}; n_r m\rangle$ . The coexistence of the electron-electron and the oscillator terms makes the exact analytic solution with the present special functions impossible.

### 2.9.2. Shifted $1/N$ Expansion Method

The shifted  $1/N$  expansion method,  $N$  being the spatial dimensions, is a pseudoperturbative technique in the sense that it proposes a perturbation parameter that is not directly related to the coupling constant [179–181]. The aspect of this method has been clearly stated by Imbo et al. [179, 180] who had displayed step-by-step calculations relevant to this method. Following, their work here is presented only by the analytic expressions, which are required to determine the energy states.

The method starts by writing the radial Schrödinger equation, for an arbitrary cylindrically symmetric potential, in a  $N$ -dimensional space as

$$\left\{ -\frac{d^2}{dr^2} + \frac{(k-1)(k-3)}{4r^2} + V(r) \right\} \psi(r) = \varepsilon_r \psi(r) \quad (273)$$

where  $k = N + 2m$ .

In order to get useful results from  $1/\bar{k}$  expansion, where  $\bar{k} = k - a$  and  $a$  is a suitable shift parameter, the large  $\bar{k}$ -limit of the potential must be suitably defined [182]. Since the angular momentum barrier term behaves like  $\bar{k}^2$  at large  $\bar{k}$ , so the potential should behave similarly. This will give rise to an effective potential which does not vary with  $\bar{k}$  at large values of  $\bar{k}$  resulting in a sensible zeroth order classical result. Hence, Eq. (273) in terms of the shift parameter becomes

$$\left\{ -\frac{d^2}{dr^2} + \frac{\bar{k}^2 [1 - (1-a)/\bar{k}] [1 - (3-a)/\bar{k}]}{4r^2} + \frac{V(r)}{Q} \right\} \psi(r) = \varepsilon_r \psi(r) \quad (274)$$

where

$$V(r) = \frac{2}{r} + \frac{1}{4} \omega^2 r^2 + m \frac{\omega_c}{2} \quad (275)$$

and  $Q$  is a scaling constant to be specified from Eq. (277). The shifted  $1/N$  expansion method consists in solving Eq. (274) systematically in terms of the expansion parameter  $1/\bar{k}$ . The leading contribution term to the energy comes from

$$\bar{k}^2 V_{\text{eff}}(r) = \frac{\bar{k}^2}{r_0^2} \left( \frac{1}{4} + \frac{r_0^2 V(r_0)}{Q} \right) \quad (276)$$

where  $r_0$  is the minimum of the effective potential, given by

$$2r_0^3 V'(r_0) = Q \quad (277)$$

It is convenient to shift the origin to  $r_0$  by the definition

$$x = \bar{k}^{1/2} (r - r_0) / r_0 \quad (278)$$

and expanding Eq. (274) about  $x = 0$  in powers of  $x$ . Comparing the coefficients of powers of  $x$  in the series with the corresponding ones of the same order in the Schrödinger equation for a one-dimensional anharmonic oscillator, we determine the anharmonic oscillator frequency, the energy eigenvalue, and the scaling constant in terms of  $\bar{k}$ ,  $Q$ ,  $r_0$ , and the potential derivatives. The anharmonic frequency parameter is

$$\bar{\omega} = \left[ 3 + \frac{V''(r_0)}{V'(r_0)} \right]^{1/2} \quad (279)$$

and the energy eigenvalues in powers of  $1/\bar{k}$  (up to third order) read

$$\varepsilon_{n_r, m} = V(r_0) + \frac{\bar{k}^2}{4r_0} + \frac{1}{r_0^3} \left[ \frac{(1-a)(3-a)}{4} + \gamma_1 \right] + \frac{\gamma_2}{\bar{k} r_0^2} \quad (280)$$

The explicit forms of  $\gamma_1$  and  $\gamma_2$  are given in Section 2.9.3. The shift parameter  $a$ , which introduces an additional

degree of freedom, is chosen so as to make the first term in the energy series of order  $\bar{k}$  to vanish, namely,

$$\frac{\bar{k}}{r_0^2} \left[ \left( n_r + \frac{1}{2} \right) \bar{\omega} - \frac{(2-a)}{2} \right] = 0 \quad (281)$$

by requiring an agreement between  $1/\bar{k}$  expansion and the exact analytic results for the harmonic and Coulomb potentials. From Eq. (281) we obtain

$$a = 2 - (2n_r + 1)\bar{\omega} \quad (282)$$

where  $n_r$  is the radial quantum number related to the principal  $n$  and magnetic  $m$  quantum numbers by the relation  $n_r = n - |m| - 1$ . Energies and lengths in Eqs. (273)–(282) are expressed in units of  $R_y^*$  and  $a_B^*$ , respectively.

For the two-dimensional case,  $N = 2$ , Eq. (277) takes the following form:

$$\sqrt{2r_0 V'(r_0)} = 2 + 2m - a = Q^{1/2} \quad (283)$$

Once  $r_0$  (for a particular quantum state and confining frequency) is determined, the task of computing the energy is relatively simple.

The results are presented in Figures 33–37 and Tables 3 and 4. The relative ground state energy  $|00\rangle$  of the relative motion, for the zero magnetic field case, against the confinement length is displayed in Figure 33. The present results (black dots) clearly show excellent agreement with the numerical results of [176] (dashed line). In Figure 34, the first low energy levels,  $|00\rangle$ ,  $|10\rangle$ , and  $|20\rangle$ , of the relative Hamiltonian are presented as a function of the effective confinement frequency  $\omega$ , using parameters appropriate to InSb, where the dielectric constant  $\kappa = 17.88$ , electron effective mass  $m_e^* = 0.014m_0$ , and confinement energy  $\hbar\omega_0 = 7.5$  meV [178]. The energy levels obviously show a linear dependence on the effective frequency. As the effective frequency  $\omega$  increases the confining energy term dominates the interaction energy term and thus the linear relationship

**Figure 33.** The relative ground state energy  $|00\rangle$  for the electrons in a quantum dot as a function of confinement length  $\ell_0 = (\hbar/m_e^* \omega_0)^{1/2}$  for zero magnetic field: this section’s calculations are given by closed circles; those of [175] are given by the solid line. between the energy and the frequency is maintained. This result is consistent with [178].

To investigate the effect of the electron–electron interaction on the energy spectra of the quantum dot, we have plotted in Figure 35 the total ground state energy  $|00; 00\rangle$  of the full Hamiltonian for independent (solid line) and interacting (dashed line) electrons as a function of the ratio  $\omega_c/\omega_0$ . The figure shows, as we expect, a significant energy enhancement when the electron–electron Coulombic interaction term is turned on. Furthermore, as the magnetic field increases, the electrons are further squeezed in the quantum dot, resulting in an increase of the repulsive electron–electron Coulombic energy and in effect the energy levels.

The energy level crossings are shown in Figure 36. We have displayed the eigenenergies of the states  $|00; 0m\rangle$ ;

**Figure 35.** The total ground state energy  $|00; 00\rangle$  for two electrons in a quantum dot as a function of the ratio  $\omega_c/\omega_0$ . **Figure 36.** The total eigenenergies of the states  $|00; 0m\rangle$ ,  $m = 0, -1, -2, \dots, -5$ , for two interacting electrons parabolically confined in the quantum dot of size  $\ell_0 = 3a_B^*$  as a function of the ratio  $\omega_c/\omega_0$ . Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

$m = 0, -1, -2, \dots, -5$ , for two interacting electrons parabolically confined in the quantum dot of size  $\ell_0 = 3a_B^*$  as a function of the ratio  $\omega_c/\omega_0$ . As the magnetic field strength increases the energy of the state  $m = 0$  increases while the energy of the states with nonvanishing quantum number  $m$  decreases, thus leading to a sequence of different ground states, as reported in [182]. In the interacting system, the interaction energy is the lower the higher the angular momentum of the relative motion. This is caused by the structure of the relative wavefunction: The larger the angular momentum the larger the spatial extent and therefore the larger the distance between the electrons [183].

**Figure 37.** The relative ground state  $|00\rangle$  energy versus the magnetic field strength for two different confinement energies. Reprinted with permission from [186], J. L. Marín et al., “Handbook of Advanced Electronic and Photonic Materials and Devices” (H. S. Nalwa, Ed.). Academic Press, San Diego, 2001. © 2001, Academic Press.

**Table 3.** The roots  $r_0$  determined by Eq. (684) for quantum dot states with nonvanishing azimuthal quantum number ( $m$ ) against the ratio  $\omega_c/\omega_0$ .

$m$	$\omega_c/\omega_0$	0	-1	-2	-3	-4	-5
1		4.262	4.827	5.457	6.075	6.659	7.209
2		3.692	3.682	4.212	4.719	5.193	5.635
3		3.188	2.943	3.398	3.825	4.229	4.586

To confirm this numerically, we list in Table 3 the roots  $r_0$  of the potential for the interacting electrons in the quantum dot, for states with different angular momenta. At particular values of the ratio  $\omega_c/\omega_0$ , as the azimuthal quantum number  $|m|$  increases, the root  $r_0$  also increases and thus the electron–electron interaction  $V_{ee}(r) = 2/r_0$ , in the leading term of the energy series expression, decreases.

In Figure 37, we have shown the dependence of the ground state energy on the magnetic field strength for confinement energies:  $\hbar\omega_0 = 6$  and 12 meV, for a constant value of the magnetic field, the larger the confinement energy and the greater the energy of the interacting electrons in the quantum dot. The spin effect can be included in the Hamiltonian Eq. (268) added to the center of mass part as a space independent term, and Eq. (270) is still an analytically solvable harmonic oscillator Hamiltonian [178].

We have compared, in Table 4, the calculated results for the ground state energies  $|00\rangle$  of the relative Hamiltonian at different confining frequencies with the results of Taut [184]. In a very recent work, Taut has reported a particular analytical solution of the Schrödinger equation for two interacting electrons in an external harmonic potential. Table 4 shows that as  $1/\omega$  increases the difference between both results noticeably decreases until it becomes  $\approx 1.4 \times 10^{-3}$  at  $1/\omega = 1419.47$ .

Quantum dots with more than two electrons can also be studied. The Hamiltonian for  $n_e$ -interacting electrons, provided that the electron–electron interaction term depends only on the relative coordinates between electrons  $V(|r_i - r_j|) = e^2/k|r_{ij}|$ , and parabolically confined in the quantum dot, is separable into a  $CM$  and a relative Hamiltonian. The parabolic potential form  $V(r_i) = m_i\omega_0^2 r_i^2/2$ ,  $i = 1, 2, 3, \dots, n_e$  is the only potential which leads to a separable Hamiltonian. The  $CM$  motion part is described by the one-particle Hamiltonian [see Eq. (270)], with the electron mass replaced by the total mass  $M = n_e m_e^*$

**Table 4.** The ground state energies (in atomic units) of the relative Hamiltonian calculated by  $1/N$  expansion at different frequencies, compared with the results of Taut [278].

and the electron charge replaced by the total charge  $Q = n_e e$ . The relative Hamiltonian part, which involves only the relative coordinates and momenta, has a cylindrically symmetric potential and can be handled by the  $1/N$ -expansion technique. When the confining potential is quadratic, FIR spectroscopy is insensitive to the interaction effects because of the  $CM$  and relative motions. If the radiation dipole operator  $\sum_i e_i \vec{r}_i = Q\vec{R}$ , being a pure  $CM$  variable, then it does not couple to  $\hat{H}_r$ , which contains all the electron–electron interactions. The dipole operator then induces transitions between the states of the  $CM$  but does not affect the states of the relative Hamiltonian. The eigenenergies for the  $CM$  Hamiltonian, Eq. (272), do not change because  $\omega_c$  in the energy expression remains the same; namely,  $QB/Mc = eB/m_e^* c$ . Consequently, the FIR absorption experiments see only the feature of the single-electron energies. There are only two allowed dipole transitions ( $\Delta m = \pm 1$ ) and the FIR resonance occurs at frequencies

$$\omega_{\pm} = \sqrt{\left(\frac{\omega_c}{2}\right)^2 + \omega_0^2} \pm \frac{\omega_c}{2} \quad (284)$$

Many different experiments on quantum dots have proved the validity of Kohn's theorem and that the observed resonance frequency of an electron system in a parabolic potential is independent of electron–electron interactions and thus the actual number of electrons in the well, as reported by Wixforth et al. in a very recent review article [185].

In conclusion we have obtained the energy spectra of two interacting electrons as a function of confinement energies and magnetic field strength. The method has shown good agreement with the numerical results of Merkt et al. [176], Taut [184], and Wagner et al. [182]. Our calculations have also shown the effect of the electron–electron interaction term on the ground state energy and its significance on the energy level crossings in states with different azimuthal quantum numbers. The shifted  $1/N$  expansion method yields quick results without putting restrictions on the Hamiltonian of the system.

### 2.9.3. Calculation of Parameters $\gamma_1$ and $\gamma_2$

The explicit forms of the parameters  $\gamma_1$  and  $\gamma_2$  are given in the following. Here  $R_y^*$  and  $a_B^*$  are used as units of energy and length, respectively

$$\gamma_1 = c_1 e_2 + 3c_2 e_4 - \bar{\omega}^{-1} [e_1^2 + 6c_1 e_1 e_3 + c_4 e_2^3] \quad (285)$$

and

$$\gamma_2 = T_7 + T_{12} + T_{16} \quad (286)$$

where

$$\begin{aligned} T_7 &= T_1 - \bar{\omega}^{-1} [T_2 + T_3 + T_4 + T_5 + T_6] \\ T_{12} &= \bar{\omega}^{-2} [T_8 + T_9 + T_{10} + T_{11}] \\ T_{16} &= \bar{\omega}^{-2} [T_{13} + T_{14} + T_{15}] \end{aligned} \quad (287)$$

with

$$\begin{aligned} T_1 &= c_1 d_2 + 3c_2 d_4 + c_3 d_6 & T_2 &= c_1 e_2^2 + 12c_2 e_2 e_4 \\ T_3 &= 2e_1 d_1 + 2c_5 e_4^2 & T_4 &= 6c_1 e_1 d_3 + 30c_2 e_1 d_5 \\ T_5 &= 6c_1 e_1 d_3 + 2c_4 e_3 d_3 & T_6 &= 10c_6 e_3 d_5 \\ T_8 &= 4e_1^2 e_2 + 36c_1 e_1 e_2 e_3 & T_9 &= 8c_4 e_2 e_3^2 \\ T_{10} &= 24c_1 e_1^2 e_4 + 8c_7 e_1 e_3 e_4 & T_{11} &= 12c_8 e_3^2 e_4 \\ T_{13} &= 8e_1 e_3 + 108c_1 e_1 e_3 & T_{14} &= 48c_4 e_1 e_3 \\ T_{15} &= 30c_9 e_3 \end{aligned} \quad (288)$$

where  $c$ 's,  $d$ 's, and  $e$ 's are parameters given as

$$\begin{aligned} c_1 &= 1 + 2n_r & c_4 &= 11 + 30n_r + 30n_r^2 \\ c_8 &= 57 + 189n_r + 225n_r^2 + 150n_r^3 \\ c_2 &= 1 + 2n_r + 2n_r^2 & c_5 &= 21 + 59n_r + 51n_r^2 + 34n_r^3 \\ c_3 &= 3 + 8n_r + 6n_r^2 + 4n_r^3 & c_6 &= 13 + 40n_r + 42n_r^2 + 28n_r^3 \\ c_9 &= 31 + 109n_r + 141n_r^2 + 94n_r^3 & c_7 &= 31 + 78n_r^2 + 78n_r^3 \\ e_j &= \kappa_j / \bar{\omega}^{-j/2} & d_i &= \delta_i / \bar{\omega}^{i/2} \end{aligned} \quad (289)$$

where  $j = 1, 2, 3, 4$  and  $i = 1, 2, 3, 4, 5, 6$ .

$$\begin{aligned} \kappa_1 &= (2 - a) & \kappa_2 &= -\frac{3(2 - a)}{2} \\ \kappa_3 &= -1 - \frac{2r_0}{Q} & \kappa_4 &= \frac{5}{4} + \frac{2r_0}{Q} \\ \delta_1 &= -\frac{(1 - a)(3 - a)}{2} & \delta_2 &= -\frac{3(1 - a)(3 - a)}{4} \\ \delta_3 &= 2(2 - a) & \delta_4 &= -\frac{5(2 - a)}{2} \\ \delta_5 &= -\frac{3}{2} - \frac{2r_0}{Q} & \delta_6 &= \frac{7}{4} + \frac{2r_0}{Q} \end{aligned} \quad (290)$$

## GLOSSARY

**Binding energy** Energy necessary to keep bound the electron-hole pair.

**Charged carrier** It is an electron or a hole.

**Conduction band** Energy band in a crystalline solid partially filled by electrons.

**Effective mass** The mass of a particle in a crystalline solid.

**Elastic scattering** A process in which the scattered particle has the same energy before and after event.

**Exciton** Electron-hole pair correlated by a coulomb-like interaction.

**Gap** Forbidden region for the electrons, which it is determined by the difference of energies between conduction and valence bands.

**Hole** Its the absence of an electron in the valence band.

**Impurity** An atom or molecule embedded in a different material.

**Inelastic scattering** A process in which the scattered particle has different energy before and after event.

**Magnetoconductivity** The conductivity of the charge carriers in presence of an external magnetic field.

**Quantum dot** A quantum system, in which the carriers are confined in all directions.

**Quantum Hall effect** The quantization of the Resistivity in a confined system due to the presence of a magnetic field.

**Quantum well wire** A quantum system, in which the carriers are confined in two directions, the other remains free.

**Quasi-dimensional system** A three-dimensional quantum system in which the movement of carriers is restricted in one, two or three directions of a few nanometers.

**Resistivity** Magnitude that characterizes the opposition to the movement of a charge carrier through a material.

**Valence band** Energy band in a crystalline solid completely filled by electrons.

## 1. INTRODUCTION

The majority of the elements in the periodic table are elements with partially filled inner *d*- or *f*-shells. Therefore there are a large number of solid-state materials that contain transition or rare-earth elements. For many decades these transition and rare-earth compounds have been investigated, mainly under the aspect of magnetism. The metals, on the one hand, and the rather insulating materials, such as ferrites or perovskites, on the other hand, dominated the field. Even the investigation of the metal–insulator transitions of the perovskites has a long-standing tradition. The magnetic semiconductors played a rather minor role for a long time because the physics of this subgroup of magnetic solid-state materials is obviously cross-disciplinary ground. Scientists working on magnetic phenomena in solids have widely ignored the semiconductors and their special properties, and, similarly, researchers in the field of semiconductors, in general, show only little interest in solid-state magnetism. A conventional semiconductor is described well in the rather simple one-electron approximation. This does not hold for a “magnetic” semiconductor, which contains localized magnetic moments, as “magnetism” requires many-particle interactions. Thus, the bridge in solid-state physics between magnetic and semiconducting phenomena

is hard to build without suitable introduction of electron–electron interactions, many-particle descriptions, and correlation effects.

The first excellent surveys of the field of magnetic semiconductors were given by Methfessel [1] as well as by Austin and Elwell [2] in 1970. The materials studied up to this time have been mainly insulating materials such as the perovskites or the Eu chalcogenides, which exhibit ferromagnetism with Curie temperatures from about 75 K for EuO or about 16 K for EuS, and the antiferromagnetic *3d* oxides like NiO, MnO, and CoO. In 1950 Jonker and van Santen [3, 4] discovered ferromagnetism up to room temperature in LaMnO<sub>3</sub> due to an insulator–metal transition caused by oxygen deficiency or by replacement of La<sup>3+</sup> by Sr<sup>2+</sup> or Cr<sup>2+</sup>. This led to an uncountable number of papers. In the 1970s the now classical semiconductors for electronics and optoelectronics (e.g., Si, Ge, GaAs, etc.) led a rather shadowy existence with respect to attempts to enhance their weak magnetic properties. On the one hand, it was not expected that their magnetic behavior could be enhanced such that applications in magnetic devices would become feasible; that is, there were always other materials. On the other hand, it was still early days for the semiconductor industry, and the quest for miniaturization was just at the beginning. Ideas for quantum computing and spin electronics were still utopian, which are currently the main driving forces for making classical semiconductors magnetic.

The situation changed after the first reports about giant enhancements of magneto-optical effects in a new group of semiconducting materials, the so-called diluted magnetic semiconductors (DMS) or semimagnetic semiconductors (SMS) by Komarov et al. [5], Galazka et al. [6, 7], Gaj [8], and Furdyna [9] at the beginning of the 1980s. The early papers reported about II–VI semiconductors, where a fraction of the cations was replaced at random by the transition metal Mn<sup>2+</sup>. An early review was given by Brandt and Moshalkov [10]. Later on, the investigations have been extended toward different magnetic ions as dopands in the II–VI host material, like Fe [11, 12], Co [13, 14], and Cr [15, 16]. Even the narrow gap IV–VI DMS became attractive, and various magnetic ions as dopands have been investigated (e.g., Mn [17], Eu [18], or Gd [19]). Rare-earth doped II–VI semiconductors, with a solubility

limit of about  $10^{18} \text{ cm}^{-3}$ , have never reached the concentration of solid solutions, but remained rather in the doping regime. The main interest in those materials was exploiting the luminescence properties of the internal transitions rather than the magnetic properties [20].

The real breakthrough for diluted magnetic semiconductors was achieved by the possibility of growing them by epitaxial methods like molecular beam epitaxy (MBE) or metal-organic vapor phase epitaxy (MOVPE). Now the way was open to prepare two-dimensional nanostructures. Early reviews of (II,Mn)VI-based semiconductor nanostructures were given by Furdyna [21] and Goede and Heimbrodt [22]. In 1989 Munekata et al. reported on MBE grown (In,Mn)As [23] as the first III-V-based magnetic semiconductor. Up to this time, manganese was considered only as an acceptor and p-dopant for III-V semiconductors. Later on further magnetic III-V semiconductors (e.g., (Ga,Mn)As [24], (Ga,Fe)As [25], (Ga,Mn)Sb [26], (Ga,Mn)N [27], (Ga,Mn)P [28], (Ga,Cr)As [29], (Ga,Fe)N [30], (Ga,Er)As [31]) as well as corresponding nanostructures were prepared.

Whether the very new (III,Mn)VI diluted magnetic semiconductors like (Ga,Mn)Se [32], (Ga,Mn)S [33] and (Ga,Fe)Se [34] will attract much attention is not yet clear. Very promising is however the first report on the group IV ferromagnetic semiconductor  $\text{Mn}_x\text{Ge}_{1-x}$  [35]. The obvious compatibility with present day semiconductor materials may be the beginning of a new era.

Modern information technology is based on highly sophisticated electronic and opto-electronic devices made of semiconductors. The charge of carriers is used to process information. Semiconductors are the appropriate materials because their conductivity can be controlled in the range of several orders of magnitude by changing the doping levels, and their bandgaps can be easily engineered by the material composition or preparation of desired heterostructures. Magnetic materials are also used to store information. The orientation of a localized magnetic moment or even of a single localized spin should be sufficient to present a bit or even a quantum bit in magnetic memories. The future aim is to combine the charge and the spin degree of freedom. This so-called magneto-electronics or spin electronics is an only recently emerging field where devices comprise small-scale magnetic elements and conventional semiconductor elements, to obtain completely new functionalities.

The beginning of this field was the discovery of the exchange coupling of Fe layers across the Cr interlayer by Grünberg et al. [36] and the subsequent observation of the giant magneto-resistance (GMR) in 1988 by Baibich et al. [37], with the current in the plane of the layers and 3 years later with the current perpendicular to the metal multilayers. The first applications are already commercially available, like magnetic field sensors in the read head of magnetic recording discs for computer information storage. These heads were a considerable improvement in size, weight, and cost. Magnetic random access memory (MRAM) cells, which will have the advantage of being nonvolatile, may replace direct random access memory (DRAM) soon. But all of the present applications are based solely on metallic multilayers. The exploitation of the spin degree of freedom in a real semiconductor electronics or optoelectronics is still ahead. Very promising candidates for key components in

devices of such a magneto- or spin electronics are the magnetic semiconductors. Understanding the electronic, optical, and magnetic properties of magnetic semiconductors with reduced dimension down to nanometer length scales (e.g., two-dimensional quantum wells, one-dimensional quantum wires, or zero-dimensional quantum dots) is, therefore, a central issue of the present magnetic semiconductor physics. This paper will give a survey of the present knowledge in this field.

We will restrict ourselves to those semiconductors which are subject to artificial structuring in one, two, or three dimensions. That means we will not consider the actually rich variety of materials which do exhibit naturally two-dimensional or one-dimensional magnetism, even not if they exhibit semiconducting properties. Although these natural low-dimensional semiconductors are most interesting from a physical point of view and are very often ideal model systems, they are unlikely to play an important role in electronic applications in the foreseeable future. The goal is to create magnetic materials which are compatible with the classical semiconductor materials and processing technology, making them attractive for integration into present-day or near-future electronics.

## 2. FUNDAMENTAL PROPERTIES OF BULK MAGNETIC AND DILUTED MAGNETIC SEMICONDUCTORS

Although this review is dedicated to nanostructured magnetic semiconductors, we will give in this chapter a short overview of the properties of the bulk crystals as far as they are necessary for the discussions of the properties of magnetic semiconductors with reduced dimensions in the following sections. For a more detailed discussion of the bulk magnetic semiconductors we refer the reader to some thorough reviews on II-VI [10, 21, 22, 38], III-V [39, 40], and IV-VI [41, 42] based materials.

### 2.1. Material Preparation and Crystal Structure

In the II-VI-based magnetic semiconductors a magnetic ion (transition metal or rare-earth metal) usually replaces a cation by contributing both the  $s^2$  electrons to the chemical bonding. All II-VI semiconductors have tetrahedral nearest-neighbor environments, and the bonding can be described well by  $sp^3$  hybrid orbitals. As the magnetic ions have the same outer electron configuration as the group II elements, the  $sp^3$  bonding is not affected by the substitution, and the local configuration of the magnetic ions is well defined. As the  $d$ - or  $f$ -shells of the magnetic ions do not contribute to the bonding in II-VI magnetic alloys, their electronic configuration is determined rather unambiguously by Hund's rule. Only at very high concentrations of the magnetic impurities might segregation effects occur, which lead to different crystallographic local environments of the magnetic ions due to the different crystal structure of the magnetic binary (e.g., ZnS:Mn has a wurtzite structure, whereas the stable phase of MnS is the rock salt structure). The situation is very different when a

with increasing  $x_{\text{Mn}}$  from zincblende to wurtzite) can be compared easily.

It is important for the following discussion of the optical and magnetic properties that the real microscopic bond lengths around the magnetic ions vary much less with increasing incorporation of magnetic ions than expected from Vegard's law. Extended X-ray absorption fine structure (EXAFS) measurements provide detailed information about the atomic environment of a given lattice site. It has been shown for (Cd,Mn)Te by Balzarotti et al. [62] that the mean Mn-Te and Cd-Te bond lengths remain practically constant throughout the entire range of composition between  $x_{\text{Mn}} = 0$  and  $x_{\text{Mn}} = 0.7$ . Only the weighted average of these bond lengths then leads to the  $d_c(x_{\text{Mn}})$  variation measured by X-ray diffraction and following Vegard's law.

The solubility of Eu in the II-VI or IV-VI semiconductor crystals is very low in the case of Bridgman techniques or chemical (e.g., iodine) transport methods. The maximum concentrations reported are less than 0.5% and in practice do not exceed the doping level. High concentrations of magnetic ions can be achieved in those cases exclusively by preparation methods away from the thermodynamical equilibrium (e.g., by MBE or MOVPE). They will be discussed in Section 3. In [63] (Pb,Eu)Te single-crystal films have been prepared by a modified hot wall technique with Eu concentrations of up to 5%.

The preparation of III-V-based diluted magnetic semiconductors in bulk form is also limited to very low Mn concentrations. Doping the III-V semiconductors with transition-metal impurities is, however, not a new issue in the III-V semiconductor technology. The solubility limits are generally about  $10^{17} \text{ cm}^{-3}$  (e.g., [64] and references therein). Beyond these limits surface segregation and phase separation effects may occur. Therefore, even for magnetic III-V semiconductors, a successful preparation of diluted magnetic semiconductors was reported only for preparation methods away from the thermodynamic equilibrium (e.g., low-temperature MBE and MOVPE). Details are also given in Section 3.

## 2.2. Bandgap and Optical Properties of Bulk Semiconductors

In this section the optical properties of the bulk crystals are reviewed only as far as necessary for the understanding of the optical properties of nanoscaled magnetic semiconductors.

The conventional optical properties of the alloys are known most precisely for the (II,Mn)VI semiconductors. All of these alloys are direct-gap semiconductors with the direct gap at the  $\Gamma$ -point of the Brillouin zone. The parent II-VI semiconductors exhibit either an open wurtzite or zincblende gap or a zero gap in the case of HgTe, HgSe, and HgS. The bandgaps of the zero-gap semiconductors open up with increasing Mn concentration. As can be seen from Figure 2, the energy gaps of all alloys except (Zn,Mn)S increase with increasing Mn concentration. (Zn,Mn)S exhibits the opposite behavior. The energy gaps of the (II,Mn)VI magnetic semiconductors are well known from the corresponding free Wannier-type A-exciton structures, which can be observed in low-temperature reflection, absorption, or photoluminescence spectra. In the case

**Figure 2.** Bandgaps of (II,Mn)VI compounds as a function of the Mn concentration. Reprinted with permission from [22], O. Goede and W. Heimbrot, *Phys. Stat. Sol. B* 146, 11 (1988). © 1988, Wiley-VCH Verlag, Berlin.

of (Cd,Mn)Te [65], (Cd,Mn)Se [66], and the (HgMn)VI [21, 67, 68] alloys a nearly linear dependence of the energy gap on the Mn concentration was found, which can be described by the following relations ( $T \leq 4.2 \text{ K}$ ):

$$\begin{aligned} (\text{Cd,Mn)Te} \quad E_{A\text{-exc}}(x_{\text{Mn}}) &= 1.595 + 1.59 \cdot x_{\text{Mn}} \text{ (eV)} [65] \\ (\text{Cd,Mn)Se} \quad E_{A\text{-exc}}(x_{\text{Mn}}) &= 1.821 + 1.54 \cdot x_{\text{Mn}} \text{ (eV)} [66] \\ (\text{Hg,Mn)Te} \quad E_{A\text{-exc}}(x_{\text{Mn}}) &= -0.3 + 3.5 \cdot x_{\text{Mn}} \text{ (eV)} [67, 68] \\ (\text{Hg,Mn)Se} \quad E_{A\text{-exc}}(x_{\text{Mn}}) &= -0.27 + 3.57 \cdot x_{\text{Mn}} \text{ (eV)} [21] \end{aligned}$$

A unique behavior has been reported for the wider-gap systems. For (Zn,Mn)Te [69], (Zn,Mn)Se [70, 71], (Cd,Mn)S [72, 73], and, probably, (Zn,Mn)S [74] and (Zn,Mn)O [54], the measured  $E_g(x_{\text{Mn}})$  dependence can be approximated by a linear function for higher manganese concentrations, but at Mn concentrations  $x_{\text{Mn}} < 0.2$ , a nonlinear deviation from the linear behavior toward lower energies becomes apparent. This bowing is much stronger than the usual bandgap bowing in solid solutions due to alloy disorder. Two possible mechanisms that may be responsible for this bowing in the wide-gap (II,Mn)VI are discussed. First, it can be due to the  $p$ - $d$  hybridization of the valence band states and the  $d$ -states, which are known to lie 3–3.5 eV energetically below the valence band edge [70, 75]. The larger bandgap, as well as the smaller lattice constant, may enhance the resulting  $p$ - $d$  hybridization at the valence band edge. Tworzydło [76, 77] showed that not only the antiferromagnetic coupling as discussed by Bylsma et al. [69], but also the spin-dependent scattering, needs to be considered to explain the bowing effect theoretically. He was able to describe the bowing of (Cd,Mn)S very well, using an approach which goes beyond the virtual-crystal approximation (VCA) and the molecular-field approximation, explicitly taking into account the chemical and magnetic disorder due to substitutional Mn ions [76, 77]. Second, the effect can be the same as reported recently for the Ga(N,As) and (Ga,In)(N,As) [78, 79] or Zn(Te,S) and Zn(Te,Se) [80] solid solutions. In (Ga,In)(N,As), a level repulsion of a nitrogen-induced  $s$ -type band above the conduction band edge and the conduction band edge itself leads to a tremendous red shift of the bandgap energy. The reason for this is the strong perturbation of the lattice by the large difference in size and

the strong difference of the electronegativity between the N ions and the anions of the host. A similar mechanism could explain the bowing in the case of wide band gap (II,Mn)VI semiconductors. The larger the bandgap the closer are the Mn-induced *s*-states to the band edge. A conclusive answer cannot be given at the moment.

In Figure 3 the bandgap bowing of (Zn,Mn)Se is given as an example. In [81] the band offsets for a series of (Zn,Mn)Se/ZnSe quantum well structures have been determined carefully from the measured light hole (lh) and heavy hole (hh) exciton splitting, including the known strain state of the samples. In this way it was possible to determine independently the offset for the conduction band edge as well as of the valence band edge as a function of *x*. As can be seen from Figure 3, the bowing has been found to be solely at the conduction band edge. The pairs of thick and thin lines, respectively, are the upper and lower limits for the band edge shifts, determined by the authors. The difference is caused mainly by the uncertainty of the deformation potentials but does not change the bowing effect. The bowing of the conduction band is a strong indication that even in the wide-gap (II,Mn)VI semiconductors the level repulsion of the Mn *s*-states and the conduction band yields the strong bowing of the bandgap rather than the change in the hybridization between the *p*-states and the Mn *3d* states.

The linear extrapolation to  $x_{\text{Mn}} = 1$  through the miscibility gap for  $E_g(x_{\text{Mn}})$  of the ternaries always yields for the corresponding Mn chalcogenides the values in Figure 2, which are the energy gaps of the unstable zincblende (or wurtzite) structures. The following mean values are obtained:

$$E_g(\text{MnTe}) = 3.2 \text{ eV}, \quad E_g(\text{MnSe}) = 3.3 \text{ eV}, \\ E_g(\text{MnS}) = 3.7 \text{ eV}$$

The available experimentally determined  $E_g$  values are not very reliable, as no sharp bandgap exciton structures in the optical spectra were observed. The measured low-temperature energetic positions are consistent, however, with the values given above [49–53].

**Figure 3.** Valence band and conduction band shift of (Zn,Mn)Se as a function of the Mn concentration (the thin line indicates the upper limit and the thick line indicates the lower limit with respect to the experimental uncertainty). Reprinted with permission from [81], W. Heimbrodt et al., *J. Lumin.* 60–61, 344 (1994). © 1994, Elsevier Science.

The IV–VI parent structures of the (IV,Mn)VI or (IV,Eu)VI diluted magnetic semiconductor alloys also exhibit a direct band gap, but at the L-point of the Brillouin zone, and, therefore, are many-valley semiconductors. For the low concentrations of the magnetic ions,  $x < 10\%$  in the (IV,Mn)VI or (IV,Eu)VI, it is found that the bandgap remains at the L-point. The following linear relations for the bandgaps for  $x < 10\%$  [42, 82] have been reported ( $T = 4.2 \text{ K}$ ):

$$\begin{aligned} (\text{Pb,Mn})\text{Te} \quad E_g(x_{\text{Mn}}) &= 0.190 + 2.510 \cdot x_{\text{Mn}} \text{ (eV)} [42] \\ (\text{Pb,Mn})\text{Se} \quad E_g(x_{\text{Mn}}) &= 0.146 + 3.800 \cdot x_{\text{Mn}} \text{ (eV)} [82] \\ (\text{Pb,Eu})\text{Te} \quad E_g(x_{\text{Eu}}) &= 0.190 + 6.000 \cdot x_{\text{Eu}} \text{ (eV)} [42] \\ (\text{Pb,Eu})\text{Se} \quad E_g(x_{\text{Eu}}) &= 0.114 + 11.370 \cdot x_{\text{Eu}} \text{ (eV)} [42] \end{aligned}$$

Of course, the values of  $E_g(x)$  in the limit  $x \rightarrow 1$  cannot be compared with the bandgaps of the binary compounds. The corresponding MnVI magnetic compounds all have the bandgap at the  $\Gamma$ -point and not at the L-point of the Brillouin zone. The band structures and absorption spectra of the Eu-chalcogenides are very complicated and are still under discussion [83]. The *4f* and *5d* states modify the *p*- and *s*-bands tremendously and make a quantitative comparison between experimental results and calculated band structures difficult.

Little is known about the band gaps of (III,Mn)V compounds. The main reason for this is that the concentrations achievable in bulk material are in the doping regime. Quasi-bulk-like epitaxial layers, where  $x_{\text{Mn}}$  values of up to 14% have been obtained, are of rather poor optical quality for  $x_{\text{Mn}} > 1\%$ , probably because Mn is a deep acceptor in the III–V materials. A small red shift of the  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  band gap with increasing  $x_{\text{Mn}}$  was observed at low temperatures on epitaxial layers grown by MOVPE [84]. A Burstein–Moss shift of the bandgap due to the acceptor properties of Mn could be ruled out at the low temperatures used in the paper, suggesting that this shift is a genuine alloying effect. Such a red shift is also observed for the  $E_1$  gap.

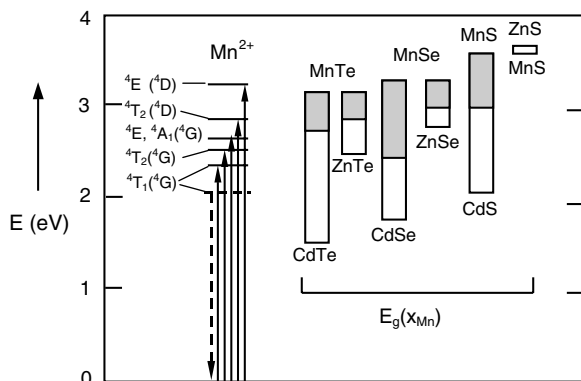

The optical properties of the magnetic semiconductors are essentially modified by the *d*- or *f*-states of the magnetic ions, as already indicated in the discussion of the bandgap bowing of the wide-gap (II,Mn)VI materials. In addition, if the band gap is wide enough, the electronic transitions within the partially filled *d*- or *f*-shells become observable. The high degeneracy of the *d*- or *f*-configurations is partially removed by the intra-ionic electron–electron interaction and by the ligand–field interaction. The electron–electron interaction, already present in the free ions, lifts the L-degeneracy and can be described by two Racah parameters, *B* and *C*. *B* in particular is often somewhat reduced in comparison with the free ion *B*-value because of covalence effects. The  $T_d$  symmetric crystal field of the chalcogen ligands, on the other hand, splits a fivefold degenerate one-electron *d*-state into  $t_2$  and *e* states. The two interactions are of the same order of magnitude in the case of *d*-states and can be accounted for by the perturbation approach after Tanabe and Sugano [85], leading to the ground and excited states of the ions as a function of the ligand field parameter *Dq*. In Figure 4 the curves are depicted for the  $\text{Mn}^{2+} 3d^5$  ion. The states are classified by the irreducible representation of  $T_d$ . The dominating occupation numbers in

**Figure 4.** Energies of the lowest excited states of a  $\text{Mn}^{2+} 3d^5$  ion in a  $T_d$  symmetric ligand field as function of the Racah parameter  $Dq$  with  $B = 50$  meV and  $C = 434$  meV obtained for  $\text{MnS}_{\text{ZB}}$  with the Tanabe–Sugano matrices [85]. Experimental points with  $Dq = -57$  meV are for  $\text{MnS}_{\text{ZB}}$ . Reprinted with permission from [22], O. Goede and W. Heimbrodt, *Phys. Stat. Sol. B* 146, 11 (1988). © 1988, Wiley-VCH Verlag, Berlin.

the one-electron picture are given in parentheses. The optical dipole transitions between the ground and excited states are forbidden by spin and symmetry selection rules, which, however, are softened by spin–orbit interaction and mixing with electronic states of suitable symmetry, respectively. In the case of the transition metals the strong hybridization between the  $3d$ -states and the anion  $p$ -states are typical for the chalcogenides. The mixing of the states also yields, apart from the bandgap bowing already mentioned, a relaxation of the spin and symmetry selection rules and is the basic mechanism for the magnetic behavior, which will be discussed in the next section. The usually suggested softening of the symmetry-induced selection rules by electron–phonon interaction or other symmetry-reducing perturbations should be comparatively less important.

As shown in Figure 5, the  $d$ – $d$  transitions of the Mn ion are observable in various (II,Mn)VI alloys, if the bandgap

**Figure 5.** Internal transitions of the  $\text{Mn}^{2+} 3d^5$  shell of (Zn,Mn)S in comparison with realizable variations of the bandgap  $E_g(x_{\text{Mn}})$  for the (Zn,Mn) and (Cd,Mn) chalcogenides. The arrows (full line) represent the internal absorption transitions, and the dashed arrow represents the Franck–Condon shifted yellow emission. Reprinted with permission from [22], O. Goede and W. Heimbrodt, *Phys. Stat. Sol. B* 146, 11 (1988). © 1988, Wiley-VCH Verlag, Berlin.

as a function of the Mn concentration is wide enough. In (Zn,Mn)S, which has the widest bandgap of all (II,Mn)VI compounds, five  $d$ – $d$  transitions (indicated in Fig. 5) can be observed in the whole Mn concentration range. The peak positions are almost independent of temperature and Mn concentration. According to the point-ion model,  $Dq$  should vary proportionally to  $d_c^{-5}$ , where  $d_c$  is the Mn anion bond length. A variation according to Vegard’s law would result in a remarkable peak shift of about 100 meV to higher energies. The experimentally observed shift of less than 20 meV is in excellent agreement with the EXAFS results discussed above. Only if the bandgap window is sufficiently opened by a corresponding high Mn concentration is the detection of a set of distinct internal transitions within the  $\text{Mn}^{2+} 3d^5$  shell possible in all of the other solid solutions. In (Cd,Mn)S, for example,  $x_{\text{Mn}} > 0.1$  is required to observe the first absorption band ( ${}^6A_1 \rightarrow {}^4T_1$ ), whereas the corresponding yellow emission is already observable for the lowest Mn concentrations. The tremendous Stokes shift between the emission and absorption bands is caused by the strong electron–phonon coupling. In (Cd,Mn)Te the PL becomes observable for  $x_{\text{Mn}} > 0.4$ , but the  ${}^6A_1 \rightarrow {}^4T_1$  absorption is resolvable only for  $x_{\text{Mn}} > 0.6$ . In the case of the closed gap Hg-chalcogenides, only for (Hg,Mn)Te would the Mn solubility allow the observation of internal  $\text{Mn}^{2+} 3d^5$  transitions.

For changing anion ligands of the  $\text{Mn}^{2+}$  ion, a chemical trend is expected for the internal transitions within the series  $\text{S} \rightarrow \text{Se} \rightarrow \text{Te}$ . The observed shift for (Zn,Mn)Se compared with (Zn,Mn)S is, however, rather vanishing, and the corresponding shift of the (Cd,Mn)Te bands is smaller than expected. The reason for this is not clear, but the expected shift to lower energies might be compensated for by growing covalence effects.

## 2.3. Magnetic Properties of Bulk Semiconductors

Now we want to review the magnetic properties of magnetic and diluted magnetic semiconductors.

It is known that the magnetic dipole–dipole interaction of the magnetic moments cannot be the reason for the magnetic ordering and the spontaneous magnetization, as it is orders of magnitude too small. It is the exchange energy as part of the Coulomb interaction which results in the magnetic phenomena which will be discussed in this review article. Dirac showed that the energy operator of the exchange interaction between two particles can be written in the form

$$H_{\text{exchange}} = -2J_{12}(r_{12})S_1S_2 \quad (1)$$

where  $J_{12}$  is the exchange integral and  $S_1$  and  $S_2$  are the spin operators. The exchange integral decreases rapidly with increasing distance  $r_{12}$  between the particles. In magnetic semiconductors interacting magnetic moments are usually separated by such large distances that a direct exchange interaction cannot be responsible for the magnetic ordering. Different mechanisms of indirect exchange interaction are known. In ionic semiconductors, the exchange interaction of cation-magnetic moments mediated via the anions situated between them is the dominant mechanism. In highly doped semiconductors, similar to metals, the mediation of

the interaction via conduction band electrons or valence band holes can be of the greatest importance. In both cases, the Hamiltonian can be approximated by the Dirac formula in Eq. (1). A system of magnetic moments, localized on lattice sites and interacting with each other according to Eq. (1), is the so-called Heisenberg model of a magnetically ordered material. A more general model has to take into account the weaker magnetic dipole–dipole interaction of the magnetic moments and the Zeeman interaction with an applied magnetic field. Two main assumptions are made by the Heisenberg model: (i) the magnetic moments are assumed to be localized completely, and (ii) the orbital magnetic moments are neglected. The first assumption is satisfied for magnetic semiconductors. The second assumption is highly satisfied for most magnetic semiconductors with transition metals due to the quenching of the orbital momenta. When the quenching is not sufficiently strong, the weak influence of the orbital momenta can be taken into account in the framework of a generalized model. It can be assumed, first, that the  $g$ -value in the Zeeman term is modified. Second, a term describing the magnetic anisotropy, which is caused by the spin–orbit interaction, is added to the Hamiltonian. In magnetic semiconductors with rare-earth ions, for example, the quenching of the angular momenta is much weaker or does not take place at all. In those cases the spin orbital interaction, which combines spin and orbital momentum to the total angular momentum, is strong. Nevertheless, the Heisenberg model may be used for such semiconductors in most cases, but the spin angular momenta in Eq. (1) must then be replaced by the total angular momenta.

In the following, we want to assemble the basic knowledge necessary for understanding the behavior of magnetic semiconductors with reduced geometrical dimensions. Most magnetic semiconductors that are considered for applications are ternary alloys. Nevertheless, we will start with the binary magnetic compounds, which represent the limits approached when the magnetic ion content of the magnetic semiconductor alloys is increased to 100%. A thorough knowledge of these binary compounds is essential for a full understanding of the magnetic properties of the corresponding ternary magnetic semiconductor alloys.

All binary compounds with a rare-earth metal or transition metal on cation site are known to exhibit, at sufficiently low temperatures, a phase transition from the paramagnetic state into an ordered magnetic state, which is either ferromagnetic or antiferromagnetic. We want to start the survey with the most prominent class of materials, the Mn chalcogenides.

### 2.3.1. Mn Chalcogenides

All Mn chalcogenides are known to become antiferromagnetic below a Néel temperature  $T_N$ , which depends on the crystal structure. In the paramagnetic phase ( $T > T_N$ ) the  $\text{Mn}^{2+} 3d^5$  spins and the corresponding magnetic moments are distributed at random. In an external field the orientation of the magnetic moment with  $M_j = -5/2$  is energetically most favored. The temperature and magnetic-field dependence of the magnetization per mole in the paramagnetic phase is given by

$$M = N_A \mu_B \tilde{g} S \cdot B_{5/2}(\xi) \quad (2)$$

where  $\tilde{g} \approx 2$  is the effective Landé factor,  $S = 5/2$ ,  $N_A$  is Avogadro's number, and

$$\langle S_z \rangle_{\text{mol}} = N_A \langle S_z \rangle = -N_A S \cdot B_{5/2}(\xi) \quad (3)$$

is the mean molar spin density, where  $B_{5/2}$  is the Brillouin function,

$$B_{5/2}(\xi) = \frac{6}{5} \coth \frac{6\xi}{5} - \frac{1}{5} \coth \frac{\xi}{5}; \quad \xi = \frac{\tilde{g} \mu_B S H}{k_B (T + \Theta)} \quad (4)$$

For  $\xi \ll 1$  (low field case) the magnetization is proportional to the external field, and from Eq. (2) the usual Curie–Weiss law for the molar magnetic susceptibility  $\chi$  can be derived:

$$\chi = \frac{\partial M}{\partial H} = \frac{N_A S(S+1) \tilde{g}^2 \mu_B^2}{3k_B (T + \Theta)}; \quad T > T_N \quad (5)$$

The appearance of a Curie–Weiss temperature  $\Theta > 0$  is an immediate consequence of the antiferromagnetic exchange interaction between the  $\text{Mn}^{2+}$  ions and leads to a decrease in the magnetic susceptibility in comparison with an ideal paramagnetic behavior ( $\Theta = 0$ ) as both the thermal disorder ( $k_B T$ ) and the antiferromagnetic interaction ( $k_B \Theta$ ) oppose the paramagnetic ordering of the spins in a magnetic field.

Some typical values for  $T_N$  and  $\Theta$  from measurements (e.g., magnetic susceptibility, specific heat, thermal expansion, electron paramagnetic resonance (EPR), inelastic neutron scattering, and neutron diffraction) are given in Table 2. The mean values for  $T_N$ , being nearly the same for MnS and MnSe, are about 150 K and 100 K for the rock salt and zinblende structures, respectively. For MnTe with NiAs structure the Néel temperature is much higher,  $T_N > 300$  K. For the zinblende phase of MnTe a value  $T_N = 67$  K was reported. The effective Landé factor in the Mn chalcogenides is found to decrease only slightly in comparison with the free-ion value, and, therefore, the maximum  $z$ -component of the magnetic moment  $gS\mu_B$  approximately equals  $5\mu_B$ .

The antiferromagnetic interaction between the  $\text{Mn}^{2+} 3d^5$  ions can be described phenomenologically to a good approximation by a Heisenberg Hamiltonian,

$$H_H = - \sum_{\substack{i, j \in \\ \text{fcc sublattice}}} J(R_{ij}) \vec{S}_i \vec{S}_j = -J_{\text{nn}} \sum_{\substack{i, k \\ (i, k = \text{nn})}} \vec{S}_i \vec{S}_k - J_{\text{nnn}} \sum_{\substack{i, l \\ (i, l = \text{nnn})}} \vec{S}_i \vec{S}_l \quad (6)$$

taking into account only the isotropic nearest-neighbor (nn) and next-nearest neighbor (nnn) interactions.  $S_i$  is the total-spin operator acting on the Mn sublattice site  $i$ , and  $R_{ij}$  is the real space vector between the sites  $i$  and  $j$ . The corresponding exchange interaction parameters  $J_{\text{nn}}$  and  $J_{\text{nnn}}$  (which are also given in Table 2) can be determined experimentally by using their relation to  $T_N$  and  $\Theta$ . In the molecular field approximation one obtains from Eq. (6), for an fcc sublattice,

$$\Theta = - \frac{(24J_{\text{nn}} + 12J_{\text{nnn}})S(S+1)}{3k_B} \quad (7)$$

$$T_N^{\text{type II}} = - \frac{12J_{\text{nnn}}S(S+1)}{3k_B} \quad (8)$$

$$T_N^{\text{type III}} = - \frac{(8J_{\text{nn}} - 4J_{\text{nnn}}) \cdot S(S+1)}{3k_B} \quad (9)$$

**Table 2.** Magnetic parameters of Eu and Mn chalcogenides.

where the superscripts type II and type III correspond to two different magnetic unit cells described below. More sophisticated relations were obtained on the basis of Eq. (6), using Green's function method [117], magnon theory, or high temperature expansion [102]. There is a surprisingly good agreement with the theoretical values for  $J_{nn}$  and  $J_{nnn}$  obtained from band structure calculations [103–105, 107, 119, 120]. Because of the strong localization of the Mn  $3d$ -states the direct Mn–Mn exchange interaction is negligible in the Mn chalcogenides, and the Anderson  $p$ – $d$  superexchange mechanism [121] dominates. A schematic picture of this anion-mediated interaction is given in Figure 6.

The negative values of  $J_{nn}$  and  $J_{nnn}$  mean that the antiparallel orientation of the spins for a considered pair of both nn and nnn is energetically favored. The resulting magnetic ordering has been studied by neutron diffraction measurements. In the case of the rock salt structure for MnS and MnSe, the so-called type II fcc antiferromagnetic ordering was found [122], which is characterized by parallel

**Figure 6.** Schematic presentation of the anion-mediated superexchange mechanism, resulting in an antiferromagnetic coupling between two  $Mn^{2+}$  ions.

orientation of all  $Mn^{2+}$  spins in a (111) plane and antiparallel orientation of the spins in neighboring (111) planes (see Fig. 7). For the zincblende MnS, MnSe, and MnTe the somewhat more complicated type III fcc antiferromagnetic ordering is found. It should be noted, however, that the definite spin orientation with respect to the crystallographic directions is determined by anisotropic contributions to the exchange Hamiltonian, which are omitted in Eq. (6) for simplicity.

**Figure 7.** Schematic picture of the type II fcc antiferromagnetic ordering.

In Figure 8 the  $\text{Mn}^{2+}$  spin orientations in the elementary clusters of the rock salt and zincblende structures are shown for both types of antiferromagnetic ordering, which reduce the symmetry of a lattice site from  $O_h$  to  $D_{3d}$  and from  $T_d$  to  $C_{2v}$ , for the RS and ZB structures, respectively. In the case of type II the spins of six of the 12 nn and of all six nnn  $\text{Mn}^{2+}$  ions are antiparallel with respect to the spin of a considered  $\text{Mn}^{2+}$  ion. In type III, however, the spins of eight nn but only two nnn  $\text{Mn}^{2+}$  ions have the energetically favored antiparallel orientations. The spins of the remaining  $\text{Mn}^{2+}$  neighbors are parallel to the spin of the central  $\text{Mn}^{2+}$  ion. The type of the antiferromagnetic ordering is determined by the ratio  $J_{\text{nnn}}/J_{\text{nn}}$ .

### 2.3.2. Eu Chalcogenides

The bulk Eu chalcogenides crystallize in the rock salt structure. The magnetic properties were investigated in detail, as already mentioned, a long time ago [123]. EuO, EuS, and EuSe are typical ferromagnets of the Heisenberg type, which can be described by Eq. (6). As can be seen from Table 2, the exchange integrals  $J_{\text{nn}}$  are positive in sign, which consequently leads to a ferromagnetic ordering, as long as a negative  $J_{\text{nnn}}$  does not become dominant. It is noteworthy that it cannot be the indirect Anderson superexchange mechanism which leads to the ferromagnetic coupling, as such  $180^\circ f-p-f$  coupling inevitably leads to an antiferromagnetic coupling. The key point is the rock salt structure of the Eu-chalcogenides. The nearest-neighbor coupling is a  $90^\circ$  coupling, which is a very weak coupling in the case of  $p$ -orbitals. According to the so-called Goodenough–Kanamori–Anderson (GKA) rules [124], the  $90^\circ$  exchange is weak and ferromagnetic. The phenomenological idea of this rule is depicted in Figure 9. It can easily be seen that in the  $90^\circ$  configuration two different  $p$ -orbitals of the same anion overlap with the  $f$ -orbitals of the two Eu ions. Assuming that one electron of either  $p$ -orbital hops into the corresponding overlapping  $f$ -shell, the spins of the two electrons remaining in the  $p$ -orbitals of the anion must be parallel according to Hund's rule. Thus, the spins of the Eu ions should be parallel too.

Another, much more straightforward, explanation is also very likely. The cation radius of  $\text{Eu}^{2+}$  is rather large

**Figure 8.**  $\text{Mn}^{2+}$  spin orientations in the elementary clusters of zincblende (left) and rock salt (right) structures in the case of an fcc type III (left) and fcc type II (right) antiferromagnetic ordering, respectively.

**Figure 9.** Schematic picture of the  $90^\circ$  superexchange interaction of the ferromagnetic coupled  $\text{Eu}^{2+}$  ions in the rock salt Eu-chalcogenides.

compared to e.g. the oxygen anion radius. Therefore the direct  $90^\circ$  overlap of the Eu ions may be the reason for the positive  $J_{\text{nn}}$ . The increasing radius from  $\text{O} \rightarrow \text{S} \rightarrow \text{Se} \rightarrow \text{Te}$  then decreases the direct exchange and therefore the ferromagnetic coupling compared to the antiferromagnetic coupling of the indirect  $180^\circ$  exchange interaction.

The  $180^\circ$  coupling via  $p$ -orbitals is as for Mn antiferromagnetic (see Fig. 6) and is much more effective. Therefore, it yields a stronger tendency for the  $J_{\text{nnn}}$  to be negative. The positive sign of  $J_{\text{nnn}}$  in the case of EuO may be caused again by a remaining contribution of the direct exchange due to the small lattice parameter. The decreasing Curie temperatures from about 70 K for EuO to about 2.8 K for EuSe are caused by a reduction of  $J_{\text{nn}}$  due to a decreasing wavefunction overlap of the localized  $f$ -orbitals of Eu with each other or with the  $p$ -orbitals of the anion as the lattice constant increases in the chalcogenides because of the increase in the anion radius from oxygen to selenium.

In a mean field approximation one derives, from Eq. (6),

$$T_C = \frac{(12J_{\text{nn}} + 6J_{\text{nnn}})2S(S+1)}{3k_B} \quad (10)$$

The increasing influence of the  $J_{\text{nnn}}$  leads to the antiferromagnetic ordering of EuTe in an fcc-type II antiferromagnetic structure with a Néel temperature  $T_N = 9.6$  K. Although  $J_{\text{nn}}$  is still positive, an antiferromagnetic phase transition occurs as  $J_{\text{nnn}} < 0$ . For EuSe an interesting and unique behavior is observable. A special antiferromagnetic structure was reported above  $T_C$  between  $T_N = 4.7$  K and  $T_C = 2.8$  K. All of the spins in two adjacent (111) planes are ferromagnetically ordered, whereas the subsequent two layers are antiferromagnetically arranged with respect to the former, yielding a NNSS antiferromagnetic order.

In the case of opposite signs of the exchange integrals, the state with the lowest energy, which can be either ferromagnetic or antiferromagnetic, will determine which spin structure is favored. Comparing Eq. (8) and Eq. (10), one obtains the condition  $|J_{\text{nnn}}| > |J_{\text{nn}}|$  for an antiferromagnetic ordering, which is defined by  $k_B T_N > k_B T_C$ . This is the case for EuTe. For EuS it holds that  $|J_{\text{nnn}}| < |J_{\text{nn}}|$ , yielding the ferromagnetic state, as it is now  $k_B T_N < k_B T_C$ . There are no reliable values for the nn and nnn exchange integrals of EuSe. Considering the exchange constants versus

the lattice parameters for the Eu-chalcogenides (Fig. 10), it can be estimated that  $|J_{\text{nnn}}| \cong |J_{\text{nn}}|$  for EuSe. This leads to the quasi-antiferromagnetic phase below 4.7 K as  $|J_{\text{nnn}}| \geq |J_{\text{nn}}|$ , yielding  $k_{\text{B}}T_{\text{N}} > k_{\text{B}}T_{\text{C}}$ . With decreasing temperature, because of the increasing overlap of the wavefunctions by reduction of the anion-anion distance, the exchange integrals are enhanced. This enhancement seems to be slightly stronger for  $J_{\text{nn}}$  compared with  $J_{\text{nnn}}$ . This might be the reason for the transition to the ferromagnetic state below 2.8 K with  $|J_{\text{nnn}}| \leq |J_{\text{nn}}|$ .

### 2.3.3. Mn-Pnictides

The Mn-pnictides are not semiconductors but show semimetallic behavior. Therefore, strictly speaking, they are not subject of this review. The recent interest in the growth of (III,Mn)V semiconductors has led, however, also to the fabrication of hybrid structures consisting of a diluted magnetic semiconductor matrix and Mn-pnictide clusters as a result of segregation processes. It was shown that Mn-V clusters can be prepared in a controlled manner during the MBE or MOVPE growth or by thermal annealing of the layers after a low temperature MBE growth (see also sections 3.1 and 3.3.2). A giant negative magnetoresistance has been observed for GaAs/MnAs [125, 126, 527] layered and granular hybrid structures which further provoked the interest. Therefore a brief review of the structural and magnetic properties of the Mn pnictides is essential for the understanding of the corresponding hybrid structures.

The bulk MnAs, MnSb and MnBi crystallize in the hexagonal NiAs structure with four atoms in the primitive unit cell. The favorable zincblende structure is thermodynamically not stable. The Mn ions are in the low spin state ( $3d^4 \text{ Mn}^{3+}$ ). The magnetic state is a ferromagnetically ordered state below the Curie temperature. It is worth noting, that the Curie temperature increases with increasing anion radius from MnAs ( $T_{\text{C}} = 318 \text{ K}$  [124] over MnSb ( $T_{\text{C}} = 587 \text{ K}$  [124]) to MnBi ( $T_{\text{C}} = 633 \text{ K}$  [124]). Above  $T_{\text{C}}$  they also undergo a structural change to the orthorhombic MnP-type structure. The MnP-type structure differs from the NiAs-type structure only by a distortion in the basal plane. It is well established (e.g. for the extensively studied MnAs) that this magnetic and structural phase transition takes place

**Figure 10.** Exchange constant  $J_{\text{nn}}$  and  $J_{\text{nnn}}$  versus the lattice parameter for the Eu-chalcogenides. Experimental points: ■ [90], ▲ [91], ● [89]. The dashed line marks the position of the EuSe lattice parameter.

at different  $T_{\text{C}}$  on heating and on cooling. On heating the spontaneous magnetization of MnAs vanishes at  $T_{\text{C}} = 318 \text{ K}$ , but on cooling the respective  $T_{\text{C}}$  is only 306 K [see [127] and refs. therein]. Furthermore it must be taken into account, that  $T_{\text{C}}$  of MnAs films is obviously somewhat dependent on the preparation conditions. Tilsley et al. [128] were able to reduce  $T_{\text{C}}$  on heating from 320 K down to 312 K by changing the substrate temperature during growth from 400 °C to 600 °C.

The orthorhombic MnP ( $a > b > c$ ) itself is ferromagnetic between 47 K and 291 K. Below 47 K a screw phase has been observed in which the moments rotate in the  $bc$ -plane. MnN is known to have a NaCl-type structure at room temperature and has been reported to be antiferromagnetic with a Néel-temperature of 650 K [129]. Studying the diluted magnetic semiconductor  $\text{Ga}_{1-x}\text{Mn}_x\text{N}$  with  $x_{\text{Mn}} < 0.01$  which grows in a hexagonal phase, Zajac et al. [130] were able to determine the Mn-Mn nearest neighbor exchange integral which was clearly antiferromagnetic with  $J_{\text{nn}}/k_{\text{B}} \approx -1.9 \text{ K}$ . The most interesting phase of the Mn-nitrides is probably the  $\text{Mn}_4\text{N}$ -type compound [131] which exhibits a ferrimagnetic phase with a high resulting magnetic moment and a Néel-temperature of 745 K.

### 2.3.4. Diluted Magnetic Semiconductors

Decreasing the concentration  $x$  of magnetic ions in diluted magnetic II-VI or IV-VI alloys restricts the spin ordering effects to the lower temperature region. As an example, Figure 11 shows schematic magnetic phase diagrams for (Cd,Mn)Te and (Cd,Mn)S. The two phase diagrams are typical for all (II,Mn)VI alloy systems. The paramagnetic phase extends to lower temperatures with decreasing  $x_{\text{Mn}}$ . A (disordered) antiferromagnetic phase (af) occurs that has a long-range spin ordering below a critical temperature  $T_{\text{N}}(x_{\text{Mn}})$  for a sufficiently high Mn concentration  $x_{\text{Mn}} > 0.8$  (beyond the miscibility gap (mg)) for (Cd,Mn)S. The corresponding phase transition is characterized by peaks at  $T_{\text{N}}$  in both the magnetic susceptibility and the specific heat. For Mn concentrations below the miscibility gap a spin-glass

**Figure 11.** Magnetic phase diagrams of (Cd,Mn)Te and (Cd,Mn)S. Experimental points are from [482].

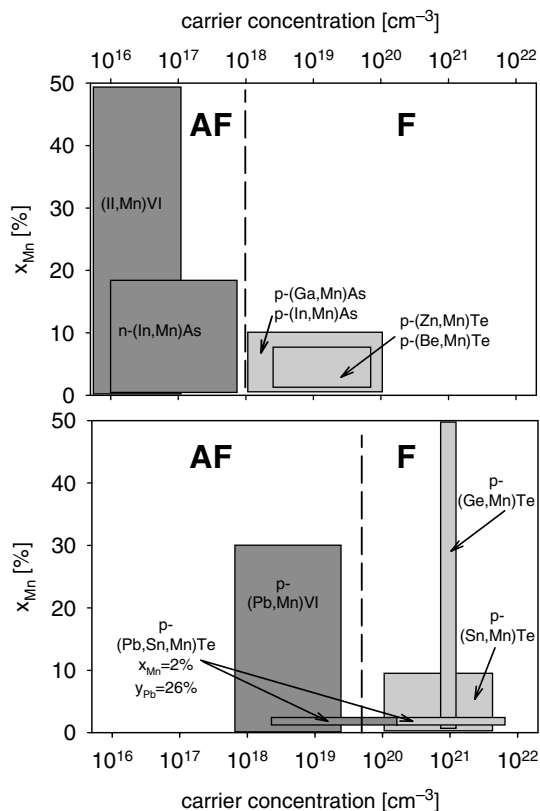

phase (sg) is observed for temperatures below  $T_{sg}(x_{Mn})$ . In the case of (Cd,Mn)Te even a transition to the antiferromagnetic phase has been reported for  $x_{Mn} = 0.7$  [132], which means that it is still below the miscibility gap. The spin-glass phase is characterized by an antiferromagnetic short-range ordering of the spins, as well as frustration effects. As an example, in Figure 12 a triangle is depicted, where the third spin can either be spin up or spin down, as both states are energetically degenerate. A quantum mechanical calculation reveals that the ground-state spin of such a closed triangle is not  $S_z = -5/2$ , but  $S_z = -1/2$  [133]. The somewhat diffuse phase transition from the paramagnetic into the spin-glass phase leads to a peak or kink at  $T_{sg}(x_{Mn})$  in the temperature dependence of the magnetic susceptibility, but no anomaly in the specific heat is observable. Neutron scattering experiments have shown that small antiferromagnetically ordered clusters already appear above  $T_{sg}$ , which grow in size with decreasing temperature. Another surprising fact is that a spin-glass phase is observable not only above the percolation limit ( $x_{Mn} \approx 0.2$ ), but also below. In the very low concentration range, a rather long-range interaction is necessary, in addition to the short-range superexchange interaction, to yield a spin-glass phase. The spin freezing temperatures below the percolation concentration are very small, for example, between 0.1 K and 1 K for  $x_{Mn} \approx 0.01$ . The dipole-dipole interaction between more distant  $Mn^{2+}$  ions is proposed to be the required long-range interaction responsible for this spin-ordering mechanism, despite the fact that the dipole-dipole interaction might be too weak to cause the ordering at finite temperatures [134].

A very striking feature of diluted magnetic semiconductors is the strong correlation of magnetism and doping. Figure 13 depicts various Mn-containing DMS arranged schematically according to their free carrier concentration and Mn concentration. It can be seen that in (II,Mn)VI and (III,Mn)V (top graph) as well as in the (IV,Mn)VI (bottom graph) semiconductors the coupling between the Mn ions changes from antiferromagnetic (AF) to ferromagnetic (F) with increasing free carrier concentration. The critical free-carrier concentration, where the transition between the two types of coupling occurs, is about  $10^{18} \text{ cm}^{-3}$  for the (II,Mn)VI and (III,Mn)V compounds and about  $10^{19} \text{ cm}^{-3}$  for the (IV,Mn)VI compounds. It should be pointed out that the (II,Mn)VI semiconductors usually have free-carrier concentrations below the critical concentrations [21, 22]. Only recently very high p-doping concentrations of  $10^{20} \text{ cm}^{-3}$  were achieved in  $Zn_{1-x}Mn_x\text{Te:N}$  with

**Figure 12.** Degeneracy of the spin states in a closed triangle of  $Mn^{2+}$  ions.

**Figure 13.** Correlation of the magnetism of the Mn subsystem and the doping of the host. Top graph: (II,Mn)VI and (III,Mn)V semiconductors. Bottom graph: (IV,Mn)VI semiconductors. AF and F denote antiferromagnetic and ferromagnetic coupling between Mn ions, respectively.

$x \approx 2\%$  [135, 136]. These samples show a ferromagnetic phase at low temperatures. Similar results have also been reported for (Zn,Mn)Te:N and (Be,Mn)Te:N with  $x$  ranging from 0.5% to 7% [137]. The (IV,Mn)VI materials can easily be prepared over a wide range of free-carrier concentrations; thus, they were the first class of DMS where samples exhibiting either antiferromagnetic or ferromagnetic coupling between the Mn ions were found [138]. The (III,Mn)V usually have very high free-carrier concentrations, as Mn acts as a dopant in these compounds. It is worth noting that Ohno et al. [139] demonstrated that it is possible to switch from ferromagnetic to antiferromagnetic coupling in one and the same (In,Mn)As layer by varying the free-carrier density with an external electric field. The structure used was a metal-insulator-semiconductor field-effect transistor with (In,Mn)As as the semiconductor material.

Because of the usually rather small carrier concentrations ( $<10^{18} \text{ cm}^{-3}$ ) in (II,Mn)VI alloys, even for the narrow gap materials, the indirect RKKY mechanism between the  $Mn^{2+}$  ions does not play a role. The magnetic ordering phenomena are determined by the Anderson superexchange as the dominant exchange mechanism.

Recently Saito et al. [140] reported the observation of ferromagnetism in  $Zn_{1-x}Cr_x\text{Te}$  layers on GaAs substrate. They found Curie temperatures of about 15 K for 3.5% chromium. As we will discuss in the next chapter the

$p$ - $d$  exchange integral (see Table 4) is actually positive e.g. ferromagnetic. It does however not necessarily mean that the  $d$ - $d$  coupling is ferromagnetic as well. The reason for the ferromagnetism of (Zn,Cr)Te is not clear to date. Shoren et al. [141] suggested a carrier-induced mechanism in case of an unintentionally doped sample. Blinowski et al. [142] discussed, however, on the basis of their theoretical calculation the opportunity of a ferromagnetic superexchange mechanism. It is known, that the  $180^\circ$  exchange interaction in case of  $3d^4$  cations (e.g.  $\text{Cr}^{2+}$ ,  $\text{Mn}^{3+}$ ,  $\text{Fe}^{4+}$ ) is ferromagnetic in most cases [124].

Dominating Anderson superexchange also seems to be valid for some of the (IV,Mn)VI alloys such as (Pb,Mn) $X$  ( $X = \text{S, Se, Te}$ ) [143, 144]. However, others (e.g., (Sn,Mn)Te [145, 146] or (Ge,Mn)Te [147, 148], which have typical free-carrier concentrations above  $10^{20} \text{ cm}^{-3}$ ) exhibit ferromagnetic interactions between the  $\text{Mn}^{2+}$  spins (i.e., the RKKY exchange mechanism dominates over the Anderson superexchange). With varying carrier concentration in the quaternary alloy  $\text{Pb}_{1-x-y}\text{Sn}_y\text{Mn}_x\text{Te}$ , either antiferromagnetic or ferromagnetic ordering is possible [149, 150]. The schematic phase diagram representative for ferromagnetic (IV,Mn)VI compounds is shown in Figure 14. An example for such compounds is  $p$ -type (Sn,Mn)Te [145].  $\text{Sn}_{1-x}\text{Mn}_x\text{Te}$  typically has a free-hole density of  $10^{20} \text{ cm}^{-3} < p < 5 \times 10^{20} \text{ cm}^{-3}$ , presumably because of Sn vacancies. At higher temperatures the system is paramagnetic (P). For concentrations  $x < 3\%$ , a spin-glass (SG) phase occurs below the spin freezing temperature, but at larger concentrations a ferromagnetic phase (F) is observed. This ferromagnetic phase is characterized by the existence of a spontaneous magnetization, in a definite range of temperatures, below the Curie temperature  $T_C$ . The ferromagnetic long-range ordering down to Mn concentrations as small as 3% is due to the RKKY indirect exchange mediated by the  $10^{20} \text{ cm}^{-3}$  holes present in the sample. At the lowest temperatures a reentrant spin-glass phase is observed. This reentrant spin-glass phase is a manifestation of the delicate interplay of the Mn concentration  $x$  and free carrier concentration  $p$ . The RKKY exchange

**Figure 14.** Schematic phase diagram of a ferromagnetic (IV,Mn)VI semiconductor.

constant  $J_{\text{RKKY}}$  is a rapidly oscillating function given by

$$J_{\text{RKKY}} \propto \frac{\sin(2k_F \cdot R_{ij}) - 2k_F \cdot R_{ij} \cdot \cos(2k_F \cdot R_{ij})}{(2k_F \cdot R_{ij})^4} \quad (11)$$

where  $k_F$  ( $\propto p^{1/3}$ ) is the Fermi wave vector and  $R_{ij}$  is the distance between the magnetic ions. For  $2 \cdot k_F R_{ij} \rightarrow 0$  the interaction is ferromagnetic. The relationship between the two characteristic lengths  $R_0$  and  $R_{\text{Mn-Mn}}$  determines the magnetism of the system.  $R_0$  is the distance at which the first change from ferromagnetic to antiferromagnetic interaction occurs. At a fixed  $x$ ,  $R_0$  is proportional to  $p^{-1/3}$ . The average distance  $R_{\text{Mn-Mn}}$  between  $\text{Mn}^{2+}$  ions is proportional to  $x^{-1/3}$ . If  $R_0 \ll R_{\text{Mn-Mn}}$  there is a competition between positive, ferromagnetic coupling and negative, antiferromagnetic coupling between  $\text{Mn}^{2+}$  spins, leading to the spin-glass phase [146]. This happens in (Sn,Mn)Te as the free carrier concentration  $p$  decreases with cooling.

The strong correlation of magnetism and doping effects is also manifested in the phase diagrams of the (III,Mn)V alloys. As an example, the phase diagram of  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  for  $x < 10\%$  is shown in Figure 15 with experimental points from [151–153]. First one should note that the  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  as a random alloy is a metastable phase and is grown far from the thermodynamical equilibrium, usually by low-temperature MBE. The upper limit of the Mn concentration is currently about 10%, where a random alloy was still grown successfully. Segregation always occurs at higher Mn contents. Similarly, annealing or raising the growth temperature always leads to the formation of MnAs clusters in a  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  matrix with a low  $x$  of about 0.1%. Also there is a competition between different sites of the Mn atom in the alloy. It can be incorporated as an acceptor on a Ga site or as donor-like centers such as small disordered sixfold-coordinated centers with As, known from closely related  $\text{In}_{1-x}\text{Mn}_x\text{As}$  [44]. At elevated temperatures the alloy is paramagnetic, but at low temperatures  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  becomes ferromagnetic. It can be seen in Figure 15 that

**Figure 15.** Phase diagram of (Ga,Mn)As. Experimental points: ○ [151], ▼ [152], ● [153].

the Curie temperature increases rather linearly with  $x$  up to  $T_C = 110$  K for  $x \approx 5\%$ . The Curie temperatures of samples with higher Mn concentrations deviate from the linear curve and are significantly lower. This drop in the Curie temperature is related to the self-compensation process in  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$ . At high  $x$  the relative amount of Mn incorporated as donors instead of acceptors is increased. This correlation was shown nicely by Matsukura et al. [151], who observed, for a series of  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  of different  $x$ , that both the net hole concentration and the Curie temperature had their maximum values at about 5%. Similar results were reported for  $(\text{In},\text{Mn})\text{As}$  [154]. It is therefore very clear that the ferromagnetic coupling of the Mn ions in  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  with sufficiently high Mn content ( $x > 0.5\%$ ) results from interaction with holes [39, 155–157]. However, the details of the mechanism are still being discussed. It is worth noting that no signs of a spin-glass phase have been reported so far for this alloy system.

Room temperature ferromagnetism in  $(\text{Ga},\text{Mn})\text{N}$  has been reported by Reed et al. [27]. Sonoda et al. [158] reported for  $\text{Ga}_{1-x}\text{Mn}_x\text{N}$  films with  $x_{\text{Mn}} = 0.057$  a Curie-temperature  $T_C \approx 940$  K on the basis of SQUID measurements. This value is higher than the known Curie-temperatures of  $\text{Mn}_4\text{N}$  or  $\text{MnGa}$ . Therefore the authors suggested, that the ferromagnetism is mediated by the free holes, which are of the order between  $10^{19}$  and  $10^{20}$   $\text{cm}^{-3}$  at room temperature. The extremely high  $T_C$  could be explained then on the basis of the mean-field model of ferromagnetism mediated by holes in tetrahedrally coordinated semiconductors developed by Dietl et al. [156, 159]. According to this model the high hole mass of GaN would be the main reason for the high  $T_C$ .

However, Overberg et al. [160] reported a Curie-temperature of only 10 to 25 K for MBE grown  $(\text{Ga},\text{Mn})\text{N}$  alloys with a Mn content of about 7%. There is obviously no clear recipe for obtaining  $(\text{Ga},\text{Mn})\text{N}$  with high Curie temperatures.

As already mentioned in the discussion of the  $(\text{II},\text{Mn})\text{VI}$  phase diagrams, even in the paramagnetic phase (i.e., above  $T_{\text{sg}}$ ), cluster formation reduces the paramagnetic response. The dependence of the (molar) magnetization on the magnetic field, temperature, and concentration of the magnetic ions can be described by a relation introducing phenomenological parameters [161, 162],

$$M(x) = a(x) \cdot x \cdot M = \tilde{g} \mu_B \langle S_z \rangle_{\text{mol}} \quad (12)$$

In the alloy the mean molar spin density is, therefore,

$$\langle S_z \rangle_{\text{mol}} = N_A x \langle S_z \rangle = -a(x) \cdot N_A \cdot x \cdot S \cdot B_S(\xi) \quad (13)$$

with

$$\xi = \frac{\tilde{g} \cdot \mu_B \cdot S \cdot H}{k_B(T + \Theta(x))}$$

where  $S$  is the spin of the magnetic ions and  $B_S$  is the corresponding Brillouin function. The Curie–Weiss parameter  $\Theta(x)$  is considered an empirical  $x$ -dependent fitting parameter, and  $a(x)$  is a scaling factor. Both parameters account for the cluster effects. The scaling factor  $a(x)$  is always smaller than unity, with the limiting property  $a(x \rightarrow 0) \rightarrow 1$ .

The parameter  $\Theta(x)$  decreases superlinearly with decreasing  $x$ , and for sufficiently low Mn concentrations an ideal paramagnetic behavior is found as  $\Theta(x \rightarrow 0) \rightarrow 0$ .

With extension of the low-temperature measurements of the magnetization to very high magnetic fields ( $H \gg 10$  Tesla), distinct steps in the magnetization have been observed at  $H_n$  ( $n = 1, 2, \dots$ ) for  $(\text{Cd},\text{Mn})\text{S}$  [109, 163, 164],  $(\text{Cd},\text{Mn})\text{Se}$  [108, 165, 166, 167],  $(\text{Cd},\text{Mn})\text{Te}$  [162, 166–168],  $(\text{Zn},\text{Mn})\text{Se}$  [109, 163, 165, 167],  $(\text{Zn},\text{Mn})\text{Te}$  [102, 103, 167, 169, 170],  $(\text{Zn},\text{Mn})\text{S}$  [164],  $(\text{Hg},\text{Mn})\text{Se}$ , and  $(\text{Hg},\text{Mn})\text{Te}$  [171]. These steps are caused by a magnetic field-induced successive alignment of antiferromagnetically ordered nn pairs of  $\text{Mn}^{2+}$  ions. The saturation steps correspond to increasing total spin quantum numbers  $S_p = 0, 1, 2, \dots, 5$  of the pairs. For isolated pairs and sufficiently low temperatures ( $k_B T \ll 2|J_{\text{nn}}|$ ),  $H_n$  is simply determined by

$$H_n = -\frac{2nJ_{\text{nn}}}{\mu_B \tilde{g}} \quad n = 1, 2, \dots, 5 \quad (14)$$

The energy levels of a Mn pair and the respective steps in the magnetization are depicted schematically in Figure 16. Taking into account the influence of the more distant  $\text{Mn}^{2+}$  neighbors on a considered pair in a mean-field approximation, a more exact relation for  $H_n$  was developed [112, 113]. Lowering the temperature in the experiments further to 20 mK allows one to determine higher exchange constants up to fourth nearest neighbors, which are more than one order of magnitude smaller than  $J_{\text{nn}}$  [172, 173]. These smaller exchange constants have been the subject of theories and conjecture [120, 174–176]. However, up to now there has been no satisfactory agreement between theory and experiment.

The antiferromagnetic nn exchange constants  $J_{\text{nn}}$  have also been determined for various Mn-containing or Eu-containing IV–VI and II–VI compounds from magnetization

**Figure 16.** Lowest energy levels of a pair of Mn spins as a function of the magnetic field. The resulting magnetization steps are depicted schematically. Adapted from [162] with permission from the American Institute of Physics.

measurements or magnetic susceptibility measurements [177–179]. The exchange constants for the diluted magnetic IV–VI semiconductors are about an order of magnitude smaller than those of the corresponding II–VI compounds. Therefore, until about 1995, no distinct magnetization steps were observed in magnetization experiments on diluted magnetic IV–VI semiconductors because  $|J_{nn}| < 2 \cdot k_B T$  held in all experiments. However,  $J_{nn}$  could be extracted by fitting the magnetization data and adding a pair term  $M_p$  to Eq. (12) [178],

$$M_p = \frac{1}{2} \tilde{g} \mu_B x_p \times \frac{\sum_{s=0}^{S_p, \max} \exp[(J_{nn}/k_B T)s(s+1)] \cdot [\sinh((2s+1)/2s)\xi_p]}{\sum_{s=0}^{S_p, \max} \exp[(J_{nn}/k_B T)s(s+1)] \cdot [\sinh((2s+1)/2s)\xi_p]} \cdot s B_s(\xi_p) \quad (15)$$

with

$$\xi_p = (s \tilde{g} \mu_B H) / (k_B T)$$

where  $x_p \approx (1 - a(x))$  is the percentage of magnetic ions forming isolated pairs, and  $S_{p, \max} = 2 \cdot S$  is the total spin of an isolated pair.  $S = 5/2$  and  $S = 7/2$  for the Mn- and Eu-containing samples, respectively. Only recently, magnetization steps have been observed in (Pb,Eu) $X$  compounds with  $X = S, Se, Te$  [180–182], which allowed a more accurate determination of  $J_{nn}$ . For isolated Eu–Eu pairs the total spin quantum number  $S_p$  can take values 0, 1, 2, . . . , 7, and, correspondingly,  $n = 0, 1, 2, \dots, 7$  in Eq. (14). Table 3 lists ranges of  $J_{nn}$  values for some diluted magnetic II–VI and IV–VI compounds.

Some interesting trends can be observed in Table 3. First, the  $J_{nn}$  of the (II,Mn)VI DMS scale with the size of the anions and the cations. For example, the  $J_{nn}$  of the sulfides are bigger than those of the selenides, and these again are bigger than those of the tellurides. Moreover, the Cd compounds have smaller  $J_{nn}$  than the corresponding Zn compounds. Spalek et al. [183] were able to relate these trends to the variation of the bond angle between adjacent  $Mn^{2+}$  ions and the anion. Second, the exchange constants in the Mn-containing II–VI alloys are about an order of magnitude bigger than those in the Mn-containing IV–VI alloys.

**Table 3.** Nearest-neighbor exchange constants of various diluted magnetic semiconductors.

DMS	Crystal structure	$J_{nn}/k_B$ (K)
Zn <sub>1-x</sub> Mn <sub>x</sub> O	W	-15

Note: W, wurtzite; ZB, zinblend; RS, rock salt.

Anderson, Gorska, and co-workers [177, 178] ascribed the reduction of  $J_{nn}$  in the (IV,Mn)VI alloys compared with the (II,Mn)VI alloys primarily to the increased separation between the Mn ion and an adjacent anion. However, one should keep in mind that the bandgaps in the materials are at different points of the Brillouin zone, and, therefore, the wavefunctions involved are different. Third, the exchange constants of the Eu-containing IV–VI alloys are smaller than those of the corresponding Mn-containing alloys by a factor of 5–10. This is mainly caused by the stronger localization of the  $4f^7$  orbitals compared with the  $3d^5$  orbitals. More interesting is the fact that the exchange constants  $J_{nn}$  of the Eu-containing IV–VI alloys are very different from those of the corresponding binary Eu-chalcogenides given in Table 2. The former are negative (i.e., antiferromagnetic), whereas, for EuS, EuSe, and EuTe, the largest antiferromagnetic exchange constant is  $J_{nnn}$ , and  $J_{nn}$  itself is ferromagnetic. Despite the fact that they share the same RS crystal structure, the pure Eu-chalcogenides and the corresponding (IV,Eu)VI have again very different electronic band structures. The bandgaps of the former are at the  $\Gamma$ -point, whereas those of the latter are at the L-point; furthermore, the positions of the  $4f^7$  levels of the  $Eu^{2+}$  contribute differently to the band structure. In general, one can conclude that the trends of the exchange mechanisms in the pure Mn- or Eu-chalcogenides as well as in the corresponding diluted II–VI and IV–VI systems are fairly well understood in the case of bulk samples, despite the lack of a comprehensive theory.

## 2.4. Magneto-Optical Properties of Bulk Semiconductors

The changes in the magneto-optical effects connected with electron and hole band states are rather large in magnetic semiconductors compared with those in conventional semiconductors. These dramatic changes in the magneto-optical properties are some of the main reasons for the considerable and continuous physical and applicative interest in these materials. In diluted magnetic semiconductors, for example, the so-called giant Zeeman splitting of free excitons is observable, which for (II,Mn)VI and (IV,Mn)VI semiconductors is about two orders of magnitude larger than the usual Zeeman splitting. The usual Zeeman splitting of conduction and valence band states is amplified strongly by the  $s$ - $d$  and  $p$ - $d$  exchange interaction with the  $Mn^{2+}$   $3d$  electrons, which are paramagnetically oriented in an external magnetic field. All of the diluted magnetic semiconductors have the advantage, compared with magnetic semiconductors, that the strong antiferromagnetic ion intersite interaction can be partly suppressed and even controlled. In magnetic semiconductors very high magnetic fields are required to overcome the “internal” fields which are induced by the ion–ion interaction, as discussed in Section 2.3. In diluted magnetic semiconductors, it is possible to adjust the magnetic ion concentration such that it is high enough to give a strong enhancement of the external field but is still low enough not to induce strong intersite correlations between the magnetic ions for the majority of the spins.

When a diluted magnetic semiconductor contains localized magnetic moments, its band structure will be modified.

Such interaction is included in the Hamiltonian  $H$  by adding a Kondo-like exchange term  $H_{\text{exch}}$  to the Hamiltonian  $H_0$ :

$$H = H_0 + H_{\text{exch}} = H_0 - \sum_i J(\vec{r} - \vec{R}_i) \vec{S}_i \vec{\sigma} \quad (16)$$

For the zincblende (II,Mn)VI and (III,Mn)V alloys, the mean-field approximation leads to a lattice-periodic form,

$$H_{\text{exch}} = -x_{\text{Mn}} \sigma_z \langle S_z \rangle \sum_{R \in \text{fcc sublattice}} J(\vec{r} - \vec{R}) \quad (17)$$

As the extended conduction band states interact simultaneously with a sufficiently large number of  $\text{Mn}^{2+}$  ions, the spin operator can be replaced by its thermal mean value. Furthermore, in a virtual-crystal approximation  $J(r - R_i)$  is replaced by  $x_{\text{Mn}} J(r - R)$ , taking the summation over all cation-sublattice sites  $R$ .

The advantage of Eq. (17) is that in this form  $H_{\text{exch}}$  has the periodicity of the lattice. This allows one to use the same wave functions for solving Eq. (17), as those used for diagonalizing  $H_0$ . In the case of a zincblende crystal this is the set of basic functions introduced in the Pidgeon–Brown model:

$$\Gamma_6 \begin{cases} |S \uparrow\rangle = \Psi_{1/2, 1/2} \\ |iS \downarrow\rangle = \Psi_{1/2, -1/2} \end{cases} \quad (18)$$

$$\Gamma_8 \begin{cases} \frac{1}{\sqrt{2}} |(X + iY) \uparrow\rangle = \Psi_{3/2, 3/2} \\ i \frac{1}{\sqrt{2}} |(X - iY) \downarrow\rangle = \Psi_{3/2, -3/2} \\ \frac{1}{\sqrt{6}} |(X - iY) \uparrow + 2Z \downarrow\rangle = \Psi_{3/2, -1/2} \\ i \frac{1}{\sqrt{6}} |(X - iY) \downarrow + 2Z \uparrow\rangle = \Psi_{3/2, 1/2} \end{cases} \quad (19)$$

$$\Gamma_7 \begin{cases} i \frac{1}{\sqrt{3}} |-(X - iY) \uparrow + Z \downarrow\rangle = \Psi_{1/2, 1/2} \\ \frac{1}{\sqrt{3}} |(X + iY) \downarrow + Z \uparrow\rangle = \Psi_{1/2, -1/2} \end{cases} \quad (20)$$

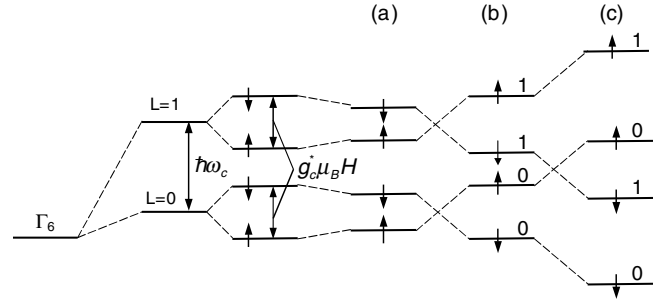

Here  $S$ ,  $X$ ,  $Y$ , and  $Z$  are the Kohn–Luttinger amplitudes, with  $s$ ,  $p_x$ ,  $p_y$ , and  $p_z$  symmetry, respectively, and  $\uparrow$ ,  $\downarrow$  are the Pauli spinors.

$$E_{k\uparrow}^c = (l + \frac{1}{2}) \hbar \omega_c \pm \frac{1}{2} (g_c^* \mu_B H - N_0 \alpha x_{\text{Mn}} \langle S_z \rangle) \quad (21)$$

where  $\omega_c$  and  $g_c^*$  are the cyclotron frequency and the Landé factor of the conduction band electron, respectively.  $l = 0, 1, \dots$  is the Landau quantum number.  $\alpha = \langle S|J|S \rangle$  is the  $s$ - $d$  exchange interaction parameter, and  $N_0$  denotes the number of unit cells per  $\text{cm}^3$ . The upper and lower signs correspond to the  $\uparrow$  and  $\downarrow$  spin states. An effective  $g$ -factor can be defined:

$$g_{\text{eff}} = g_c^* - \frac{x_{\text{Mn}} N_0 \alpha \langle S_z \rangle}{\mu_B H} \quad (22)$$

The consequences for a  $\Gamma_6$  conduction band are illustrated schematically in Figure 17 for *narrow gap* semiconductors. Since the sign of  $N_0 \alpha$  is positive, the exchange term in

**Figure 17.** Conduction band states of a narrow gap semiconductor in a magnetic field. (a) Since the sign of  $N_0 \alpha$  is positive, its sign is opposite that of  $g_c^*$  and reduces the usual Zeeman splitting. (b) If  $g_{\text{eff}} > 0$  a reverse of the total Zeeman splitting occurs. (c) For large values of  $g_{\text{eff}}$  ( $|g_{\text{eff}} \mu_B H| > |\hbar \omega_c|$ ) a mixture of the Landau level sequence occurs.

Eq. (22) has a sign opposite that of  $g_c^*$  and reduces the usual Zeeman splitting (Fig. 17a). If  $g_{\text{eff}} > 0$ , a reverse of the total Zeeman splitting occurs (Fig. 17b), and for large values of  $g_{\text{eff}}$  ( $|g_{\text{eff}} \mu_B H| > |\hbar \omega_c|$ ) even a mixture of the Landau level sequence is possible (Fig. 17c). It must be taken into account, however, that the Brillouin function saturates at higher fields while the cyclotron splitting is continuously increasing.

In *zero gap* (II,Mn)VI materials like (Hg,Mn)Te with small Mn concentrations ( $x_{\text{Mn}} < 0.1$ ) the situation is even more complicated because of the degeneracy of the conduction and valence band at the  $\Gamma$ -point. The relevant exchange integral is now  $N_0 \beta$ , where  $\beta = \langle X|J|X \rangle$  is the corresponding  $p$ - $d$  exchange interaction parameter, which exhibits a negative sign. The negative exchange integral enhances the usual Zeeman splitting, as depicted in Figure 18a. But still a mixing of the Landau levels might occur (Fig. 18b) if the exchange interaction is strong enough. In the case of an open gap (Hg,Mn)Te ( $x_{\text{Mn}} > 0.2$ )  $N_0 \alpha$  becomes again a relevant exchange integral as the conduction band is now dominantly made of  $s$ -states.

The situation is considerably simpler in the case of *wide bandgap* (II,Mn)VI alloys. Here, the intrinsic spin splitting (usual Zeeman splitting) and the Landau-level splitting are much smaller than the exchange splittings. This is due to the rather heavy effective masses of the wide-gap semiconductors. In this approximation the magnetic splitting of the

**Figure 18.** Possible  $\Gamma_8$  spin splitting of the first two Landau levels in zero-gap II–VI DMS in an applied magnetic field. The negative exchange integral  $N_0 \beta$  enhances the usual Zeeman splitting (a), but a mixing of the Landau levels might occur (b) if the exchange interaction is strong enough.

energy levels is entirely due to the exchange terms. Excitonic effects are primarily devoted to the bottom of the conduction band and to the top of the valence band at  $k = 0$ . One obtains for the  $\Gamma_6$  conduction band splitting and for the  $\Gamma_8$  valence band splitting, respectively,

$$\langle \Psi_{1/2} | H_{\text{exch}} | \Psi_{1/2} \rangle = \begin{vmatrix} a & 0 \\ 0 & -a \end{vmatrix} \quad (23)$$

and

$$\langle \Psi_{3/2} | H_{\text{exch}} | \Psi_{3/2} \rangle = \begin{vmatrix} b & 0 & 0 & 0 \\ 0 & \frac{1}{3}b & 0 & 0 \\ 0 & 0 & -\frac{1}{3}b & 0 \\ 0 & 0 & 0 & -b \end{vmatrix} \quad (24)$$

with

$$a = \frac{1}{2} N_0 \alpha x_{\text{Mn}} \langle S_z \rangle \quad (25a)$$

$$b = \frac{1}{2} N_0 \beta x_{\text{Mn}} \langle S_z \rangle \quad (25b)$$

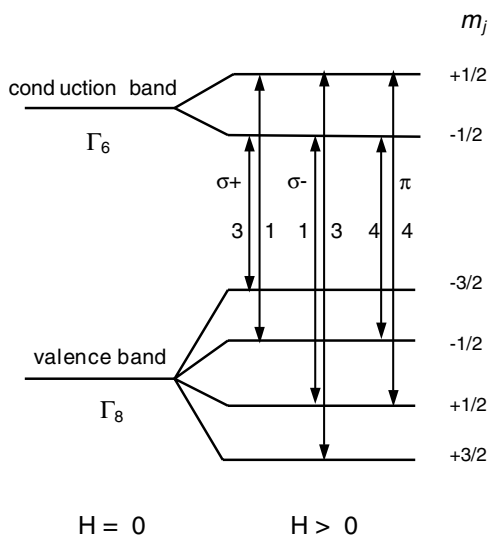

The shift and splitting of the conduction band states are now

$$\Delta E_C = -x_{\text{Mn}} N_0 \alpha \langle S_z \rangle m_j, \quad m_j = \pm \frac{1}{2} \quad (26)$$

and the corresponding splitting of the valence band states

$$\Delta E_V = -\frac{1}{3} x_{\text{Mn}} N_0 \beta \langle S_z \rangle m_j, \quad m_j = \pm \frac{1}{2}, \pm \frac{3}{2}. \quad (27)$$

A schematic picture of the exchange interaction-induced spin splitting is depicted in Figure 19. The diagram also shows the electrical dipole allowed transitions for the circular polarizations rotating transverse to the applied field, designated by  $\sigma^+$  and  $\sigma^-$  for right and left circular polarization ( $\Delta m_j = \pm 1$ ), respectively, in Faraday configuration, with the propagation vector of the light parallel to the field direction. The linear  $\pi$  polarization ( $\Delta m_j = 0$ ) is observable in the Voigt configuration only, with the propagation

**Figure 19.** Giant Zeeman splitting of wide-gap II–VI DMS in an applied magnetic field. Reprinted with permission from [22], O. Goede and W. Heimbrodt, *Phys. Stat. Sol. B* 146, 11 (1988). © 1988, Wiley-VCH Verlag, Berlin.

vector perpendicular to the field direction. The numbers in Figure 19 give the relative transition probabilities. As a typical example, Figure 20 depicts the excitonic splitting of a thick epitaxial layer of (Zn,Mn)Se, with  $x_{\text{Mn}} = 0.16$ , grown by MBE. The zero field splitting of the light hole (lh) and heavy hole (hh) excitons is caused by the biaxial strain in the sample, due to epitaxial growth on a GaAs substrate. The strain influence in the case of epitaxial structures is discussed in Section 4.1.

Similar results of excitonic splitting in bulk samples have been reported for (Cd,Mn)Te [161, 168, 184–188], (Zn,Mn)Te [189–192], (Cd,Mn)Se [193–195], and (Cd,Mn)S [196–199]. Only for (Zn,Mn)S and (Zn,Mn)O are reliable results still not available. By evaluation of the splitting energies for all of the excitonic components,  $N_0\alpha$  and  $N_0\beta$  can be determined independently. Representative values are given in Table 4. It is found that in the case of (II,Mn)VI alloys  $N_0\alpha > 0$  and  $N_0\beta < 0$  always, which means that the conduction band electrons are coupled ferromagnetically to the Mn spins, whereas the valence band electrons are coupled antiferromagnetically to them. The positive sign of  $N_0\alpha$  results from the direct exchange of the conduction band states with the  $d$ -electrons of Mn (see, e.g., the paper by Kacman [221]). The negative sign of  $N_0\beta$  is due to a dominant role of the hybridization-mediated  $p$ - $d$  kinetic exchange. An essentially different situation was found for Cr-containing crystals. A ferromagnetic  $p$ - $d$  coupling  $N_0\beta > 0$  was observed. This sign can easily be understood by considering virtual jumps of the  $p$ -electrons to the  $d$ -states and back. In the case of half-filled  $d$ -shells ( $\text{Mn}^{2+}$ ), or even in the case of  $\text{Fe}^{2+}(3d^6)$  or  $\text{Co}^{2+}(3d^7)$ , the spin has to be aligned antiferromagnetically, as jumps are possible only into the unoccupied spin  $3d$  states. For ions with less than half-filled  $d$ -shells, like  $\text{Cr}^{2+}(3d^4)$ , a ferromagnetic coupling is possible, as the spin of the hopping electron should be aligned parallel to the others according to Hund's rule.

The situation is even more complicated in the case of (Ga,Mn)As, where for the smallest Mn concentrations a ferromagnetic  $p$ - $d$  coupling was found by Heimbrodt et al. [219]. This ferromagnetic coupling is compensated for by an antiferromagnetic coupling with increasing  $x_{\text{Mn}}$  along with the formation of MnAs clusters. The physical reason for

the sign reversal, however, is the same as that already discussed. Only recently the same authors [222] found that the sign of the exchange integral in (Ga,Mn)As is correlated with the type of conductivity. For *n*-type conductivity all of the Mn acceptors are compensated and  $A^-$  centers will be dominant. The coupling of the *p*-orbital to the half-filled  $3d^5$  with all of the spins aligned is now antiferromagnetic. For *p*-type conductivity a hole is bound to the Mn acceptor at low temperatures with a polarized spin and can therefore accommodate preferably valence band electrons with a spin parallel to the spins in the *d*-shell. Such an  $A^0$  center behaves, therefore, in a manner similar to that of the  $3d^4$  state, which couples ferromagnetically as discussed above.

From Eqs. (13), (26), and (27) it follows for the splitting of the hh excitons that

$$\Delta E_{\text{hh}} = x_{\text{Mn}} N_0 (\alpha - \beta) a(x_{\text{Mn}}) S B_{5/2} \left( \frac{\tilde{g} \mu_B S H}{k(T + \Theta)} \right) \quad (28)$$

The splitting of the hh depends strongly on the manganese concentration. In Figure 21 the hh splitting is depicted for a series of (Zn,Mn)Se epitaxial layers versus the magnetic

**Figure 21.** Heavy-hole excitonic giant Zeeman splitting for a series of  $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$  epitaxial layers. (a) Increasing splitting up to  $x_{\text{Mn}} = 12\%$ . (b) Decreasing for  $x_{\text{Mn}} > 16\%$ .  $T = 1.8$  K. Curves are calculated with  $N_0\alpha = 0.26$  eV,  $N_0\beta = -1.31$  eV, and the parameters given in Table 5.

field strength. For small  $x_{\text{Mn}}$  (Fig. 21a) the splitting increases with increasing Mn concentration, whereas for higher  $x_{\text{Mn}}$  the hh splitting decreases again because of increasing cluster effects. At the saturation field strength of 7.5 Tesla the maximum hh splitting has been found at  $x_{\text{Mn}} \approx 0.15$ , as can be seen from Figure 22, where the saturation values are depicted versus the Mn concentration. The curves in Figure 21 have been calculated with Eq. 28. The resulting  $a(x_{\text{Mn}})$  and  $\Theta(x_{\text{Mn}})$ , obtained from the best fit to the experimental points, are given in Table 5.

At low Mn concentrations  $\Delta E_{\text{hh}}$  increases because of increasing mean spin density, whereas for larger  $x_{\text{Mn}}$  the Curie–Weiss parameter increases and the parameter  $a(x_{\text{Mn}})$

**Figure 22.** Saturation values  $\Delta E_{\text{hh}}$  (see also Table 5) of the heavy-hole excitonic giant Zeeman splitting of (Zn,Mn)Se layers as a function of the manganese concentration.  $B = 7.5$  T,  $T = 1.8$  K.

decreases strongly because of the antiferromagnetic coupling of pairs, triples, and higher clusters, which reduces the effective Mn concentrations and subsequently the mean spin density and  $\Delta E_{\text{hh}}$ . The values given in Table 5 are typical for MBE-grown thick epitaxial layers. To a certain extent these parameters depend on the real growth conditions, as, for example, segregation and clustering effects are completely different in crystals grown at thermodynamical equilibrium (when a random distribution of the magnetic ions is likely) compared with growth methods away from the thermodynamical equilibrium, like MBE or other thin-film technologies. These growth methods are discussed in Section 3. It was shown by Bednarski et al., Weston et al., and Harrison et al., using different theoretical approaches, that  $a(x_{\text{Mn}})$  and  $\Theta(x_{\text{Mn}})$  can vary dramatically if the distribution of the Mn ions is changed [223–226].

The description of the magneto-optical phenomena in diluted magnetic IV–VI semiconductors also uses Eq. (16) as a starting point. However, as the direct bandgap is situated at the L-point of the Brillouin zone, the situation is more complex. The conduction band minimum is associated with the point group representation  $L_6^-$  (odd parity,  $p$ -like) and the valence band maximum with  $L_6^+$  (even parity,  $s$ - and  $d$ -like). The constant energy surfaces are ellipsoids along the  $\langle 111 \rangle$  direction. The many-valley character of the IV–VI DMS, together with the rather small bandgaps, makes the description of the band structure and, in particular, of their magneto-optical properties rather difficult because of the different orientations of the ellipsoids with respect to the applied magnetic field. The  $k \cdot p$  treatment is described in detail in [41] and references therein.

We will outline briefly the main steps of the calculation. As there are slight differences in the conduction band structure of the various IV–VI, we will discuss as an example Eu- and Mn-containing PbTe. In the  $k \cdot p$  theoretical approach the lowest conduction bands and the highest valence bands are included exactly, while two higher conduction and two lower valence bands are taken into account in approximation to  $k^2$  terms. A set of four basis functions is used:

$$L_6^- \begin{cases} C^+ = -i \sin \theta^- Z \uparrow - \cos \theta^- X_+ \downarrow \\ C^- = i \sin \theta^- Z \downarrow - \cos \theta^- X_- \uparrow \end{cases} \quad (29)$$

$$L_6^+ \begin{cases} V^+ = i \cos \theta^+ R \uparrow + \sin \theta^+ S_+ \downarrow \\ V^- = i \cos \theta^+ R \downarrow + \sin \theta^+ S_- \uparrow \end{cases}$$

where  $C^\pm$  and  $V^\pm$  are, respectively, the lowest conduction band and highest valence band wave functions at the L-point. The pairs  $C^\pm$  and  $V^\pm$  are both Kramer's pairs. Because of the spin-orbit coupling, they do not correspond to pure spin states and are nondegenerate [227]. The spin functions  $\uparrow$  and  $\downarrow$  refer to the eigenstates of  $\sigma_z$  in the atomic coordinate system with  $z$  along the  $[120]$  axis of the valley,  $x$  along  $[-1-12]$ , and  $y$  along  $[1-10]$ . The spatial parts of the wave functions have the following transformation properties about the site of the metal nucleons:  $R$  is isotropic (atomic  $s$ -state), and  $X_\pm$  and  $Z$  transform like atomic  $p$ -states with  $m_z = \pm 1$  and  $m_z = 0$ , respectively.  $S_\pm$  transform like atomic  $d$ -functions with  $m_z = \pm 1$ . The spin-orbit mixing parameters  $\theta^\pm$  are obtained from band structure calculations [228].

Assuming that the magnetic field is in the  $xz$  plane, one obtains the  $k \cdot p$ -Hamiltonian

$$H = \begin{bmatrix} \widehat{V}^+ & \frac{1}{2}g_T^+ \mu_B H_x & \nu_L \hbar k_z & \sqrt{2}\nu_T \hbar k_- \\ \frac{1}{2}g_T^+ \mu_B H_x & \widehat{V}^- & \sqrt{2}\nu_T \hbar k_+ & -\nu_L \hbar k_z \\ \nu_L \hbar k_z & \sqrt{2}\nu_T \hbar k_- & \widehat{C}^+ & \frac{1}{2}g_T^- \mu_B H_x \\ \sqrt{2}\nu_T \hbar k_+ & -\nu_L \hbar k_z & \frac{1}{2}g_T^- \mu_B H_x & \widehat{C}^- \end{bmatrix} \quad (30)$$

where

$$[c]\widehat{V}^\pm = \frac{-E_g}{2} - \frac{\hbar^2 k_x^2 + \hbar^2 k_y^2}{2m_T^\pm} - \frac{\hbar^2 k_z^2}{2m_L^\pm} \pm \frac{1}{2}g_L^\pm \mu_B H_z$$

$$\widehat{C}^\pm = \frac{E_g}{2} - \frac{\hbar^2 k_x^2 + \hbar^2 k_y^2}{2m_T^\mp} - \frac{\hbar^2 k_z^2}{2m_L^\mp} \pm \frac{1}{2}g_L^\mp \mu_B H_z$$

$$\nu_L \hbar k_z = \frac{\hbar}{m_0} \langle V^+ | \hat{\pi} | C^+ \rangle \mathbf{k} = -\frac{\hbar}{m_0} \langle V^- | \hat{\pi} | C^- \rangle \mathbf{k} \quad (31)$$

$$\sqrt{2}\nu_T \hbar k_+ = \frac{\hbar}{m_0} \langle V^- | \hat{\pi} | C^+ \rangle \mathbf{k}$$

$$\sqrt{2}\nu_T \hbar k_- = \frac{\hbar}{m_0} \langle V^+ | \hat{\pi} | C^- \rangle \mathbf{k}$$

$$\hat{\pi} = \mathbf{p} + \frac{\hbar}{4m_0 c^2} (\hat{\sigma} \times \nabla V_0)$$

$m_L^\pm, m_T^\pm, g_L^\pm, g_T^\pm$  denote the effective masses and  $g$ -factors. The subscripts L and T refer to the longitudinal and transverse axes of the ellipsoids. The superscripts + and – refer traditionally to the valence and conduction bands, respectively.  $\hat{\pi}$  is the sum of momentum operator and spin-orbit interaction, where  $\hat{\sigma}$  presents the Pauli spin operators,  $V_0$  is the periodic crystal potential, and  $m_0$  is the free-electron mass.

The interaction between the extended band states and the magnetic ions is accounted for in a fashion similar to that for the (II,Mn)VI compounds. Equation (16) becomes

$$H_{\text{exch}} = x \langle S_0 \rangle \sum_{R \in \text{sublattice}} J(\vec{r} - \vec{R}) \cdot [\sin \varphi \cdot \sigma_x + \cos \varphi \cdot \sigma_z] \quad (32)$$

Again, it was assumed that the magnetic field is in the  $xz$  plane.  $\varphi$  is the angle between the magnetic field  $H$  and the  $z$  axis.  $\langle S_0 \rangle$  is the thermal mean value of the spin of the magnetic ions which is parallel to  $H$ . Evaluating the Hamiltonian

by using the basis function set given in Eq. (29) yields an exchange matrix of the form

$$H_{\text{exch}} = \frac{1}{2}x\langle S_0 \rangle \begin{pmatrix} A \cos \varphi & a_1 \sin \varphi & 0 & 0 \\ a_1 \sin \varphi & -A \cos \varphi & 0 & 0 \\ 0 & 0 & B \cos \varphi & -b_1 \sin \varphi \\ 0 & 0 & -b_1 \sin \varphi & -B \cos \varphi \end{pmatrix} \quad (33)$$

where the coefficients are combinations of exchange integrals and band structure parameters given by [229]

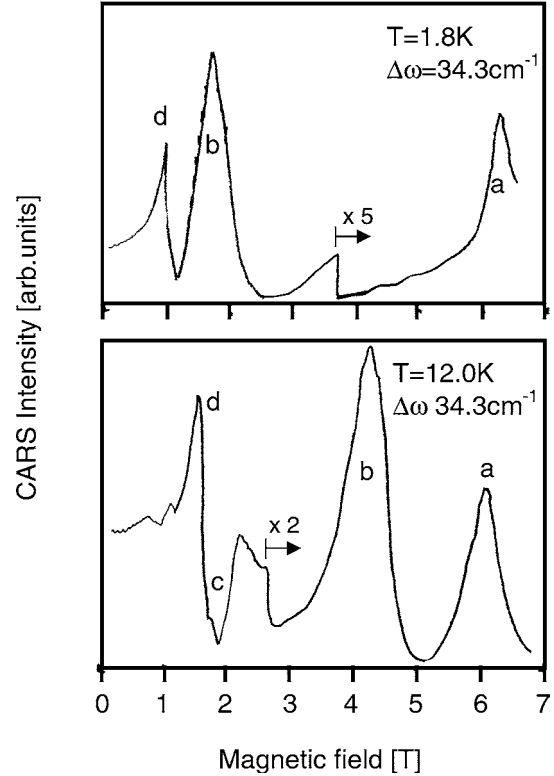

$$\begin{aligned} A &= \alpha \cos^2 \theta^+ - \delta \sin^2 \theta^+ & a_1 &= \alpha \cos^2 \theta^+ \\ B &= \beta_{\parallel} \sin^2 \theta^- - \beta_{\perp} \cos^2 \theta^- & b_1 &= \beta_{\parallel} \sin^2 \theta^- \end{aligned} \quad (34)$$

The exchange integrals are defined via the  $s$ ,  $d$ , and  $p$ -like wave function components,

$$\begin{aligned} \alpha &= \frac{1}{\Omega_0} \langle R|J|R \rangle & \delta &= \frac{1}{\Omega_0} \langle S_{\pm}|J|S_{\pm} \rangle \\ \beta_{\parallel} &= \frac{1}{\Omega_0} \langle X_{\pm}|J|X_{\pm} \rangle & \beta_{\perp} &= \frac{1}{\Omega_0} \langle Z|J|Z \rangle \end{aligned} \quad (35)$$

where  $\Omega_0$  is the volume of the unit cell. It is worth noting that the definition of the exchange integrals for the IV–VI diluted magnetic semiconductors in Eq. (35) differs slightly from that of the II–VI diluted magnetic semiconductors. The factor  $\Omega_0^{-1}$  corresponds to the  $N_0$  of Eqs. (21) and (25).

The major optical spectroscopic techniques employed to study the band structure of the IV–VI diluted magnetic semiconductors are magneto-reflectivity or magneto-absorption experiments examining the interband transitions and coherent anti-Stokes Raman scattering (CARS) and the spin-flip transitions in the conduction and valence bands. Usually a combination of the methods is needed to acquire a sufficiently large data set to compare experiment and theory. Applying a magnetic field lifts the degeneracy at the L-point, and signals arising from L-valleys with different orientations with respect to the magnetic field direction can be observed simultaneously. This is illustrated in Figure 23, where plots of the CARS intensity (at  $\omega + \Delta\omega$ ) versus magnetic field are shown for a  $\text{Pb}_{0.94}\text{Mn}_{0.06}\text{Te}$  sample at 1.8 K and 12 K, respectively [229]. For the chosen magnetic field orientation  $B \parallel [-110]$ , two valleys in the conduction and in the valence band are oriented with an angle  $\varphi = 90^\circ$  between their main axis and the applied field, and the other two valleys are oriented with an angle  $\varphi = 35.26^\circ$ . Four resonances are observed. These correspond to spin-flip transitions within the  $n = 0$  Landau states of holes (b:  $\varphi = 90^\circ$ ; d:  $\varphi = 35.26^\circ$ ) and electrons (a:  $\varphi = 90^\circ$ ; c:  $\varphi = 35.26^\circ$ ). Tuning the frequency difference  $\Delta\omega$  by using various combinations of  $\text{CO}_2$  laser frequencies allows one to obtain fan diagrams of the resonance positions versus magnetic field, as shown in Figure 24, which can be compared with theory. In most publications, only the parameters  $A$ ,  $B$ ,  $a_1$ , and  $b_1$  extracted from the magneto-optical data are given, and the  $s$ - $d$ ,  $p$ - $d$  and  $d$ - $d$  exchange integrals are not calculated explicitly. However, for the sake of comparison with the data for the II–VI diluted magnetic semiconductors, we have tabulated some average exchange integrals in Table 6.

### 3. PREPARATION OF MAGNETIC SEMICONDUCTOR NANOSTRUCTURES

The growth of two-dimensional semiconductors in the form of heterostructures, quantum wells, or superlattices is a standard technology at present. The MBE is a favorable growth technique for magnetic semiconductor quantum wells (QWs), as it provides epitaxial layers and heterostructures

**Figure 24.** Plot of the resonance positions of electron and hole spin-flip transitions as a function of magnetic field for  $\text{Pb}_{0.94}\text{Mn}_{0.06}\text{Te}$ . Reprinted with permission from [229], H. Pascher et al., *Phys. Rev. B* 36, 9395 (1987). © 1987, American Physical Society.

of very high quality. An overview of two-dimensional structures is given in Section 3.1. Far less work has been carried out on magnetic one- and zero-dimensional semiconductor nanostructures. Again the methods are similar to those used for the fabrication of other semiconductor nanostructures. A clear distinction between methods for fabricating one- and zero-dimensional structures cannot be made. For example, the lithographic and etching techniques for obtaining quantum dots (QDs) and quantum wires (QWRs) from two-dimensional epitaxial structures are very similar. Nevertheless, we will address the fabrication of diluted magnetic QWs and QDs in two separate sections, 3.2 and 3.3, respectively. More general overviews of the fabrication of semiconductor nanostructures are given in the reviews of Gossard and Fafard [231], Bryant [232], Nötzel [233], Pileni [234], and Ekimov [235].

A high degree of order of QDs or QWRs can only be obtained so far by combining lithographic pattern definition with epitaxial semiconductor growth techniques, either by growing structures on patterned substrates or by post-growth patterning and etching of the epitaxial semiconductor layers. However, the smallest lateral sizes achievable by those techniques are still bigger than 10 nm. Other approaches, such as DMS clusters in silicate glass, DMS clusters in reverse micelles, or self-assembling by Stranski-Krastanov growth, yield cluster sizes below 10 nm but show a much smaller degree of order. The major challenge in the fabrication of magnetic nanostructures for most desired applications is to achieve simultaneously small lateral dimensions of the individual nanostructures and a high degree of order of the ensembles (e.g., size distribution, geometrical arrangement, high density of nanostructures). If this is achieved magnetic nanostructures will provide the link between magnetism on a microscopic atomic level and the macroscopic magnetic state, and the interesting properties can be successfully studied, which are expected as the geometrical dimensions of the clusters become comparable to the characteristic nanoscopic and mesoscopic length scales (e.g., magnetic exchange length, domain width).

### 3.1. Growth of Epitaxial Layers and Quantum Wells

The first successful preparation of magnetic semiconductor quantum well structures was reported in 1984 by Bicknell and co-workers [236] and Kolodziejski and co-workers [237]. They prepared CdTe/(Cd,Mn)Te by MBE. Up to now MBE is by far the dominating growth method for II-VI, IV-VI, and III-V based magnetic semiconductors, which will be considered first (Section 3.1.1). Only a few attempts at growing two-dimensional systems by MOVPE

have been reported, which will be discussed in Section 3.1.2. Other technologies, like liquid phase epitaxy (LPE), hot wall epitaxy (HWE), pulsed laser evaporation epitaxy (PLEE), electron beam evaporation (EBE), or atomic layer epitaxy (ALE), are of minor importance.

#### 3.1.1. Molecular Beam Epitaxy

**(II,Mn)VI Semiconductors** MBE has typically a low growth rate of about 1  $\mu\text{m/h}$  and relatively low growth temperatures for the (II,Mn)VI semiconductor layers. For CdTe/(Cd,Mn)Te superlattices the substrate temperatures are usually in the range of 200 to 325  $^{\circ}\text{C}$  [238–241]. Different substrates have been successfully used, for example, (100) or (111) GaAs covered with a thick CdTe buffer layer to avoid misfit dislocations in the superlattices [239, 241] or the better lattice matched (001) InSb [238, 240]. The growth temperatures of ZnSe-based diluted magnetic semiconductors are somewhat higher and were in the range of 300 to 450  $^{\circ}\text{C}$  [242, 243] and the substrate was always GaAs. For (Zn,Mn)Te-based systems, however, the better lattice matched GaSb was preferred [244, 245].

The ability of abrupt cessation or initiation of growth by mechanical shutters for each effusion source (Knudsen cell) is useful in preparing a smooth surface on an atomic scale. The atoms form a well-collimated beam, because the ultra-high-vacuum (UHV) environment (about  $10^{-11}$  torr) permits a ballistic transport on the way to the substrate. In principle it is difficult to control the crystal stoichiometry in MBE growth, but the UHV makes it possible to utilize electron or ion-based *in-situ* methods, like mass spectrometry, Auger electron spectroscopy (AES), low-energy electron diffraction (LEED), reflection high-energy electron diffraction (RHEED), and X-ray as well as ultraviolet photoemission spectroscopy (XPS and UPS). RHEED is, however, the standard analytical tool used *in-situ* during MBE growth. Usually the following information can be derived from RHEED: (i) The general appearance of the RHEED pattern provides information about the crystallinity and the surface reconstruction. (ii) Counting the number of RHEED intensity oscillation periods gives the number of monolayers grown. By these two standard methods, however, the potential of RHEED is not exhausted. Hoffmann et al. [246] used the so-called phase-locked epitaxy to grow ZnSe/(Zn,Mn)Se quantum well structures. Operating the shutter in different phases of RHEED intensity oscillations and comparing the layer thickness with the number of oscillation periods provides information about the relation between surface coverage and the RHEED intensity oscillation phase. Furthermore, they obtained information about the Mn concentration by comparing the oscillation periods observed when either ZnSe or (Zn,Mn)Se is grown. It has been found that the oscillation period varies with the composition  $x_{\text{Mn}}$  of the Zn<sub>1-x</sub>Mn<sub>x</sub>Se layers. The expected MnSe mole fraction can be determined from the RHEED oscillation period of ZnSe and Zn<sub>1-x</sub>Mn<sub>x</sub>Se by the empirical expression for  $0 \leq x_{\text{Mn}} \leq 0.3$  given in [246]:

$$x = -0.71 \ln \frac{t(\text{ZnMnSe})}{t(\text{ZnSe})} \quad (36)$$

where  $t(\text{ZnMnSe})$  and  $t(\text{ZnSe})$  are the oscillation times of the  $(\text{Zn,Mn})\text{Se}$  and  $\text{ZnSe}$ , respectively. The underlying physics for this expression is the high sticking coefficient of Mn and the resulting superlinear increase in the  $(\text{Zn,Mn})\text{Se}$  growth rate.

In the case of solid solutions like diluted magnetic semiconductors, it turned out, however, that a strong damping of the oscillation does not allow monitoring of the growth of thick epitaxial layers. The surface becomes rough under these circumstances because of growth fluctuations. Surfaces can be smoothed by a growth interruption. It was reported that the growth interruption was most effective under Se-rich conditions. Two processes contribute to the smoothing of the surface: a fast process acting within seconds and a slow process acting within minutes. Growth interruption must therefore last several minutes with the Se shutter open [247, 248]. The growth of magnetic semiconductor structures has therefore proceeded as follows. After the growth of a few lattice planes, a growth interruption of about 10 s took place, leading to a recovery of RHEED oscillations. In Figure 25a the RHEED oscillations are depicted as a typical example of the growth of a  $\text{ZnSe}/\text{Zn}_{0.8}\text{Mn}_{0.2}\text{Se}$  multiple quantum well structure with well widths of 16 monolayers and 85-nm barrier widths. The structure has been grown on a  $\text{ZnSe}$  buffer of 0.8- $\mu\text{m}$  thickness. The  $\text{ZnSe}$  wells have been grown in the phase-locked epitaxial mode, where the shutter was closed  $240^\circ$  after each fourth RHEED intensity maximum. A short break of 10 s after every growth cycle leads to complete recovery of the oscillations. In Figure 25b the RHEED pattern of the growth of a  $(\text{Zn,Mn})\text{Se}$  layer in the normal mode is shown for comparison.

**Figure 25.** RHEED oscillations recorded (a) during the growth of a  $\text{ZnSe}/\text{Zn}_{0.8}\text{Mn}_{0.2}\text{Se}$  MQW with a well width of 16 monolayers and 85-nm-thick barriers in phase-locked epitaxial mode and (b) during the growth of a thick  $(\text{Zn,Mn})\text{Se}$  epitaxial layer in normal mode. **(III,Mn)V Semiconductors** The first successful growth of a diluted magnetic III-V semiconductor was reported in 1989 by Munekata et al. [23]. This was  $(\text{In,Mn})\text{As}$  on  $(100)$   $\text{GaAs}$  substrates. The key parameters for the growth on  $(100)$   $\text{GaAs}$  substrates are the temperatures and the Mn concentration. For very low substrate temperatures ( $T_s = 200^\circ\text{C}$ ) the  $(\text{In,Mn})\text{As}$  layers have been  $n$ -type, and no indication of a segregation of  $\text{MnAs}$  has been found up to a Mn concentration of 24%. At higher substrate temperatures ( $T_s = 300^\circ\text{C}$ ) the layers are  $p$ -type, at least at low Mn concentrations. At higher concentrations the  $\text{MnAs}$  clusters start to form, and the layers become  $n$ -type again [40]. No epitaxy was observed at substrate temperatures above  $400^\circ\text{C}$ . Contrary to these results,  $p$ -type conductivity has been found for layers also grown at  $T_s = 200^\circ\text{C}$  but on thick buffer layers of  $\text{AlSb}$  or  $(\text{Al,Ga})\text{Sb}$ , which were grown on  $\text{GaAs}$  substrates before the growth of  $(\text{In,Mn})\text{As}$  [164, 249].

A systematic study of  $(\text{Ga,Mn})\text{As}$  growth has been made by Shen et al. [250]. The samples have also been prepared on  $\text{GaAs}$  substrates. For substrate temperatures below  $200^\circ\text{C}$  they found polycrystalline growth, whereas above  $350^\circ\text{C}$  the growth of  $\text{MnAs}$  clusters occurs. In the intermediate range  $p$ -type  $(\text{Ga,Mn})\text{As}$  layers can be formed with Mn concentrations up to 4%.

$(\text{Ga,Mn})\text{N}$  films have also been grown by MBE on  $(0001)$  sapphire substrates using either ammonia as nitrogen source [250] or a nitrogen plasma source [27, 30].

**(IV,Mn)VI and (IV,Eu)VI Semiconductors**  $\text{PbTe}/\text{Pb}_{1-x}\text{Mn}_x\text{Te}$  QWs with  $x < 4\%$  were grown by MBE on cleaved  $(111)$   $\text{BaF}_2$  substrates. The effusion cells of  $\text{PbTe}$ ,  $\text{Mn}$ , and  $\text{Te}$  were at temperatures of 800, 870–900, and  $350\text{--}400^\circ\text{C}$ , respectively. The substrate temperature was between 300 and  $400^\circ\text{C}$ . Typical growth rates were about  $4\ \mu\text{m}/\text{h}$ . After an initial three-dimensional nucleation of  $\text{PbTe}$  or  $\text{Pb}_{1-x}\text{Mn}_x\text{Te}$  on the  $\text{BaF}_2$  surface, a 2D growth mode is established after about 100 nm. This growth mode is kept stable during the deposition of the superlattice by opening and closing of the Mn shutter [252]. The growth was controlled by RHEED [253]. A serious problem in the growth of these superlattice structures is Mn diffusion [254]. Further details are given in [255].

$\text{PbSe}/\text{Pb}_{1-x}\text{Mn}_x\text{Se}$  with  $x < 3\%$  were also grown by MBE with effusion cells for  $\text{PbSe}$ ,  $\text{Mn}$ , and  $\text{Se}$ . A thick  $\text{PbSe}$  layer was deposited on the  $(111)$   $\text{BaF}_2$  substrate before the growth of the superlattice to ensure nearly complete strain relaxation. The lattice mismatch between the  $\text{PbSe}$  and the  $\text{Pb}_{1-x}\text{Mn}_x\text{Se}$  layers is comparatively small. Thus, the thicknesses of the  $\text{Pb}_{1-x}\text{Mn}_x\text{Se}$  layers ( $d < 20\ \text{nm}$ ) as well as that of the entire superlattice stack are well below the critical thickness. Therefore, the  $\text{Pb}_{1-x}\text{Mn}_x\text{Se}$  are under biaxial tensile strain, whereas the  $\text{PbSe}$  QWs are unstrained [256]. A detailed description of the growth is given in [255].

$\text{PbTe}/\text{Pb}_{1-x}\text{Eu}_x\text{Te}$  QWs with  $x < 4\%$  were grown by MBE on cleaved  $(111)$   $\text{BaF}_2$  substrates by a few groups [254, 258]. Typically, the beam flux rates from the  $\text{PbTe}$ ,  $\text{Eu}$ , and  $\text{Te}_2$  effusion cells were measured by an ion gauge beam flux monitor. *In-situ* RHEED was used to monitor the growth process. For low substrate temperatures a large number of RHEED intensity oscillations were observed, which could be used to determine the absolute growth rates [259].

These were close to 1  $\mu\text{m}/\text{h}$ . Detailed growth conditions are described elsewhere [258, 260].

**Mn-VI/II-VI and Eu-VI/IV-VI Multilayers** Although MBE is a nonequilibrium growth technique, the substrate temperatures required for good crystallinity are still fairly high, some 100 °C. As a consequence, it is, in most cases, very difficult to grow thick epitaxial layers of metastable magnetic binaries (such as MnSe, MnTe, EuTe, etc.) on the available substrates. Therefore, it is necessary to stabilize these metastable phases by inserting semiconductor spacer layers, that is, by growing superlattices. The preparation with this stabilizing method of structures consisting of more than 100 periods has been reported. Because of the excellent control of the thickness of all of the layers, such MBE-grown multilayered structures, consisting of ferromagnetic or antiferromagnetic layers separated by diamagnetic semiconducting spacer layers, are ideal model systems for studying magnetic phenomena (such as magnetic interlayer coupling and 2D breakdown of magnetic order).

MnSe/ZnSe is a type I heterosystem with ZnSe acting as the quantum well and MnSe as the barrier. It was the first of a large variety of magnetic binary-containing superlattices realized up to now. Ultrathin MnSe layers in the zincblende structure separated by ZnSe spacer layers on GaAs substrates were grown first by Kolodziejski et al. [53]. The superlattice structure consisted of 100 periods of  $8 \pm 1$  Å MnSe separated by 45 Å ZnSe on a 2- $\mu\text{m}$  ZnSe buffer, which was deposited on  $n^+$  Si-doped GaAs (100) substrates. The structures were grown in a Perkin-Elmer model 400 MBE system. The substrate temperature was 400 °C. The oven temperatures of the separate effusion cells for Zn, Mn, and Se were 296, 860, and 190 °C, respectively. The growth rates were 0.5–1.5 Å  $\text{s}^{-1}$ . The sharp interfaces and the high degree of periodicity of the superlattice structure were controlled by *in-situ* RHEED monitoring and later confirmed by TEM studies. Klosowski et al. grew MnSe/ZnSe as well as MnSe/ZnTe superlattice structures with thick ZnSe and ZnTe buffer layers on (100) GaAs substrates [261, 262]. This allows a variation of the biaxial strain in the magnetic layers from compressive to tensile and, thus, changes the ratio of the  $J_{\text{nn}}$  coupling parameters for perpendicular and parallel to the growth direction. The samples were grown with a Riber MBE 32 R&D system equipped with effusion cells for Zn, Te, Se, and Mn. Heimbrodt et al. grew MnSe/ZnSe superlattices on (100) GaAs substrates at substrate temperatures of 300 °C. Above a critical thickness of 5 nm per MnSe sublayer, a partial phase transformation into the stable rock salt structure was found [51], even in the stabilized multilayered heterosystem.

MnTe-containing superlattice structures, with either CdTe or ZnTe as spacer materials, were also studied. It is worth noting that the growth of thick epitaxial layers of zincblende MnTe has been achieved up to 0.5  $\mu\text{m}$ , in contrast to the few nanometers of MnSe. This was possible because CdTe was available as a suitable substrate [240]. Durbin et al. were also the first to grow MnTe/CdTe SQW structures of different well widths, which confirm that this system has also a type I band alignment. Superlattices of MnTe/ZnTe on (100) GaAs have been grown by Giebultowicz et al. [116]. Recently, studies of Cl-doped MnTe/ZnTe superlattices on

(100) GaAs have been reported [263]. The doping levels were nominally between  $10^{17}$  and  $10^{18}$   $\text{cm}^{-3}$ . Doping of these structures is of interest, as it is expected that an increased carrier density modifies the interlayer coupling. MnTe/CdTe superlattices can also be prepared by ALE [264–266]. In this technique a “self-regulatory” growth mode allows a precise thickness control of the CdTe layers ( $\geq 2$  monolayers). For this system the lattice mismatch of 2.2% is considerably less than that of the Mn-VI/Zn-VI system. Another important aspect of this material combination is that, because of the excellent thickness control of the nonmagnetic layers, superlattices with very thin CdTe layers can be grown, where interlayer spin-spin correlations become observable.

Superlattice structures consisting of EuTe and PbTe are also thoroughly studied. Rock salt EuTe is also antiferromagnetic, as are the zincblende Mn-VI compounds, but exhibits a type II antiferromagnetic order instead of the more complex type III antiferromagnetic order of the Mn-VI compounds with zincblende structure. Thus, EuTe layers of the superlattice structures with a (111) growth plane consist of ferromagnetic sheets of  $\text{Eu}^{2+}$  spins which are antiferromagnetically coupled to the adjacent  $\text{Eu}^{2+}$  sheets [266]. In the case of an odd number of  $\text{Eu}^{2+}$  sheets per EuTe layer, a net magnetization per layer can be obtained (i.e., the layers are ferrimagnetic), giving rise to a very significant interlayer coupling.  $[(\text{EuTe})_{\xi}(\text{PbTe})_{\eta}]_n$  superlattices of various compositions ( $\xi = 2\text{--}14$ ,  $\eta = 6\text{--}25$ , and  $n = 300\text{--}600$ ) were fabricated by MBE at the Johannes Kepler University in Linz. The Riber MBE system was equipped with effusion cells for PbTe, Eu, and  $\text{Te}_2$ . The substrate material was (111)  $\text{BaF}_2$ . A 2000–4000-nm PbTe buffer layer was grown on top of the substrate at a temperature of 350 °C. This ensures a complete strain relaxation of the PbTe buffer. For the growth of the actual superlattice structure the substrate temperature was lowered to 250–280 °C. At this temperature, EuTe can only be deposited with the use of separate effusion cells for Eu and  $\text{Te}_2$ . Detailed descriptions of the growth can be found elsewhere [267–272]. The superlattices are of very high quality and have abrupt interfaces between the EuTe and PbTe layers showing very little interdiffusion [273, 274]. The interface roughness is on the order of a single monolayer [275]. All of the Mn-VI/II-VI and Eu-VI/IV-VI multilayers discussed so far consist of antiferromagnetic layers separated by nonmagnetic semiconducting layers. EuS/PbS superlattices represent a ferromagnetic/nonmagnetic semiconductor-based system [276]. The epitaxial EuS/PbS multilayers were grown by thermal evaporation of PbS from a tungsten boat and by electron beam evaporation of EuS in oil-free vacuum ( $10^{-6}$  to  $10^{-7}$  torr) and their sequential condensation on (100) KCl or (111)  $\text{BaF}_2$  substrates at 250 °C. Before the growth of the actual superstructure a 20–70-nm-thick PbS layer was grown to accommodate the lattice mismatch between the superlattice and the substrate. Typically, X-ray diffraction rocking curves of the multilayers show full widths at half maximum of 300 arcsec and diffraction patterns with satellite peaks of second and third order. Wosnitza et al. studied EuS/SrS ferromagnetic/nonmagnetic multilayers [277]. The samples were grown by MBE on (111) Si substrates. EuS and SrS were used as starting materials and alternatively evaporated onto the substrate by two electron guns. The substrate

temperature was between 600 and 1000 °C. The growth rate was about 0.4 μm/h.

Another class of ferromagnetic/nonmagnetic semiconductor-based multilayer systems that may be of interest in the future is Mn-V/III-V systems. Great progress has been made in the MBE growth of MnAs films on (100) GaAs [278–281] and of MnSb on (100) GaAs and (0001) sapphire [282]. First ferromagnetic/ferromagnetic MnAs/MnSb multilayers on (100) GaAs [283] as well as ferromagnetic/antiferromagnetic MnSb/MnTe heterostructures [284] have been reported.

### 3.1.2. Metal-Organic Vapor Phase Epitaxy

There have been only a few attempts to grow magnetic semiconductors by MOVPE [84, 219, 285–287]. The relatively high growth temperatures, which used to be necessary to obtain high-quality layers of nonmagnetic semiconductors, impede the achievement of a high concentration of magnetic ions in the semiconducting host material.

Lusson et al. [285] reported the preparation of CdTe/(Cd,Mn)Te quantum wells on GaAs substrates. A horizontal commercial reactor (MR Semicon Quantax 226) containing an IR-heated graphite susceptor was used. The samples were grown at a substrate temperature of 365 °C, with diisopropyltelluride (DIPTe), dimethylcadmium (DMCd), and methylpentacarbonylmanganese (PCMMn) as precursors. The carrier gas was hydrogen. Before the growth of the quantum wells a buffer layer of about 1.5 μm was always prepared. The low pyrolysis temperature of PCMMn molecules of about 100 °C, which is much less than the decomposition temperature of DIPTe and DMCd, actually raises enormous problems in achieving homogeneous layers. With a total flow rate increased to 8 L/min and rotation of the substrate, high-quality heterostructures have been obtained.

The successful growth of Ga<sub>1-x</sub>Mn<sub>x</sub>As layers on (100) GaAs substrates by means of MOVPE has been reported by Hartmann et al. [84] and Heimbrodt et al. [219]. Bis(methylcyclopentadienyl) manganese ((MeCp)<sub>2</sub>Mn) has been selected to be the source compound because of its thermal decomposition characteristics, which are appropriate for the MOVPE of the Ga<sub>1-x</sub>Mn<sub>x</sub>As material system. At room temperature, (MeCp)<sub>2</sub>Mn is in the solid phase with an estimated vapor pressure of about 10<sup>-2</sup> hPa. The following chemical synthesis of the compound has been chosen:

where C'p is CH<sub>3</sub>-C<sub>5</sub>-H<sub>4</sub>. The chemical identity of the product of this synthesis was confirmed by gas chromatography combined with mass spectrometry. The yield of this synthesis was between 70% and 90%. MOVPE growth has been performed in a horizontal reactor system (Aix 200-GFR; Aixtron Corporation) at a reduced reactor pressure of 50 mbar with 6.8 L/min of H<sub>2</sub> carrier gas. Triethylgallium (TEGa)

and tertiarybutylarsine (TBAs) have been used as efficient source compounds. A strong dependence of the layer constitution on the growth temperature range has been found. For substrate temperatures below 450 °C a whisker growth can be seen, as depicted in the scanning electron micrograph (SEM) in Figure 26a. For higher temperatures up to about 600 °C (Ga,Mn)As layers of high structural quality can be

(a)

(b)

(c)

**Figure 26.** SEM images of MOVPE (Ga,Mn)As phases. (a) Whisker growth at substrate temperatures below 450 °C. (b) Layers of high structural quality can be grown at substrate temperatures up to about 600 °C. (c) At higher (MeCp)<sub>2</sub>Mn partial pressure the formation of Mn(Ga)As clusters takes place.

grown, but the manganese concentration is limited to less than 1%. The smooth surface is clearly seen in Figure 26b. With increasing  $(\text{MeCp})_2\text{Mn}$  partial pressure the formation of  $\text{Mn}(\text{Ga})\text{As}$  clusters takes place as depicted in Figure 26c. Details of the formation process are reported in [528]. For the application of these clusters it is important to realize that they are embedded in the  $(\text{Ga},\text{Mn})\text{As}$  matrix, almost lattice matched and without any indication of dislocations, as can be seen in the TEM images in Figure 27. In addition, their crystallographic orientation is well defined; that is, the  $c$  axis of the hexagonal  $\text{MnAs}$  is parallel to the (111) directions of the zincblende  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  host.

The successful preparation of  $(\text{Ga},\text{Mn})\text{N}$  by MOVPE was also reported. Reed et al. [287] prepared 40 nm buffer layers on (0001) sapphire at a low temperature of about 500 °C. The growth was followed by a high temperature annealing to achieve a recrystallization. 2  $\mu\text{m}$  GaN epitaxial layers were deposited on top of the buffer layer at about 1000 °C. Afterwards Mn was deposited by a laser technique on the

nitride sample. The background vacuum during deposition was about  $10^{-8}$  torr. The Mn thickness ranged from 10 to 100 nm. Mn doping was achieved by deposition and annealing at different temperatures ranging from 250–800 °C. The film quality of the  $(\text{Ga},\text{Mn})\text{N}$  layers during deposition and after annealing was checked by RHEED, X-ray diffraction and TEM. By SIMS measurements the authors verify the diffusion of Mn into the hexagonal GaN layer, forming a concentration gradient that levels out at about 1% of Mn.

Using  $(\text{DPM})_3$  as Er source Morinaga et al. [31] reported the successful preparation of a rare-earth based diluted magnetic semiconductor by MOVPE. Er concentrations up to  $2 \times 10^{20} \text{ cm}^{-3}$  have been reported in GaAs films grown in the temperature range from 530 °C to 630 °C.

### 3.2. Growth and Preparation of Quantum Wires

Different ways of preparing one-dimensional nanostructures have been reported. The easiest way is to start with two-dimensional quantum wells and to use a subsequent etching procedure. This method will be described in Section 3.2.1. Another elegant and successful method is the epitaxial overgrowth of substrates patterned by selective etching procedures discussed in Section 3.2.2. In Section 3.2.3 a rather novel approach is introduced where  $(\text{II},\text{Mn})\text{VI}$  semiconductors are incorporated into mesoporous  $\text{SiO}_2$  matrices with a highly homogeneous and well-ordered pore structure via an intrapore formation process from solution.

#### 3.2.1. Lateral Patterning by Lithographic Methods Followed by Etching

The most commonly used lithographic technique for the fabrication of QWRs based on diluted magnetic semiconductors is electron beam lithography (EBL), as it allows the writing of patterns with very high accuracy (down to a few nanometers in width) together with a flexibility of choice of pattern (e.g., wire width, distances between wires, etc.) [289–292]. However, other lithographic patterning techniques can also be used; for example, Darhuber et al. [293] used laser holographic patterning to write wire structures with a width of about 100 nm. The major obstacle in nanostructure fabrication starting from epitaxial two-dimensional structures is, however, pattern transfer into the semiconductor by etching. Different etching processes have been developed, that is, wet-chemical etching methods [290–292], dry etching techniques such as reactive ion etching (RIE) [293] or ion-beam etching (IBE), or combinations of dry and wet etching steps [289]. All etching techniques have their advantages and disadvantages. For example, wet-chemical etching is usually fairly isotropic, making it difficult to obtain an accurate pattern transfer into the semiconductor because of the underetching of the etch masks. IBE allows high aspect ratios but causes a damaged layer of poor optical quality close to the surface of the nanostructures. RIE is probably the best technique, as fairly high aspect ratios and steep sidewalls of the nanostructures can be obtained.

Oka et al. fabricated  $\text{Cd}_{1-x}\text{Mn}_x\text{Se}/\text{Zn}_{1-y}\text{Cd}_y\text{Se}$  QWRs of different widths ranging from 26 to 300 nm, starting from MBE-grown  $\text{Cd}_{1-x}\text{Mn}_x\text{Se}/\text{Zn}_{1-y}\text{Cd}_y\text{Se}$  QW samples with  $x_{\text{Mn}} = 8\%$  and  $y_{\text{Cd}} = 30\%$  on (100) GaAs [290–292].

**Figure 27.** TEM images of  $\text{Mn}(\text{Ga})\text{As}$  clusters in a  $\text{Ga}_{1-x}\text{Mn}_x\text{As}$  host matrix of low  $x_{\text{Mn}}$ . (a) Bright-field TEM image. (b) High-resolution image of a cluster–matrix interface.

After spin-coating of the QW samples with ZEP-520 resist and prebaking, homogeneous wire-array patterns of  $0.5 \times 0.5 \text{ mm}^2$  were defined by EBL (Elionics ERA-8000 FE) on the two-dimensional structure. After a postbaking step and a developing step of the resist, the pattern was transferred by wet-chemical etching with a solution of  $\text{K}_2\text{Cr}_2\text{O}_7:\text{HBr}:\text{H}_2\text{O}$  to a depth of 100 nm.

Klar et al. obtained  $\text{ZnSe}/(\text{Zn,Mn})\text{Se}$  QWRs and  $(\text{Zn,Cd,Mn})\text{Se}/\text{ZnSe}$  QWRs of different widths ranging from 50 to 500 nm from the corresponding MBE-grown quantum well structures by an EBL pattern definition followed by a combination of IBE and wet-chemical etching. Figure 28 depicts the end of a single  $\text{ZnSe}/(\text{Zn,Mn})\text{Se}$  QWR after IBE and wet-chemical etching before removal of the Ti-etch mask [289]. The nanofabrication process consists of nine steps and is similar to that employed for the fabrication of QD samples, which is described in detail in Section 3.3.1.

One-hundred-nanometer-wide  $\text{CdTe}/\text{MnTe}$  multiple QWRs were realized by holographic lithography (Ar ion laser operating at 457.8 nm) and subsequent RIE with a mixture of  $\text{CH}_4$  and  $\text{H}_2$  [293]. The two-dimensional structure was an MBE-grown superlattice consisting of 20 periods of 17 nm  $\text{CdTe}$  and 2 nm  $\text{MnTe}$ . The ionization of the molecules was done with a 13.56-MHz radio frequency source in a parallel-plate reactor (Oxford 80 Plus). The supplied power was 180 W, and the total pressure during operation was 10 mTorr. The etch rate of the  $\text{CdTe}/\text{MnTe}$  layers was determined to be 15 nm/min, and the total etch time was 30 min. Very high aspect ratios and very steep sidewalls were obtained, as can be seen in Figure 29.

### 3.2.2. Epitaxial Growth on Patterned Substrates

In addition to the direct patterning of two-dimensional layers to obtain QWRs, the epitaxial growth on patterned substrates is an important technology for the fabrication of one-dimensional semiconductor nanostructures by both MOVPE [294] and MBE [295]. The ALE of GaAs QWRs was successfully demonstrated by Isshiki et al. [296]. Basically the growth on patterned substrates is a selective growth method, which provides control of the lateral dimensions of semiconductors. In contrast to the lateral structuring

**Figure 28.** SEM image of the end of a single  $\text{ZnSe}/(\text{Zn,Mn})\text{Se}$  QWR after IBE and wet-chemical etching before the removal of the Ti-etch mask.

**Figure 29.** SEM image of  $\text{CdTe}/\text{MnTe}$  QWR structures obtained by RIE. Reprinted with permission from [293], A. A. Darhuber et al., *Mater. Sci. Forum* 182–184, 423 (1995). © 1995, Trans Tech Publications.

discussed in Section 3.2.1, this technique does not generate additional chemical or mechanical defects in the wires.

Although the selective epitaxial growth on patterned substrates is well established for nonmagnetic semiconductors, this technique has hardly been used for growing magnetic semiconductor nanostructures. Parthier and co-workers [297] reported the successful growth of  $\text{ZnSe}/(\text{Zn,Mn})\text{Se}$  and Chen et al. [298] the growth of  $(\text{Cd,Mn})\text{Te}/(\text{Cd,Mg})\text{Te}$  QWRs by MBE on patterned GaAs substrates. The preparation method for the  $\text{ZnSe}/(\text{Zn,Mn})\text{Se}$  QWRs was described in detail in [295, 297]. The (001)-oriented GaAs substrates were structured by photolithography or EBL followed by wet-chemical etching. The orientation of the masks (stripes of about 1–2  $\mu\text{m}$ ) were along the [110] or [1–10] directions. To prepare grooves with  $\{111\}_A$  sidewalls an etching solution,  $\text{H}_3\text{PO}_4/\text{H}_2\text{O}_2/\text{H}_2\text{O}$  or  $\text{KBrO}_3/\text{H}_2\text{O}_2/\text{H}_2\text{O}$ , was used. Nearly V-shaped grooves could be grown in the [1–10] direction, and trapezoid-shaped grooves could be grown in the [110] direction. Grooves with  $\{111\}_B$  sidewalls were obtained by etching with  $\text{KHCO}_3/\text{H}_2\text{O}_2/\text{H}_2\text{O}$  solution. The resulting shape of the grooves is complementary to  $\{111\}_A$ . The reported dissolution rates of the (001) surface at room temperature were about 0.8  $\mu\text{m}/\text{min}$  for  $\text{H}_3\text{PO}_4$ , about 0.72  $\mu\text{m}/\text{min}$  for  $\text{KBrO}_3$ , and about 0.17  $\mu\text{m}/\text{min}$  for  $\text{KHCO}_3$  etchant, respectively. Patterned GaAs substrates with structures with a strip width on top of the etched wires between 1 and 0.1  $\mu\text{m}$  were obtained. Figure 30 shows SEM pictures of a cleaved  $\{110\}$  cross section of selectively grown ZnSe on A-anisotropically etched (001) GaAs with top stripes oriented along the [1–10] direction. The huge difference in strip width for the structures depicted in Figure 30 was realized by means of different etching solutions. With the use of a mask with 2- $\mu\text{m}$  stripes, the  $\text{H}_3\text{PO}_4$  etchant yields a 0.15- $\mu\text{m}$  width (Fig. 30a), whereas  $\text{KBrO}_3$  etchant leads to stripes with a width of 1.4  $\mu\text{m}$  on the top (see Fig. 30b). Different growth rates  $R$  on the individual surfaces  $R_{\{111\}_A} < R_{(001)}$  can be used to prepare QWRs. Parthier et al. [297] reported a growth rate ratio  $R_{\{111\}_A}/R_{(001)} = 0.36$ . An overgrowth of the patterned substrate leads to a strong narrowing of the top stripes. This is clearly seen in Figure 30b. The GaAs substrate (grayish dark) has been overgrown by MBE with a ZnSe-layer (grayish-bright). The plateau becomes smaller with increasing MBE overgrowth. This effect has been

**Figure 30.** SEM image of cleaved  $\{110\}$  cross sections of selectively grown ZnSe on A-anisotropically etched (001) GaAs for different etching conditions (a–b). Reprinted with permission from [295], L. Parthier et al., *J. Cryst. Growth* 159, 99 (1996). © 1996, Elsevier Science.

used to prepare ZnSe quantum wires between magnetic (Zn,Mn)Se barriers. In Figure 31 a SEM picture is seen, with the cross section perpendicular to the wire direction. A 55-nm ZnSe buffer layer has been grown on the patterned GaAs substrate. Afterward a (Zn,Mn)Se/ZnSe superlattice structure consisting of five periods of 13-nm  $\text{Zn}_{0.78}\text{Mn}_{0.22}\text{Se}$  and 11-nm ZnSe has been grown on top to reduce the strain. The superlattice structure is well resolved in the grooves of the structure. After another 40-nm (Zn,Mn)Se barrier, a 4-nm ZnSe quantum well has been grown, which is still resolvable in the groove but is hardly to be seen on top of the stripes. From geometrical considerations, the lateral extension of the wire is expected to be less than 1 nm.

Morishita et al. reported the growth of MnAs wire-like structures by MBE on (111)A facets of V-grooved GaAs substrates [297]. The V-grooves with (111)A sidewalls were prepared by conventional chemical etching of the (100) GaAs substrates. Afterward an undoped GaAs buffer layer was grown at  $T_S = 600^\circ\text{C}$ . With  $T_S$  lowered to about  $250^\circ\text{C}$  and

**Figure 31.** SEM image of the cleaved  $\{110\}$  cross section of a 4-nm ZnSe QWR within 40-nm (Zn,Mn)Se barriers grown on a ZnSe(11 nm)/(Zn,Mn)Se(13 nm) MQW buffer with five periods and 50 nm ZnSe (ZnSe is bright). adjustment of the direction of the Mn flux, MnAs grew only the (111)A facets of the V-grooves that faced the Mn flux.

One can state that overall, the overgrowth of patterned substrates is an excellent technique for preparing high-quality QWRs with dimensions in the real quantum limit.

### 3.2.3. Template-Directed Growth of Ordered Arrays of Nanostructures

The organic-template-directed synthesis of mesoporous silica in 1992 by Mobil Oil Company opened new pathways in material design [300, 301]. Depending on the synthesis conditions, highly ordered organic-template/SiO<sub>2</sub> superstructures can be prepared. The superstructures of these so-called M41S materials are either of hexagonal (MCM-41; MCM = Mobil Composition of Matter), cubic (MCM-48), or lamellar (MCM-50) symmetry. Removal of the organic template of the three-dimensional superstructures (i.e., MCM-41 and MCM-48) in a calcination process leaves a highly ordered mesoporous SiO<sub>2</sub> matrix with regular wire-like pores. Figure 32 is a high-resolution TEM image of a grain of a MCM-48 SiO<sub>2</sub> matrix. The pore diameters as well as the distances between neighboring pores are only a few nanometers and can be accurately adjusted during the synthesis process [302]. These mesoporous SiO<sub>2</sub> materials are well suited as host materials for semiconductors and even magnetic semiconductors because of their high degree of order as well as the large bandgap of the SiO<sub>2</sub> (which serves as barrier material). The first successful incorporation of the semimagnetic semiconductor  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$  into MCM-41 SiO<sub>2</sub> was reported in [303–305]. It is a very interesting way of creating highly ordered arrays of magnetic QWRs for possible applications in magneto and spin-electronics.

The preparation procedure was as follows. A gel mixture of 1 SiO<sub>2</sub>:0.25 CTABr:0.2 TMAOH:35 H<sub>2</sub>O was used for the synthesis of the MCM-41 SiO<sub>2</sub> matrix. The gel mixture was stirred at  $60^\circ\text{C}$  for 30 min. It was poured into a Teflon-lined steel autoclave and kept there at room temperature for 24 h. Afterward it was synthesized for 24 h at  $150^\circ\text{C}$  under autogeneous pressure. The product was washed with water several times and calcined at  $550^\circ\text{C}$ . The pore size and the wall thickness were determined to be  $3.1 \pm 0.1$  nm and about 2 nm, respectively. The  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$  was implanted in a MCM-41 SiO<sub>2</sub> matrix as follows: 0.5 g calcined MCM-41 silica was suspended in a 0.5 M solution of cadmium

**Figure 32.** High-resolution TEM image of a grain of MCM-48 SiO<sub>2</sub> matrix.

acetate and manganese acetate in water with different ratios of Cd/Mn and stirred for 10 min. The precipitate was centrifuged and vacuum dried. The acetates were converted into the sulfide by thermal treatment in a  $\text{H}_2\text{S}$  atmosphere. Samples with Mn contents of  $0 \leq x \leq 30\%$  and  $80\% \leq x \leq 100\%$  were synthesized. Figure 33 depicts a TEM image of a  $\text{SiO}_2$  MCM-41 host after incorporation of  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$ . The lattice has a regular hexagonal structure with wirelike filled pores 3.5 nm in diameter. The Mn concentrations  $x$  were determined by chemical analysis. (Cd,Mn)Se and (Zn,Mn)S QWRs have recently been synthesized in a similar fashion [306, 529]. It is also possible to vary the wire diameter (i.e., 3 nm, 6 nm, and 9 nm were realized) by using different organic templates in the synthesis process [529].

### 3.3. Growth and Preparation of Quantum Dots

There are two completely different approaches for obtaining quasi-zero-dimensional nanostructures. The first approach is based on epitaxial growth techniques, such as those introduced in Sections 3.1 and 3.2. The second approach is the direct growth of nanocrystals in an organic or inorganic matrix. With two-dimensional epitaxial growth on a substrate as the starting point, two principal ways of realizing quantum dots (QDs) can be distinguished. One is the subsequent etching procedure, which will be discussed in Section 3.3.1, and the other is the exploitation of the self-organized (often called self-assembled) growth of island-like dots from a wetting layer by the so-called Stranski–Krastanov method, which is discussed in Section 3.3.2. The other fundamental approach is the growth of QDs in a matrix, which also has to be considered a self-activated growth. In particular, growth in inorganic glass matrices is a diffusion-controlled process which exhibits some analogies to the self-activated growth from a wetting layer and is also described in Section 3.3.2. Currently, an effort is being made to grow magnetic binary QDs in ternary semimagnetic semiconductors by the control of segregation effects. These structures are possible candidates for ferromagnetic semiconductor hybrids, which can be

**Figure 33.** TEM image of a grain of a MCM-41  $\text{SiO}_2$  matrix after intrapore formation of (Cd,Mn)S.

combined with conventional semiconductors for magneto-electronics and spin-electronics at room temperature. Some of these magnetic semiconductor hybrids are also discussed in Section 3.3.2. The growth of nanocrystals in liquid or micelle media as well as in polymers is also controlled by, in addition to the diffusion-limited mechanism, chemical reactions and is therefore discussed in an extra Section, 3.3.3.

#### 3.3.1. Lateral Patterning by Lithographic Methods

The techniques employed for the fabrication of QDs by lithographic methods are very similar to those introduced in Section 3.2.1 for the fabrication of QWRs. Again the main lithographic technique is EBL followed by one or several etching steps for transferring the pattern into the semiconductor [307–311]. There is an alternative lithographic approach, which combines lithography and pattern transfer. This is the so-called focused ion beam lithography, where dots are fabricated by controlled intermixing of quantum well and barrier materials due to a bombardment with 100-keV  $\text{Ga}^+$  ions [312, 313].

Ribayrol et al. fabricated QD samples from CdTe/(Cd,Mn)Te QW samples grown by MBE on (100) InSb as well as on (100) (Cd,Zn)Te substrates [307]. Various patterns of  $400 \mu\text{m} \times 400 \mu\text{m}$  consisting of dots of the same diameter were defined on the QW samples with EBL. After the resist was developed, 30 nm of Ti was evaporated onto the sample, and the resist was removed in a lift-off process. The titanium served as an etching mask in the RIE process. The pattern was transferred by RIE to a depth of about 400 nm with the use of a plasma of  $\text{CH}_4:\text{H}_2:\text{O}_2$ . Steep sidewalls were obtained with the use of 1:8  $\text{CH}_4:\text{H}_2$  and a small amount of  $\text{O}_2$  at a RF power density of 0.44–0.66  $\text{W cm}^{-2}$ . Details of control of the dot profile in the described RIE process can be found elsewhere [314, 315].

Klar et al. fabricated QD samples in various wide-gap (II, Mn)VI systems (i.e., CdTe/(Cd,Mn)Te [309], ZnTe/(Zn,Mn)Te [308], ZnSe/(Zn,Mn)Se [310], and (Zn,Cd,Mn)Se/ZnSe [311]). The nanofabrication started from MBE-grown quantum well structures and consisted of nine steps. First, the specimen was cleaned with acetone in an ultrasonic bath and rinsed with isopropanol. In the second step, it was spin-coated with a two-layer resist consisting of a 140-nm bottom layer of copolymer P(MMA-MAA) and a 50-nm top layer of 950k PMMA. Afterward, the EBL was carried out with a JEOL JBX 5DII system with a  $\text{LaB}_6$  cathode and an acceleration voltage of 50 kV, a final aperture of  $60 \mu\text{m}$ , a working distance of 14 nm, and a beam current of 1 nA. Typically a patterned area covered  $3.2 \times 3.2 \text{ mm}^2$  on the specimen. Squares of  $200 \times 200 \text{ nm}^2$  were exposed with a nominally homogeneous dose (typical values are  $220 \mu\text{C cm}^{-2}$  for Te-based dots and  $200 \mu\text{C cm}^{-2}$  for Se-based dots). These squares were arranged on a lattice with a lattice constant of 400 nm. The diameter of the beam and the proximity effect result in a circular exposure profile under these conditions. In the fourth step, the exposed sample was developed in a solution of 20 ml of isopropanol and 2 ml of distilled water for 60 s. Afterward, a 30-nm Ti film was deposited on the resist mask, and after subsequent lift-off in warm acetone, a pattern of circular Ti dots with a

diameter of about 200–220 nm was obtained. This pattern was transferred onto the semiconductor to the desired depth with the use of  $\text{Ar}^+$  IBE under normal incidence with a relatively low acceleration voltage of 200 V and a current density of  $0.16 \text{ mA cm}^{-2}$ . The etch rate varied for the different semiconductors (e.g., about  $18 \text{ nm min}^{-1}$  for the tellurides and about  $8 \text{ nm min}^{-1}$  for the selenides). An additional optional wet-etching step can be introduced to reduce the lateral dimensions of the QDs further. This has been done in the case of the Se-based QDs [310, 311]. For the wet-etching step either a solution of  $\text{Br}_2 : \text{HOCH}_2\text{CH}_2\text{OH}$  at 2:1000 or a solution of  $\text{HBr} : \text{K}_2\text{Cr}_2\text{O}_7 : \text{H}_2\text{O}$  at 1:195:250 has been used. Typical etching times were 30 s. In the final step, the Ti etch mask was removed with hydrofluoric acid. As typical examples for specimens obtained by employing solely  $\text{Ar}^+$  IBE in the etching step, SEM images of 200-nm and 100-nm QDs fabricated from a  $\text{CdTe}/(\text{Cd},\text{Mn})\text{Te}$  MQW structure are depicted in Figure 34a and b, respectively. To allow a better view of the individual QDs, the SEM images were taken at defects or at the edge of the QD arrays and with the specimens tilted by  $30^\circ$ . The arrays of QDs were very homogeneous over the whole area of  $3.2 \times 3.2 \text{ mm}^2$ , with only a few macroscopic defects. It can be seen in the figures that the top of the 200-nm QDs is still flat in contrast to the tiplike shape of the 100-nm QDs. This indicates that damage of the QWs closest to the surface of the MQW structure has occurred in the 100-nm QDs, whereas for the 200-nm sample the core of the QDs is undamaged by the nanofabrication process. The sidewalls of the QDs are inclined, as is typical for  $\text{Ar}^+$  ion etched specimens [316]; similar inclinations

**Figure 34.** SEM images of 200-nm and 100-nm  $\text{CdTe}/(\text{Cd},\text{Mn})\text{Te}$  QDs obtained by IBE.

were observed by other groups in II–VI materials with the use of similar acceleration voltages [317, 318]. Figure 35 shows an SEM image of a  $\text{ZnSe}/(\text{Zn},\text{Mn})\text{Se}$  QD sample prepared with a combination of  $\text{Ar}^+$  IBE and wet-chemical etching to transfer the dot pattern into the semiconductor. The specimen is tilted by  $40^\circ$ , and the Ti etch mask is not removed. An underetching of the Ti mask is observed, which is typical for the rather isotropic wet etching.

Bacher et al. [312, 313] prepared buried  $\text{CdTe}$  QD samples from MBE-grown  $\text{CdTe}/\text{Cd}_{0.76}\text{Mn}_{0.24}\text{Te}$  on (100)  $\text{Cd}_{0.96}\text{Zn}_{0.04}\text{Te}$  substrates by focused ion beam lithography. A single 6-nm  $\text{CdTe}$  QW is embedded between a  $\text{Cd}_{0.76}\text{Mn}_{0.24}\text{Te}$  buffer and a 40-nm  $\text{Cd}_{0.76}\text{Mn}_{0.24}\text{Te}$  capping layer. The ion implantation for creating the dots was carried out with an EIKO 100 focused ion beam system with a  $\text{Ga}^+$  source. The beam diameter is about 30 nm, the ion energy is 70 keV, and the implantation doses varied between  $6 \times 10^{12}$  and  $5 \times 10^{13} \text{ cm}^{-3}$ . To create single dots small mesas with lateral dimensions of  $20 \mu\text{m} \times 20 \mu\text{m}$  were implanted homogeneously, except for a circle with a diameter of  $2 \mu\text{m}$  in the center of the mesas. The ion bombardment already leads to an intermixing of the barrier and well material. This intermixing can be further enhanced by a rapid thermal annealing step after the implantation. The annealing temperature was varied between 330 and  $500^\circ\text{C}$ . The ion dose and the annealing temperature allow one to reduce the effective dot size and to control the effective confining potential of the dots, which corresponds to an inverted Gaussian profile. It should be noted that the effective extension of the ground-state excitonic wavefunction of the dot is only about 50 nm.

### 3.3.2. Self-Organized Growth

The term “self-organized growth” is misleading, as, strictly speaking, any growth process is self-organized. From a physical point of view the processes that are called self-organized are those which go through a transformation from a thermodynamically unstable state (e.g., prepared by a low-temperature growth) into a thermodynamically stable state with a reduced overall energy. Two very different methods, which make use of self-organization, have been used to prepare QDs on the basis of magnetic semiconductors. First, we shall consider the so-called Stranski–Krastanov method.

**Figure 35.** SEM image of a  $\text{ZnSe}/(\text{Zn},\text{Mn})\text{Se}$  QD sample prepared by a combination of  $\text{Ar}^+$  IBE and wet-chemical etching. Reprinted with permission from [310], P. J. Klar et al., *Phys. Rev. B* 57, 7114 (1998). © 1998, American Physical Society.

The driving force of this growth process is a strain misfit between the layer materials of a quantum well heterostructure. The strain has to exceed a critical value, leading to a transition from 2D growth to 3D growth. Second, we shall discuss the preparation procedure of dots in a glass matrix. The diffusion permits the formation of energetically favored clusters. The cluster size is determined by the minimum of the free energy.

**Stranski–Krastanov Growth** Kuroda et al. [319, 320] reported the successful growth of self-organized QDs of zincblende MnTe on CdTe layers on a (100) GaAs substrate by MBE. The CdTe layer thickness varied from about 0.5  $\mu\text{m}$  to 2  $\mu\text{m}$  to permit lattice relaxation. The deposition of MnTe was performed by two different methods. (i) The Mn and Te fluxes were supplied simultaneously, which is the conventional MBE. The Mn/Te ratio was about 1:10, and the growth rate was about 0.1 monolayer per second. (ii) Both fluxes were supplied subsequently. This technique is comparable to ALE. For both methods the substrate temperature was about 300–325 °C. Self-organized cone-shaped dots were formed after the deposition of about 10–13 monolayers. The QDs obtained by method (i) were (70  $\pm$  10) nm in height and (140  $\pm$  10) nm in diameter, whereas those obtained by method (ii) were only (8  $\pm$  1) nm in height and had diameters of (60  $\pm$  5) nm.

In a similar fashion the same authors grew  $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$  QDs with  $x = 0$ –18% on a (100) ZnTe buffer layer of 0.6–1.0  $\mu\text{m}$  deposited on (100) GaAs [321, 322]. Typically these dots had diameters of about 20 nm and were about 2 nm in height. The dot density was about  $10^{11} \text{ cm}^{-2}$  for  $x = 3\%$ , but decreased significantly with increasing Mn concentration of the QDs. Mackowski et al. [323] grew  $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$  QDs in ZnTe in a similar fashion. Some details about the growth can be found in a publication on a related system, CdTe QDs in ZnTe [324].

Takahashi et al. prepared  $\text{Cd}_{1-x}\text{Mn}_x\text{Se}$  QDs on (100) ZnSe in a Stranski–Krastanov growth mode by MBE [292]. A smooth wetting layer for the dot system was realized by the growth of two monolayers of CdSe. Subsequently, a five-monolayer-thick  $\text{Cd}_{1-x}\text{Mn}_x\text{Se}$  layer was grown at a temperature of 280 °C with the use of vapor fluxes of Cd, Se, and Mn. Self-organization was initiated by raising the substrate temperature to 310 °C. After the formation process, the dots were covered with a ZnSe capping layer. The effective dot size was about 5 nm and  $x \approx 3\%$ . (Cd,Mn)Se QD samples in a ZnSe matrix were also grown by Mackowski et al. [323].

Xin et al. [325] prepared CdSe QDs in  $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$  matrices with  $x = 0, 5,$  and 10% by MBE from elemental sources. Before the growth of the CdSe QDs a  $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$  buffer of about 2  $\mu\text{m}$  was deposited on a (100) GaAs substrate at 300 °C. For the growth of the CdSe QDs, the substrate temperature was raised to 350 °C. A typical effective growth rate for the QD layer was 0.4 monolayers per second. The best results were obtained for a thickness of 2.5 monolayers. At the beginning of the CdSe deposition, a clear transformation of the RHEED pattern from streaky to spotty, indicative of the onset of Stranski–Krastanov growth, was observed. Uncapped and capped samples for AFM and optical studies, respectively, were prepared. In the latter case, the capping layer was about 500 Å. Examination of the

uncapped samples within 1 h after the growth revealed a typical dot density of 25 dots/ $\mu\text{m}^2$ , a uniform dot diameter of (40  $\pm$  5) nm, and an average height of (10  $\pm$  3) nm for the samples with  $x = 0\%$ . The Mn-containing samples show higher QD densities and reduced QD sizes. A possible reason for this might be the smaller lattice mismatch between (Zn,Mn)Se and CdSe compared with that between ZnSe and CdSe. However, other effects due to the presence of Mn cannot be ruled out.

Zhou et al. prepared Mn-including InAs dots embedded in GaAs by MOMBE in a Stranski–Krastanov growth mode [326].

Vertically aligned quasi-regular arrays of QDs have been prepared by MBE in the IV–VI system  $\text{PbSe/Pb}_{1-x}\text{Eu}_x\text{Te}$  [327–330]. The samples were grown by MBE on thick PbTe buffer layers predeposited on (111)  $\text{BaF}_2$  substrates. The substrate temperature was 360 °C. The growth rates were 0.08 ML/s and 0.96 ML/s for PbSe and  $\text{Pb}_{1-x}\text{Eu}_x\text{Te}$ , respectively. The superlattices consist of up to 100 periods of five monolayers of PbSe, alternating with diluted magnetic  $\text{Pb}_{1-x}\text{Eu}_x\text{Te}$  spacer layers with thicknesses ranging from 200 to 1000 Å. Because of the  $-5.4\%$  lattice mismatch with respect to the PbTe, PbSe grows in Stranski–Krastanov mode, with the formation of 3D islands once the critical coverage of 1.5 ML is exceeded [331]. During the overgrowth a rapid replanarization takes place such that, after 200 Å, a smooth 2D surface is regained [327]. The only difference in the samples was the thickness and composition of the ternary  $\text{Pb}_{1-x}\text{Eu}_x\text{Te}$  layers, where  $x$  was adjusted to achieve a complete strain symmetrization of the superlattice stack (e.g.,  $x = 7\%$  for 470-Å spacers) with respect to the PbTe buffer layer [327]. The possibility of simultaneously achieving in-plane ordering and vertical stacking in the dot superlattices as the spacer thickness is varied is very interesting. Three regimes are observed as shown in the TEM images of Figure 36: (i) for thin spacers vertically aligned dot columns are obtained, but with a changing dot shape along the growth direction (Fig. 36a); (ii) for intermediate spacer thicknesses an fcc-stacking ABCABC of adjacent dot layers

**Figure 36.** TEM images of vertically stacked PbSe QDs in a (Pb,Eu)Te matrix for different (Pb,Eu)Te spacer thicknesses. Reprinted with permission from [330], G. Springholz et al., *Phys. Rev. Lett.* 84, 4669 (2000). © 2000, American Physical Society.

is observed, with constant dot spacing and dot size throughout the superlattice stack (Fig. 36b); and (iii) for the thickest spacers the vertical correlation disappears again (Fig. 36c). The scaling behavior of the lateral dot separation  $L$  versus the vertical superlattice period  $D$  for the PbSe/Pb<sub>1-x</sub>Eu<sub>x</sub>Te dot stacks is shown in Figure 37. The three regimes also show different in-plane ordering, as can be seen in the three AFM images of Figure 38. The insets are fast Fourier transformation (FFT) power spectra of the AFM images. For samples of regime (i), although the dots seem to nucleate at random positions, six broad satellite peaks are visible in the FFT spectrum, indicating a preferred hexagonal arrangement (Fig. 38a). In regime (ii) the degree of in-plane order is even higher (Fig. 38b). The FFT spectrum shows a sixfold symmetry and a large number of higher order peaks, indicating the existence of large hexagonally ordered dot domains. In regime (iii) no in-plane ordering is observed, indicated by the diffuse ring in the FFT spectrum (Fig. 38c). The magnetic properties of these superlattice structures have not yet been studied; however, interesting effects can be expected, considering the enhanced magnetic properties of (Pb,Eu)Te.

**Quantum Dots in Glass Matrices** The range of semiconductor materials used for the preparation of QDs in glass matrices covers almost all kinds of known substances. Well-elaborated preparation methods and theories are known which give detailed information about the diffusion-controlled growth process and the correlation between annealing temperature and annealing time on one hand and the mean dot sizes and size distribution on the other. For a detailed review see, for example, the book by Woggon [332]. There are, however, only a few papers concerning magnetic nanocrystals in glass matrices prepared by RF sputtering [333–337] or by sol–gel processes [338–341]. In particular, in the latter case the preparation procedures can vary considerably.

**Figure 37.** Scaling behavior of the lateral PbSe dot separation versus vertical PbSe/Pb<sub>1-x</sub>Eu<sub>x</sub>Te SL period. Reprinted with permission from [330], G. Springholz et al., *Phys. Rev. Lett.* 84, 4669 (2000). © 2000, American Physical Society.

**Figure 38.** AFM images of the in-plane ordering in the three regimes (see text for details). Reprinted with permission from [330], G. Springholz et al., *Phys. Rev. Lett.* 84, 4669 (2000). © 2000, American Physical Society.

Nanocrystals of (Cd,Mn)Te and (Cd,Mn)Se were prepared by RF sputtering with a composite target which consisted of small pieces of (Cd,Mn)Te or (Cd,Mn)Se crystals on a SiO<sub>2</sub> disk [333–337]. By simultaneous sputtering of the magnetic semiconductor and SiO<sub>2</sub> thin films of about 1- $\mu$ m thickness were obtained. The films were heat treated at 300–600 °C for several hours. During this thermal treatment QDs of (Cd,Mn)Te or (Cd,Mn)Se were formed. The diameters of the QDs can vary from 1 to 50 nm.

Wang et al. were the first to report the preparation of (Zn,Mn)S clusters in glass matrices by a sol–gel method [338]. The fabrication process is described in detail in their paper. In summary, two solutions were prepared. The first solution consisted of tetramethylorthosilicate in methanol. The second solution was a mixture of manganese and zinc nitrate (the ratio of Zn/Mn nitrates determined the doping level in the QDs) in diluted nitric acid. The two solutions were added together, vigorously stirred for a few minutes, and then transferred into polypropylene vials. When the vials are left at room temperature overnight a rigid gel is formed. The gel was then dried and calcinated at elevated temperatures to obtain a dried porous glass. To generate Zn<sub>1-x</sub>Mn<sub>x</sub>S clusters, the porous glass, which already contains Zn<sup>2+</sup> and Mn<sup>2+</sup> ions, was exposed to H<sub>2</sub>S at 200 °C. The glass containing the Zn<sub>1-x</sub>Mn<sub>x</sub>S clusters was impregnated with methylmethacrylate in a final step. The resulting composite is strong enough to allow cutting and polishing of thin disks.

Morita et al. prepared sol–gel ZrO<sub>2</sub> films with CdS : Mn<sup>2+</sup> (or Eu<sup>3+</sup>) QDS by a dipping method [340]. Small quartz slides were dipped successively in mother solutions of *n*-propanol which contained the following reagents: zirconia tetrapropoxide, cadmium acetate, manganese acetate (or europium nitrate), and sodium thiocyanate. After dip coating the samples were dried at room temperature for a day and afterward heated in an electric oven at 350 °C for another 24 h to form the QDs. The whole process can be repeated several times to obtain thick samples.

Artemyev et al. [341] and Chamarro et al. [339] used approaches where Cd<sub>1-x</sub>Mn<sub>x</sub>S QDs were first synthesized by a precipitation process (see Section 3.3.3) and then dispersed in a sol–gel matrix for stabilization.

**Formation of Binary Ferromagnetic Quantum Dots by Controlled Segregation Effects** As mentioned in Sections 3.1.1 and 3.1.2, a segregation of ferromagnetic MnAs clusters can occur under certain conditions in the MBE and MOVPE growth of (Ga,Mn)As epitaxial layers.

An alternative approach to obtaining MnAs clusters in GaAs is Mn<sup>+</sup> ion implantation and subsequent annealing [342, 343]. The formation of MnAs has also been observed in the MBE growth of (Ga,In,Mn)As [344]. Ferromagnetic MnSb clusters have also been prepared on S-passivated (100) GaAs surfaces [345], and MnSb clusters occur in the MBE growth of (Ga,Mn)Sb [346]. Thus, this segregation of binary ferromagnetic Mn-V can be considered a general feature of all Mn-containing III-V. It is worth noting that at present this is not simply considered an undesired effect. On the contrary, there are now serious efforts to control the formation (e.g., size, position in the structure, etc.) of such ferromagnetic clusters in semiconductor structures. De Boeck et al. [347, 348] clearly demonstrated that size control and positioning of MnAs clusters within GaAs layers in annealed (Ga,Mn)As/AlAs and (Ga,Mn)As/(Ga,In)As superlattices is possible. First the whole superlattice structure is grown under growth conditions where no MnAs segregation occurs. In a subsequent annealing step, clusters with a small size distribution will be formed within the (Ga,Mn)As layer. The cluster formation is restricted to these layers, and the cluster size can be increased by choosing a higher annealing temperature. At this time, this is the only way of achieving quasi-ferromagnetic semiconductor material with Curie temperatures above room temperature.

### 3.3.3. Preparation by Liquid Solution Precipitation

A very common method of preparation of nanocrystals is based on chemical reactions and precipitation in aqueous solution or organic solvents (see, e.g., [234, 348, 350]). The dilemma of these chemical preparation methods is that, on the one hand, high synthesis temperatures (>300 °C) are required to obtain good quality material (as known from the binary QDs of CdSe, CdS, etc. [351]), whereas, on the other hand, doping with Mn works best at low temperatures. The reason for this is that, because in a QD any embedded Mn<sup>2+</sup> ion is always close to the surface (within a few lattice constants), the thermal energy at higher synthesis temperatures is in general sufficient to anneal out the Mn<sup>2+</sup> ions [352]. Thus the same thermal effect which drives out unwanted defects leads to an elimination of Mn from the QD.

**Cd<sub>1-x</sub>Mn<sub>x</sub>S** Cd<sub>1-x</sub>Mn<sub>x</sub>S quantum dots with a size distribution in the range 2–100 nm and 0 ≤ x ≤ 0.5 have been synthesized by Bandaranayake et al. [353] on the basis of a reaction in aqueous solution of Na<sub>2</sub>S with a mixture of MnCl<sub>2</sub> and CdCl<sub>2</sub>. The water used in the preparation has to be distilled, deionized, and deoxygenated. The latter can be accomplished by bubbling the solution with argon gas. The desired Cd/Mn ratio was prepared with appropriate volumes of manganese and cadmium chlorides. The pH of the solution has to be adjusted to 1.5–2.0 by the addition of HCl to avoid the formation of Mn hydroxide after the addition of Na<sub>2</sub>S. Na<sub>2</sub>S was added to reach a stoichiometry of the reaction.

The precipitate has to be dried afterward. The as-grown particles have a cubic, zincblende structure and a mean

crystallite size of about 2.5 nm. By a subsequent annealing procedure in argon gas, a phase transformation into the stable hexagonal, wurtzite structure occurs. The phase transformation temperature was found to be about 300 °C. In [353] it was reported that the mean particle size increases during the annealing process, depending on the annealing temperature. The particle size can reach about 100 nm for an annealing temperature of about 500 °C.

A different way to prepare Cd<sub>1-x</sub>Mn<sub>x</sub>S was reported by Levy et al. [354, 355]. The syntheses of the QDs were performed in reverse micelles. A coprecipitation takes place with the mixing two micellar solutions: one is sodium di(ethyl-2-hexyl) sulfosuccinate (Na-(AOT)), and the other is a mixed micellar solution of Cd(AOT)<sub>2</sub>, Mn(AOT)<sub>2</sub>, and Na(AOT)<sub>2</sub>. A selective surface reaction occurs between the derivate and the cadmium and manganese ions at the interface. The solvent can be removed simply by evaporation. This allows the extraction of the particles. The coated dots have to be washed in ethanol to remove the surfactants. The very narrow size distribution of the Cd<sub>1-x</sub>Mn<sub>x</sub>S dots can be changed somewhat from an average size of about 1.8 nm to about 3.2 nm by varying the water content. The reported manganese concentration was 0 ≤ x ≤ 0.23.

**Zn<sub>1-x</sub>Mn<sub>x</sub>S** The first preparation of Mn-doped ZnS nanocrystals by a precipitation approach was reported by Bhargava et al. [356]. The QDs with sizes varying from 3.5 to 7.5 nm were precipitated by a reaction of diethylzinc with hydrogen sulfide in toluene to form ZnS. To dope the dots of ZnS, manganese chloride was reacted with ethylmagnesium chloride to form diethylmanganese in a tetrahydrofuran solvent and added to the reaction. The separation of the dots is maintained by coating with the surfactant methacrylic acid.

Bol and Meijerink [357, 358] prepared (Zn,Mn)S by an organometallic and an inorganic synthesis method. In the organometallic procedure Zn(C<sub>2</sub>H<sub>5</sub>)<sub>2</sub> and manganese cyclohexabutyrates were dissolved in toluene, and a methacrylic acid (stabilizer) was added. After the addition of a saturated solution of H<sub>2</sub>S in toluene, a white suspension appeared instantaneously. The inorganic procedure is similar to the standard method of nanocrystalline II-VI semiconductors. The synthesis was done in aqueous solution. Zn(CH<sub>3</sub>COO)<sub>2</sub>, Mn(CH<sub>3</sub>COO)<sub>2</sub>, and Na(PO<sub>3</sub>)<sub>n</sub> (stabilizer) were used. Again after the addition of Na<sub>2</sub>S solution a white fluid is obtained. In both methods the particles can be separated from the solution by centrifuging and must be rinsed with distilled water and dried. The X-ray diffraction pattern reveals a zincblende modification of the QDs. The size distribution was analyzed by transmission electron microscopy and was found to range from 3 to 5 nm; the majority of the particles were about 4 nm.

**Zn<sub>1-x</sub>Mn<sub>x</sub>Se** Norris et al. [359] prepared Zn<sub>1-x</sub>Mn<sub>x</sub>Se QDs with low x < 1% by adapting the high-temperature, organometallic synthesis of ZnSe reported by Hines and Guyot-Sionnest [360]. Dimethylmanganese (MnMe<sub>2</sub>) was used as organometallic Mn source. It was freshly prepared in a helium glovebox by reacting 0.5 ml of a 0.2 M MnCl<sub>2</sub> slurry in anhydrous tetrahydrofuran (THF) with 0.2 ml of 3 M methylmagnesium chloride in THF. The resulting clear golden solution was then diluted in 1.8 ml of anhydrous toluene. Subsequently, 0.5 ml of this 0.04 M MnMe<sub>2</sub> solution

was added to a syringe containing 4 ml of troctylphosphine (TOP), 1 ml of 1 M Se in TOP, and 82  $\mu\text{l}$  of diethylzinc. The syringe was removed from the glovebox and was used to inject the solution into a vigorously stirred reaction vessel with 15 ml of distilled hexadecylamine at 310°C under dry nitrogen.  $\text{Zn}_{1-x}\text{Mn}_x\text{Se}$  nanocrystals were then grown at 240–300 °C. The QDs were isolated from the growth solution by standard filtering techniques. The Mn concentration was adjusted by changing the amount of  $\text{MnMe}_2$  added to the reaction. Despite relatively high Mn:Zn ratios of the precursors, only a fraction of Mn (1–5% of the available Mn) was actually incorporated into the nanocrystals. Therefore, the reported Mn concentrations  $x_{\text{Mn}}$  are only in the range of 0.025–0.125%.

#### 4. PROPERTIES OF MAGNETIC AND DILUTED MAGNETIC SEMICONDUCTOR NANOSTRUCTURES AND ULTRAFINE PARTICLES

The presence of magnetic ions in nanostructures does not necessarily lead to completely new physics compared with nonmagnetic semiconductors. This holds in particular for diluted magnetic semiconductor nanostructures. In a zero magnetic field, the electronic and optical properties of these nanostructures can be described theoretically as being very similar to those of other semiconductor nanostructures. Quantum confinement effects and strain effects are dealt with in the same fashion as in nonmagnetic structures. For example, in  $\text{CdTe}/(\text{Cd},\text{Mn})\text{Te}$  or  $\text{ZnSe}/(\text{Zn},\text{Mn})\text{Se}$  multiple quantum wells, it is possible to treat the electronic states of the wells in the framework of the envelope function approximation by using the respective parameters (e.g., effective masses, dielectric constants, deformation potentials, etc.) of bulk  $\text{CdTe}$ ,  $\text{ZnSe}$ ,  $(\text{Cd},\text{Mn})\text{Te}$ , and  $(\text{Zn},\text{Mn})\text{Se}$ , respectively. In Section 4.1, we give an overview of these “nonmagnetic” effects due to the reduction of dimensions, as the knowledge of these effects is of fundamental importance for understanding their interplay with the modified magnetic properties. This will be discussed, in detail, for the diluted magnetic semiconductor nanostructures in Section 4.2. As there have been numerous publications over the last decade concerning two-dimensional diluted magnetic semiconductor structures such as quantum wells and superlattices, the corresponding sections about two-dimensional systems cannot be fully comprehensive. The major aim of the first two sections is to highlight the fact that today’s understanding of diluted magnetic semiconductor nanostructures is such that these structures have the potential to serve as good model systems in semiconductor technology. This offers interesting research possibilities for the future, for example, by making contributions to the development and improvement of growth and nanofabrication processes. Special heterostructures and nanostructures can be designed to address specific questions that can only be answered by using the magnetic properties of DMS. In addition, there are still many fundamental physical questions for which DMS heterostructures and nanostructures can offer novel ways of providing answers. Section 4.3 addresses semiconductor nanostructures which

exhibit spontaneous magnetization phenomena. We will discuss the effect of reduced dimensions on magnetic phase transitions as well as coupling phenomena between magnetic nanostructures.

### 4.1. Optical and Electronic Properties of Magnetic Semiconductor Nanostructures

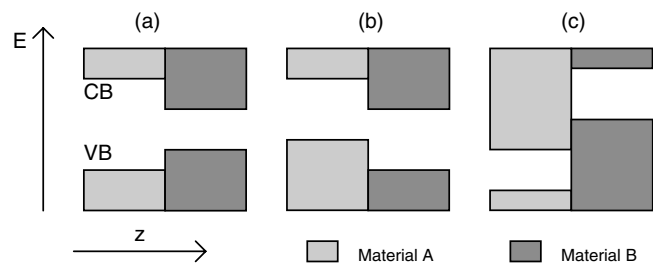

#### 4.1.1. Quantum Wells and Superlattices

Conventionally the band structure of a heterostructure is represented only by the band lineup of the conduction band minimum and the valence band maximum as a function of the spatial coordinate  $z$  in the growth direction. Three possible band lineups can be imagined between a layer of material A and a layer of material B. These are depicted in Figure 39 as the “straddling” lineup, the “staggered” lineup, and the “broken gap” lineup. A priori it is not obvious if the band lineup is an intrinsic property of two materials A and B or mainly results from the growth conditions. Several theories have been developed over the last four decades, and many experiments have been performed to answer this question (for reviews see [361, 362]). The tuning of such interface discontinuities has now become a major tool in bandgap engineering [363, 364].

The band lineups with respect to the vacuum level of some wide-bandgap II–VI compounds, including Mn–VI and Mg–VI, are depicted in Figure 40. Data for zincblende  $\text{MnTe}$  and  $\text{MnSe}$  are deduced from the calculations of Wei and Zunger [365]; the data for the other compounds are from Faschinger et al. [366]. For the wide-bandgap compounds the band lineups are either “staggered” or “straddling” lineups. In this context a characteristic parameter, the chemical valence band offset (VBO), can be defined as the difference in the absolute energy positions of the valence band maxima of the two isolated materials:

$$\Delta E_v(A/B) = E_v(B) - E_v(A) \quad (39)$$

A linear change in the chemical VBO as a function of composition following the linear composition dependence of the bandgap is observed for the chemical VBO in heterosystems where material A is a ternary alloy and material B is one of the parent binary compounds, such as  $\text{Al}_{1-x}\text{Ga}_x\text{As}/\text{GaAs}$  or  $\text{Cd}_{1-x}\text{Mn}_x\text{Te}/\text{CdTe}$  [367, 368]. It is therefore meaningful to describe alloy systems by a chemical VBO ratio defined as chemical VBO per total bandgap difference (e.g., 35% for  $\text{Al}_{1-x}\text{Ga}_x\text{As}/\text{GaAs}$  and 35% for  $\text{Cd}_{1-x}\text{Mn}_x\text{Te}/\text{CdTe}$ ). Only a

**Figure 39.** Possible band lineup between two semiconductors A and B. (a) Straddling. (b) Staggered. (c) Broken gap.

**Figure 40.** Band lineups with respect to the vacuum level for various wide-gap II-VI compounds, Mn-VI, and Mg-VI compounds.

few chemical VBO investigations have been carried out for the two systems  $\text{Zn}_{1-x}\text{Mn}_x\text{Te}/\text{ZnTe}$  and  $\text{Zn}_{1-x}\text{Mn}_x\text{Se}/\text{ZnSe}$ , which both show a nonlinear compositional dependence of the alloy bandgap. The results of Heimbrodt et al. [81] suggest that this leads to a nonlinear compositional behavior of the chemical VBO ratio. Optical experiments on electronic and excitonic states in quantum well structures offer a variety of possibilities for determining the chemical VBO. Two types of quantum well structures can be derived from the staggered or straddling band lineups. These are denoted as type I and type II, with electrons and holes spatially confined either in the same layer or in different layers. The two situations are depicted in Figure 41.

In the case of pseudomorphic growth the successive layers in the heterostructures are alternately subjected to biaxial tensile or compressive stresses, because of the different lattice parameters of the quantum well and the barrier material, respectively. Such biaxial stress fields can be considered as a sum of a hydrostatic and a uniaxial stress parallel to the growth direction. The influence of both stress fields on the bandgap energies of the individual layers of a heterostructure is well known. Strain effects contribute strongly to the net VBO.

Most II-VI and III-V DMS are grown on (100) substrates. The only relevant stress tensor elements in this case are

$$\sigma_{xx} = \sigma_{yy} = \sigma \neq 0 \quad (40)$$

$$\sigma_{zz} = 0 \quad (41)$$

**Figure 41.** Type I and type II band alignments in QW structures.

It follows for the strain that

$$\varepsilon_{xx} = \varepsilon_{yy} = \frac{C_{11}}{(C_{11} - C_{12})(C_{11} + 2C_{12})} \cdot \sigma = \varepsilon \quad (42)$$

$$\varepsilon_{zz} = \frac{-2C_{12}}{(C_{11} - C_{12})(C_{11} + 2C_{12})} \cdot \sigma \quad (43)$$

$$\varepsilon_{xy} = \varepsilon_{xz} = \varepsilon_{yz} = 0 \quad (44)$$

The corresponding shifts of the energy bands and the valence band splitting can be calculated on the basis of the Bir-Pikus theory [369],

$$\Delta E_c = 2a_c \frac{C_{11} - C_{12}}{C_{11}} \cdot \varepsilon$$

$$\Delta E_{hh} = \left[ 2a_v \frac{C_{11} - C_{12}}{C_{11}} + b \frac{C_{11} + 2C_{12}}{C_{11}} \right] \cdot \varepsilon \quad (45)$$

$$\Delta E_{lh} = \left[ 2a_v \frac{C_{11} - C_{12}}{C_{11}} - b \frac{C_{11} + 2C_{12}}{C_{11}} \right] \cdot \varepsilon$$

where  $a_c$ ,  $a_v$ , and  $b$  are the deformation potentials and  $C_{11}$ ,  $C_{12}$  are the elastic constants.

In Figure 42 the strain dependence of the band structure is shown schematically for a zincblende-type semiconductor in the case of a biaxial strain. The valence band degeneracy at the  $\Gamma$ -point, caused by the cubic symmetry, is lifted. Schematic band diagrams for  $\text{CdTe}/(\text{Cd},\text{Mn})\text{Te}$  and  $\text{ZnSe}/(\text{Zn},\text{Mn})\text{Se}$  assuming a type I band alignment are depicted in Figure 43. For the  $\text{CdTe}$  wells the heavy hole (hh) is above the light hole (lh) band because of compressive strain in the well, whereas for the  $\text{ZnSe}$  wells the lh band is above the hh, because of the tensile strain.

Most IV-VI DMS are grown on (111) substrates. In this case, it is convenient to describe the stress tensor in the coordinate system  $(x', y', z')$ , where  $x' \parallel [1-10]$ ,  $y' \parallel [11-2]$ , and  $z' \parallel [111]$ . The stress tensor element  $\sigma_{z'z'}$  along the growth direction is zero, whereas the stresses in plane  $\sigma_{x'x'}$  and  $\sigma_{y'y'}$  are nonzero and no torsion occurs. Again the stress

**Figure 42.** Band structure at the  $\Gamma$ -point for a zincblende-type semiconductor under biaxial compressive ( $\varepsilon_{xx} < 0$ ), zero ( $\varepsilon_{xx} = 0$ ), and tensile ( $\varepsilon_{xx} > 0$ ) strain.

**Figure 43.** Schematic diagrams for the  $\Gamma$ -point band structure in (a) compressively strained CdTe QWs with (Cd,Mn)Te barriers under tensile strain and (b) tensilely strained ZnSe QWs with (Zn,Mn)Se barriers under compressive strain, assuming a free-standing superlattice.

tensor is related to the strain tensor elements  $\varepsilon_{x'x'}$ ,  $\varepsilon_{y'y'}$ , and  $\varepsilon_{z'z'}$ , where  $\varepsilon_{x'x'} = \varepsilon_{y'y'} = \varepsilon$ . The in-plane strain is usually determined by x-ray diffraction. The following relationship holds [258]:

$$\varepsilon_{z'z'} = -2 \frac{C_{11} + 2C_{12} - 2C_{44}}{C_{11} + 2C_{12} + 4C_{44}} \varepsilon \quad (46)$$

where  $C_{11}$ ,  $C_{12}$ , and  $C_{44}$  are elastic constants given in the crystallographic  $(x, y, z)$  coordinate system. The strain leads to energy shifts only of the conduction band and valence band states at the L-point, which are already nondegenerate because of the spin-orbit splitting [370]. However, because of the reduction of the symmetry the valleys in the conduction and valence band at the L-point are no longer equivalent. Different energy shifts arise for the [111] and the three equivalent, oblique (i.e., [11-1], [1-11], and [-111]) valleys of constant energy [371]:

$$\begin{aligned} \Delta E_{c,v}^{[111]} &= D_d^{c,v} (2\varepsilon_{x'x'} + \varepsilon_{z'z'}) + D_u^{c,v} \varepsilon_{z'z'} \\ \Delta E_{c,v}^{\text{oblique}} &= D_d^{c,v} (2\varepsilon_{x'x'} + \varepsilon_{z'z'}) + D_u^{c,v} \left( \frac{8}{9} \varepsilon_{x'x'} + \frac{1}{9} \varepsilon_{z'z'} \right) \end{aligned} \quad (47)$$

where  $D_d^{c,v}$  and  $D_u^{c,v}$  are the deformation potentials of the conduction (c) and valence (v) band states. The corresponding strain Hamiltonians are diagonal in the basis Bloch function sets used for the  $k \cdot p$  description of the  $\Gamma$ -point of III-V and II-VI DMS (Eqs. (18–20)) and of the L-point of the IV-VI DMS (Eq. (29)), respectively.

In Figure 44 the interplay of confinement and strain effects is seen on the lowest lh and hh excitons of ZnSe/(Zn,Mn)Se quantum wells with varying well width and  $x_{\text{Mn}} = 0.25$  in the barriers of same widths. The higher energy, in spite of the bigger hole mass of the hh exciton in the  $z$  direction, is due to the overcompensation of the confinement effect by tensile strain. The stronger confinement effect of the lh exciton with decreasing well width is due to the lighter effective mass in the  $z$  direction. The envelope function approximation is the most commonly used empirical approach to describing theoretically electronic states in heterostructures, taking into account band alignment, strain, and quantum confinement. There are several other methods, either other empirical ones such as tight-binding methods and pseudo-potential methods, or “first principal” ones such as local density functional methods and self-energy calculations in the local density approximation (for a review see [372]). The band lineup in a heterostructure consisting of layers of different semiconductors with abrupt interfaces

**Figure 44.** Exciton energies of ZnSe/(Zn,Mn)Se MQWs measured by reflection spectroscopy (five wells, barrier width  $L_b = 85$  nm,  $x_{\text{Mn}} = 0.25$ ). Reprinted with permission from [81], W. Heimbrodt et al., *J. Lumin.* 60–61, 344 (1994). © 1994, Elsevier Science.

acts on the band electrons as a slowly varying potential along the growth direction  $z$  in addition to the fast varying lattice-periodic crystal potential in each layer. Assuming that the valence and conduction bands in each layer can be described by the corresponding Hamiltonians in the framework of the Kane model and that the set of basis Bloch functions used is the same for all layers allows a separation ansatz for the wavefunction. The Hamiltonian splits into a bulk-like contribution in the layer ( $xy$  plane) and a contribution along the  $z$  direction, which can be interpreted as a Hamiltonian of an electron of band effective mass in a confining potential given by the band lineup. In its solution the envelope function has to fulfil boundary conditions at the interfaces between adjacent layers, leading to energy quantization in the  $z$  direction. The two assumptions restrict the applicability of the envelope function approximation to heterostructures with a conduction band minimum and valence band maximum, respectively, at the same points of the Brillouin zone. They also imply that no mixing between bands takes place at the interface. Both of these implications are reasonably fulfilled for almost all DMS heterostructures.

The Hamiltonian in the vicinity of the conduction band minimum and the valence band maximum can be written, respectively, as sums of  $k \cdot p$  contribution, strain contribution, and magnetic field contribution, for each layer. The matrix elements  $H_{ij}^{\text{tot}}$  of the respective total Hamiltonians in the representation of the corresponding set of basis functions are [373, 374]

$$\begin{aligned} H_{\text{tot}}^{ij} &= H_k^{ij} + H_{\text{strain}}^{ij} + H_{\text{mag}}^{ij} \quad i, j \in \{1, \dots, N\} \\ &= \sum_{\alpha, \beta} \{ D_{ij}^{\alpha\beta} k_\alpha k_\beta + P_{ij}^\alpha k_\alpha + E_{ij} \} \quad \alpha, \beta \in \{x, y, z\} \end{aligned} \quad (48)$$

To account for the band lineup, the constants on the diagonal of the  $k \cdot p$  Hamiltonian representing the band energy positions for  $k = 0$  must be given with respect to the vacuum level. Magnetic field and strain are  $k$ -independent quantities, so that the coefficients  $D_{ij}^{\alpha\beta}$  and  $P_{ij}^\alpha$  originate solely from the  $k \cdot p$  contribution, whereas the  $E_{ij}$  are sums of the band energy positions at  $k = 0$  and the strain and magnetic field contributions. The crystal periodicity in the layer plane is conserved in the heterostructure, so that  $k_x$  and  $k_y$

(the in-plane components of the momentum) remain good quantum numbers, whereas  $k_z$  is no longer a good quantum number because the periodicity along the  $z$  direction is disturbed by the additional potential originating from the band lineup across the heterostructure. To account for this,  $k_z$  is replaced by  $-i\frac{\partial}{\partial z}$  in Eq. (48). The following ansatz for the wavefunction in each layer can be made:

$$\begin{aligned}\psi^A(r) &= \sum_{j=1}^N F_j^A(r) u_{j0}^A(r) \\ F_j^A(r) &= \exp(ik_x x + ik_y y) \chi_j^A(z) \quad \forall j \in \{1, \dots, N\}\end{aligned}\quad (49)$$

The  $F_j^A$  are the coefficients of the wavefunction in the representation of the basis set ( $u_j^A$ ) in layer A. Combining Eqs. (48) and (49) gives a Schrödinger-like matrix equation for the envelope functions  $\chi_j^A$  for each layer A, with  $k_x$  and  $k_y$  acting as parameters:

$$\sum_{i=1}^N H_{ji}^A \chi_i^A(z) = E \chi_j^A(z) \quad \forall j \in \{1, \dots, N\} \quad (50)$$

where the operators  $H_{ij}^A$  are quadratic forms in  $-i\frac{\partial}{\partial z}$ . This is a system of  $N$  coupled second-order linear differential equations which can be solved for any value of  $E$  for each layer. The boundary conditions at the interface between layers of different materials A and B define the eigenvalues  $E$  of the heterostructure.

Usually continuity of the total wavefunction  $\psi(r)$  and a continuity condition for its derivative based on the conservation of particle current are demanded. Assuming the sets of basis functions in layers A and B are similar,

$$u_{j0}^A(r) = u_{j0}^B(r) \quad \forall j \in \{1, \dots, N\} \quad (51)$$

which is reasonable, given that the structural and chemical similarities between the host materials and their magnetic alloys (this has been shown for III–V materials [375–377] and can be shown in a similar way for the IV–VI and II–VI materials) allow the continuity conditions to be transferred to the envelope functions. The following  $2N$  conditions are obtained at the interface [374]:

$$\begin{aligned}\chi_j^A(z=0^-) &= \chi_j^B(z=0^+) \\ &\times \sum_{l=1}^N \left[ (D_{jl}^{zx} + D_{jl}^{xz}) k_y - 2i D_{jl}^{zz} \frac{\partial}{\partial z} \right]^A \chi_l^A(z=0^-) \\ &= \sum_{l=1}^N \left[ (D_{jl}^{zx} + D_{jl}^{xz}) k_y - 2i D_{jl}^{zz} \frac{\partial}{\partial z} \right]^B \\ &\times \chi_l^B(z=0^+) \quad \forall j \in \{1, \dots, N\}\end{aligned}\quad (52)$$

The second boundary condition for the derivative reduces in the  $N = 1$  case, assuming that  $D^{\alpha\beta}$  is diagonal in  $\alpha$  and  $\beta$ , to

$$\frac{1}{m_A^*} \frac{\partial}{\partial z} \chi^A(z=0^-) = \frac{1}{m_B^*} \frac{\partial}{\partial z} \chi^B(z=0^+) \quad (53)$$

as derived by other authors [378–380].

Solving Eq. (51) for all of the layers of the heterostructure and matching the envelope functions at each interface

according to Eq. (52) allows one to calculate the energy quantization in the  $z$  direction. Calculating for different parameters  $k_x$  and  $k_y$  gives the energy dispersions within these subbands.

This treatment of the heterostructure assumes ideal interfaces with no changes in the lattice periodicity of the basis functions and no additional potentials in the interface monolayer. It is shown in several papers that interface effects modify the boundary conditions given in Eq. (52). Zhu and Kroemer [381, 382] and Ando et al. [383, 384] have investigated the effects of discontinuity potentials at the interface monolayer. Trzeciakowski has investigated the effects of different symmetries of the basis functions and different lattice periodicity in the adjacent layers [385, 386]. All of these investigations show as well that the modifications of the boundary conditions are negligible in the case of a type I quantum well structure with bands of similar symmetry in the quantum well and the barrier, and structurally similar well and barrier materials.

The resulting set of  $N$  linear second-order differential equations is usually solved by a transfer matrix approach. In most cases the electronic states of the II–VI and III–V DMS can be calculated by a simple one-dimensional transfer matrix method [387–389]. This also holds in magnetic fields (as discussed in Section 4.2) as long as the quantization directions due to magnetic field, strain, and confinement are the same. If this is not the case (for example, magnetic field experiments in Voigt geometry) the Hamiltonian in the valence band has nonzero off-diagonal elements due to the magnetic field coupling of light and heavy holes, and a higher-dimensional transfer matrix method needs to be applied [390–394] (see also Section 4.2.3). Also for the IV–VI DMS, a higher-dimensional transfer matrix method is needed [395].

Another important aspect which needs to be considered in a theoretical treatment of semiconductor structures is excitonic effects. In several optical experiments an electron is excited from a state in the fully occupied valence band into a state in the unoccupied conduction band, leaving an unoccupied state in the valence band behind. This state, commonly denoted as a hole, can be treated as a positively charged particle of the valence band effective mass. The Coulomb interaction binds electron and hole together into an electron–hole pair called an exciton [396]. In the effective mass approximation the exciton energy levels can be described by a hydrogenic energy level scheme given for 3D and 2D excitons by [397]

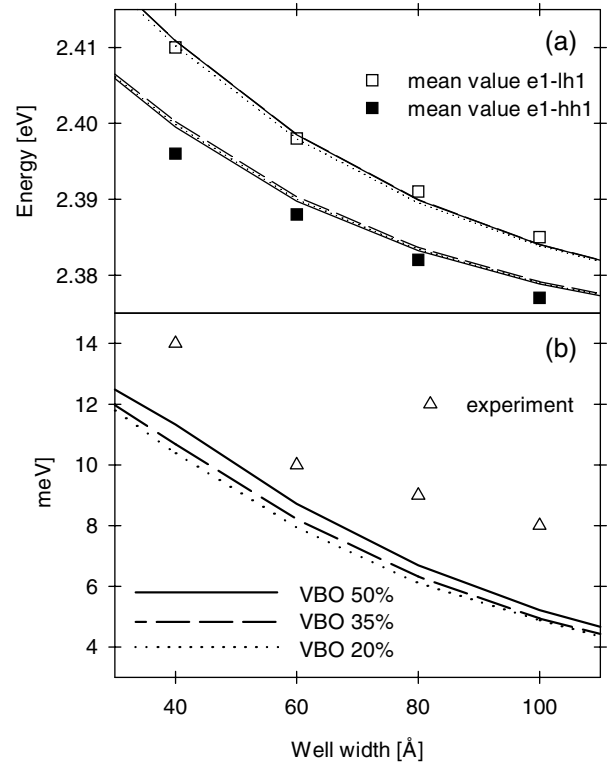

$$E_{3D} = E_g - \frac{\mu}{m_0} \frac{1}{\varepsilon^2} R_y \frac{1}{n^2}, \quad E_{2D} = E_g - \frac{\mu}{m_0} \frac{1}{\varepsilon^2} R_y \frac{1}{(n-1/2)^2} \quad (54)$$

where  $R_y = 13.6$  eV is the Rydberg constant,  $\mu$  is the reduced mass of the electron–hole pair, and  $\varepsilon$  is the dielectric constant of the semiconductor material. Typical parameters are  $\varepsilon \approx 10$  and  $\mu \approx 0.1m_0$ , giving 3D exciton binding energies on the order of 10 meV. The Bohr radii, defined by analogy with the hydrogen atom, are on the order of 100 Å, which justifies the use of a macroscopic dielectric constant. The dimensionality of the system has a major impact on the magnitude of the exciton binding energy. The 2D binding

energy in the lowest excitonic state  $n = 1(1s)$  representing a QW of zero width and with infinitely high barriers is already four times larger than the respective binding energy in the 3D case. QWs in semiconductor heterostructures have finite widths and finite barrier heights. Models used to calculate  $1s$  exciton binding energies in heterostructures have to account for the dimensionality aspect and should, therefore, give binding energies somewhere between the 3D and 2D limits.

Various approaches to calculation of the exciton binding energies have been reported in the literature. As examples, we want to discuss three approaches. One is a simple analytical approach applicable to calculation of the exciton binding energy between the lowest electron and the lowest hole state in type I quantum structures. This approach accounts for the dimensionality effect by introducing a fractional dimension  $\alpha$  with values between 2 and 3 [398–400]. The other two methods are variational approaches solving the Schrödinger equation for an electron and a hole in the conduction band and valence band lineup plus a Coulomb interaction term. In one of the methods the Coulomb interaction is treated as a perturbation, assuming that the confining potentials in the conduction and the valence band are bigger than the exciton binding energy [401, 402]. The second variational method is applicable in the case where the confinement potential in the conduction band is bigger than the exciton binding energy but the confinement energy in the valence band can be of the same magnitude or even smaller than the exciton binding energy [403]. This method has to be used in the calculation of excitonic transitions in the vicinity of a magnetic field-induced type I–type II transition. Many more sophisticated calculations of excitonic energies have been carried out in recent years, taking into account refinements such as valence band mixing [404], Coulomb coupling with continuum states, nonparabolicity of the conduction band, and the effective mass and dielectric constant mismatch [405] for systems where better knowledge of the material parameters is available (e.g., the  $\text{Ga}_{1-x}\text{Al}_x\text{As}/\text{GaAs}$  system).

A full knowledge of the band structure of DMS heterostructures in a zero magnetic field is essential for studying the magneto-optical properties of these systems. Because of the strong influence of strain and band alignment on the band states, these parameters also influence the interplay of the band states with the subsystem of the localized magnetic ions (e.g., the giant Zeeman splitting, etc.). In general, strain state and band alignment of semiconductor heterostructures can be determined by careful experimental studies of the optical transitions in these structures and then comparing the experimental values with model calculations, as described above. For example, the splitting between the lowest hh exciton and the lowest lh exciton as a function of QW width is very sensitive to the VBO in many structures. This has also been used to determine the VBO for several DMS systems such as  $\text{CdTe}/(\text{Cd},\text{Mn})\text{Te}$  [368]. In other systems, where the strain splitting is comparable to the band gap difference, such as  $\text{ZnTe}/\text{Zn}_{1-x}\text{Mn}_x\text{Te}$  [398] with  $x < 10\%$  or  $\text{ZnSe}/\text{Zn}_{1-x}\text{Mn}_x\text{Se}$  with  $x \approx 20\%$  [406], this measurement is not a good probe of the VBO. This is shown in Figure 45 for  $\text{ZnTe}/\text{Zn}_{0.93}\text{Mn}_{0.07}\text{Te}$  QWs. The lh-hh splitting  $\Delta$  as a function of well width is not a sensitive probe of the

**Figure 45.** Splitting between hh exciton and lh exciton as a function of well width for  $\text{ZnTe}/\text{Zn}_{0.93}\text{Mn}_{0.07}\text{Te}$  QWs. See text for details. Experimental points are from [398], with permission from Institute of Physics Publishing.

VBO. In the case of DMS heterostructures, it is also possible to determine the VBO by approaches which are based on the unusual magneto-optical properties of DMS, and, thus, to explore the strong dependence of the giant Zeeman splitting on overlap of the band states with the localized magnetic ions. These approaches comprise studies of the magnetic-field-induced type I–type II transition [407–410], spin-flip Raman scattering studies of the electrons confined in the QWs [406, 411], as well as studies of the giant Zeeman splittings between  $\sigma^+$  and  $\sigma^-$  QW excitons [406], or even specially designed structures [412]. However, these DMS-specific approaches also yield some difficulties; in particular, one needs to account for the modified magnetic properties of the magnetic ions in heterostructures compared with bulk material. Some of these aspects are discussed in more detail in Section 4.2. Most of the work dealing with the band alignment of II–VI DMS heterostructures has been carried out on  $(\text{Cd},\text{Mn})\text{Te}/\text{CdTe}$ . A nearly complete list of references concerning the VBO of this system can be found in [412]. In the case of IV–VI DMS a combination of zero-field and magnetic field experiments is usually required to determine the band alignment accurately, as the band structure is more complex in this class of DMS than in the case of the II–VI DMS [256, 413, 418]. Table 7 gives an overview of the band alignments of various heterostructures containing DMS. In particular for IV–VI structures, strong temperature dependences of the VBO were reported for some material systems (e.g., Heinrich et al. observed a type I–type II transition for  $\text{PbSe}/(\text{Pb},\text{Eu})\text{Se}$  with decreasing temperature [428]).

**Table 7.** VBO for various DMS quantum well structures.

Semiconductor A	Semiconductor B	$x$ (%)	$y$ (%)	$z$ (%)	$T$ (K)	VBO ratio (%)	Type [Ref.]
PbTe	$\text{Pb}_{1-x}\text{Mn}_x\text{Te}$	$\leq 3$			2	0	I [413]
PbTe	$\text{Pb}_{1-x}\text{Eu}_x\text{Te}$	5			300	50	I [414]
		$\approx 3$			5, 77	$45 \pm 20$	I [415]
PbTe	$\text{Pb}_{1-x}\text{Eu}_x\text{Te}_{1-y}\text{Se}_y$	$\leq 3$			2–5	$50 \pm 30$	I [416]

#### 4.1.2. Quantum Wires and Quantum Dots

There are not many papers about optical and electronic properties of diluted magnetic QWRs, but there are numerous papers about QDs made of magnetic and diluted magnetic semiconductors. Therefore, we will discuss results on both types of nanostructures together if possible.

**Enhanced Bowing of the Band Gap with Mn Concentration** The bandgap variation with increasing Mn concentration was measured for (Cd,Mn)S and (Cd,Mn)Se QWRs by Brieler et al. [305] and Chen et al. [306]. Figure 46 shows a comparison of the energy positions of the band gaps of bulk  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$  and  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$  wires. Because of the quantum confinement of the excitons in the wires

**Figure 46.** Bandgap variation for  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$  QWRs as a function of  $x$ . Inset: Bandgap variation as a function of  $x_{\text{Mn}}$  of  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$  QDs of two different sizes.

an increase in the direct bandgap of about 200 meV was observed for (Cd,Mn)S. Similar results were found for  $\text{Cd}_{1-x}\text{Mn}_x\text{Se}$  bulk and wires. The quantum confinement effect in this system is about 350 meV. The larger blue shift for (Cd,Mn)Se is due to the larger exciton Bohr radius. An interesting result is that both wire systems exhibit a larger bowing of the bandgap depending on the manganese concentration than do the corresponding bulk samples. This agrees with results reported for (Cd,Mn)S QDs [355] by Levy et al., who were able to show that the exchange interaction-induced bandgap bowing becomes stronger with decreasing dot diameter (see schematic inset of Fig. 46). As already discussed in Section 2.2, such a bowing is known for bulk (II,Mn)VI. In bulk, as a rule of thumb, the bowing is stronger when the bandgap is wider (i.e., bulk (Cd,Mn)S shows a band gap bowing, but (Cd,Mn)Se bulk does not).

The present interpretation of this effect, based on the discussion in Section 2.2, is twofold: (i) a change in the exchange integrals and in the  $p$ - $d$  hybridization may cause this enhanced bowing or (ii) the  $s$ -level repulsion model may explain the effect. It should be mentioned at this point that the magneto-optical measurements, which are discussed in Section 4.2.2, will give further indications that an enhancement of the  $p$ - $d$  exchange integrals takes place. Albe et al. [429] determined the effects of the inclusion of manganese in small ZnS dots in the framework of a tight-binding model with renormalized parameters. The main result was that Mn doping enhances the energy gap in addition to the confinement. However, in the calculation hardly any shift of the valence band compared with undoped ZnS is observed, and the main shift occurs in the conduction band. The effect is stronger when the dots are smaller. This result somewhat contradicts the above interpretation. However, only a single

Mn impurity in the center of the ZnS cluster was assumed in the calculation (corresponding to  $x \approx 0.5\%$  for a spherical cluster with a 3-nm diameter), and no explicit concentration dependence was calculated. We address the possible effects of reduced dimensions on the  $p$ - $d$  hybridization again in Section 4.2 in the context of the magneto-optical properties.

### Energy Transfer from the Band States into the Mn Subsystem

In 1994 Bhargava et al. [356] reported that Mn-doped ZnS nanocrystals can yield both high luminescent efficiencies and lifetime shortening of the  $\text{Mn}^{2+}$  transitions. They studied Mn-doped ZnS nanocrystals with sizes varying from 3.5 to 7 nm. The measured external quantum efficiency was about 18% and increased with decreasing particle size. The luminescence decay was at least five orders of magnitude faster than the corresponding  $\text{Mn}^{2+}$  transitions in bulk crystals. The explanation given by Bhargava et al. was twofold: first, there was an enhanced energy transfer to the Mn states, because of the strong localization of the free carriers in the dots, and second, there was a faster decay of the Mn transition because of an enhanced  $s$ ,  $p$ - $d$  mixing. In a theoretical paper, Yan et al. [430] presented a possible mechanism to explain the results of Bhargava et al. Yan et al. considered the exchange Coulomb interaction between the  $d$  electrons of the manganese and the electrons of the host lattice of the dot. The authors could demonstrate, assuming that the spin of the ground state of the dot is not zero and that the exchange interaction causes a mixing between the excited  ${}^4T_1(3d)$  state of the manganese ions and a certain excited state of the dot, that the spin forbidden transition could almost be allowed. Furthermore, it was shown that the degree of mixing increases with decreasing particle size. A completely different explanation was given by Bol and Meijerink [358]. They showed that the normal decay time of the  $\text{Mn}^{2+}$  internal transition is not really changed and is still about 2 ms, as known from the bulk material, but a fast component is observable, which has to be attributed to processes of transfer into defect related bands, which differ for various preparation methods. Tanaka et al. [431] studied the energy levels of the  $3d^5$  multiplet in  $\text{ZnS}:\text{Mn}^{2+}$  and concluded that the degree of mixing of the  $s$  and  $p$  states with the  $3d$  orbitals does not change significantly in the dots with a reduction of the diameter down to a few nanometers.

There are other reports of the introduction of  $\text{Mn}^{2+}$  ions into samples with self-activated growth of dots (e.g., by the Stranski-Krastanov method). It is assumed that the influence of different surface states of such dots is reduced compared with dots in glassy or liquid matrices or even as powder samples. It was reported that by introducing only a small amount of Mn either into the QDs [432, 433] or into the matrix with undoped QDs [433, 434], the excitonic luminescence is drastically reduced compared with that of undoped samples. In particular, by the application of an external magnetic field, the excitonic luminescence can be strongly enhanced. The reason for this is a very effective energy transfer from the excitonic states into the  $3d$  shell. This effect is also observable in bulk samples if the bandgap is wide enough to excite and observe the internal  $\text{Mn}^{2+}(3d^5)$  states. The crucial point is the spin selection rule for the overall system of the excited band state and the  $3d$  shell.

The transfer channel can be suppressed because of the Zeeman spin splitting. This energy transfer, however, is not a special property of nanostructures made of diluted magnetic semiconductors. Therefore, it will not be further discussed here. The reader may refer to papers that are particularly devoted to this subject (e.g., [435, 436, 530]).

### Changes of Band Alignment Due to Nanofabrication

In Section 4.1.1 we discussed in detail the interplay of strain and quantum confinement effects on the electronic and excitonic band structures of 2D semiconductor heterostructures. In what follows we show that this interplay is also of importance in lower dimensional structures. In particular, we show that changes in the strain state in QWRs and QDs prepared by combinations of lithography and etching from MBE- or MOVPE-grown parent structures already occur at length scales much bigger than those where additional quantum confinement effects become relevant. This feature is again common to all semiconductor nanostructures prepared in this fashion. However, we still want to discuss this point, as this zero-field effect has a considerable impact on the magneto-optical properties of the samples. As an example, Figure 47 shows photomodulated reflectance spectra of a  $\text{ZnTe}/\text{Zn}_{0.93}\text{Mn}_{0.07}\text{Te}$  QD sample and its parent MQW structure [308]. The dot diameter is 200 nm. For these lateral dimensions no additional quantum confinement effects are expected. Nevertheless, the energy positions of the excitonic features shift dramatically, as indicated by the arrows in the figure. This effect can be fully explained by a change in the strain state of MQW region of the sample due to

**Figure 47.** Photomodulated reflectance spectra of a  $\text{ZnTe}/\text{Zn}_{0.93}\text{Mn}_{0.07}\text{Te}$  quantum disc sample and its parent MQW structure. Reprinted with permission from [308], P. J. Klar et al., *Semicond. Sci. Technol.* 11, 1863 (1996). © 1996, Institute of Physics Publishing.

the nanofabrication process. The MQW layers of the parent structure were pseudomorphically strained to the ZnTe buffer layer (giving rise to a splitting of the  $\text{Zn}_{0.93}\text{Mn}_{0.07}\text{Te}$  barrier states in the corresponding spectrum). The more or less freestanding dot pillars show a strain relaxation and are strained, to good approximation, to an intermediate value of the ZnTe and the  $\text{Zn}_{0.93}\text{Mn}_{0.07}\text{Te}$  lattice constant weighted by the overall thickness of the corresponding layers in the dot pillar. This effect leads to a reversal of the order of light hole and heavy hole states such that the lowest excitonic state in the QD sample is the  $e1lh1$  exciton, whereas the lowest state in the MQW parent sample is the  $e1hh1$  exciton. This leads to very different magneto-optical properties of the two samples, as shown by magneto-PL [437]. Strain changes have also been observed in  $\text{ZnSe}/(\text{Zn,Mn})\text{Se}$  QD pillar structures of similar lateral dimensions (see also Fig. 48) [310].

#### Improving the Sample Quality by Nanofabrication

Again this is an aspect peculiar to QWRs and QDs prepared by combinations of lithography and etching with lateral dimensions where no additional confinement effects are expected ( $100 \text{ nm} < d < 500 \text{ nm}$ ), but those lateral sizes are comparable to length scales concerned with doping and dislocations. Figure 48 depicts photoluminescence spectra of two QD samples with diameters of 200 nm and 100 nm, respectively, and the corresponding parent  $\text{ZnSe}/\text{Zn}_{0.72}\text{Mn}_{0.28}\text{Se}$  SQW structure [310].  $D^0X$  and  $X_{e1lh1}$  denote the donor-bound and the free exciton emission bands, respectively, from the QW layer in each specimen. There are several interesting changes in the PL from the ZnSe well. The shifts of the  $D^0X$  and the  $X_{e1lh1}$  lines toward lower energy in the two disc samples are due to changes in a strain relaxation in the QD pillars as discussed above. Here, we focus on two other noticeable features: (i) the

**Figure 48.** Photoluminescence spectra of two QD samples with diameters of 200 nm and 100 nm, respectively, and the corresponding parent  $\text{ZnSe}/\text{Zn}_{0.72}\text{Mn}_{0.28}\text{Se}$  SQW structure.  $D^0X$  and  $X_{e1lh1}$  denote the donor-bound and the free exciton emission bands, respectively, from the QW layer in each specimen. Reprinted with permission from [310], P. J. Klar et al., *Phys. Rev. B* 57, 7114 (1998). © 1998, American Physical Society.

sharpening of the two emission lines in the QD samples compared with the parent SQW which is also observed in the PLE excitation spectra and (ii) the decrease in intensity of the  $D^0X$  emission relative to the  $X_{e1lh1}$  emission. The former can be explained as follows. The linewidth in the original SQW is determined mainly by the inhomogeneous strain fields associated with dislocations. Assuming a typical value of  $10^7 \text{ cm}^{-2}$  for the dislocation density implies a mean separation of 3000 nm between dislocations. The strain fields of the dislocations overlap and lead to a non-uniform perturbation of the excitonic potential, resulting in an inhomogeneous broadening of the emission lines. This perturbation is obviously switched off in the QD pillars which do not contain a dislocation; thus the emission of such a QD pillar is much sharper. With decreasing dot size the relative number of dot pillars without dislocations increases. Point (ii) is related to the doping. The samples were unintentionally doped  $n$ -type. An upper limit is about  $10^{16} \text{ cm}^{-3}$ . A simple estimate shows that this corresponds on average to about two donors in the ZnSe well region per pillar of the 200-nm QD sample and to about 0.5 donors in the ZnSe well region per pillar of the 100-nm QD sample. Statistically the number of QDs without donor ions in the well increases with decreasing QD diameter. For this argument to hold, one has to assume that the cross-sectional area for exciton capture by a donor is bigger than the lateral dimension of the QD. However, this is a reasonable assumption, as discussed in [310].

Of course, other effects come into play when the dot size is decreased further in the fabrication of nanostructures by combined lithography and etching techniques. These are surface damage, interdiffusion, etc. caused by etching, which can cause the sample quality to seriously deteriorate. We discuss some of these aspects in the next section and show how the degree of interdiffusion between the well region and the DMS barrier due to IBE etching can be accessed in  $\text{CdTe}/\text{Cd}_{1-x}\text{Mn}_x\text{Te}$  QDs by magneto-optical experiments. However, in the dot size regime between 500 and 100 nm, nanofabrication allows one to improve the sample quality considerably without altering the 2D character of the samples. Such samples can prove very useful in the study of magneto-optical phenomena in DMS [311, 438].

## 4.2. Diluted Magnetic Semiconductor Nanostructures in an External Magnetic Field

As has been remarked previously, most interesting magnetic phenomena observed in diluted magnetic semiconductors are based on the  $s,p-d$  exchange interaction between the extended band states and the localized magnetic ions. As a consequence the electronic and excitonic states experience giant Zeeman splittings when a magnetic field is applied. Interesting phenomena arise in nanostructures consisting of alternating layers of magnetic and nonmagnetic semiconductors, since the band edges of the magnetic semiconductor experience large shifts and splittings, whereas the corresponding splittings in the nonmagnetic layers are negligible. The conduction and valence band offsets can be tuned simply by applying a magnetic field. It is possible, for example, to convert a type I band alignment into a type II and

vice versa [423, 439, 440]. Furthermore, the tuning is spin selective. Spin-up and spin-down electrons experience different band shifts and therefore different band offsets. This can be used to separate spins with different spin orientations into different layers. Such spin superlattices were first suggested by von Ortenberg [441] and have been realized on the basis of the ZnSe/(Zn,Mn)Se heterosystem by various authors [420, 424, 442]. Furthermore, the field dependence can be used to control the coupling between wells which are separated by a barrier of a diluted magnetic semiconductor. Tunneling processes in particular can be studied in great detail [443–445].

We emphasize that a huge number of papers have been published concerning these interesting phenomena, which cannot be reviewed here. But it is interesting to note that most of the effects are rather universal and are not properties specific to diluted magnetic semiconductor nanostructures. The diluted magnetic semiconductor nanostructures are, however, an excellent tool for the study of those phenomena in one and the same sample. In the case of nonmagnetic semiconductor nanostructures, the preparation of series of samples would be necessary to obtain a comparable amount of information. Thus, the value of such information is often restricted by the limited reproducibility of the preparation parameters in series of nanostructures.

In the following we want to focus on properties and effects which are rather unique for the magnetic nanostructures. These are the magnetic properties, with special emphasis on their dependence on the restricted geometries (e.g., reduced dimensions).

#### 4.2.1. *s,p-d Exchange Interaction: Influence of the Interface*

The giant Zeeman splitting caused by the *s,p-d* exchange interaction is reduced in quasi-two-dimensional layers of heterostructures consisting of alternating DMS and non-DMS layers. This is valid for DMS QWs between nonmagnetic barriers as well as for nonmagnetic QWs between DMS barriers because of the reduced interaction of the carrier wavefunctions with the manganese ions. A part of the probability density experiences a layer without magnetic ions in both cases. The reduction of the giant Zeeman splitting is determined by the penetration of the barriers by the wavefunctions. Let us consider, for example, the type I CdTe/(Cd,Mn)Te heterosystem, where (Cd,Mn)Te is the barrier. The CdTe QW states in the magnetic field can be calculated in the framework of the envelope function approximation simply by using the known bulk values for the splittings of the conduction band and valence band states of (Cd,Mn)Te as a function of the magnetic field to define at each field confining potentials for the different spin orientations. The splitting of the barrier potential results then in a respective field-dependent splitting of the QW excitonic states. At first sight it seems that no additional new physics needs to be introduced, as the applied magnetic field can be considered simply as a parameter. The calculation is basically a calculation of QW states for different barrier heights (see Section 4.1.1). It has been found, however, that doing so leads to poor agreement with the experimental results [442, 446, 447]. The reduced effective Mn concentration  $x_{\text{eff}} = a(x_{\text{Mn}}) \cdot x_{\text{Mn}}$  introduced in Eq. (12) is due to the cluster

formation as result of the statistical distribution of the Mn<sup>2+</sup> ions on the cation lattice, as already mentioned in Section 2.4, which yields a reduced mean molar spin density. Mn-Mn pairs on nn cation sites couple antiferromagnetically and do not contribute to the magnetization, as they do not respond to magnetic fields of moderate strengths. The ground state of three Mn<sup>2+</sup> ions on nn sites depends on whether they are an open triple or a closed triangle. Nagata et al. [133] determined the ground-state spin of an open triangle to be  $S_{\text{OT}} = 5/2$ , and the ground state of the closed triple to be  $S_{\text{CT}} = 1/2$ . At a surface or interface of a diluted magnetic semiconductor the number of clusters is drastically reduced, yielding an enhanced paramagnetism at the surface compared with the bulk value for the same concentration  $x$ . This effect is further enhanced by the fact that a real interface is never an abrupt interface. The interface roughness can be considered an extra dilution with corresponding enhanced paramagnetism.

Most theoretical work on the behavior of the Mn<sup>2+</sup> ions at the interface [446, 448] is based on the work of Behringer on the formation of single, double, and triple clusters in a lattice occupied by two different atomic species [449]. Grieshaber et al. and Ossau and Kuhn-Heinrich were able to explain qualitatively the intrinsic magnetic properties of an interface such as the increase in the scaling parameters  $a$  and the decrease in the Curie–Weiss-like parameter  $\theta$  in Eq. (13) by modifying the expressions derived in [449] for the cluster formation probabilities in bulk material for the case of an ideal interface. There are two theoretical approaches in the literature that include extrinsic interface effects. Both approaches neglect the effects of Mn clusters formed by three and more Mn<sup>2+</sup> ions. The first model of Grieshaber et al. [448] is applicable to arbitrary interface profiles. A local average Mn<sup>2+</sup> spin  $S_{\text{local}}(x_{\text{NN}}(z), B, T)$  of the Mn<sup>2+</sup> ions is assigned to each monolayer in the growth direction, where  $x_{\text{NN}}$  is the average of the actual Mn contents in the monolayer at  $z$  and the two adjacent layers. Using a known empirical dependence of the bulk average Mn<sup>2+</sup> spin  $S_{\text{bulk}}(x, B, T)$  given in Eq. (13), the following relation is assumed:

$$S_{\text{local}}(x(z), B, T) = S_{\text{bulk}}(x_{\text{NN}}(z), B, T) \frac{x(z)}{x_{\text{NN}}(z)} \quad (55)$$

With the use of this model the effects of interface roughness and diffusion [447, 451], interface profiles, and segregation [452, 453] have been investigated for asymmetric Cd<sub>1-x</sub>Mn<sub>x</sub>Te/CdTe/ Cd<sub>1-y</sub>Zn<sub>y</sub>Te QW structures. The interface yields an important contribution to the enhanced Zeeman splitting of the QW states [450, 452, 454]. Cibert et al. [447] and Gaj et al. [452] were able to show that the roughness of a CdTe/(Cd,Mn)Te interface is very different from that of a (Cd,Mn)Te/CdTe interface and can be clearly distinguished by their difference in Zeeman splitting, because of the different paramagnetic response. The QW excitons in heterostructures with DMS barriers (such as CdTe/(Cd,Mn)Te, ZnSe/(Zn,Mn)Se, etc.) are extremely sensitive to the interface, as the probability density at the interface (i.e., the first few monolayers) is high compared with the bulk of the barrier due to the exponential decay of the wavefunction. These results are summarized in the

publication by Grieshaber et al. [448]. Recently, Syed et al. added a thorough study of the dependence of the optical properties of (Zn,Mn)Se/ZnSe small-offset superlattices on the magnetic-nonmagnetic interface structure [531].

The second model by Fatah et al. [450] simulates a bulk effective Mn concentration  $x_{\text{eff}}$  numerically as the number of Mn singlets per total number of cation sites in a cube lattice consisting of  $2 \times 10^5$  atoms. Analyzing the two monolayers at the surface of the cube allows one to determine the enhanced effective Mn concentration at an ideal interface. The results have been compared with experimental results on bulk II–VI DMS materials, and good agreement was obtained, although the formation of higher clusters was neglected. The results are independent to a first approximation of the II–VI host material. The model has been extended to investigate extrinsic effects in four-monolayer-wide steplike interfaces as displayed in Figure 49. The height of the step is characterized by the roughness parameter  $\chi$  [454, 455]. The effective Mn concentrations calculated for the monolayers *a* to *f* are depicted for two values of  $\chi$  in Figure 50. In agreement with the other studies, it can be seen that interface effects are of considerable importance for Mn concentrations  $x > 10\%$  and can be ignored for lower Mn concentrations.

It has been shown by Klar et al. for the ZnSe/(Zn,Mn)Se [406] and ZnTe/(Zn,Mn)Te [407] heterosystems that a careful consideration of both effects, the interface roughness and the enhanced paramagnetism at the interface, is needed to get accurate values of the conduction and valence band offsets of paramagnetic–diamagnetic interfaces. This is illustrated in Figures 51 and 52. For a fixed depth of the zero-field potential of a particular single particle, an enhanced paramagnetism leads to an increase in the magnetic-field splitting between the two spin components of the single particle. Neglect of the enhanced paramagnetism of the interface region in the calculation of such a splitting would have to be compensated for by a decreased potential depth compared with the real potential depth. The authors performed two types of experiments: (i) spin-flip Raman scattering on donor-bound QW electrons to determine the saturation Raman shift  $S_{\text{sat}}$  (i.e., probing the Zeeman splitting in the conduction band only) and (ii) magneto-optical experiments to probe the giant Zeeman splitting  $\Delta_{\text{hh}}$  of the e1hh1 QW states (i.e., probing a combination of conduction band and valence band splitting). Neglecting the paramagnetism in the analysis of the  $S_{\text{sat}}$  data would lead to an underestimation of the chemical conduction band offset which is equivalent

**Figure 49.** Step-like interface profile as proposed by Stirner et al. [454]. The parameter  $\chi$  is a measure for the step height.  $\chi = 0$  corresponds to an ideal interface. The interface is four monolayers wide (*a*, *b*, *c*, *d*).

**Figure 50.** Calculated effective Mn concentrations as a function of bulk barrier Mn content  $x$  for the monolayers *a* to *f* depicted in Figure 49.

to an overestimation of the VBO. Because of a magnetic field splitting between the two heavy hole components in the barrier that is five times bigger than the magnetic splitting between the two electron components in the barrier,  $\Delta_{\text{hh}}$  will be dominated by the contribution from the valence band. Thus, neglect of the enhanced paramagnetism would lead to an underestimation of the VBO in the calculation of  $\Delta_{\text{hh}}$ . A combined analysis of  $\Delta_{\text{hh}}$  and  $S_{\text{sat}}$  allows the elimination of interface roughness effects in the determination of the VBO and, furthermore, should allow a determination of the interface parameter  $\chi$ . In this case the combined analysis yields a value of 20% for the VBO and an interface roughness described by  $\chi = 0.1$ .

As a second example we will show how knowledge of the interplay of band states (in this case conduction band states only, probed by spin-flip Raman scattering) and enhanced paramagnetism of the  $\text{Mn}^{2+}$  ions at interfaces and interdiffused layers can be used to access damage in DMS nanostructures due to the fabrication process. This highlights again the usefulness of DMS structures as model systems in semiconductor technology. Figure 53 depicts series of spin-flip Raman (SFR) spectra of a QD sample with a dot diameter of 100 nm and the corresponding parent CdTe/Cd<sub>0.93</sub>Mn<sub>0.07</sub>Te MQW. The QD sample was prepared by EBL followed by Ar<sup>+</sup> IBE, as described in Section 3.

**Figure 51.** Calculated dependences of the spin-flip saturation shift  $S_{\text{sat}}$  on well width and different VBOs for three different interface parameters  $\chi = 0.0$  (left),  $\chi = 0.1$  (center), and  $\chi = 0.2$  (right) together with the experimental data obtained by fitting spin-flip Raman scattering spectra. An SEM image of the QD sample is shown in Figure 54. In Figure 53 the left graph depicts the series of SFR spectra of the MQW and the right graph the SFR spectra of the 100-nm QDs. The two displayed series cover the same range of excitation energies, 1.615–1.625 eV. The spectra of the MQW show two bands, SF1 and SF2, which have previously been assigned to SFR signals of electrons bound, respectively, to donors in the QW and to donors near the well–barrier interface [411, 456]. The arrows in the figure

**Figure 53.** Spin-flip Raman scattering spectra for  $\text{Cd}_{1-x}\text{Mn}_x\text{Te}/\text{CdTe}$  QD and MQW samples ( $T = 1.5$  K,  $B = 6$  T) for excitation energies ranging approximately from 1.615 eV to 1.625 eV. The spectra are displaced vertically for clarity. The QD sample was prepared by EBL followed by  $\text{Ar}^+$  IBE (see Fig. 54).

**Figure 54.** SEM image of 100-nm  $\text{CdTe}/\text{Cd}_{1-x}\text{Mn}_x\text{Te}$  QD sample prepared by EBL followed by  $\text{Ar}^+$  IBE.

mark the positions of the signals SF1 and SF2. The SF1 signal (which is the stronger signal in the MQW) is much reduced for the 100-nm QD sample and can hardly be distinguished from SF2 by eye. This can be interpreted in terms of increased interdiffusion with Mn in the sidewalls of the QDs and a destruction or interdiffusion with Mn of the top QWs, both of which increase the number of donor positions where the bound electrons have a large overlap with  $\text{Mn}^{2+}$  ions. Thus, SF2 is enhanced and SF1 is reduced. This shows that the damage due to the  $\text{Ar}^+$  etching during the nanofabrication process is quite considerable in this sample. This becomes clear when we look again at the SEM image of this QD sample in Figure 54. The QDs have a pointed top, indicating that the Ti protection mask was already destroyed before the IBE process had ended, leading to an exposure of the original sample surface to the  $\text{Ar}^+$  ions for the remaining time of the etch process. The depth of such a damaged layer in  $\text{Cd}_{1-x}\text{Zn}_x\text{Te}/\text{CdTe}$  QD samples etched under comparable conditions has been estimated by Gourgon et al. [457] and Mariette et al. [458] to be approximately 30 nm. An interesting point to note in Figure 53 is the Raman signal at  $5.5\text{ cm}^{-1}$ , which is the PMR (i.e., a spin-flip of an  $e^-$  in the  $3d$  orbital of a  $\text{Mn}^{2+}$  ion). The PMR signal, like the spin-flip signal of the QW electrons, is strongly enhanced in resonance with the QW transitions [459], and its resonance width is an indication of the range of energies of the respective excitonic transitions. The sharp resonance of the SF1 signal in the MQW sample is associated with a sharp resonance of the PMR signal; the width of the resonance is in both cases about 4 meV. A different behavior is observed for the PMR signal in the series of spectra of the 100-nm QDs. It shows a much wider resonance from 1.615–1.622 eV. This is associated with an enhanced SF2 signal for the higher excitation energies in the spectra of the QDs compared with the MQW, where neither a SF signal nor a PMR signal is visible. The Raman shift of the SF2 signal of the QDs hardly changes in this range. This can be explained by assuming that the SF2 signal in this range originates from the QWs on top of the QDs, which are probably totally interdiffused with Mn and therefore have SF signals with a larger Raman shift and excitonic transitions with a magnetic field behavior different from that of lower QWs which are still intact.

### 4.2.2. *s,p-d* Exchange Interaction: Influence of the Dimensional Crossover

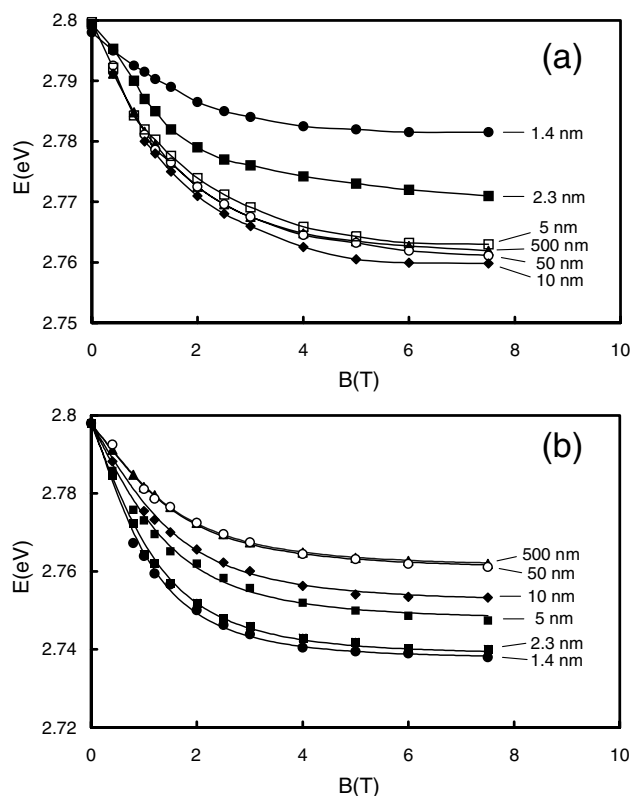

In addition to the relevance of the interface in the discussion of magneto-optical effects in DMS nanostructures, another important aspect needs to be considered: whether the *s-d* and *p-d* exchange integrals themselves show a dimensional dependence. As already shown in Section 4.1.2, the bowing of the bandgap energy increases tremendously with enhanced quantum confinement. It is known that in the series (Cd,Mn)Te–(Cd,Mn)Se–(Cd,Mn)S, as a chemical trend, the *p-d* and *d-d* exchange interactions increase. The value of the exchange integrals is determined by the anion-derived upper valence band, as discussed in detail by Larson et al. [120]. In the case of bulk material, the difference between the *d*-states and the valence band edge, however, is almost constant ( $E_v - E_{3d} \approx 3 \dots 3.5$  eV). This rather surprising result is caused by the fact that the shift of the valence band edge is compensated for by a corresponding shift of the *d*-level energy to lower energies because of the larger Mn-to-anion charge transfer. The reason for the increasing exchange integrals of the bulk series is the enhanced hybridization due to the reduced anion–cation distance. The situation is different in the case of quantum confinement, as discussed in Section 4.1.2 for nanowires and nanodots. Now the decreasing  $E_v - E_{3d}$ , apart from possible strain effects, should be the dominant reason for the enhanced bowing. Decreasing  $E_v - E_{3d}$  will lead to an increased exchange interaction integral. A direct experimental determination of the dimensional dependence would be desirable. Because of the interface effects, which have been discussed above, an unambiguous deduction of the pure exchange integrals, however, is not an easy task.

Magneto-optical studies have been performed by Heimbrodt et al. [442, 460], with special emphasis on the dimensional dependence of the *s,p-d* exchange interaction in (Zn,Mn)Se layers. A series of layers with  $x_{Mn} = 0.04$  and layer thicknesses between 500 nm and five monolayers have been studied. It is known that because of the exchange-induced bowing of the bandgap of the (Zn,Mn)Se alloys, ZnSe/Zn<sub>0.96</sub>Mn<sub>0.04</sub>Se forms a so-called spin superlattice [441]. In a zero magnetic field no band offsets between the ZnSe layers and the (Zn,Mn)Se layers occur. Applying an external field the giant Zeeman splitting of the magnetic (Zn,Mn)Se layers modifies the band structure, as depicted schematically in Figure 55. For one spin component of the conduction band and the valence band, the (Zn,Mn)Se layer

**Figure 55.** Schematic band alignment of a ZnSe/ZnMnSe superlattice with  $x_{Mn} = 0.045$ . - - - -  $B > 0$  T; ———,  $B = 0$  T.

forms a QW, and the corresponding spin bands of ZnSe act as barriers. For the other spin states the situation is reversed (i.e., the (Zn,Mn)Se is a barrier and the ZnSe acts as the QW). In that way it was ensured in [442] that the excitonic oscillator strength of the  $\sigma^+$  component of the (Zn,Mn)Se excitons was sufficient to be measured, even for samples with only a few monolayers of (Zn,Mn)Se. In Figure 56a the energy positions are given for various (Zn,Mn)Se layers, depending on the magnetic field. In many publications such curves were simply fitted by Brillouin functions, and reduced exchange integrals  $N_0\alpha$  and  $N_0\beta$  were claimed. The main reason for the strong effective decrease in the exchange integral, however, is the tremendous penetration of the excitonic wavefunction into the barriers where no  $Mn^{2+}$  ions are located and not a genuine 3D  $\rightarrow$  2D crossover effect. To take into account the different amounts of penetration of the excitonic wavefunctions, Heimbrodt et al. [442] determined the corresponding shifts of the (Zn,Mn)Se well bottom energies by eliminating the confinement effects. The genuine Zeeman shift of (Zn,Mn)Se and its dependence on the field and well widths are given in Figure 56b. It has been shown in the paper that, with decreasing layer width, a strong increase in  $a(x_{Mn})$  and a strong decrease in the Curie–Weiss parameter  $\Theta$  in Eq. (13) were necessary to fit the experimental curves with a modified Brillouin function. The experimental values are given as full squares for  $a(x_{Mn})$  and full circles for  $\Theta$  versus the well

**Figure 56.** (a) Experimental determined energies of the  $\sigma^+$  excitonic states of (Zn,Mn)Se QWs of different thicknesses ( $x_{Mn} = 0.045$ ). width in Figure 57, respectively. The full line, including the enhanced paramagnetism at the interface, was calculated. As discussed in [442], even a realistic interdiffusion profile of three or four monolayers is not sufficient to explain the strong enhancement of the experimental  $a(x_{\text{Mn}})$  with decreasing well width. In a subsequent paper the authors gave further indications that interface effects alone cannot account for the enhanced paramagnetism. Using a series of (Zn,Mn)Se/ZnSe QW samples with  $x_{\text{Mn}} = 0.12$ , one can transform the type I heterosystem into a type II system [460] by applying a magnetic field. The electrons remain in the ZnSe wells, whereas the holes will move into the (Zn,Mn)Se layers. The resulting spatially indirect excitons are an extremely sensitive probe of the interface behavior, as they are constrained to stay at the interface because of the Coulomb interaction. It has been shown that even in this case, where excitons are strongly localized near the interface, a tremendous enhancement of  $a(x_{\text{Mn}})$  with decreasing thickness of the magnetic layer is necessary to explain the observed Zeeman splitting. It could be concluded convincingly that this is not due to an increasing influence of the interface with its interdiffusion profile (which, of course, becomes more important with decreasing layer width compared with the volume effect), but rather to a change in the paramagnetic response itself. The authors concluded that an extra dimensional dependence of the paramagnetic response is very likely.

What are the possible physical reasons for a dimensional dependence of the paramagnetic response? There are basically two explanations: (i) An enhanced exchange integral  $N_0(\alpha - \beta)$  could explain the experimental findings. This would be in agreement with the enhanced bandgap bowing, discussed above. (ii) The existence of a long-range  $d-d$  exchange interaction could give rise to a smaller  $a(x_{\text{Mn}})$  than calculated by assuming nearest-neighbor interaction only. Such long-range  $d-d$  interaction would then lead vice versa to a quasi-enhanced paramagnetism in the case of a  $3\text{D} \rightarrow 2\text{D}$  transition, because a strong dimensional dependence is expected. Such a long-range effect could be the magnetic dipole-dipole interaction. A dipole-dipole interaction would also explain the fact that a spin glass transition

is observable in the diluted magnetic semiconductors, even below the percolation limit, as discussed in Section 2.3.

Let us start with some remarks about the second explanation. Some measures of the rather long-range interaction are the Curie-Weiss parameter  $\Theta_{(\text{B})}$  in the modified Brillouin function and the Curie-Weiss temperature  $\Theta$ . The high temperature susceptibility  $\chi$  shows a Curie-Weiss behavior,

$$\chi = C/(T - \Theta) \quad (56)$$

It must be considered that the Curie-Weiss parameter  $\Theta_{(\text{B})}$  and the Curie-Weiss temperature  $\Theta$  are not necessarily identical, as the former is usually determined at low fields and low temperatures. In the low-field and low-temperature case, nn pairs do not contribute to the paramagnetic response. Therefore only more distant pairs lead to a finite  $\Theta_{(\text{B})}$  in the case of diluted magnetic semiconductors. As shown by Spalek et al. [183], the Curie-Weiss temperature can be calculated in the high-temperature limit:

$$\Theta(x_{\text{Mn}}) = -\frac{2}{3}x_{\text{Mn}}S(S+1)\sum_p J_p z_p / k_B \quad (57)$$

In this expression  $J_p$  is the exchange integral for a pair of the  $p$ th neighbor shell, and  $z_p$  is the number of cations on the  $p$ th sphere around a given cation. In the case of the Curie-Weiss temperature  $\Theta$  the sum runs from  $p = 1$  to infinity, but in the case of the Curie-Weiss parameter  $\Theta_{(\text{B})}$  the sum runs in the simplest approximation from  $p = 2$  to infinity. The Curie-Weiss temperature  $\Theta$  probes the sum of all interactions, whereas the low-temperature Curie-Weiss parameter  $\Theta_{(\text{B})}$  mainly probes the long-ranged tail of the interaction. Evidence for the correctness of these statements is obtained from the steplike behavior of the magnetization as discussed in Section 2. Apart from other higher order corrections, which are necessary at low temperatures, it is evident from Eq. (57) that a  $3\text{D} \rightarrow 2\text{D}$  crossover will reduce the Curie-Weiss parameter simply by reducing the number of cations on all neighbor shells. Theory predicts that the exchange integral  $J_p$  should decrease rapidly with increasing distance of the neighbor shell, since the physical origin is the exchange interaction with an exponential decay. It has been found by various authors, however, on the basis of experimental data on thermodynamic properties like specific heat, magnetization, susceptibility, and the paramagnetic spin glass phase transition, that a phenomenological power law describes the experimental findings much better. A detailed discussion of the experimental results and interpretation has been given by de Jonge and Swagten [138]. The determined exchange interaction parameters behave like

$$J_p(R) \propto R^{-n} \quad (58)$$

where  $R$  is the distance of the  $p$ th neighbor shell. The parameter  $n$  varies in the range of  $n \approx 7.6$  for (Zn,Mn)S and 6.8 for all of the (Cd,Mn)-chalcogenides, (Zn,Mn)Se, and (Zn,Mn)Te. For the narrow gap diluted magnetic semiconductors (Hg,Mn)Te and (Hg,Mn)Se a somewhat smaller value of  $n \approx 5$  has been found. Recent magnetization experiments on (II,Mn)VI performed at 20 mK revealed magnetization steps which allowed a determination of higher

**Figure 57.** Experimental values of  $a(x_{\text{Mn}})$  and of the Curie-Weiss parameter  $\Theta(x_{\text{Mn}})$  as a function of the (Zn,Mn)Se QW width ( $x_{\text{Mn}} = 0.04$ ). The full line is calculated (see text for details). Reprinted with permission from [442], W. Heimbrodt et al., *Mat. Sci. For.* 182–184, 755 (1995). © 1995, Trans Tech Publications.

exchange constants, that is,  $J_1(=J_{nn})$ ,  $J_2(=J_{nnn})$  to  $J_4$ . It was found that the exchange constants do not decrease monotonically with increasing distance. In particular, it was always  $|J_4| > |J_2|$  [172, 173].

The important point for our discussion is that the increasing number of cations in the  $p$ th shell leads to remarkable contributions of the pair interactions in the case of bulk 3D diluted magnetic semiconductors. The strong decrease in  $\Theta$  with decreasing well width (see Fig. 57) is a clear hint that this might be the underlying effect. Those long-range interactions must then consequently have an effect on the overall value  $a(x_{Mn})$ , and a 3D  $\rightarrow$  2D transition would eventually result in an increasing parameter  $a(x_{Mn})$ , as was observed in the experiment.

Let us now come back to the first explanation. As already mentioned, it is very likely that the enhanced  $p$ - $d$  exchange integral may contribute to the enhanced paramagnetism. This has been suggested already in [460]. The quantum confinement effect shifts the  $p$ -states to lower energies, and the better energetic overlap between the  $p$ -states and the  $d$ -states leads to the increasing  $p$ - $d$  hybridization. This is in good agreement with the semiempirical tight-binding calculations of Larson et al. [120], where the valence band exchange integral has been determined to be

$$N_0\beta = -32V_{pd}^2[(E_{3d} + U_{\text{eff}} - E_v)^{-1} + (E_v - E_{3d})^{-1}] \quad (59)$$

where  $V_{pd}$  is the hybridization parameter and  $U_{\text{eff}}$  is the electron-electron interaction term of the Hubbard form. As a rather intra-atomic property of manganese,  $U_{\text{eff}}$  is not expected to change appreciably. So it is obvious from Eq. (59) that the hybridization parameter  $V_{pd}$  (mainly dependent on the Mn-anion distance) and the energy separation of the valence band edge and the  $3d$  levels  $E_v - E_{3d}$  determine the exchange integral  $N_0\beta$ . In our opinion, it is not clear currently which effect is the dominant one. It is very likely, however, that each plays a role.

It must be mentioned that there are more experimental results which seem to be in contradiction to the second effect and make the whole situation even more puzzling. In a very recent paper Yasuhira et al. [461] made a similar analysis of the photoluminescence Zeeman shift of magnetic (Cd,Mn)Te QWs between (Cd,Mg)Te barriers. They described the Zeeman shift by a reduction factor which accounts for the penetration into the nonmagnetic barriers of the electrons and holes, respectively. This description is physically equivalent to the calculation done in [442]. Nevertheless, Yasuhira et al. [461] needed a second reduction factor which accounts for the dimensionality effect. This reduction factor varies from about 0.95 for 114-nm QWs down to about 0.75 for 2.8-nm QWs. In contrast to this, the exchange integral  $J_{nn}$ , which was estimated from the magnetization steps, did not show any well width dependence. The authors ascribed this discrepancy to the fact that  $J_{nn}$  is based on a rather local interaction, and a larger range of  $k$  values may influence the exchange integral, whereas for  $N_0\beta$  a rather limited  $k$  range comes into play. This explanation is based on a theoretical calculation of Bhattacharjee [462], who studied the Zeeman splitting at reduced dimensions in the framework of an effective mass approximation for the confined states and the wave vector dependence of

the  $s,p$ - $d$  exchange interaction parameters in bulk diluted magnetic semiconductors. Bhattacharjee could show that the wave vector dependence of the  $s,p$ - $d$  exchange interaction parameters leads to a dimensionality effect. Mackh et al. [463] studied QWs of (Cd,Mn)Te/(Cd,Mn,Mg)Te with a substantial band offset but only a small discontinuity in the fractional Mn concentration across the interfaces. The assumption was that there is no discontinuity in the  $s,p$ - $d$  or  $d$ - $d$  exchange interactions. The giant Zeeman splitting of the heavy hole excitons was found, however, to be reduced with respect to the bulk by a factor which depends on the (Cd,Mn)Te well width. A minimum of about 0.9 at a well width of 4.5 nm was reported. In the aforementioned paper, Bhattacharjee calculated an effect which was much smaller than these experimental findings, but the minimum could be shown to be in qualitative agreement with the experimental data. In a recent paper Merkulov et al. [464] studied a sample similar to that used by Mackh et al. [463] by spin-flip Raman scattering and found a strong reduction of the  $s$ - $d$  exchange integral by 25%. As a responsible mechanism they suggested again the kinetic exchange term of the conduction band electrons with finite momentum. They could achieve a quantitative agreement between the experimental data and the calculations.

There are not many experimental results on samples with further reduced dimensions, (e.g., QWRs or QDs). Recently Chen et al. [298] studied the magneto-photoluminescence of mesa-shaped (Cd,Mn)Te/(Cd,Mg)Te QWRs. The Zeeman shift of the excitonic photoluminescence from the mesas in a magnetic field was significantly decreased compared with a similar QW. The wire width, however, was about 70 nm, and therefore no lateral confinement effect was observed. Because of the relaxation of the (Cd,Mn)Te well inside the wire compared with the compressive strained QW, a red shift was seen. The relaxation is accompanied by an increase of the Mn-anion distance, and, therefore, as has been mentioned, the  $p$ - $d$  exchange parameter in Eq. (59) should be reduced, which inevitably explains the reduced Zeeman shift.

Feltn et al. [465, 466] reported recently on the magnetic properties of (Cd,Mn)S nanoparticles of diameters in the range 1.8–4 nm and various concentrations in the range  $0 < x_{Mn} < 0.25$ . The authors fitted the Zeeman shifts with a modified Brillouin function and found that the effective spin  $S_{\text{eff}}$  (which is based on the nomenclature used in this review,  $S_{\text{eff}} = a(x_{Mn}) \cdot S$ ) is smaller in the nanoparticles than in bulk samples. The authors concluded that the number of spin-correlated clusters is higher in the nanocrystals, which should be due to a stronger  $Mn^{2+}$ - $Mn^{2+}$  interaction in the dots compared with bulk. The stronger interaction was directly derived from increasing ESR linewidth with decreasing cluster size, at the same Mn concentration. It was not discussed, however, how much the ESR linewidth is broadened because of the increasing fluctuation of the Mn concentration with decreasing dot sizes. Furthermore, the authors did not take into account that an increasing  $d$ - $d$  interaction, which is the basis for a stronger coupling, is based on or is, at least, correlated with an increase in the  $p$ - $d$  exchange interaction, which was assumed to be constant. On the basis of the above-mentioned semiempirical

tight-binding calculations of Larson et al. [120], the  $d$ - $d$  exchange integral has been determined to be

$$J_{dd}(R_{ij}) \propto -2V_{pd}^4 [U_{\text{eff}}^{-1}(E_v - E_{3d} - U_{\text{eff}})^{-2} - (E_v - E_{3d} - U_{\text{eff}})^{-3}] \quad (60)$$

In a comparison of Eqs. (59) and (60), the correlation between the superexchange interaction and the  $p$ - $d$  exchange integral is obvious. This would partly relax, however, the interpretation of the authors where an unchanged  $p$ - $d$  exchange integral  $N_0\beta$  was used. The Zeeman shift and splitting (see Eqs. (26) and (27)) are determined, however, by the product of  $N_0\beta$  and  $S_{\text{eff}}$ , as  $\Delta E \propto a(x_{\text{Mn}}) \cdot S \cdot x_{\text{Mn}} \cdot N_0(\alpha - \beta)$ . Thus, a different interpretation might be possible, which is based on a reduced  $s$ , $p$ - $d$  exchange interaction integral similar to the results discussed above. But even a second effect must be taken into account. All of the interpretations are based on the assumption of a random distribution of the Mn ions. A deviation of the random distribution (e.g., a higher probability to form clusters) would immediately lead to a similar reduction of the effective spin. As already mentioned, there have been several reports of the correlation of preparation parameters and the probability of an enhanced segregation or enhanced clustering. This actually opens up a Pandora's box, and an interpretation is impossible without exact knowledge of the real distribution of the magnetic ions.

Summarizing all of the present information, it is not easy to find the way out of this apparently puzzling situation. Further experimental work is needed to definitely determine whether the  $s$ - $d$  and  $p$ - $d$  exchange integrals exhibit a dimensional dependence.

### 4.2.3. Magneto-Optical Anisotropy

A particular problem one faces in semiconductor nanostructures is the change of symmetry due to the reduced dimensions. The symmetry reduction of QW layers is caused by the two-dimensional character of the layer or by the lattice mismatch induced strain. For example, for zincblende structures the symmetry is reduced from  $O_h$  for bulk (neglecting the lack of inversion symmetry) to  $D_{2d}$  for a [001] QW. As a consequence of the reduced symmetry, the zone center heavy hole and light hole valence band states split. In most II-VI and IV-VI DMS heterostructures, in contrast to most nonmagnetic heterostructures, the zero-field splitting between light and heavy holes (which is on the order of tens of meV) is comparable to the giant Zeeman splittings. As both perturbations of the band structure (induced by the reduced dimensions or strain and by the magnetic field) are of the same order of magnitude and may have different quantization directions, a competition between the two occurs. This leads to a mixing of the valence band states, and, hence, a magneto-optical anisotropy of the excitonic transition energies occurs, which has been reported by various authors [394, 467–470, 511]. It is worth noting that a magneto-optical anisotropy is also observed in hexagonal bulk DMS, in which the  $c$  axis is the symmetry axis. This was demonstrated for (Cd,Mn)Se [194], (Cd,Fe)Se [215], and (Cd,Mn)S [215]. The energies and transition probabilities for wurtzite DMS have been calculated by Gubarev [471].

In the case of two-dimensional nanostructures, made of DMS of cubic symmetry in the bulk, different Zeeman splittings can be observed for orientations of the magnetic field either parallel or perpendicular to the symmetry axis of the heterostructure. In Figure 58 a typical splitting pattern is depicted, which was obtained by reflection spectroscopy of the excitons of a (Cd,Mn)Te layer constrained to the lattice constant of CdTe. Because of the tensile strain the lh exciton is lower in energy than the hh state. It is interesting to note that the hh splitting, which is strongest in the Faraday configuration with the magnetic field parallel to the observation direction, is almost zero at very low magnetic field strengths in the Voigt configuration with the field in the plane of the sample and perpendicular to the observation direction. The splitting of the lh is enhanced, however, in the Voigt configuration compared with the Faraday configuration. Another important feature is the anticrossing behavior of the states in the Voigt configuration. From the latter fact we can conclude that a coupling of the states should explain this surprising effect.

Peyla et al. [468] explained the splitting pattern in the Voigt configuration by the anisotropy of the band structure, which causes a coupling of lh and hh states of finite momentum. A theoretical approach was given by Suisky et al. [394] and Stirner et al. [393], where the lh-hh coupling is mediated by the magnetic field itself. This effect is common for all zincblende semiconductors with reduced symmetry but is strongly enhanced in diluted magnetic semiconductors by the  $s$ , $p$ - $d$  exchange interaction. Whereas the Zeeman splitting of the conduction band is isotropic and independent of the field orientation, the valence band splitting can be calculated by the matrix

$$H_{\text{mag}}^v = \begin{pmatrix} \frac{3}{2}\delta & \gamma & 0 & 0 \\ \gamma^* & \frac{1}{2}\delta & \lambda & 0 \\ 0 & \lambda^* & -\frac{1}{2}\delta & \gamma \\ 0 & 0 & \gamma^* & -\frac{3}{2}\delta \end{pmatrix} \quad (61)$$

**Figure 58.** Magneto-optical anisotropy in a strained (Cd,Mn)Te layer observed by reflection spectroscopy ( $x_{\text{Mn}} = 0.21$ ,  $T = 2$  K). Experimental points: ●, Faraday configuration; ○, Voigt configuration.  $\sigma_{\pm}$ ,  $\sigma$ , and  $\pi$  indicate the polarization of the light with respect to the magnetic field direction. with

$$\lambda = i(G_x^v + G_y^v), \quad \gamma = i\frac{\sqrt{3}}{2}\lambda, \quad \delta = G_z^v \quad (62)$$

and

$$(G_x^v, G_y^v, G_z^v) = a \cdot x \cdot B_{5/2} \cdot \frac{\vec{B}}{|\vec{B}|} \quad (63)$$

As has been shown in [394], the formalism enables the calculation for all of the orientations of the magnetic field and is not restricted to the preferential Faraday and Voigt configurations. Using the transfer matrix method in the framework of the envelope function approximation, the authors were even able to calculate the magneto-optical anisotropy of any QW structure. Recently, Klar et al. [438, 530] demonstrated that there is a magneto-optical anisotropy not only of the transition energies, but also of the linewidth of excitonic transitions and the energy transfer from the excitonic states into the Mn-subsystem in (Zn,Cd,Mn)Se samples.

### 4.3. Spontaneous Magnetization of Magnetic Semiconductor Nanostructures

In a paper by Mermin and Wagner [472] in 1966 it was shown mathematically that in one- and two-dimensional magnetic systems of the Heisenberg type no spontaneous phase transition into a magnetically ordered ferromagnetic or antiferromagnetic state is possible. This theorem can be proved even for different models like the Hubbard model, the sf model, or the XY model. It is noteworthy, however, that the theorem is not proved for  $T = 0$  K. According to the spin-wave theory for the Heisenberg model, the number of excited spin waves at finite temperatures diverges in one- and two-dimensional systems. This implies that a phase transition from the paramagnetic state to the ordered state does not occur. The Mermin–Wagner theorem is strictly based, however, on an isotropic system. Any anisotropy may break this strong theorem, and a transition to a magnetically ordered state becomes possible.

Relativistic corrections which break the rotational invariance with respect to the spin quantization axis are the dipole–dipole interaction and the spin–orbit coupling. In a bulk crystal this will result in a shape anisotropy (entirely based on dipole–dipole interaction) and in magnetocrystalline anisotropy (based on spin–orbit coupling). As was pointed out by Néel in 1954 [473], atoms near an interface have a different environment compared with bulk atoms, and this gives additional contributions to the magnetic anisotropy, which may be especially relevant for nanostructures with large interfaces or surfaces. Another source of anisotropy is the strain of epitaxially grown layers. Unfortunately less is known about the influence of the two-dimensional strain on spin–orbit coupling as the source for magnetic anisotropy. This may differ considerably for the various systems. Two remarks are important. First, all of the anisotropy terms are orders of magnitude smaller than the exchange interaction terms, as the former arise from relativistic corrections. Second, the anisotropy terms are effective mainly in the case of ferromagnetic samples. In the case of antiferromagnetic samples, which is the majority of magnetic semiconductors, the relevance is not obvious. The shape anisotropy, for example, is negligible anyway.

In the following we survey the present knowledge of the magnetic behavior of magnetic semiconductors, which are known to be a good approximation of Heisenberg-type systems as bulk samples. We consider the magnetic properties by the reduction of geometrical extensions of the magnetic semiconductors toward two-dimensional systems (Section 4.3.1) and one- or zero-dimensional systems (Section 4.3.3). In Section 4.3.2 we focus on a subject of very recent interest, namely the interlayer coupling of magnetic semiconductors across diamagnetic semiconductors. Whereas in metallic systems, where free carriers are always present, the coupling between ferromagnetic layers across diamagnetic metals can be explained either by the RKKY model or by the quantum state model, a respective explanation for semiconductor systems is not yet given. We shall concentrate mainly on the present experimental knowledge.

#### 4.3.1. Two-Dimensional Systems

There are several crystals which have naturally two-dimensional ferromagnetic and antiferromagnetic layers (e.g.,  $K_2CuF_4$ ,  $CrBr_3$ ,  $Rb_2MnF_4$ , etc.). These are nonartificial magnetic nanostructures and thus are not a subject of this review, but why they show spontaneous magnetization is, of course, an interesting question. The answer is: A strong anisotropy is responsible for the magnetic phase transition taking place in these quasi-2D systems. The situation is not clear in the case of material systems, which are highly isotropic in the 3D case, like the zincblende magnetic semiconductors. Those systems can be well described by an isotropic Heisenberg Hamiltonian. There are some reports of the absence of a phase transition from a paramagnetic state to an ordered magnetic state or to a spin-glass state for thin layers of magnetic semiconductors [51, 53, 474–476]. In the following we want to address the paramagnetic–antiferromagnetic, the paramagnetic–spin-glass, and the paramagnetic–ferromagnetic phase transitions. Finally, carrier-induced ferromagnetism in (II,Mn)VI QWs, a somewhat related phenomenon, is discussed.

#### Paramagnetic–Antiferromagnetic Phase Transition

Let us consider antiferromagnetic MnSe as an example. Bulk MnSe is thermodynamically stable in the octahedral coordination (rock salt) and exhibits an fcc-type II antiferromagnet phase transition with a Néel temperature of about 120 K (see Section 2, Table 2). Zincblende MnSe could be prepared as thin polycrystalline films by thermal evaporation on glass or quartz substrates with substrate temperatures  $T_s < 50$  K. The Néel temperature of those unstable tetrahedrally coordinated zincblende (fcc-type III) MnSe films was found to be about 70 K [51]. However, highly crystalline material can only be obtained by a stabilized MBE growth method (described in Section 3.1.1) as layers of only a few monolayers in ZnSe/MnSe superlattices. Such ultrathin zincblende MnSe layers seem to exhibit paramagnetic behavior down to the lowest temperatures. This has been shown, for example, by Kolodziejski et al. [53, 474] by means of Zeeman measurements of such MnSe/ZnSe QW structures. The authors reported no shift of the ZnSe excitonic photoluminescence for  $d_{MnSe} > 3$  nm. This was interpreted as evidence that the MnSe layers are in the antiferromagnetic state. For ultrathin MnSe layers

with  $d_{\text{MnSe}} \leq 1$  nm, however, a peak shift based on the  $s, p-d$  exchange interaction between the ZnSe band states and the magnetic moments of the MnSe layers was found, which is clear evidence of the paramagnetic giant Zeeman effect.

From neutron diffraction studies of zinc-blende MnSe/ZnSe superlattices, Klosowski et al. [261] reported an antiferromagnetic phase transition at 70 K even for 3 monolayers only of MnSe. The reported phase transition temperature of thicker layers of MnSe was  $T_N = (107 \pm 5)$  K. The high Néel-temperature is however an indication for fractional phase transitions into the stable rocksalt structure with  $T_N = 120$  K.

Precht et al. performed a similar magneto-PLE experiment on a CdTe/(Cd,Mg)Te QW structure grown on a (001) Cd<sub>0.96</sub>Zn<sub>0.04</sub>Te substrate with a single monolayer of MnTe in the center of the CdTe layer to study the paramagnetic-antiferromagnetic phase transition of the MnTe layer [477, 532]. In the temperature dependences of the inverse Zeeman splitting as well as the linewidth of the PLE bands, the authors observed a kink and a peak, respectively, at a temperature of 50 K. This temperature value is assigned to the Néel temperature. In a later publication, the same group presented results on fractional MnTe monolayers embedded in nonmagnetic QWs. For half of a MnTe monolayer and for a quarter of a MnTe monolayer of MnTe they found critical temperatures of 34 K and 13 K, respectively [478]. In particular, in the case of the fractional layers it is not clear whether the observed effect really is an indication of a paramagnetic-antiferromagnetic phase transition or rather of a paramagnetic-spin-glass transition.

An alternative but very sensitive optical method for the study of the magnetic phase transition from the paramagnetic to the antiferromagnetic state is the detection of energy shifts of the internal Mn<sup>2+</sup> transitions below the Néel temperature. This method can only be applied for wide bandgap semiconductors, where the internal Mn<sup>2+</sup> ( $3d^5$ ) transitions are observable. Those shifts of the internal transitions below the Néel temperature have been reported earlier for bulk samples of MnS, (Cd,Mn)S [479, 480], and MnO [481]. It was reported in [51] that with this method MnSe-MBE layers of up to 3 nm did not show clear hints of a phase transition down to a temperature of 1.6 K. In Figure 59 are depicted the energy positions of the Mn<sup>2+</sup> ( $3d^5$ ) internal transitions ( ${}^6A_1 \rightarrow {}^4A_1$ ,  ${}^4E$ ,  ${}^6A_1 \rightarrow {}^4T_2$ ) in bulk MnSe, measured by photoluminescence excitation spectroscopy. The photoluminescence was detected on the yellow manganese luminescence band ( ${}^4T_1 \rightarrow {}^6A_1$ ). An almost steplike shift is seen, which occurs just below the indicated Néel temperatures of about 120 K for the MnSe<sub>oct</sub> in the rock salt structure and about 70 K for the polycrystalline MnSe<sub>tet</sub> thin film of about 5  $\mu\text{m}$  in the zincblende modification. The Néel temperatures for these bulk samples have been measured by EPR. The determination of  $T_N$  by EPR is very accurate. The method is based on the linewidth divergence of the Mn<sup>2+</sup> EPR line due to the corresponding decrease in the spin-spin relaxation time [482], which is correlated with the divergence of the correlation length.

The successive spin-ordering below the spin freezing temperature leads to an energy relaxation of the various internal Mn<sup>2+</sup> ( $3d^5$ ) states and subsequently to the shift of the

excitation bands, which is depicted in Figure 59. No such steplike behavior was found for MBE layers with thicknesses up to 4 nm. In Figure 59 the measured Mn<sup>2+</sup> ( $3d^5$ ) internal transitions ( ${}^4A_1$ ,  ${}^4E \rightarrow {}^6A_1$ ,  ${}^4T_2 \rightarrow {}^6A_1$ ) for a MnSe/ZnSe superlattice with a MnSe layer thickness of 6 nm are also shown. Again no clear evidence for a magnetic phase transition down to the lowest temperatures is seen. However, it should be mentioned that a partially structural phase transition has been observed in samples in which the MnSe layers exceed a critical thickness of about 5 nm. From absorption measurements it has been concluded that about 60% of the MnSe layer exhibits the zincblende structure, whereas about 40% changes into the stable rock salt phase. It was not clear whether a grainlike separation took place or rather complete monolayers transform. In summary, it can be stated that zincblende MnSe layers with thicknesses of  $\leq 4$  nm do not show any clear and convincing indications of a magnetic phase transition.

In the following we want to examine briefly the physical reason for the energy shift of the excitation bands below the Néel temperature. The energy relaxation of the various states can be estimated again in the framework of an isotropic Heisenberg Hamiltonian describing the  $d-p-d$  superexchange interaction in zincblende MnSe (see also Section 2.3),

$$H = - \sum_{i,j} J_{ij} S_i S_j \quad (64)$$

Including only the nearest neighbor (nn) and next nearest neighbor (nnn) interaction by  $J_{nn}$  and  $J_{nnn}$ , respectively ( $J_{nn}, J_{nnn} < 0$ ), the exchange interaction induced relaxation

**Figure 59.** Energy positions of the Mn<sup>2+</sup> ( $3d^5$ ) internal transitions in bulk MnSe and in MnSe/ZnSe superlattices as a function of temperature. For quasi-bulk-like structures a shift to higher energies below the Néel temperature is observable, which disappears for quasi-2D layers.

$E(T)$  per  $\text{Mn}^{2+}$  ion is then obtained in a mean-field approximation (MFA),

$$\begin{aligned} E(T) &= \langle H_{i=1} \rangle = - \sum_j J_{1j} \langle S_1^z \rangle \langle S_j^z \rangle \\ &= - \langle S_1^z \rangle \left[ J_{\text{nn}} \sum_{\text{nn}} \langle S_j^z \rangle + J_{\text{nnn}} \sum_{\text{nnn}} \langle S_j^z \rangle \right] \end{aligned} \quad (65)$$

As fluctuation effects are neglected in the MFA one obtains  $E(T \geq T_N) = 0$  and a complete antiferromagnetic spin ordering at  $T = 0$ , corresponding to an fcc-type II and an fcc-type III spin superlattice in the cases of RS and ZB, respectively. To apply Eq. (65) to the zincblende and rock salt MnSe of Figure 59, one has to sum over the given spin-up and spin-down states of the nearest neighbor and next nearest neighbor shells. For a  $\text{Mn}^{2+}$  ion in the ground state ( $S = 5/2$ ) this leads to

$$E_g(0) = \begin{cases} 6J_{\text{nnn}}S^2 & \text{for MnSe}_{\text{RS}} \\ (4J_{\text{nn}} - 2J_{\text{nnn}})S^2 & \text{for MnSe}_{\text{ZB}} \end{cases} \quad (S = 5/2) \quad (66a)$$

$$(66b)$$

At sufficiently low excitation densities an excited (single)  $\text{Mn}^{2+}$  ion can be assumed to be placed in an unchanged mean spin field of neighboring  $\text{Mn}^{2+}$  ions. For the spin-ordering-induced energy relaxation  $E_{\text{ex}}(0)$  of such an excited  $\text{Mn}^{2+}$  ion in one of the lowest energy (quartet) states ( $S' = 3/2$ ) one derives

$$\begin{aligned} E_{\text{ex}}(0) &= \begin{cases} 6J_{\text{nnn}}^{\text{ex}}SS' & \text{for MnSe}_{\text{RS}} \\ (4J_{\text{nn}}^{\text{ex}} - 2J_{\text{nnn}}^{\text{ex}})SS' & \text{for MnSe}_{\text{ZB}} \end{cases} \quad (S=5/2, S'=3/2) \end{aligned} \quad (67a)$$

$$(67b)$$

where  $J_{\text{nn}}^{\text{ex}}, J_{\text{nnn}}^{\text{ex}}$  denote the various exchange interaction parameters between the considered excited  $\text{Mn}^{2+}$  ion and an nn or nnn  $\text{Mn}^{2+}$  ion in the ground state. The measured total spin-ordering-induced shift of the various excitation peaks,  $\Delta E(0) = (E_{\text{ex}} - E_g)_{T=0} - (E_{\text{ex}} - E_g)_{T_N}$ , is then given by

$$\Delta E(0) = E_{\text{ex}}(0) - E_g(0) \quad (68)$$

The otherwise hardly accessible exchange parameters for the excited  $\text{Mn}^{2+}$  states can now be obtained from Eq. (68). For the  $\text{Mn}^{2+}$  ground state we use the exchange parameter of  $\text{MnSe}_{\text{RS}}$ ,  $J_{\text{nnn}}/k_B = -12.8$  K [22]. For the zincblende modification the value for the exchange integral  $J_{\text{nn}}/k_B$  varies between  $-8.1$  and  $-9.9$  K [22]. Using a mean value for  $\text{MnSe}_{\text{ZB}}$ ,  $J_{\text{nn}}/k_B \approx -9$  K, and assuming  $|J_{\text{nnn}}| \ll |J_{\text{nn}}|$  (which is a good approximation for the zincblende antiferromagnets), one can deduce from Eqs. (66) and (67) that  $J_{\text{nnn}}^{\text{ex}}/k_B = +14.8$  K for the  ${}^4T_2$  state of the octahedrally coordinated MnSe. For zincblende MnSe one obtains  $J_{\text{nn}}^{\text{ex}}/k_B = +4.3$  K for the  ${}^4T_2$  and  $J_{\text{nn}}^{\text{ex}}/k_B = +1.8$  K for the  ${}^4A_1, {}^4E$  state. It is an important result that the exchange integrals of the excited states show a significant trend toward a ferromagnetic coupling. The same tendency was already reported for MnS [479]. The excited state for the spin-flipped electron is a rather delocalized state. The remaining localized core is then rather a  $S = 4/2$  state, which now explains the tendency to show a ferromagnetic  $p$ - $d$  coupling, as already explained

in more detail in Section 2.4, and, consequently, a ferromagnetic superexchange coupling to the nearest neighbor  $\text{Mn}^{2+}$  ions in the ground state with  $S = 5/2$ . It is important to note that even in the case of an ideal two-dimensional layer a shift of the internal transition is expected. For a (001) plane of the zincblende lattice with  $|J_{\text{nnn}}| < |J_{\text{nn}}|$  the magnetic ordering is a two-dimensional cubic lattice with antiferromagnetic ordering of type I. This means that all four nn ions are aligned antiparallel, but the four nnn ions are aligned parallel. Proceeding in the same fashion as for bulk (see Eqs. (66), (67), and (68)), one obtains the following nonzero energy shift of the internal  $3d$  transitions at the paramagnetic–antiferromagnetic phase transition for the 2D case:

$$\Delta E(0) = E_{\text{ex}}(0) - E_g(0) = 4(J_{\text{nn}}^{\text{ex}} - J_{\text{nnn}}^{\text{ex}})SS' - 4(J_{\text{nn}} - J_{\text{nnn}})S^2 \quad (69)$$

The high quantum efficiency of the internal transitions permits a measurement down to the smallest sample sizes, which is a big advantage over other methods like neutron diffraction or magnetic susceptibility measurements. Finally we want to discuss the temperature dependence of the peak shift, which exhibits a typical Brillouin-like behavior. The temperature dependence of the spin-ordering-induced peak shifts can be described again in MFA. This will be shown for  $\text{MnSe}_{\text{RS}}$  as an example. In the case of fcc-type II antiferromagnetic spin-ordering it is

$$\langle S_1^z \rangle = S_1 B_{S_1} \left( \frac{12S_1 J_{\text{nnn}} \langle S_{\text{nnn}}^z \rangle}{k_B T} \right) \quad (70)$$

$B_{S_1}$  is the Brillouin function. For the central  $\text{Mn}^{2+}$  ion in the ground state ( $S_1 = 5/2$ ) it is

$$\langle S_1^z \rangle_g = - \langle S_{\text{nnn}}^z \rangle_g = S \cdot m(T) > 0 \quad (71)$$

Here  $m(T)$  is the spin-ordering parameter. According to Eq. (70)  $m(T)$  is implicitly given by the self-consistency condition

$$m(T) = B_S \left( \frac{3S}{S+1} \frac{T_N}{T} m(T) \right) \quad (72)$$

where the MFA expression for the Néel temperature  $k_B T_N = 4|J_{\text{nnn}}|S(S+1)$  is used. According to Eq. (65) it follows that

$$E_g(T) = 6J_{\text{nnn}}S^2 m^2(T) \quad (73)$$

For the central ion considered it follows for the excited (quartet) state that

$$E_{\text{ex}}(T) = 6J_{\text{nnn}}^{\text{ex}}S^2 m(T) \langle S_1^z \rangle_{\text{ex}} \quad (74)$$

with

$$\langle S_1^z \rangle_{\text{ex}} = S' B_{S'} \left( \frac{3S'}{S+1} \frac{J_{\text{nnn}}^{\text{ex}} T_N}{J_{\text{nnn}} T} m(T) \right) \quad (75)$$

The calculated curve  $\Delta E = E_{\text{ex}}(T) - E_g(T)$  is represented by the dashed line in Figure 59. It is seen that the temperature dependence can be well described by Eq. (75).

**Paramagnetic–Spin-Glass Phase Transition** For spin-glass systems based on metallic alloys, it is known that the spin-glass (sg) freezing temperature decreases with decreasing layer thickness, but the sg phase survived down to mono-layer thicknesses [483–485].

Awschalom et al. [475, 476] studied the sg transition in (111)-oriented  $\text{Cd}_{0.8}\text{Mn}_{0.2}\text{Te}$  layers of different thicknesses grown by MBE. They reported that no sg phase was observable down to the lowest temperatures for layers with thicknesses of 2 nm and smaller. This rather surprising result was drawn from ac magnetic susceptibility measurements versus temperature. A distinct kink was observable for  $d = 8.6$  nm at about 3.8 K. Even for a layer thickness of 4 nm a sg freezing temperature of about 3.8 K was found, which equals the value of an 8.6-nm sample and is almost the sg transition temperature known from the bulk  $\text{Cd}_{0.8}\text{Mn}_{0.2}\text{Te}$ . For a 2-nm sample no distinct kink, but a hysteresis effect of the ac susceptibility versus temperature was seen.

Sawicki et al. [117] carried out similar studies on (100) oriented  $\text{Cd}_{0.5}\text{Mn}_{0.5}\text{Te}/\text{CdTe}$  superlattices, where the thickness of the CdTe layer was 5.2 nm for all samples and the thickness of the  $\text{Cd}_{0.5}\text{Mn}_{0.5}\text{Te}$  layer was varied between 1.6 and 6.4 nm. The sg freezing temperature was determined very accurately with thermoremanent magnetization experiments. A sg transition was observed in all specimens. The freezing temperature seems to depend linearly on the layer thickness in the range of thicknesses studied. Thus, there are no signs of a discontinuity below a thickness of 5 nm. The following values for  $T_{\text{sg}}$  were obtained: 6, 11, 14, and 17.5 K for layer thicknesses of 1.6, 3.2, 4.8, and 6.4 nm, respectively. The value of the 6.2-nm sample was close to the corresponding bulk value.

**Paramagnetic–Ferromagnetic Phase Transition** A series of multilayer structures of ferromagnetic EuS with varying layer thicknesses and diamagnetic PbS spacer layers was grown by Stachow-Wójcik [276] by electron beam evaporation. In addition to the interesting result of an antiferromagnetic interlayer coupling, which is discussed in the next section, they investigated the dependence of the transition from the paramagnetic to the ferromagnetic phase. The Curie temperature  $T_C$  was determined from magnetization measurements versus temperature. They determined a decreasing  $T_C$  with decreasing EuS layer thickness. The measured Curie temperatures were somewhat different for different orientations and substrates. In the case of KCl substrates with (100) orientation a quasi-bulk value (200 monolayers) of  $T_C \approx 17.3$  K was determined. On (111)  $\text{BaF}_2$  substrates the quasi-bulk value was found to be  $T_C \approx 13.6$  K. The discrepancy between these quasi-bulk values and the known bulk value of EuS should be caused by strain effects in the EuS layers due to the substrate. For thin layers ( $d_{\text{EuS}} < 10$  monolayers) a systematic reduction of  $T_C$  with decreasing layer thickness was measured. Even for a thickness of just two monolayers a  $T_C = 10$  K for EuS on (100) KCl and  $T_C = 9$  K for EuS on (111)  $\text{BaF}_2$  were found. From the angle dependence of the ferromagnetic resonances a strong anisotropy effect could be deduced. The reason for the surprisingly strong anisotropy may be the strain or the shape anisotropy, which is especially important for ferromagnetic layers but only plays a minor

role for antiferromagnetic samples. Therefore, one can conclude that for ferromagnetic semiconductors (even if they are, as bulk crystals, rather Heisenberg-type ferromagnets) anisotropy effects (most likely shape anisotropy) lead to a 3D  $\rightarrow$  2D transition with decreasing but still relatively high Curie temperatures down to almost 2D layers.

In conclusion, there is no consistent picture concerning the behavior of the magnetic phase transition in case of the 3D  $\rightarrow$  2D crossover. This is not really surprising, however. Although the magnetic semiconductor systems discussed in this section are considered to be rather isotropic Heisenberg-type ferro- or antiferromagnets, the amount of anisotropy is not really known, but most likely is never really zero. In particular, the influence of two-dimensional strain on spin–orbit coupling as one of the most important sources for magnetic anisotropy is not known and may differ considerably for the various systems.

**Carrier-Induced Ferromagnetism** As already discussed in Section 2.3, it is known from IV–VI DMS materials that it is possible to overcome antiferromagnetic superexchange coupling by RKKY interaction via free carriers. Use of this effect in the case of II–VI nanostructures was motivated by a theoretical paper of Dietl et al. [486], who predicted a paramagnetic–ferromagnetic phase transition for highly  $p$ -doped (II,Mn)VI bulk ( $p \approx 10^{19}$  to  $10^{20}$   $\text{cm}^{-3}$ ) and modulation-doped heterostructures ( $p \approx 10^{11}$  to  $10^{12}$   $\text{cm}^{-2}$ ) when the RKKY exchange mechanism dominates over the Anderson superexchange. Corresponding experiments were carried out with the use of modulation-doped heterostructures consisting of an 8-nm  $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$  QW with  $x$  varying between 2 and 4% embedded between  $\text{Cd}_{0.66}\text{Mg}_{0.27}\text{Zn}_{0.07}\text{Te}$  barriers [487–490]. The barriers were  $\delta$ -doped with nitrogen. The doped region in the front barrier is located close to the QW (spacer thickness 10–20 nm). In addition, both barriers had doped layers 100 nm from the QW. The doping was such that sheet densities in the QW of  $1\text{--}3 \times 10^{11}$   $\text{cm}^{-2}$  could be obtained. The authors employed magneto-optical spectroscopy to study the phase transition and its dependence on Mn concentration and hole sheet density. The findings were as follows: (i) In the absence of an external magnetic field  $H$  and below a characteristic temperature  $T_C$ , the luminescence of the QW (excited in energy below the  $\text{Cd}_{0.66}\text{Mg}_{0.27}\text{Zn}_{0.07}\text{Te}$  barrier) exhibits a splitting into two bands and a slight red shift. In addition, the PL decay time increases significantly. These bands are assigned to the spontaneous spin-splitting of the band states due to the ferromagnetism. (ii) As  $T_C$  is approached from above, the magnetic susceptibility  $\chi(T)$  diverges at  $T_C$ .  $\chi$  can be determined at each temperature in the paramagnetic regime from the low-field limit of the giant Zeeman splitting  $\Delta E$  between the  $\sigma^+$  and  $\sigma^-$  components of the heavy-hole QW exciton, with the use of

$$\chi = \lim_{H \rightarrow 0} \frac{g\mu_B N_0}{|N_0\alpha - N_0\beta|} \left( \frac{\partial(\Delta E)}{\partial H} \right) \quad (76)$$

where  $g = 2$  is the  $g$ -factor of the  $\text{Mn}^{2+}$  ions, and  $N_0\alpha$  and  $N_0\beta$  are the  $s$ - $d$  and  $p$ - $d$  exchange integrals, respectively. (iii) The behavior described in (i) and (ii) is observed neither in an undoped sample nor in the modulation-doped samples under illumination with light in energy above the barriers. The latter strongly decreases the free hole density in the QW

by trapping photo-excited holes in the barrier and by partly neutralizing the remaining holes by photo-excited electrons from the barriers. The authors interpret these results as evidence of a paramagnetic–ferromagnetic phase transition in these modulation-doped  $p$ -(Cd,Mn)Te/(Cd,Mg,Zn)Te QWs. The dependence of the Curie temperature on the Mn concentration and sheet doping density is in agreement with the predictions of the mean-field model developed in [486]. The Curie temperatures reported are about 2 K. Further confirmation that carrier-induced ferromagnetism is possible in heavily doped wide-gap (II,Mn)VI systems was given recently by the experiments on  $p$ -type (Zn,Mn)Te (see also Section 2.3) [135–137].

### 4.3.2. Interlayer Coupling

It is a very interesting effect that an interlayer coupling of magnetic semiconductors has been observed in a variety of systems with nonmagnetic spacers [263, 491–494]. In metallic superlattices consisting of ferromagnetic and diamagnetic layers carrier-assisted mechanisms were discussed as possible explanations for the ferro- or antiferromagnetic coupling between the ferromagnetic layers, depending on the thickness of the intermediate layers. In the case of semiconducting or insulating layers the situation seems to be much more difficult, as the density of carriers is several orders of magnitude lower than in metals. Although not all results from semiconductor systems are clearly understood, the experimental facts provide strong evidence that there are specific mechanisms capable of transferring magnetic information across thick nonmagnetic layers without the assistance of mobile carriers.

Two classes of magnetic superlattices with an interlayer coupling have been studied. One is made of the antiferromagnetic layers EuTe and MnTe, and the other is made of the ferromagnetic layers EuS and (Ga,Mn)As. The appropriate research tool for detecting the correlations between the layers is neutron diffraction. This method, especially the way to distinguish the ferromagnetic and antiferromagnetic coupling of the layers, has been described in detail by Giebultowicz et al. [495]. Pronounced coupling effects have been reported for the zincblende MnTe across CdTe or ZnTe layers [263, 491, 492], but the systems behave very differently. The MnTe layers in CdTe/MnTe superlattices with a [001] growth axis are under tensile strain. It was reported by Giebultowicz et al. [496] that a transition from the commensurate type III antiferromagnetic ordering to a new phase with a helical structure was observed. The axis of the spin helix is in-plane, and the helix pitch is incommensurate with the lattice parameter. Neutron diffraction studies of samples with different CdTe spacer layers show that the pitch of the helix gradually increases with increasing spacer thickness from 2 to 14 monolayers, which can be explained only by assuming a correlation between adjacent layers. In contrast to CdTe/MnTe superlattices, the MnTe layers are under compressive strain in the ZnTe/MnTe superlattices. Lin et al. [492] performed measurements on ZnTe/MnTe samples with different spacer thicknesses. They found that the spins in adjacent MnTe layers couple in an in-phase antiferromagnetic structure with identical spin orientations in all MnTe layers. With increasing temperature the ordering

transforms into an antiphase coupling in which the alternate MnTe layers have reversed spin directions. For increasing ZnTe layer thickness, a systematic reduction in the magnetic correlation range was observed. It was shown by Stumpe et al. [263] that by Cl doping of ZnTe the correlation range could be extended from about 22.5 nm (five bilayers) for the undoped samples to about 45 nm for the Cl-doped samples at low temperatures ( $T \approx 15$  K). The individual spacer thicknesses were up to 2 nm and have been somewhat shorter than in CdTe/MnTe.

The largest spacer thicknesses with interlayer interaction have been reported for the EuTe/PbTe superlattices, where the interaction could be measured for spacers as thick as 7 nm. The samples have been grown in the [111] direction. EuTe is an antiferromagnet with an fcc type II ordering. The spins are aligned in (111) planes, and the planes are antiferromagnetically coupled to one another. An antiferromagnetic coupling between ferromagnetic layers has also been observed for (001) EuS/PbS all-semiconductor superlattices [495]. As mentioned in Section 2.4, EuS is a ferromagnet with a Curie temperature  $T_C = 16.6$  K. The maximum spacer thickness for which coupling was observed was 2 nm.

For the (Ga,Mn)As/(Al,Ga)As/(Ga,Mn)As trilayer system a magnetic interaction between the ferromagnetic (Ga,Mn)As layers has been reported for spacer thicknesses of 10 monolayers (about 3 nm) by Ohno [497]. It is interesting to note that the coupling disappeared when the Al content of the spacer was as high as 29%. Although the conclusion of Ohno concerning this result was that the RKKY interaction may play a role in the interlayer coupling of those trilayer systems, one has to state that the physical origin of the interlayer interaction is still an open question. It is quite clear that the number of free carriers in most of the presented systems is orders of magnitude too small to be the reason for a coupling.

There have been some attempts to present a theoretical approach to the problem. Rusin [498] proposed a model using “hydrogenic centers,” which might be formed by electrons bound to impurities or defects. Those centers may have Bohr radii of several nanometers. These centers may polarize  $Mn^{2+}$  ions at the interface or may couple the polarization between adjacent interfaces, which eventually may couple the layer polarizations themselves. Blinowski and Kacman [499] studied the coupling in a three-dimensional tight-binding model, accounting for the band and magnetic structure of the constituent superlattice components. They calculated the spin-dependent part of the total electronic energy and found for EuS/PbS superlattices as well as for EuTe/PbTe that the antiferromagnetic coupling is energetically favored. Only recently there were first results of calculations reported which predict the possibility to obtain an antiferromagnetic coupling of ferromagnetic layers via virtual conduction band states with self-polarization effects [500].

### 4.3.3. One- and Zero-Dimensional Systems

There has not been much work reported to date concerning the question of magnetic phase transitions in magnetic semiconductor QWRs and QDs. We discuss the present results in the next two paragraphs. In the third paragraph we briefly mention the hybrid system consisting

of a paramagnetic (Ga,Mn)As matrix and ferromagnetic Mn(Ga)As dots. A somewhat different aspect, namely the formation of magnetic polarons in QDs, is discussed in the fourth paragraph.

### Paramagnetic–Antiferromagnetic Phase Transition

Brieler et al. [305] and Chen et al. reported MnS and MnSe QWRs with diameters of  $<3$  nm in silica matrices [306]. Template-directed growth is described in Section 3.2.3. Bulk samples of zincblende MnS and MnSe are known to be antiferromagnets of the fcc type III with Néel temperatures of 100 K and 70 K, respectively (see Table 2). Even the stable rock salt modification exhibits antiferromagnetism with Néel temperatures of about 150 K. Brieler and co-workers [305] and Chen and co-workers [306] used EPR measurements to study the phase transition of QWRs. In bulk samples, the linewidth  $\Delta H$  of the EPR signal diverges at the Néel temperature when approaching it from higher temperatures, as can be seen in the top graph of Figure 60. In contrast,  $\Delta H$  of the EPR signal of the corresponding wire samples does not diverge down to the lowest achievable temperatures of about 1.6 K, as shown in the bottom graph of Figure 60. Thus, no phase transition was observed, for either MnS or MnSe wire samples. It is worth noting that

**Figure 60.** EPR linewidth as a function of temperature for MnSe and MnS bulk samples (top graph) and MnSe and MnS quantum wires (bottom graph). A suppression of the paramagnetic–antiferromagnetic phase transition in MnSe and MnS wires with diameters of about  $d = 3$  nm is seen.

both the linewidth  $\Delta H$ , as well as the Curie–Weiss parameters  $\theta$  derived from inverse plots of the EPR intensity as a function of temperature, is about one order of magnitude smaller in the wires compared with bulk. This indicates that the antiferromagnetic coupling between the  $\text{Mn}^{2+}$  spins in the samples is strongly suppressed because of the reduced dimensions of the nanowires.

**Paramagnetic–Spin-Glass Phase Transition** He et al. studied the magnetic properties of rf-sputtered  $\text{Cd}_{1-x}\text{Mn}_x$ Te with  $x = 0.5$  and  $0.6$  and with grain sizes ranging from 80 to 100 nm [501, 502]. They deduced Curie–Weiss parameters  $\theta = 11$  and  $13$  K from plots of the inverse susceptibility  $\chi(T)^{-1} \propto (T + \theta)$  for  $x = 0.5$  and  $0.6$ , respectively. The  $\theta$  values are considerably reduced compared with bulk (e.g., Oseroff et al. reported  $\theta$  values of 310 K and 350 K for bulk  $\text{Cd}_{0.47}\text{Mn}_{0.53}\text{Te}$  and  $\text{Cd}_{0.4}\text{Mn}_{0.6}\text{Te}$  [503]). Nevertheless, a paramagnetic–spin-glass transition was still observable for these relatively large clusters. It manifested itself as a cusp in the susceptibility when the samples were zero-field cooled. Surprisingly, the values  $T_{\text{sg}} = 14$  K and  $17$  K observed for the nanoclusters with  $x = 0.5$  and  $0.6$ , respectively, are approximately the same as the corresponding bulk values (see, for example, [132, 504]).

Bandaranayake et al. [353] reported SQUID measurements of (Cd,Mn)S ultrafine particles. They reported a size and field dependence of the spin-glass transition. The susceptibility was measured versus temperature for  $\text{Cd}_{0.5}\text{Mn}_{0.5}\text{S}$  particles of different size. They found a decreasing freezing temperature  $T_{\text{sg}}$  with decreasing particle size. The measured bulk value was  $T_{\text{sg}} = 18$  K, but  $T_{\text{sg}} = 15.5$  K and  $T_{\text{sg}} = 14$  K were found for mean dot diameters of  $d = 50$  nm and  $d = 16$  nm, respectively. The important observation was, however, the absence of a cusp for small particles with a mean size of  $d < 3$  nm.

Chen et al. [306] studied  $\text{Cd}_{1-x}\text{Mn}_x\text{S}$  QWR samples with  $x \leq 0.2$  and  $\text{Cd}_{1-x}\text{Mn}_x\text{Se}$  with  $x \leq 0.3$  and with lateral dimensions smaller than 3 nm by EPR and SQUID measurements. The samples showed no sign of a paramagnetic–spin-glass phase transition in the temperature range studied, that is, down to 1.8 K in the case of the (Cd,Mn)S QWRs and down to 4 K in the case of the (Cd,Mn)Se QWRs. The  $\theta$  values obtained by analyzing the SQUID and EPR data increase with increasing Mn content. Again, the  $\theta$  values are more than an order of magnitude smaller than for corresponding bulk samples. The results lead to the conclusion that the antiferromagnetic coupling between the  $\text{Mn}^{2+}$  spins in the samples is strongly suppressed because of the reduced dimensions of the nanowires.

**Ferromagnetic Mn(Ga)As dots** Hybrid ferromagnet–semiconductor structures have received considerable attention because they may provide various spin-dependent applications. An interesting subclass are ferromagnetic dots embedded in a semiconducting matrix. As already mentioned in section 3.1.2 the Mn(Ga)As dots fit almost perfectly into the (Ga,Mn)As matrix with their  $c$ -axes along the GaAs [111] direction. The Curie temperature reported for the clusters is 330 K [84, 219, 343]. From energy dispersive X-ray analysis (EDX) it is known that there is a certain amount of Ga in the MnAs dots. From

high-resolution TEM we know that all the Ga-ions which are present in our MnAs-dots are on lattice site. The reason for the higher Curie-temperature is the tensile strain inside the MnAs dots, which are not entirely lattice-matched to the (Ga,Mn)As matrix. The pressure coefficient of  $T_C$  has been found to be negative for MnAs with NiAs-structure [506]. At room temperature the  $c$ -axes of MnAs is 0.571 nm. The basal plane distance  $d = 0.2855$  nm is therefore much smaller, than the distance  $d_{\text{GaAs}} = 0.3262$  nm of the (111) planes of GaAs at room temperature. The incorporation of Mn into the GaAs matrix might even enhance this difference. Consequently it means that the tensile strain, which enhances  $T_C$ , dominates over the size effects, which alone should reduce  $T_C$ . If the size of the dots is as low as about 6 nm they show superparamagnetic behavior with a blocking temperature of about 200 K [125]. With increasing dot size the blocking temperature increases further and was about 270 K for 13 nm diameters of the MnAs nanoclusters. Hartmann et al. [507] performed ferromagnetic resonance studies of Mn(Ga)As dots with diameters varying between 50 and 100 nm in a semiconducting (Ga,Mn)As matrix. The authors observed an abrupt reduction of the ferromagnetic resonance field at about 290 K. The Curie temperature of the dots was again 330 K. The abrupt change of the resonance field might be ascribed to the blocking temperature for larger dots.

Using annealing temperatures of 750 K to cause MnAs precipitation in low temperature grown (Ga,Mn)As, hybrid material with Curie temperatures up to 360 K was obtained by Wellmann et al. [343]. These Curie temperatures are well above that of  $T_C = 318$  K of bulk MnAs. It is known, however, that  $T_C$  of MnGa precipitations in GaAs is about 400 K. Thus, the very high  $T_C$  found by Wellmann et al. [343] is most likely due to additional MnGa precipitations. For metallic particles it is established, that the Curie temperature is strongly size dependent, but decreases as the particle volume is reduced. The reduction is an obvious consequence of finite size and surface effects [505].

Other hybrid structures consisting of ferromagnetic inclusions in a semiconducting matrix are currently under study. Park et al. [508] reported about nanoscale  $\text{Mn}_{11}\text{Ge}_8$  ferromagnetic clusters in a  $\text{Mn}_x\text{Ge}_{1-x}$  dilute magnetic matrix and Theodoropoulou et al. [509] studied ferromagnetic (Ga,Mn)N platelets in GaN:Mn.

**Magnetic Polarons in Quantum Dots** The formation of magnetic polarons is basically not a special issue of nanostructures. There is, however, an interesting fact which makes the magnetic polarons in QDs of diluted magnetic semiconductors interesting and may open up new device applications. For ZnSe:Mn dots [359] and CdS:Mn dots [510] it was reported that there is a zero-field splitting which is caused by the presence of  $\text{Mn}^{2+}$  ions in the nanocrystals. The splitting is caused by the polaron effect, with the unique situation of just one polaron per dot. Unfortunately, the splitting cannot be observed on an ensemble of nanocrystals at zero field since the dot spins are randomly oriented. Nevertheless, at a modest external magnetic field this splitting can be revealed, as the dots align like micromagnets in an external field. The method of investigation is, therefore, single-dot spectroscopy as used by Maksimov et al. [512] on

(Cd,Mn)Te dots in a (Cd,Mg)Te matrix and Bacher et al. on CdSe dots in a (Zn,Mn)Se matrix [513]. They could show that the alignment of the spins inside the magnetic polaron volume leads to a strong line narrowing.

The interesting aspect concerning the DMS dots is the opportunity to align the Mn spins inside a dot by optical excitation via the polaron effect, without applying an external magnetic field. It is likely that even after the annihilation of the electron hole pair this alignment may persist, since the Mn spin relaxation time is much longer. This means that the dot carries information on a time scale much longer than the carrier lifetime and could be read out by a probe beam even after a delay. This is essentially the basic principle of a magneto-optical memory on a semiconductor basis.

## 5. CONCLUDING REMARKS AND OUTLOOK

In this review, we have addressed fundamental properties of diluted magnetic and magnetic semiconductor nanostructures. The emphasis was on the magnetic properties and phenomena specific to these structures (which do not occur in “non-magnetic” semiconductor nanostructures) rather than on applications. We intended to compile the current knowledge in the field. During this process it became obvious that the properties of two-dimensional structures are currently much better understood than those of one- and zero-dimensional structures. On the one hand, this is due to the high quality of state-of-the-art layered structures obtained by MOVPE and MBE, which can be grown with monolayer precision. So far, there is no fabrication technique for QWRs and QDs which may yield samples of comparable quality. On the other hand, it has to be noted that geometric and statistical aspects become more and more important with decreasing dimensionality of the magnetic semiconductor nanostructures. For example, in QDs the surface-to-volume ratio increases dramatically with decreasing diameter. This will strongly modify the magnetic properties compared with bulk. Moreover, the number of magnetic ions in DMS QDs as well as their location with respect to the surface will vary strongly, even in dots consisting of the same number of atoms due to ion statistics. Therefore, most of the studies of ensembles of diluted magnetic QDs are rather unsatisfactory because the “real” physics of the low dimensions is hidden by statistics. To overcome this problem studies of single nanostructures will become increasingly important. The first studies of this kind have been reported [312, 512–519]. In addition, it will be necessary to characterize the single nanostructure under study on the atomic level. For the extraction of the physics of the low dimensions, it will be essential to know the lattice sites of each magnetic ion, which, of course, poses severe experimental challenges. The difficulties in studying these one-dimensional and zero-dimensional magnetic semiconductor nanostructures experimentally also explains the small amount of theoretical work published, particularly that concerning the modification of magnetic properties by reduction of the dimensions. Therefore, there is currently no full consistent picture of the properties of magnetic semiconductor nanostructures and their modification with reduced dimensionality.

Our review presents a snapshot of the knowledge at the beginning of a new millennium—a new millennium not only in the calendrical sense, but also from the viewpoint of application. The current drive toward “spin electronics” (i.e., of introducing the quantum mechanical entity spin into semiconductor electronics and optoelectronics) has strongly enhanced the interest in magnetic semiconductor structures which may act as key components, such as spin filters and spin aligners of future spin electronic devices [515–517]. Apart from aspects of manipulation of single spins (such as optical spin polarization, spin transport, and spin conversion into a photon) in semiconductors in general, the aspect of miniaturization of magnetic semiconductors (mainly for magnetic spin polarization) in particular will be of major importance. The dimensional dependence of the magnetism of magnetic semiconductor nanostructures, magnetic coupling phenomena between magnetic and nonmagnetic semiconductor nanostructures, etc., which are all aspects addressed in this review, will need to be further understood and developed. A further understanding of these phenomena will immediately yield new device ideas as fundamental physics and application go hand in hand. It is beyond the scope of this chapter to determine whether spin electronics and spin optoelectronics based on magnetic semiconductors are feasible in the near future. The ideas for devices containing magnetic semiconductors are manifold, ranging from electrical devices such as the spin transistor suggested by Datta and Das [518], active opto-electronic devices such as polarization-switchable lasers [519–522], and passive opto-electronic devices such as Faraday rotators and optical isolators [523, 524], to spin quantum computers [515]. It is very likely that an all-semiconductor spin electronics at low temperatures can be realized in the very near future [520, 521, 525, 526]. However, a major breakthrough of all-semiconductor spin electronics will depend strongly on whether ferromagnetic semiconductor nanostructures with Curie temperatures sufficiently above room temperature can be realized.

## GLOSSARY

**Anderson superexchange** Exchange interaction between magnetic ions on adjacent cation sites mediated via the  $p$ -orbital of the anion between them in diluted magnetic semiconductors such as (II,Mn)VI and magnetic oxides such as MnO. The Anderson superexchange leads to an antiferromagnetic coupling of the Mn-spins.

**Diluted magnetic semiconductor** Class of semiconductors where a fraction  $x$  of the cations is replaced by magnetic ions such as rare earths or transition metals. Large subgroups are the  $\text{II}_{1-x}\text{Mn}_x\text{VI}$ ,  $\text{III}_{1-x}\text{Mn}_x\text{V}$  and  $\text{IV}_{1-x}\text{Mn}_x\text{VI}$  alloys.

**Energy transfer** Between the semiconductor band states and the localized  $d$ - or  $f$ -shells of the incorporated magnetic ions. These energy transfer processes in wide-gap diluted magnetic semiconductors such as ZnS:Mn can lead to a quenching of the bandgap-related emission in favor of  $d$ - or  $f$ -shell internal emission.

**Europium chalcogenides** Binary compounds AB formed by Eu and group VI elements, i.e. ferromagnetic EuO, EuS, EuSe, and antiferromagnetic EuTe.

**Giant Zeeman effect** Strong enhancement of the Zeeman splitting of the conduction band states ( $s = 1/2$ ,  $s_z = \pm 1/2$ ) and of the valence band states ( $j = 3/2$ ,  $j_z = \pm 3/2, \pm 1/2$ ) in diluted magnetic semiconductors due to the  $s,p-d$  exchange interaction with the localized magnetic moments of the magnetic ions.

**Internal transitions** Transitions between excited states and the lowest state of an inner  $d$ - or  $f$ -shell of a transition-metal or rare-earth ion incorporated in a wide-gap diluted magnetic semiconductor such as ZnS:Mn or ZnS:Eu or a magnetic semiconductor such as MnS. The transition energies depend strongly on the crystal at the site of the magnetic ion. The energies are usually described in the framework of Tanabe-Sugano diagrams.

**Magnetic interlayer coupling** Coupling between magnetic layers separated by a layer of nonmagnetic (diamagnetic) material often leading to a ferromagnetic or antiferromagnetic coupling.

**Magnetic polarons** A local stable state formed by Mn-ions and a free carrier or exciton via the  $s,p-d$  exchange interaction. The free carrier or exciton locally aligns the spins of the magnetic ions leading to a reduction of its energy and to a self localization.

**Magnetic semiconductor hybrid structure** Layered or granular structures consisting of a semiconductor and a ferromagnetic material (often a metal or semimetal). Examples are GaAs/MnAs hybrids or Ge/Mn<sub>11</sub>Ge<sub>8</sub> hybrids.

**Magnetic semiconductor nanostructure** Nanostructured dilute magnetic or magnetic semiconductor exhibiting modified electronic, vibronic or magnetic properties due to reduced lateral dimensions.

**Magnetic semiconductor** Term often used for semiconductors exhibiting spontaneous magnetization i.e. antiferromagnetism or ferromagnetism such as ferromagnetic (III,Mn)V or the manganese chalcogenides and europium chalcogenides.

**Magneto-electronic** Metal-based electronics making use of the magnetic properties of layered magnetic structures such as the giant magnetoresistance (GMR) effect or the tunneling magnetoresistance (TMR) effect.

**Magneto-optical anisotropy** Anisotropy of the Giant Zeeman splitting arising due to a competition of the quantization direction of the electronic states due to crystal structure (or strain) and the quantization direction induced by the magnetic field.

**Manganese chalcogenides** Antiferromagnetic binary compounds AB formed by Mn and group VI elements, i.e. antiferromagnetic MnO, MnS, MnSe, MnTe.

**Manganese pnictides** Binary compounds AB formed by Mn and group V elements, i.e., antiferromagnetic MnN and ferromagnetic MnP, MnAs, MnSb, MnBi.

**Mermin–Wagner theorem** Mathematical theorem stating that in one- and two-dimensional magnetic systems of the Heisenberg-type (i.e. isotropic magnetic interactions) no spontaneous phase transition into a magnetically ordered ferromagnetic or antiferromagnetic state is possible.

**Modified Brillouin function** The Brillouin function describing the magnetic field response of an ensemble of non-interacting localised spins is modified to account for a weak

antiferromagnetic coupling between the spins in paramagnetic  $\text{II}_{1-x}\text{Mn}_x\text{VI}$  diluted magnetic semiconductors. This is done by introducing two parameters, a prefactor  $a$  ( $0 \leq a \leq 1$ ) which describes an effective reduction of the Mn-concentration  $x$  and a Curie-Weiss parameter  $\Theta$  which accounts for the effective increase of the temperature due to the antiferromagnetic coupling.

**Quantum dot** Semiconductor nanostructure exhibiting quantum confinement along all three lateral dimensions.

**Quantum well** Layered (two-dimensional) semiconductor nanostructure consisting of a thin (typically a few nanometers) layer of semiconductor A embedded between two layers of semiconductor B. Usually the band gap of A is smaller than that of B leading to confinement of the carriers in the conduction and/or valence band of A perpendicular to the layer plane.

**Quantum wire** Semiconductor nanostructure exhibiting quantum confinement along two lateral dimensions.

#### Rudermann-Kittel-Kasuya-Yosida interaction (RKKY)

Mechanism to explain long-range coupling between magnetic ions. The coupling is mediated via the magnetic polarization of a free carrier gas. The RKKY mechanism is the basis for current theories of the ferromagnetism in (III,Mn)V semiconductors.

**$s,p$ - $d$  exchange interaction** Exchange interaction between the pseudo-spins of the free carriers in the  $s$ -like conduction band (or  $p$ -like valence band) and the localized  $S = 5/2$  spins of the Mn-ions in Mn-based diluted magnetic semiconductors.

**Semimagnetic semiconductor** Synonym for diluted magnetic semiconductor.

**Spin-optoelectronics** Semiconductor-based optoelectronics where the spin-selectivity of the optical selection rules is explored.

**Spintronics** Short for spinelectronics, semiconductor-based magnetoelectronics.

## 1. INTRODUCTION

Over the last few years there has been an explosion of interest in the magnetic behavior of nanostructures from a wide range of scientific disciplines. Mesoscopic magnetism is not as well understood as in either the atomic or bulk regimes and there is a fascination by physicists and chemists to obtain a better fundamental grasp of the consequences of restricting the magnetic electrons within systems only a few atomic spacings in dimension. This increase in interest has been coupled with the development of technologies that can manufacture tightly controlled magnetic nanostructures including quantum dots, monolayers, self-organized islands, quantum wires, and deposited nanoclusters. Undoubtedly much of the enthusiasm comes from a growing realization of the enormous potential of magnetic nanostructures in the formation of high performance magnetic materials and devices.

In addition there is a growing interest in natural magnetic nanostructures that are to be found in a diverse variety of environments. An example is the MV-1 bacterium that manufactures nanoparticles of magnetite arranged in chains to

maintain alignment with the earth's magnetic field [1]. Similar magnetite chains discovered in meteorites from Mars are considered to be the strongest evidence for the previous existence of extraterrestrial bacteria [2]. It has also been suggested that magnetic nanoparticles play a crucial role in seeding the condensation of the interstellar medium to form free-floating planets [3].

This chapter will review the recent research on magnetic nanostructures produced by forming clusters in the gas phase and depositing them on surfaces. Just over two decades ago, based on earlier work at Karlsruhe on cryogenic free jet expansions [4], the technology to produce beams of gas-phase, size-selected metal nanoclusters was developed [5]. In the case of magnetic clusters this afforded the wonderful opportunity to study how the magnetism in matter develops as a substance is built atom by atom from the monomer. Magnetism is well understood at the limiting scales of atoms and the bulk but in mesoscopic systems containing a few to a few thousand atoms (1–5 nm), magnetic behavior depends on size and can change significantly with the addition or removal of a single atom.

Nanoclusters are single-domain particles (i.e., systems in which it is energetically unfavorable to form a domain boundary). These have held enormous fascination since the classic work of Stoner and Wohlfarth [6] and Néel [7] over half a century ago. The particles, notwithstanding complications such as canted spins at the surface [8], can be considered as giant moments of ferromagnetically coupled atomic spins. At temperatures much lower than those required to perturb the internal magnetic alignment, the particle moment as a whole can fluctuate over the anisotropy barrier separating different spin directions at time scales varying from nanoseconds to eons. At low temperatures, there is interest in the possibility of the tunneling of the magnetization vector through the barrier—one of the few examples of macroscopic quantum tunneling [9–11].

At  $T = 0$  K, reversing the direction of the cluster magnetization requires an external field to drive the magnetization vector across the anisotropy boundary  $KV$  separating different magnetic alignments, where  $K$  is the anisotropy constant and  $V$  is the particle volume. At elevated temperatures when  $kT \gg KV$  the anisotropy barrier becomes

unimportant but the external field must compete with thermal fluctuations of the moment. In general, when a saturating field is removed from a particle (or an assembly) at temperature,  $T$ , the magnetization decays with a relaxation rate,  $\tau$ , that can be approximated by the Arrhenius relationship

$$\frac{1}{\tau} = f_0 \exp\left(\frac{-KV}{k_B T}\right) \quad (1)$$

where  $f_0$  is the natural gyromagnetic frequency of the particle. For volumes typical in deposited transition metal clusters, observations must be done at cryogenic temperatures ( $\leq 5$  K) for the magnetic relaxation to be slower than typical measurement times. At room temperature, the thermal energy  $k_B T$  is much greater than the anisotropy energy of each particle so that all magnetization directions are almost energetically equal. The magnetization is then described by the classical Langevin function

$$M = N\mu_{\text{cluster}} \left[ \coth\left(\frac{\mu_{\text{cluster}} H}{k_B T}\right) - \frac{k_B T}{\mu_{\text{cluster}} H} \right] \quad (2)$$

where  $\mu_{\text{cluster}}$  is the magnetic moment of each cluster. This can be several hundred atomic spins and so, unlike isolated atoms where very low temperatures or very high fields are required to achieve saturation, assemblies of clusters can be saturated easily. The temperature at which half the cluster moments have relaxed during the time of a measurement is known as the blocking temperature,  $T_B$ , and only a narrow temperature region around  $T_B$  separates, essentially, permanently frozen moments from superparamagnetic behavior. The quest to find deposited clusters smaller than 5 nm in which  $T_B$  is above room temperature is an important challenge for future generations of magnetic recording technology (see Section 8).

For particles smaller than about 5 nm, either as free clusters or supported on a surface, the fundamental spin and orbital moments per atom can be substantially increased over the bulk value [12–18]. This was originally discovered by magnetic deflection experiments using gradient magnetic fields applied to free clusters in flight [12] but it is now known that isolated clusters maintain significant enhancements after they have been deposited on a surface [15, 16] or embedded in a matrix [18].

As the flux from cluster sources has steadily improved [19], the field has evolved to consider not just isolated clusters but films up to several  $\mu\text{m}$  thick built out of the preformed clusters. These can be deposited in conjunction with a vapor of another material to form a granular material of the particles embedded in a matrix. This affords independent control over the grain size and volume fraction and it is even possible to effect some control over the cluster shape by adjusting the impact energy on the surface [20]. In addition it has been shown that the clusters maintain their identity in a matrix of a material that alloys with that of the particles [21] enabling the production of nanoscale *granular* mixtures of *miscible* materials. This is not possible by any other fabrication technique. This degree of control over the nanostructure has generated great interest in

cluster deposition as a technique for producing high performance magnetic materials. Examples include high saturation moment films [22] and giant magnetoresistance sensors [23].

In all such industrial applications, the required cluster volume fraction is high—at or near the percolation threshold—so there are strong interactions between the clusters. Understanding the detailed nature of the cluster interactions has therefore become increasingly important. Interparticle interactions produce a rich variety of magnetic configurations resulting from competing energy terms. The dipolar interaction introduces frustration as it is impossible to obtain an optimum alignment for every particle. In addition there is frustration resulting from the competition between the interparticle dipolar and exchange terms and the intraparticle anisotropy energy (magnetocrystalline, shape, magnetoelastic etc.) that requires the magnetization vector to be aligned along specific axes in each particle.

In the next two sections the experimental methods used to produce clusters and measure their magnetic properties will be described. This is followed in Section 4 by a brief description of the morphology and atomic structure expected in transition metal clusters. Sections 5–7 will review the magnetic behavior of clusters in three different environments, that is, as free particles, as exposed clusters adsorbed on a surface in ultrahigh vacuum (UHV), and as embedded clusters in a matrix. Section 7 will also discuss the effect of interparticle interactions in dense interacting assemblies. In the last section some technological applications of cluster-assembled films will be described.

## 2. PRODUCTION OF SIZE-SELECTED NANOCCLUSERS

### 2.1. Cluster Sources

Sources capable of producing free beams of nanoscale metal clusters with a wide range of sizes were first reported more than 20 years ago [5, 24]. The technology continues to develop rapidly, however, as beam intensities are pushed ever higher and new capabilities are introduced such as UHV compatibility [25, 26], the production of binary metal clusters [27], new mass-selection techniques, etc. At the heart of most cluster sources is a region in which a supersaturated vapor of the material to be studied is generated by ejecting a gas-phase metal plume into a flow of a cooled inert gas. The metal vapor can be generated by laser ablation [24], sputtering [28], a pulsed [29] or continuous [30] arc, or thermally [5].

Monte Carlo simulations [31] show that the dominant cooling mechanism for the growing clusters is by evaporation of atoms. This is approximately balanced by the heating due to the adsorption of new atoms (latent heat) and the cooling by the gas, although inefficient, provides the *extra* cooling required to allow the clusters to grow. The simulation also revealed that the initial formation of dimers is a critical bottleneck to the clustering process. The growth of clusters is complete after a dwell time in the source of the

order of 10 ms after which the cluster size is described by a log-normal distribution [32]

$$F(n) = \frac{1}{\sqrt{2\pi} \ln \sigma} \exp - \left( \frac{\ln n - \ln \bar{n}}{\sqrt{2} \ln \sigma} \right)^2 \quad (3)$$

where  $n$  is the number of atoms per cluster and  $\sigma$  is the variance.

The region in which the metal vapor initially mixes with the rare gas is typically at a pressure of a few mbar to a few bar and at the end of this region there is an aperture with a diameter of a few  $\mu\text{m}$  to a few mm. In some sources clustering continues in the region just after the aperture in the free jet expansion. This expansion accelerates the clusters and in the limit of high pressure differential between the two regions separated by the aperture, the clusters can acquire the full thermal distribution of the bath gas atom velocities. In weaker expansions there is a velocity slip between the carrier gas and the metal clusters.

Brief descriptions of the operation of various sources based on gas condensation are given next (see Fig. 1). For more comprehensive descriptions of these and other types the reader is referred to existing reviews [19, 34].

**Figure 1.** Basic layout of sources using rare gases to produce super-saturated vapors. (a) Seeded supersonic nozzle source. (b) Gas aggregation source. (c) Laser evaporation source. (d) Pulsed arc cluster ion source. Reprinted with permission from [33], C. Binns, *Surf. Rev. Lett.* 44, 1 (2001). © 2001, Elsevier Science.

### 2.1.1. Seeded Supersonic Nozzle Source

These are designed to produce very high fluxes of low melting point (usually alkali) metals (Fig. 1a). The furnace containing the melt is heated to a sufficiently high temperature to yield a metal vapor pressure in the region of 10–100 mbar and this vapor is mixed with (seeded into) a rare gas introduced at a pressure of several atmospheres. The hot mixture expands adiabatically into vacuum through a small aperture and the rapid cooling occurring close to the nozzle condenses the metal into clusters. The clustering continues until the mean free path becomes too long to allow significant interactions between the condensed particles. The technical difficulty of the containment of the melt in a relatively large furnace has restricted the temperatures achievable to below 1600 K. The source is thus confined to the study of high vapor pressure materials. It is, however, capable of producing a flux in excess of  $10^{18}$  atoms/sec of clustered material. The very high rate of consumption has encouraged the development of *in-situ* refilling devices [35].

### 2.1.2. Gas Aggregation Source

This was the first type of metal cluster source reported [5] and a common design is illustrated in Figure 1b. Improvements since 1980 include the *in-situ* positioning of the crucible assembly within the gas flow to optimize the output and an adjustable gap between the first aperture and the skimmer [25]. Generally there is a larger aperture to the high vacuum region and the free jet expansion is weaker than in the seeded supersonic nozzle source (SSNS). Since only the crucible is heated, with a careful design, materials can be contained at temperatures above 2000 K and thermal sources have been built that are capable of producing beams of magnetic transition metal clusters [25]. As with the SSNS, with careful outgassing, the source is particularly suited to producing very clean cluster beams and to UHV-compatible operation [25, 36]. The inert gas pressure within the clustering region in a typical gas aggregation source (GAS) is compatible with magnetron sputtering and the thermal source can be replaced by a sputtered target [28]. This brings several advantages including the ability to produce clusters of the most refractory materials and, with a hollow cathode target geometry, very high fluxes can be attained [37]. Clustering is highly efficient as the sputtered vapor is rich in dimers overcoming the initial bottleneck for condensation. In addition, the emerging cluster beam is highly ionized with a greater proportion of ions than achievable with a conventional ionizer. This is an important factor if the clusters are to be mass-selected since most mass analyzers filter charged particles.

### 2.1.3. Laser Evaporation Source

Light pulses from a Nd-YAG laser focused onto a suitable target can vaporize even refractory materials and if the laser pulse coincides with a gas burst across the target produced by a pulsed valve, suitable conditions for clustering can be achieved (Fig. 1c). The first report of this type of source [24] was quickly followed by improvements including a mechanism for driving the target rod in a screw motion so that a fresh region is exposed to each laser pulse [38]. Clustering occurs within the nozzle as the metal vapor encounters the

rare gas and continues in the strong expansion as the mixture is ejected. There is a strong adiabatic cooling despite the relatively large nozzle diameters since the instantaneous carrier gas pressure is very high—up to several atmospheres. The processes are thus a combination of those found in the SSNS and the GAS and, as in the former type, clustering is complete within a nozzle diameter of the aperture. Despite the short duty cycle of the laser, the peak output is so high that the average flux from the source easily competes with the other types previously described. A useful variable is the phase of the laser pulse relative to the valve opening that can be used to control the size distribution of clusters by altering the average gas pressure during the pulse [39]. Phasing becomes particularly powerful in sources employing two targets to produce binary clusters [27, 40] since it can be used to control the distribution of elements within the cluster. The pulsed output couples efficiently to time-of-flight analyzers (see following section).

#### 2.1.4. Pulsed Arc Cluster Ion Source

This is closely related to the laser evaporation source (Fig. 1d) but in this case the evaporated plume is produced by a pulsed arc coinciding with the gas burst [29]. The clustering process is very similar to that found in the laser evaporation source (LES). As with the GAS employing sputtering, the cluster output contains a high proportion of ions (~10%) and is particularly suited to charged-particle mass analyzers.

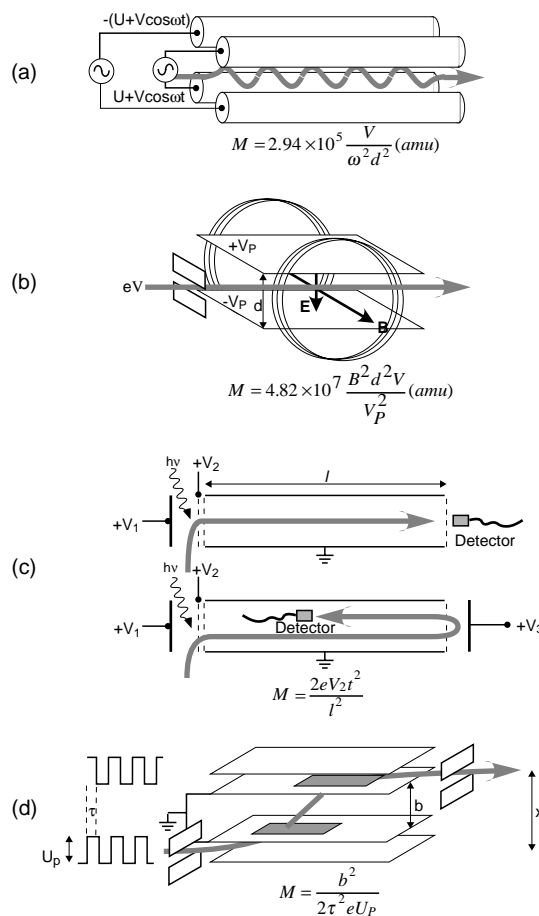

## 2.2. Mass Selection

Due to the relatively low rate of deposition produced by most sources, the mass resolution used for studies of deposited particles is normally less than in the case of free clusters where individual particles are counted. In fact much of the work reported so far has been on assemblies of clusters where no postaggregation filtering has been carried out. In this case there is still some degree of control over the size distribution by changing the source parameters such as the gas temperature or pressure in the aggregation region. Some sources employ two mass filters: a high resolution instrument such as a time-of-flight analyzer to measure the mass-spectrum in the free beam and a lower resolution high-throughput device to narrow the native mass distribution prior to deposition [39]. Most mass separators require the clusters to be charged and, with the exception of sources that rely on sputtering to produce the metal plume, which inherently produce a large proportion of charged clusters, ionization is inefficient so that the majority of clusters are discarded.

In general a mass separator for charged particles must be able to determine the mass independently of the initial ion velocity. In the case of a hard free jet expansion in the source in which the clusters all have the same velocity distribution irrespective of mass, filtering can be achieved by a simple parallel-plate electrostatic deflector. If this is not the case a more sophisticated device is required and various charged-particle mass separators that can operate without assuming an initial velocity distribution are described below as well as schemes for mass selection of neutral clusters.

### 2.2.1. Radio Frequency Quadrupole

This instrument, illustrated in Figure 2a, operates using electric fields only and was first described by Paul et al. [41, 42]. Four cylindrical poles in the geometry shown have a radio frequency (rf) modulation on a dc offset ( $U + V \cos \omega t$ ) applied to one pair of opposite poles and the negative of the same potential to the other pair. In order to be transmitted by the filter, the oscillatory motion of an ion as it moves along the poles must have a stable amplitude and this can only occur, irrespective of its mass, if the ratio  $U/V$  is less than 0.168. For ratios lower than this the instrument passes specific masses given by the absolute value of  $V$ . For a quadrupole operating at the stability limit, the range of masses passed depends on the energy of the ions entering the filter, the frequency,  $\omega$ , and the length of the poles. Operating with  $U/V$  ratios below the stability limit produces a band pass filter with a top hat amplitude function. One of the attractive features of the instrument is that a simple electronic adjustment of  $U/V$  allows a trade-off between flux and resolution. Other advantages are that the filter is light and compact, and it operates axially, which is convenient in a deposition source. Technically the maximum resolving power

**Figure 2.** Mass separators for charged clusters. (a) Rf quadrupole. (b) Wien filter. (c) Time-of-flight mass spectrometer with direct and reflectron configurations. (d) Pulsed field mass selector. $(M/\Delta M)$  obtainable from this type of mass spectrometer is about 4000 and so for a resolution of 1 amu or better the mass range is restricted to clusters smaller than about 100 atoms. If the single amu resolution requirement is relaxed and the instrument is treated as a band pass filter with a variable bandwidth, it is possible to pass arbitrarily large masses. For a quadrupole operating at the stability (high resolution) limit the central mass passed is

$$7.45 \times 10^7 \frac{V}{f^2 d^2} \quad (\text{amu}) \quad (4)$$

and the resolution is

$$\Delta M = 3.92 \times 10^9 \frac{E_z}{f^2 L^2} \quad (\text{amu}) \quad (5)$$

where  $E_z$  is the ion energy entering the filter (in V),  $f$  is the rf frequency ( $=\omega/2\pi$ ),  $d$  is the diameter, and  $L$  is the length of the rods. The maximum mass range reported for a quadrupole filter [25] is 60,000 amu with a resolution of about 200 amu (resolving power = 300). In the case of Fe for example, this corresponds to clusters containing  $1000 \pm 4$  atoms, or in terms of size, particles with a diameter of  $2.82 \pm 0.008$  nm.

### 2.3. Wien Filter

This type of mass filter, illustrated in Figure 2b, applies orthogonal electric and magnetic fields to a charged particle with velocity  $v$ . The antiparallel forces on the ion balance when

$$v = \frac{2V_p}{Bd} \quad (\text{ms}^{-1}) \quad (6)$$

where  $2V_p$  is the voltage applied across the electrostatic plates and  $d$  is the plate spacing. The device is really a velocity filter and it is operated as a mass filter by initially accelerating the ions through a fixed potential  $V$  so each mass has a different velocity. The mass passed by the filter is then given by

$$4.82 \times 10^7 \frac{B^2 d^2 V}{V_p^2} \quad (\text{amu}) \quad (7)$$

The resolution is determined by the collimating slits and the velocity spread in the ion beam prior to acceleration. The effect of the latter can be minimized by using a high accelerating potential but this puts a heavy demand on the magnetic field strength required to operate up to a high mass. A thorough analysis of the performance of a commercial Wien filter for the mass separation of clusters emerging from a pulsed arc cluster ion source (PACIS) was carried out by Wrenger and Meiwes-Broer [43]. They showed that the instrument was capable of distinguishing clusters with specific numbers of atoms,  $N$ , up to about  $N = 20$ . With a constant magnetic field there was good agreement between the calculated and actual voltage settings to pass a given mass for the small clusters and so the calculated values could be used to set up a band pass filter for unresolved masses up to  $N \approx 1000$ .

### 2.4. Time-of-Flight Mass Spectrometers

In this scheme (Fig. 2c) a well defined pulse of ions is created, usually by a pulsed ultraviolet laser or electron gun. The packet of ions is accelerated into a field-free drift tube and the arrival time at the end of the tube is recorded by an ion detector. The resolution of the simple instrument is limited mainly by the timing accuracy and the preionization spread in position and velocity. These latter two effects can be minimized by the reflectron scheme [44–46] shown in the figure that uses a simple diode reflector at the end of the drift tube. Slower ions of a given mass take a shorter path in the reflector than faster ones so ions of the same mass will be bunched closer together on reflection. With this system resolving powers of  $10^5$  have been achieved.

The analyzer can be used as a filter by adding an electrostatic kicker mechanism that pulses a set of steering plates a set time after each ionizing pulse to expel ions of a given mass from the drift tube. A potential problem with this scheme is harmonics (i.e., simultaneously selecting slow heavy ions from a previous pulse and lighter ions from the present pulse). This type of mass analyzer is most efficiently matched to a pulsed cluster source such as the PACIS or LES types that typically operate at around 100 Hz. The ionizing laser in the case of a LES is operated at the same frequency as the evaporation laser so the ion packets are separated by around 10 ms while typical flight times are of the order of 0.1 ms so harmonics are unlikely to be a problem with the typical time structures presently used.

### 2.5. Pulsed Field Mass Selector

Recently a simple and ingenious mass filter was reported [47] that uses an electric field pulse to displace an ion beam sideways into a field-free region (Fig. 2d). For a given strength and timing of the pulse the lateral velocity of the ions in the field-free region depends on their mass. A given time later a second decelerating pulse deflects the ions onto a path parallel to the original one and through an aperture. The timing between the accelerating and decelerating pulses determines the selected mass. The instrument can filter masses up to an arbitrarily high limit with a transmission greater than 50%, and with a mass resolution given by

$$\frac{M}{\Delta M} = \frac{x}{\Delta x} \quad (8)$$

where  $x$  is the ion beam lateral displacement and  $\Delta x$  is the exit slit width. In practice this is in the range 20–50 (i.e., not as high as the other filters but sufficient for most studies of deposited clusters). As stated earlier, in real deposition experiments, if a mass filter is used, it is normally detuned to pass an adequate cluster flux.

### 2.6. Mass Separation of Neutral Clusters

Mass selecting neutral particles has always been a highly prized goal since most ionizers are inefficient and even in sputter sources that produce a high proportion of ions, the majority of the emitted clusters are uncharged. Most attempts to mass-select neutral particles to date are based on the size-dependent velocity slip between the carrier gas and the clusters during the free jet expansion [48]. Roux

et al. [49] used a velocity selector made from a pair of rotating slotted wheels based on the design by Hostettler and Bernstein [50]. The filter was able to shift the peak of the mass distribution of the neutral clusters but due to its low resolution was not found to significantly affect the width.

Mechanical velocity selectors can also be used to mass select in conjunction with sources that naturally produce a pulsed output such as the pulsed arc or laser ablation types. At typical repetition rates of about 100 Hz the bunches of clusters are about a meter apart and well separated. Each packet will have an expanding cylindrical envelope due to the different velocities of the clusters within it and, because of the size dependence of the velocity slip in the free jet expansion, the leading edge will become increasingly rich in small clusters and the trailing edge will accumulate the larger clusters. Thus a mechanical chopper operating at the same frequency as the source but phased to be transparent to only a portion of the cluster bunches will size-select with 100% transparency irrespective of the resolution setting. This scheme has yet to be tested.

Recently a new scheme has been suggested by Di Fonzo et al. [51] and Tafreshi et al. [52] that exploits “aerodynamic focusing” [53]. This is produced by a series of orifices that induce several expansions and contractions of the gas flow with the result that at each stage the particles become more collimated within the gas flow. Deposited features with linewidths of 50  $\mu\text{m}$  were demonstrated without the use of micronozzles. The cluster beam collimation is size-dependent and by careful design of the lenses it should be possible to spatially separate particles with different sizes. This remains to be demonstrated.

### 3. MAGNETIC MEASUREMENTS ON CLUSTERS

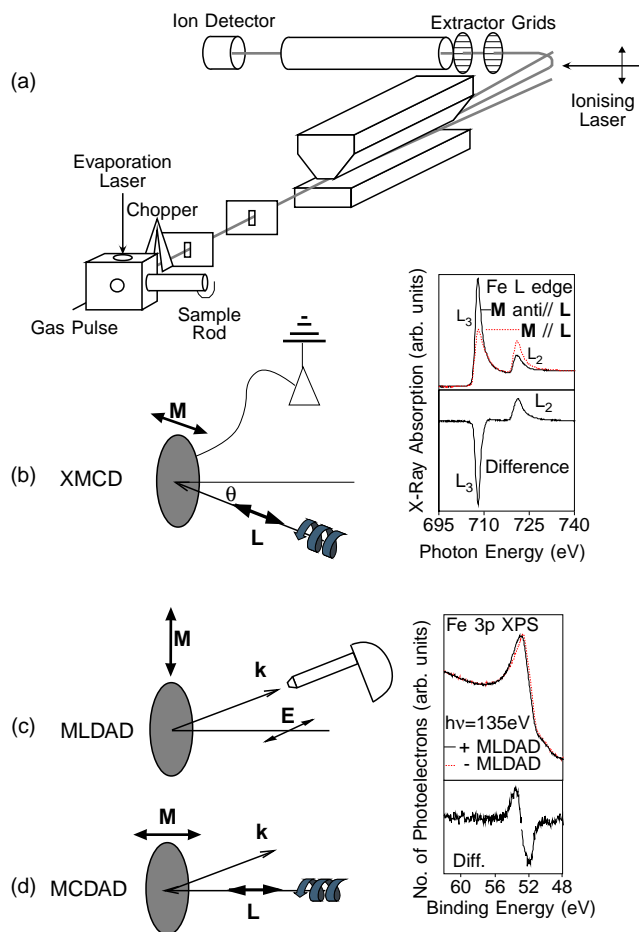

#### 3.1. Free Clusters

##### 3.1.1. Gradient Field Deflection

The founding experiments on cluster magnetism were carried out on free particles and determined the magnitude of the magnetic moment as a function of cluster size [12, 13, 54–56]. The first setup capable of this measurement was reported by Cox et al. [54] and is based on the classic Stern–Gerlach experiment that first detected the electron spin [57]. Figure 3a shows, schematically, a typical arrangement. A collimated cluster beam generated by a pulsed laser evaporation source with a variable temperature nozzle is guided into a magnetic field gradient  $dB/dz$  that will deflect vertically any particle with a magnetic moment  $\mu$  by an amount

$$d = \mu \frac{dB}{dz} L^2 \frac{(1 + 2D/L)}{2Mv_x^2} \quad (9)$$

where  $L$  is the length of the magnet,  $D$  is the distance from the end of the magnet to the detector,  $M$  is the cluster mass, and  $v_x$  is its velocity when it enters the magnet. A pulsed ionizing laser probes the beam profile after the magnet and is the source for a time-of-flight mass filter. Thus it is possible to measure the deflection of a given mass and determine its magnetic moment as long as  $v_x$  is known. This can be defined by a controlled delay between the evaporation laser

**Figure 3.** (a) Schematic of experiment to measure the magnetic moment of free clusters. (b) X-ray magnetic circular dichroism (XMCD) measures the difference in  $L$ -edge absorption between parallel and antiparallel alignment of the magnetization vector and photon spin. The magnetic field is applied along the direction of the photon beam and at a variable angle,  $\theta$ , relative to the sample normal. (c) Magnetic linear dichroism in the angular distribution (MLDAD) measures the difference in the Fe  $3p$  photoemission spectra taken with linearly polarized extended ultra-violet (XUV) light on reversing the magnetization in the sample plane and perpendicular to the photon polarization vector. (d) Magnetic circular dichroism in the angular distribution (MCDAD) measures the difference in the Fe  $3p$  photoemission spectra taken with circularly polarized XUV light on reversing the magnetization along the direction of the photon spin. All data shown were obtained from Fe nanoclusters on highly oriented pyrolytic graphite (HOPG) [15, 61]. Reprinted with permission from [62], C. Binns, *J. Nanosci. Nanotechnol.* 1, 243 (2001). © 2001, American Scientific Publishers.

and the ionizing laser. Since the duration of the pulse of clusters can be several ms wide, a mechanical chopper in front of the source (also shown in Fig. 3a) is used to better define the pulse start time. The chopper can be phased with the vaporizing laser to define clusters emerging from the nozzle at a specific time relative to the vaporizing pulse, a feature that was found to be important in order to define the cluster temperature.

Interpreting the data from clusters provided by the instrument is, however, not straightforward and requires a careful consideration of the detailed operation of the source. The problem is in accurately defining the cluster vibrational

temperature,  $T_{\text{vib}}$ . It is found for transition metals that they always deflect toward the direction of highest field, which is indicative of superparamagnetism. That is, clusters enter the magnet with a rapidly fluctuating moment and within the field become magnetized to a degree depending on the temperature and the field, as described by Eq. (2). Since the residence time in the magnet ( $\sim$ ms) is orders of magnitude longer than the time scale of the magnetic fluctuation ( $\sim$ ns), clusters of a given size will attain the same mean magnetization and deflect by the same amount.

During the initial experiments on free cluster magnetism, significant deviations from the predictions of the superparamagnetic model were found for small residence times of the clusters in the source. The original proposal to explain this [58] was that for short times ( $<1$  ms) after the laser pulse, the gas pressure within the source is still high and the clusters are cooled well below the nozzle temperature by the adiabatic expansion. This was based on the observation that Ar added to the He bath gas was adsorbed onto the surface of the clusters indicating that they were much colder than the temperature within the source. The nonequilibrium conditions can create a situation where the rotational temperature ( $T_{\text{rot}}$ ) is less than the vibrational temperature ( $T_{\text{vib}}$ ) and may be of the same order of magnitude as the magnetic precessional frequency in the applied field, which can lead to a resonant spin rotation coupling that reduces the magnetization [12, 59]. In order for the clusters to be thermalized with the nozzle temperature, the chopper must select clusters produced after delays that are sufficient for the gas pressure to drop below the values where significant cooling occurs in the free jet expansion. The cluster temperature is then the nozzle temperature and the cluster magnetization is superparamagnetic in the case of Fe, Co, and Ni clusters. An alternative mechanism proposed by Douglass et al. [13] is that at short residence times the metal vapor is still hot and requires time to thermalize with the carrier gas. They found no significant supercooling in their free jet expansion and were unable to produce the rare gas adsorption results obtained by Milani and de Heer [58]. In either case, for sufficiently long residence times, the clusters attain the nozzle temperature, which can be controlled, and then all results for the transition metals are consistent with the superparamagnetic model. A more subtle consideration is whether a nanocluster containing a few tens of atoms has a sufficient density of states to constitute a heat bath so that thermodynamically based laws are valid. This is assumed to be the case based on the success of the superparamagnetic model in describing the results after the above technical considerations are addressed [60].

In rare earth clusters, rotational effects can again become important since the spin-orbit interaction can be sufficiently strong to lock the cluster magnetic moment to its atomic lattice. Douglass et al. [13] showed that whether Gd clusters display superparamagnetic or locked-moment behavior is a sensitive function of their size. The results are discussed in detail in Section 5.

### 3.2. Exposed Clusters on a Surface

The gradient-field deflection technique is the only one that can determine the magnetic moments in free clusters. Next are described several experiments that can be used to study

magnetism *in-situ* in clusters deposited on a surface and exposed in ultrahigh vacuum.

#### 3.2.1. X-Ray Magnetic Circular Dichroism

This is a powerful technique for studying magnetic behavior at surfaces and in nanostructures. In the case of transition metals, it involves the measurement of the difference in  $L$ -edge X-ray absorption spectra obtained using circularly polarized X-rays with their angular momentum parallel or antiparallel to the sample magnetization. The orbital ( $m_L$ ) and spin ( $m_S$ ) contributions to the total magnetic moment can be determined independently and (in heterogenous systems) for each element by applying magneto-optical sum rules to the absorption spectra [63, 64]. The experimental geometry and an  $L$ -edge absorption spectrum taken from Fe clusters deposited on graphite [15] are shown in Figure 3b.

More precisely, the technique measures the quantities  $\langle L_z \rangle$  and  $\langle S_z + 7T_z \rangle$  per valence band hole,  $n_h$ , where  $\langle L_z \rangle$  and  $\langle S_z \rangle$  are the expectation values of the  $z$  (static) components of the orbital and spin angular momenta of the atoms, and  $\langle T_z \rangle$  is the expectation value of the magnetic dipole operator given by

$$T = \frac{1}{2}[\mathbf{S} - 3\hat{\mathbf{r}}(\hat{\mathbf{r}} \cdot \mathbf{S})] \quad (10)$$

This averages to zero over all directions and does not appear in conventional magnetic measurements but since the X-rays sample a directional cut through the atomic electron density, the term must be included in the sum rule. It can be eliminated, yielding the pure spin moment, by averaging measurements over all X-ray incidence angles, making a single measurement on a polycrystalline sample or, for samples with rotational symmetry about the substrate normal, making a single measurement at the “magic” angle [65, 66]. The number of valence band holes can be determined by measuring the integrated (white line)  $L$ -edge absorption strength, which is proportional to  $n_h$ , of a thick film of the same material *in-situ* and comparing it to that of the clusters. One of the powerful attributes of XMCD is that, since it is derived from an X-ray absorption edge, it is element-specific. Thus it can determine, separately, the orbital and spin moments localized in different magnetic elements in heterogenous systems.

The only sources that emit a sufficiently high flux of circularly polarized X-rays to study nanostructures by XMCD are synchrotron storage rings. These produce circularly polarized radiation of either helicity above and below the orbit plane of the electrons and also from insertion devices such as helical undulators [67].

#### 3.2.2. Dichroism in Photoelectron Spectroscopy

A dichroism is also observed in the  $3p$  angle-resolved photoemission spectra of the transition metals taken with linearly or circularly polarized light with the geometries shown in Figure 3c and d. The techniques measure the difference in the spectra in response to reversing the alignment between the in-plane sample magnetization and the linear polarization of the XUV light (MLDAD [68]) or between the

out-of-plane sample magnetization and angular momentum of circularly polarized light (MCDAD [69]). Since angle-resolved photoemission spectra must be collected in zero field, the techniques are, in general, restricted to measuring remanence but they are surface sensitive and capable of measuring submonolayer quantities of material. Schemes using magnetic substrates that expose the clusters to fields  $\sim 1$  T but still allow photoemission measurements have also been developed [70]. As with XMCD, a synchrotron source must be used to provide the polarized XUV radiation and endstations at which light of variable polarization is available can be fitted with movable magnetizing coils allowing both geometries to be combined in a single experiment. This enables the comparison of in-plane and out-of-plane remanent magnetization.

### 3.2.3. Surface Magneto-Optical Kerr Effect

In a surface magneto-optical Kerr effect experiment, the rotation of the polarization of a light beam when it is reflected from a magnetic surface is measured [71]. The rotation is by the same process as Faraday rotation in transmission. It is a popular method for measuring magnetism in surfaces and ultra-thin films since it is relatively inexpensive to set up and is easily made compatible with UHV since the light source, usually a He-Ne laser, and all the polarization detection equipment are external to the vacuum system with the incident and reflected beams transmitted through windows. The optical penetration depth of visible light is of the order of 20 nm in metals and the signal from a deposited monolayer is a small fraction of the total signal so the rotation of the polarization vector is a fraction of a degree. With careful design and good quality optics it is possible to measure hysteresis loops in magnetic monolayers. Three geometries are used: polar, longitudinal, and transverse. The maximum signal is obtained when the  $\varepsilon$  vector of the light is perpendicular to the sample magnetization [72].

### 3.2.4. UHV Vibrating Sample Magnetometry

Vibrating sample magnetometry is a standard technique for measuring the magnetic moment in materials that was originally described by Foner [73] over 40 years ago. The magnetic moment of a sample is determined by vibrating it between conducting coils and measuring the alternating voltage developed at the same frequency. The sensitivity of the technique has steadily improved and modern instruments can measure moments as low as  $10^{-7}$  A m<sup>2</sup>, corresponding to  $\sim 10^{16}$  Fe atoms. Recently, a system that allows *in-situ* measurements on exposed clusters in UHV has been demonstrated [74]. A deposited cluster layer is deposited onto a substrate and then sealed, in its UHV environment, within an ampoule that can be withdrawn and inserted into the magnetometer without exposing the sample to atmosphere.

The technique is not sensitive enough to measure significantly less than a single cluster layer so it cannot be used to study isolated particles. The ability to measure exposed layers is, however, important since, as will be shown in Section 7, even thick cluster films show a marked change in magnetic behavior when coated with a protective nonmagnetic capping layer to allow removal from the vacuum for *ex-situ* measurements.

## 3.4. Isolated Embedded Clusters

In the case of embedded clusters, it is unnecessary to make *in-situ* measurements as the samples can be taken into air without contaminating the magnetic clusters and so the whole range of magnetic measurements becomes possible. The two techniques presented below are sufficiently sensitive to measure the magnetization in a *single* embedded nanocluster.

### 3.4.1. Micro-SQUID Measurements

Superconducting quantum interference devices (SQUIDS) are the most sensitive magnetic detectors known and recent developments in lithographed devices of  $\mu\text{m}$  dimension have enabled the measurement of the switching field of individual nanoclusters [75]. The technique involves making the loop and Josephson junctions out of a cluster-assembled film consisting of nanoclusters embedded in a superconducting matrix. The film is deposited over a whole substrate that is then patterned using lithography into superconducting loops with weak links. Although every loop contains clusters over its entire surface, there is only significant flux coupling from those that are embedded within the bridge. In the devices reported the junction regions have an area  $30 \times 50$  nm<sup>2</sup> and the clusters are embedded in a 20 nm thick Nb film. Thus if clusters with a volume  $\sim 20$  nm<sup>3</sup> are embedded with a volume fraction  $\sim 0.1\%$ , there will be on average 1 cluster per bridge region. One then makes measurements from a number of SQUIDS on the sample and it is clear from the switching field distribution which ones are detecting a single particle.

### 3.4.2. Micro-Hall Probes

Using conventional photolithography and wet chemistry it is possible to produce submicrometer size III-V semiconductor Hall bars in which the conducting layer is an ultrathin two-dimensional electron gas (2DEG) localized at the surface [76, 77]. A magnetic particle deposited onto the central bar produces an intense local magnetic field that penetrates the 2DEG and generates a significant Hall voltage. Wirth and von Molnár [77] have shown how matching the size of the particle array to the active area of the Hall bar produces the optimum sensitivity and recently, Li et al. [78] measured the magnetization curve at temperatures up to 75 K, of a single Fe nanoparticle with a diameter of 5 nm. At present the technique does not quite match the sensitivity of the micro-SQUID but it is much more versatile since it can measure over a much wider temperature range ( $\leq 100$  K) and is not restricted to particles embedded in superconducting materials.

## 4. MORPHOLOGY AND STRUCTURE OF CLUSTERS AND CLUSTER-ASSEMBLED FILMS

### 4.2. Morphology

The high proportion of surface atoms in nanoclusters magnifies the importance of the surface energy and it is the competition between this and the local bonding forces that

determines their morphology. Simple metal clusters with highly isotropic bonding are at one extreme and are pulled into spheres with the system behaving very much like a liquid drop. In fact the abundance spectra show “magic numbers” that correspond to especially stable electronic configurations within a spherical jellium model [79, 80]. In the case of the transition metals the magic numbers always correspond to stable atomic geometries rather than filled electronic shells. For example the body-centered cubic (bcc) metals Fe, Nb, and Ta show magic numbers at  $n = 7, 13,$  and  $15$  that correspond to a pentagonal pyramid, an icosahedron, and a double icosahedron respectively [81]. In this situation, in larger clusters, faceting becomes thermodynamically stabilized and in the case of metals with close-packed cubic crystal structures, the clusters tend to form truncated octahedrons [23, 82]. Generally the growth in the gas phase occurs in shells with the successive filling of layers of the cuboctahedral structure [83–85]. From a given stable configuration, reaching the next larger size begins by growth at a (111) face and switches to an adjacent (111) or (100) face when the first is full.

The morphology can change when the clusters land on a substrate, either by direct damage from the impact or due to subsequent diffusion and aggregation of clusters. These latter effects dominate the morphology of simple metal clusters deposited on graphite surfaces and they tend to form large fractal structures in which the original cluster morphology is lost [86]. This is not the case with transition metal clusters which, for landing energies less than  $\sim 0.5$  eV/atom, maintain their free cluster shape. Diffusion is also limited so that films build up by a random positioning of clusters. This type of structure is seen in Figure 4, which shows deposits of Fe clusters on Si(111) surfaces [87]. There is no tendency for the clusters to line up along atomic steps or to coalesce when they come into contact but remain as distinct grains. This remains the case even in very dense assemblies in which there is more than one layer of clusters. Closer inspection (Fig. 4b) reveals faceting of the clusters and that they tend to align along the facets when they come into contact. As shown in Figure 5, the faceted morphology is also preserved in nanoclusters embedded in matrices [74].

### 4.3. Structure

The atomic structure of a transition metal nanocluster is a size-dependent property and for metals with close packed cubic structures in the bulk, very small clusters are generally predicted to have icosahedral structures. Above some critical size the structure changes to a cubic close packed though this may be a face-centered cubic (fcc) structure in metals that are hexagonal close packed in the bulk. An example is Co and Figure 5 shows a transmission electron microscopy (TEM) image of a single cuboctahedral Co cluster embedded in amorphous carbon with a fcc structure [75]. In the case of metals with a bulk bcc structure, one expects an intermediate fcc phase between the icosahedral and bcc structures. There is evidence for this transition in Fe clusters from the free cluster magnetization measurements by Billas et al. [12] that indicate a change in the magnetic behavior at sizes of about 100 atoms. From specific heat measurements by Gerion et al. [90] of free Fe clusters containing about 270 atoms there is also evidence for a phase transition at about 600 K.

## 5. MAGNETISM IN FREE CLUSTERS

Studying mass-selected magnetic clusters as free particles enables one to address fundamental questions regarding the development of magnetism in materials as they are built atom by atom from the monomer. Various novel behaviors have been observed in free clusters including enhanced magnetic moments in ferromagnetic metals [12], magnetism in metals that are nonmagnetic in the bulk [56], ferrimagnetism in antiferromagnetic metals [88], canted spin arrangements in ferromagnetic rare earths [13, 89], and lowered [12, 90] or increased [91] Curie temperatures. Theoretical models have been developed that explain many of these phenomena. Ab initio methods and total energy calculations can be used to determine the cluster structure as well as their magnetic properties but are restricted to small clusters containing up to about 10 atoms. Hartree–Fock based methods can be used to calculate the magnetic behavior of much larger clusters but an atomic structure must be assumed. It is found in all cases that the atomic structure and the nearest neighbor distance are critical to determining the magnetic properties in clusters. Experimentally this information is sparsely

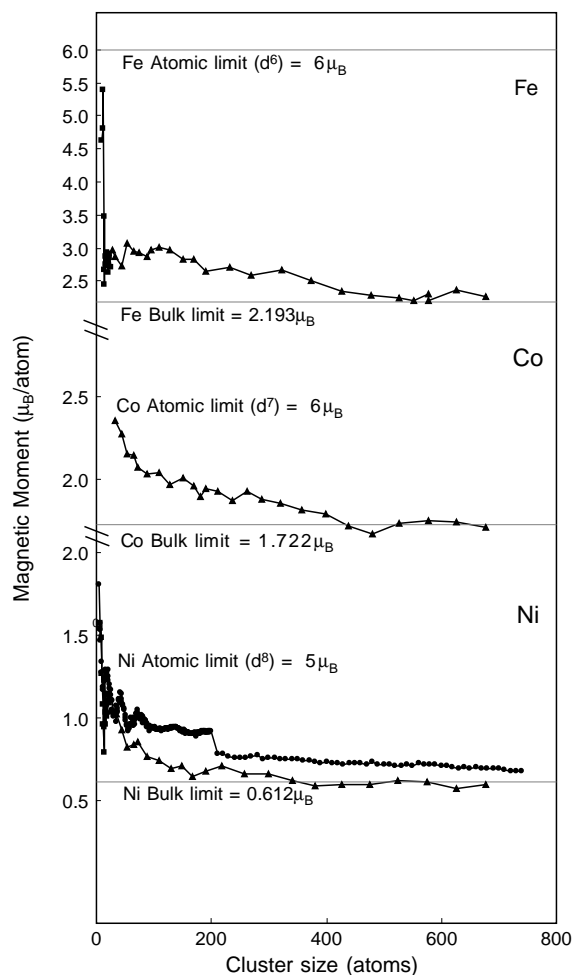

available at present and has been determined in a limited number of cases by indirect methods such as the observation of magic numbers in the mass spectra of the clusters [81]. The situation is complicated by the existence in some cases of several isomers of clusters of a give size.

The magnetic measurements are restricted to the gradient-field experiment described in Section 3 that measures the deflection and the modification of the beam profile of a beam of clusters by an inhomogenous magnetic field. In principle this can measure the total magnetic moment of a mass-selected cluster as a function of the field magnitude and the cluster temperature. As discussed earlier, initial controversies regarding the interpretation of data have been resolved. It is generally accepted that in transition metal clusters with their low magnetocrystalline anisotropy, at typical temperatures encountered in cluster sources the moment is decoupled from the atomic lattice and the magnetization obeys the superparamagnetic model. The magnetization of rare-earth clusters on the other hand is described by the superparamagnetic model only at some cluster sizes. Clusters with different sizes show locked-moment behavior. A review of results on free clusters of various types is presented below. For measurements on superparamagnetic clusters, the magnetization measured at finite temperatures is used to extract the intrinsic value of  $\mu_{\text{cluster}}$  (usually expressed in  $\mu_B/\text{atom}$ ) using Eq. (2).

### 5.1. Ferromagnetic 3d Transition Metals

Figure 6 shows a compilation of the total moments in free  $\text{Fe}_N$ ,  $\text{Co}_N$ , and  $\text{Ni}_N$  clusters for  $N = 10\text{--}740$  atoms, measured by Billas et al. [92], Apsel et al. [93], and Knickelbein [94, 95] using the gradient-field deflection technique. The step in the Ni data reported by Apsel et al. [93] at  $N = 200$  arises from a change in the measurement temperature and a resulting change in the systematic error. The total moment is enhanced relative to the bulk in all three metals but there is a convergence to the bulk value for cluster sizes greater than  $\sim 600$  atoms. The convergence is not monotonic, however, as gentle ripples in the moment are observed above the noise level throughout the size spectrum. It has recently been suggested that these weak variations may be due to an oscillation of the magnetic anisotropy energy and thus the systematic error with size, rather than changes in the magnetic moment [96].

For clusters smaller than about 20 atoms, dramatic changes occur. The most prominent is observed in Fe clusters in which going from  $\text{Fe}_{12}$  to  $\text{Fe}_{13}$  changes the moment per atom from nearly the atomic limit to close to the bulk value. The detailed changes in small  $\text{Fe}_N$  and  $\text{Ni}_N$  clusters for  $N < 100$  are shown in Figure 7. It is observed that  $\text{Fe}_{12}$  has a moment ( $5.4\mu_B/\text{atom}$ ), which is close to the atomic limit of  $\mu_z = 6\mu_B$ , assuming a  $d^6$  configuration of the valence shell, as in the case of atomic Fe [97]. In order to achieve this the atoms in the cluster must have most of the atomic spin moment ( $3\mu_B$ ) and most of the atomic orbital moment ( $3\mu_B$ ). The addition of a single atom, however, reduces the moment by almost  $3\mu_B$  to  $2.44\mu_B$  observed in  $\text{Fe}_{13}$ . Independent measurements by Knickelbein [94] and Apsel et al. [93] also demonstrate an especially low moment in  $\text{Ni}_{13}$ . Mass spectra of several types of metal cluster including Fe, Ti, Zr,

**Figure 6.** Total moments (in  $\mu_B/\text{atom}$ ) observed in free Fe, Co, and Ni clusters as a function of size measured by Knickelbein [94, 95] (squares), Billas et al. [92] (triangles), and Apsel et al. [93] (circles).

Nb, and Ta [81] have identified  $N = 13$  as a magic number and the structure is assumed to be the densely packed icosahedron shown in the figure.

The results of some calculations are also shown in Figure 7. In all cases the calculation of the magnetic moment is restricted to the spin component; that is, the orbital contribution is neglected and this leads to a general underestimation of the magnetic moment. The tight binding molecular dynamics calculation by Andriotis and Menon [98] of the moment in free  $\text{Fe}_N$  clusters in the range  $N = 1\text{--}169$  shows good agreement with the measured values for  $N > 13$  atoms. In the smallest clusters, however, it continues to predict a moment of about the same size as the larger clusters while the experimental data show the large step up to close to the atomic limit for  $N = 12$ . This discrepancy is interesting as it implies that the step is due to the appearance of the orbital moment at close to its atomic value. It seems therefore that the formation of the close-packed icosahedron at  $N = 13$  almost completely quenches the orbital moment and it does not reappear at larger cluster sizes. For  $N > 13$  the moment is mostly due to spin but is still enhanced significantly relative to the bulk value. Fujima [101] predicted that  $\text{Fe}_7$  clusters with a pentagonal bipyramidal structure have a

**Figure 7.** Total moments (in  $\mu_B/\text{atom}$ ) in free  $\text{Fe}_N$  and  $\text{Ni}_N$  clusters as a function of  $N$  for  $N < 100$  measured by Knickelbein [94, 95] (squares), Billas et al. [92] (triangles), and Apsel et al. [93] (circles). The measured values are compared with calculations by Andriotis and Menon [98] (open circles), Reddy et al. [99] (open circles plus line), and Reuse and Khanna [100] (open squares).

spin moment of  $2.86\mu_B/\text{atom}$  for the bulk interatomic spacing but a slight contraction results in a coplanar (i.e., not collinear) arrangement of the moments.

The calculations for  $\text{Ni}_N$  clusters by Reddy et al. [99] shows a minimum in the moment for  $N = 16$  rather than  $N = 13$  as observed. This is probably due to omission of the orbital moment as in the case of Fe implying again that formation of the icosahedron at  $N = 13$  quenches the orbital moment in Ni clusters though the effect is not as big as in Fe clusters. Reuse and Khanna [100] calculated moments in free Ni clusters for sizes up to  $N = 13$  and found a low moment at this size as well as predicting the icosahedral structure. They did not continue the calculation to larger sizes, however, so the minimum moment predicted by the model may not be at  $N = 13$ .

## 5.2. Antiferromagnetic 3d Transition Metals

The small number of atoms in nanoclusters of metals that are antiferromagnetic in the bulk leads to the possibility of an imbalance of the spin sublattices and frustration. Thus a ferrimagnetic or even ferromagnetic ground state may be expected. An initial experimental study of Cr clusters by Douglass et al. [102] using the gradient field deflection technique showed that  $\text{Cr}_N$  did not have a detectable net magnetic moment for  $N$  in the range 9–31 atoms. The sensitivity of the apparatus led them to conclude that the upper bounds for any net moment varied from  $0.77\mu_B/\text{atom}$

for  $\text{Cr}_9$  to  $0.42\mu_B/\text{atom}$  for  $\text{Cr}_{31}$ . This result was in contrast to many early calculations that predicted large and easily measurable net moments for  $\text{Cr}_N$  clusters for  $N$  up to 51 [103–105], though the expected moments were shown to be highly sensitive to the structure [105]. Lee and Callaway [106] calculated the magnetic moment in  $\text{Cr}_9$  and  $\text{Cr}_{15}$  clusters in a bcc structure as a function of lattice spacing and observed the disappearance of a net moment below a critical value. They found that at the bulk Cr spacing the magnetic moment for both  $\text{Cr}_9$  and  $\text{Cr}_{15}$  clusters was below the detectable threshold of the experiment. A structure-optimized calculation by Cheng and Wang [107] showed a unique growth by dimers up to  $\text{Cr}_{11}$  after which the bcc structure is stabilized. They found that the clusters were always antiferromagnetic with a size-dependent atomic moment. Subsequent calculations have investigated the stability of noncollinear moments resulting from frustration [101, 108]. Kohl and Bertsch [108] found that  $\text{Cr}_N$  clusters for  $N \leq 13$  strongly favor noncollinear configurations and Fujima [101] found that with decreasing interatomic spacing in  $\text{Cr}_7$  clusters, with a pentagonal bipyramid structure, the spin configuration changes from collinear (antiparallel) to coplanar.

Recently the field gradient deflection experiment on Cr clusters was repeated by Bloomfield et al. [109] using a more sensitive apparatus and it was found that all clusters studied in the size range  $N = 8$ –156 atoms showed a net magnetic moment that varied from almost zero to  $1.87\mu_B/\text{atom}$ . Even more interesting was the discovery that at a given cluster size there were always two isomers with different moments. The null result of the earlier experiment was due to the fact that the isomers with the largest moments had a low abundance. For example  $\text{Cr}_9$  has an abundant isomer with a moment of  $0.65\mu_B/\text{atom}$  and a rare one with a moment of  $1.87\mu_B/\text{atom}$ . In this latter case, for a collinear alignment of the moments even if the localized atomic moment was close to the free atom value of  $5\mu_B$  ( $d^5$  configuration), at least six of the nine spins must be parallel. The finding of multiple moments at a given cluster size, however, is not necessarily due to isomers with a different atomic structure. An earlier calculation by Lee and Callaway [110] revealed that  $\text{Cr}_9$  clusters with a bcc structure could exist in several magnetic states with different moments simultaneously. They found that for some atomic spacings four or five states could coexist. The data of Bloomfield et al. [109] may well be an experimental confirmation of this prediction.

Figure 8 shows the magnetic moments in free  $\text{Mn}_N$  clusters for  $N = 11$ –99 measured by Knickelbein [88]. He observed a moment across the size range that attains a maximum value of  $1.5\mu_B/\text{atom}$  for  $N = 15$ . Deep minima were also observed for  $N = 13$  and  $N = 19$  suggesting an icosahedral and double icosahedral structure at these cluster sizes. Calculations are not available for Mn clusters in this size range but density functional calculations for  $\text{Mn}_2$ – $\text{Mn}_5$  [111] find compact and symmetrical equilibrium geometries but also the existence of isomers whose binding energy is only slightly higher than the ground state structure. In all cases magnetic moments of  $5\mu_B$  were found; that is, the spin configuration is ferromagnetic and the spin moment has the atomic value. The conditions required for noncollinear

**Figure 8.** Total moments (in  $\mu_B/\text{atom}$ ) in free  $\text{Mn}_N$  clusters as a function of  $N$  for  $N = 1-99$ . Reprinted with permission from [88], M. B. Knickelbein, *Phys. Rev. Lett.* 86, 5255 (2001). © 2001, American Physical Society.

alignment of the moments in  $\text{Mn}_7$  clusters with a pentagonal bipyramidal structure were examined by Fujima [101]. He found that as the interatomic spacing relative to the bulk value varies between 0.8 and 1 the spin configuration changes from collinear (antiparallel) to disordered to coplanar.

### 5.3. Nonmagnetic 3d and 4d Metals

The Stoner criterion for itinerant magnetism [112] is  $D(E_F)I > 1$  where  $D(E_F)$  is the density of states at the Fermi level and  $I$  is the exchange integral

$$I = \int \gamma^2(\mathbf{r})K(\mathbf{r}) d\mathbf{r} \quad (11)$$

in which  $K(\mathbf{r})$  is the exchange-correlation enhancement of the applied field and  $\gamma(\mathbf{r})$  is proportional to the charge density at the Fermi level. Both  $D(E_F)$  and  $I$  are modified at interfaces and in nanostructures leading to the possibility of stabilizing magnetism in small clusters of elements that are paramagnetic in the bulk. Despite several theoretical predictions for permanent magnetic moments in V clusters [103, 113, 114] none have been detected [102].

There is a general decrease in  $I$  with increasing atomic number [115] so that magnetism is less favored in 4d and 5d elements and is not found in any bulk elements from these series. Although many 4d and 5d metals have been predicted to show magnetism as monolayers [116] there are only two experimentally proven examples of 4d magnetism, that is, Ru monolayers on graphite [117] and free Rh nanoclusters [56].

The magnetic moment per atom as a function of Rh cluster size is shown in Figure 9 and compared with the unrestricted Hartree–Fock calculations by Villaseñor-Gonzalez et al. [118]. The calculation optimized the structure at each size by determining the optimum bond length for icosahedral, fcc, and bcc atomic arrangement and then observing which of these had the highest cohesive energy. The predicted structure at each point is shown in Figure 9 and it is seen that the most stable arrangement alternates between all three structures. The calculations of the magnetic moment

**Figure 9.** Total moments (in  $\mu_B/\text{atom}$ ) in free  $\text{Rh}_N$  clusters for  $N < 100$  measured by Cox et al. [56] (open circles). The measured values are compared with calculations by Villaseñor-Gonzalez et al. [118] (filled circles). The most stable structure, for which the calculation was performed, is shown at each cluster size. Reprinted with permission from [118], P. Villaseñor-Gonzalez et al., *Phys. Rev. B* 55, 15084 (1997). © 1997, American Physical Society.

of the most stable structures at each cluster size reproduce the data reasonably well and in particular reproduce the minima at  $N = 13$ ,  $N = 17$ , and the maximum at  $N = 19$ . Interestingly the most stable structure at  $N = 13$  is found to be bcc-like instead of the icosahedra assumed in the case of the 3d transition metals. A 13-atom icosahedral Rh cluster is found to show a magnetization maximum in contrast to the data. The double icosahedron at  $N = 19$  also shows a maximum in agreement with the measurements. The variations in the magnetic moment per atom derive not only from changes in magnitude of the individual atomic moments but also from spin alignments that are sometimes antiferromagnetic. The neglect of the orbital contribution in this type of calculation may, however, change the agreement with the experiment, in which the total (orbital + spin) moment is measured. Cox et al. [56] also attempted to detect magnetism in Pd and Ru clusters in the size range 10–115 atoms but found no measurable moment and set upper limits of  $0.32\mu_B/\text{atom}$  for  $\text{Ru}_{10}$  clusters and  $0.4\mu_B/\text{atom}$  for  $\text{Pd}_{13}$  clusters. A tight binding calculation including  $s$ ,  $p$  and  $d$ -orbitals of  $\text{Pd}_N$  and  $\text{Rh}_N$  clusters up to  $N = 19$  showed either small or zero moments for Pd clusters and larger values for Rh clusters [119].

### 5.4. Rare Earths

The character of magnetism in rare earths is very different from that of transition metals because the 4f orbitals, which produce most of the magnetic moment, are screened from the environment by the 6s electrons. The localization of the 4f electrons within screening orbitals generally results in both the orbital and spin moments maintaining their full atomic values in the bulk. The large orbital moment and spin–orbit coupling is responsible for the very high values of the magnetic anisotropy energy observed in rare earths.

Magnetic deflection experiments on free Gd clusters [13, 91, 120] at temperatures around 100 K have revealed two types of behavior depending on the number of atoms in the cluster. At some cluster sizes, the deflection profiles show that the cluster magnetization scales with  $B/T$  and these

are assumed to be superparamagnetic as in the case of transition metal clusters. At other sizes the cluster moment, measured from the deflection profile, does not scale with  $B/T$  and in this regime the behavior is ascribed to the moments being blocked so that they are locked to the crystal lattice and undergo the same rotation as the cluster. The simplest interpretation of these observations is that the magnetic anisotropy, which is higher in the rare earths than the transition metals, varies with the number of atoms in the cluster producing a consequent variation in the cluster blocking temperature  $T_B$ . For example Gerion et al. [91] found that  $T_B$  is between 45 and 75 K for  $Gd_{13}$  and  $Gd_{21}$  but around 180 K for  $Gd_{22}$ .

The different experiments disagree, however, on the cluster sizes that show the different behaviors. Douglass et al. [120] found that all cluster sizes in the range  $Gd_{11}$ – $Gd_{26}$  displayed locked-moment behavior with the exception of  $Gd_{22}$ , which was superparamagnetic. In contrast, Gerion et al. [91] showed that  $Gd_{13}$  and  $Gd_{21}$  were superparamagnetic while  $Gd_{22}$  was blocked. Tb also shows the locked-moment or superparamagnetic behaviors described above depending on the cluster size [121].

For the superparamagnetic clusters it is possible to extract the total moment per atom from the magnetization vs  $B/T$  using Eq. (2) as with the transition metals and in all cases moments/atom significantly lower than the bulk value were found. For example  $Gd_{13}$  and  $Gd_{21}$  clusters have moments of 5.4 and  $5\mu_B$ /atom respectively compared with a bulk value of  $7.55\mu_B$ /atom. This has been explained by a theoretical model that takes into account an Ruderman, Kittel, Kasuya and Yosida (RKKY)-type interaction between the atoms in which the exchange force between nearest neighbors is ferromagnetic but switches to antiferromagnetic between second nearest neighbors [89]. The clusters are found to adopt a hexagonal structure and within a range of the ratio of the ferromagnetic to antiferromagnetic coupling strengths, canting of individual atomic spins away from perfect ferromagnetic alignment is predicted. Thus the moment per atom measured along the applied field will be reduced. The reduction in moment relative to the bulk is also observed in Tb clusters [121], presumably for the same reason.

### 5.5. Magnetic Ordering Temperature

The thermal behavior of the moment has so far been discussed in terms of superparamagnetism where the cluster supermoment is excited over the cluster anisotropy barrier. At sufficiently high temperatures the internal spin alignment will be disrupted leading eventually to normal paramagnetism. Gerion et al. [90] measured the specific heat of free  $Fe_{250-290}$ ,  $Co_{200-240}$ , and  $Ni_{200-240}$  clusters in the temperature range 80–900 K. The method involves using an experimental setup similar to that used in measuring the magnetic moments and the perturbation of the beam profile in response to a heating laser is used to determine the specific heat. The clearest results are for  $Ni_{200-240}$  which shows a broad peak centered at 340 K on top of a nearly constant baseline of 6 cal/(mol K)—the classical Dulong and Petite value for bulk Ni. The peak is interpreted as due to the ferromagnetic to paramagnetic phase transition in the clusters

and its width is well described by the mean-field approximation. The temperature of the transition is significantly reduced relative to the bulk value of 627 K. The specific heat for the  $Co_{200-240}$  clusters shows a monotonic rise from 5.5 cal/(mol K) at 300 K to 15 cal/(mol K) at 900 K implying that the phase transition is not reachable in the temperature range of the experiment. The behavior of  $Fe_{250-290}$  clusters is more enigmatic showing specific heat values significantly lower than the Dulong and Petite values. A peak at around  $T = 600$  K does occur but is poorly described by mean-field theory. One possibility discussed in the paper is that Fe clusters undergo a magnetic transition between a high-moment and low-moment state with different lattice parameters.

Billas et al. [12] observed the magnetic ordering temperatures in  $Fe_N$  and  $Ni_N$  clusters directly by measuring the magnetic moment as a function of temperature up to over 900 K. In all cases they found the magnetic moment was constant above some critical temperature  $T_C(N)$ , which was interpreted as the transition temperature for paramagnetism. The magnetization in this state,  $\mu_{para}$ , should attain a value  $\mu_{T=0}/\sqrt{N}$  corresponding to  $N$  randomly aligned atomic moments so that in a cluster where  $N \sim 100$ ,  $\mu_{para}$  is significantly above zero. In fact it was found that  $\mu_{para}$  was higher than  $\mu_{T=0}/\sqrt{N}$ . This was later explained by Pastor and Dorantes-Dávila [122] as due to short-range magnetic order (SRMO) above the transition temperature, which is also observed in bulk magnetic materials. The effect of this is to increase the paramagnetic moment to  $\mu_{T=0}\sqrt{\nu/N}$  where  $\nu$  is the average number of atoms in a SRMO domain.

The high temperature behavior of rare-earth clusters contrasts with that of the transition metals. The measured ordering temperatures (420 K for  $Gd_{21}$  and over 500 K for  $Gd_{13}$ ) are significantly higher than the bulk value of 293 K. In addition the moment above the ordering temperature tends asymptotically to  $\mu_{T=0}/\sqrt{N}$  [91] indicating that there is no SRMO above the ordering temperature and the disorder is on the atomic scale. The decay in magnetic moment per atom with temperature found for  $Gd_{13}$  clusters is consistent with the canted spin model [91, 123].

## 6. MAGNETISM IN EXPOSED CLUSTERS ADSORBED ON SURFACES

In this section, the behavior of magnetic clusters deposited on a surface and left exposed to vacuum will be considered. Working in this regime requires that the cluster deposition must be done *in-situ* and the measurements performed in very good UHV conditions ( $\sim 10^{-11}$  mbar) to avoid contamination of the clusters. In the case of free clusters, some gas adsorption on the clusters can be tolerated as the mass separation can distinguish the clean clusters from those with gas molecules attached. In deposited samples, most *in-situ* magnetic measurements have been done with spatially averaged techniques that measure the entire cluster assembly and are unable to discriminate between the behavior of clean and contaminated clusters. There are, however, several experimental advantages in studying adsorbed clusters; for example, it is possible to exert accurate control over the cluster temperature down to low cryogenic values allowing the blocked state to be observed. In addition structural

techniques such as X-ray diffraction, STM, and TEM can be used as well as more powerful magnetic probes such as XMCD, which is able to determine the spin and orbital components of the total moment. Finally, the interactions between the clusters can be studied by accumulating a sufficient density on the surface.

### 6.1. Magnetism in Isolated Adsorbed Clusters

A natural starting point in describing adsorbed clusters is to review measurements carried out at very low coverages to determine the behavior of the isolated particles. An important question to address is whether the enhanced magnetic moments observed in free transition metal clusters are retained if the cluster is adsorbed on a surface. The earliest reported studies of isolated and exposed magnetic clusters deposited from the gas phase onto surfaces in UHV were of size-selected 2.5 nm (700-atom) Mn clusters at very low coverages on HOPG substrates [124, 125]. Photoelectron spectroscopy using synchrotron radiation was used to probe shallow core levels and showed changes in the lineshape of the Mn 3s photoemission spectra that were consistent with an increased magnetic moment of the atoms in the cluster estimated at about 20% larger than the bulk value. The experiment was insensitive to the spin configuration.

More recently the powerful XMCD technique has been utilized in deposited cluster experiments and as well as addressing the magnitude of the moment it is possible to obtain information on the separate contributions of the spin and orbital components. To gain some understanding of the effect of the interaction with the substrate it is useful to consider results from isolated atoms of Fe, Co, and Ni adsorbed on K and Na films obtained by Gambardella et al. [126]. They studied films with coverages as low as 0.2% of a monolayer and used the most accurately measured quantity obtainable by the XMCD technique, that is, the ratio (see Section 3)

$$R = \frac{\langle L_z \rangle}{2\langle S_z \rangle + 7\langle T_z \rangle} \quad (12)$$

to determine how “atomic-like” the adsorbed atoms were. The valence state of each element was determined by modelling the shape of the  $L_{2,3}$  absorption edge and was found to be  $d^7$  for Fe,  $d^8$  for Co, and  $d^9$  for Ni. Knowing this the quantities in Eq. (12) can be obtained by Hund’s rules and the atomic value of  $R$  ( $R_{\text{atom}}$ ) compared with the measured one ( $R_{\text{exp}}$ ). The ratio  $R_{\text{exp}}/R_{\text{atom}}$  was found to be 100%, 89%, and 63% for Ni, Co, and Fe respectively; that is, Ni has the same moments as in a free atom with the same valence while Co and Fe show a 10% and a 37% decrease respectively. The reductions are due to a partial quenching of the orbital moment but even in the case of Fe the quenching is much less than in isolated Fe impurities embedded in a bulk host.

Mass-selected  $\text{Fe}_N$  clusters with sizes  $N = 2-9$  adsorbed, at the dilute limit, on Ni thin film substrates have been studied by Lau et al. [127]. For such small clusters it is important to ensure a soft landing and this was achieved by depositing the clusters, decelerated to 2 eV/atom onto Ar multilayers that were physisorbed at 15 K on the substrate. These

were then removed by flash-heating to 100 K. Substantial increases in the orbital to spin ratio and the spin and orbital moments per valence band hole relative to the bulk were observed but uncertainty in  $n_h$  and the  $\langle T_z \rangle$  term meant that absolute values were not given. Larger clusters in the size range 180–690 atoms deposited at low coverage on graphite were studied using XMCD by Baker et al. [128]. In this study the value of  $n_h$  was obtained by comparing the total Fe  $L_{2,3}$  absorption cross section of the clusters with that of a thick conventional film deposited *in-situ* and was found to be the same within experimental uncertainty. Thus  $n_h$  could be taken as the bulk value of 3.39 [129]. In addition the  $\langle T_z \rangle$  term was obtained by measuring the dichroism as a function of the incident angle of the X-rays so absolute values of the magnetic moments were obtained and the total moment was found to be about 10% greater than the bulk value with about half of this enhancement coming from an increased orbital contribution.

The different datasets for adsorbed Fe atoms [126], small  $\text{Fe}_N$  ( $N = 1-9$ ) clusters [127], and large Fe clusters [128] can be compared directly by plotting the orbital ( $\langle L_z \rangle$ ) and spin ( $\langle S_z \rangle$ ) angular momenta per valence band hole,  $n_h$ , as is done in Figure 10. For the adsorbed Fe atoms on K, the valence state was identified as  $d^7$  so  $n_h = 3$  [126]. The orbital and spin moments for the isolated atoms shown in Figure 10 were derived from the published  $R$  value, assuming that most of the reduction in  $R$  is due to a partial quenching of the orbital moment. For the small clusters the published data for the orbital component,  $\langle L_z \rangle/n_h$ , can be entered directly on the plot. The spin term is given as  $\langle S_z \rangle + 7/2\langle T_z \rangle$  and the pure spin component has been extracted assum-

**Figure 10.** Angular momentum values  $\langle S_z \rangle$  and  $\langle L_z \rangle$  measured by XMCD for Fe clusters adsorbed on surfaces.  $\text{Fe}_1/\text{K}$  data from Gambardella et al. [126],  $\text{Fe}_1\text{--}\text{Fe}_9/\text{Ni}$  data from Lau et al. [127], and  $\text{Fe}_{180}\text{--}\text{Fe}_{690}/\text{HOPG}$  data from Baker et al. [128].

ing that  $\langle T_z \rangle$  is the average of the value in isolated atoms ( $-1/7$ ) and that in the larger deposited clusters ( $-0.11/7$ ) [128]. The  $\langle L_z \rangle/n_h$  and  $\langle S_z \rangle/n_h$  values for the larger clusters were obtained from the published orbital and spin magnetic moments and dividing by the value of  $n_h$  (3.39) measured during the experiment. Whatever the inaccuracies in the assumptions made in the comparison of the different datasets and notwithstanding the different substrates used in the experiments some general conclusions can be drawn from Figure 10 about the size-dependent magnetic behavior of supported Fe nanoclusters. Both the orbital and spin components decrease rapidly with cluster size and with only three atoms/cluster values close to the bulk value are found for both  $\langle L_z \rangle/n_h$  and  $\langle S_z \rangle/n_h$ . This is different from the behavior of free Fe clusters in which moments close to the atomic limit were found up to  $N = 12$ . There is evidence for short and long period oscillations in both moments as a function of size. Over a wide size range the total magnetic moment is about 10% larger than the bulk with about half of the enhancement coming from the orbital moment. The adsorbed cluster moments converge with the bulk values for  $N \geq 700$ , as observed in free clusters.

Ab initio calculations of the spin moment in small  $4d$  metal clusters with different geometries on Ag(100) were carried out by Wildbererger et al. [130]. While they found a permanent moment in dimers for elements between Mo and Rh in the periodic table, magnetism was less favored as the cluster size increased. In the case of the largest clusters studied (i.e., nine-atom flat islands), only Ru and Rh had stable moments. The Rh moment was  $0.6\mu_B$ , which compares with  $0.8\mu_B$  measured in nine-atom free Rh clusters [56].

## 6.2. Effect of Cluster-Cluster Interactions

All the results presented are at the dilute limit when the clusters can be assumed to be noninteracting. As the density on a surface is increased the effect of the interaction between the clusters can be observed. Figure 11 shows how the orbital and spin moments, measured by XMCD, vary with coverage for unfiltered Fe clusters with a mean size of 600 atoms deposited on HOPG [14]. The coverage is expressed as the equivalent film thickness in  $\text{\AA}$  so for clusters of this size a complete monolayer corresponds to  $\sim 20 \text{\AA}$ . Also shown on the diagram (filled symbols) are the measured moments for a mass-selected deposit with the filter set to the mean value of the unfiltered distribution. It is evident that the orbital and spin values at low coverage in the filtered and unfiltered deposits are similar. With increasing coverage the orbital moment drops toward the bulk value as the clusters come into contact. The spin term increases but this is due to a decreasing contribution from the (negative)  $\mu_T$  (dipole) component as the film becomes more bulklike.

Figure 12 shows the development with cluster density of the remanence at 40 K of films produced by depositing unfiltered Fe clusters with a mean size of  $\sim 450$  atoms on Cu and HOPG substrates [61]. The data were obtained using magnetic linear and circular dichroism in the angular distribution of Fe  $3p$  photoelectrons (MLDAD and MCDAD) that measure, respectively, the in-plane and out-of-plane

**Figure 11.** Orbital (unfilled squares) and spin (unfilled circles) moments for unfiltered Fe clusters (mean size 600 atoms) deposited on HOPG as a function of cluster coverage expressed as the equivalent film thickness. The filled symbols are the values for a mass-filtered deposit with the filter central mass set to 600 atoms. An STM image at a coverage of approximately 0.2 cluster monolayers ( $4 \text{\AA}$ ) is shown. Reprinted with permission from [14], K. W. Edmonds et al., *Phys. Rev. B* 60, 472 (1999). © 1999, American Physical Society.

remanent magnetization. At this temperature, isolated clusters are superparamagnetic and will have zero remanence. The behavior is independent of substrate and for coverages below half a cluster monolayer, the MLDAD signal is zero within experimental error. A small but finite MLDAD signal

**Figure 12.** MCDAD (out-of-plane remanent magnetization) and MLDAD (in-plane remanent magnetization) signals as a function of coverage for unfiltered Fe clusters with an average size  $\sim 450$  atoms deposited on graphite (open circles) and Cu (filled circles). All measurements were at 40 K. The dense film shows an in-plane anisotropy with a remanence higher than a molecular beam epitaxy-grown film deposited *in-situ*. An STM image at a coverage of approximately 0.2 cluster monolayers is shown. Reprinted with permission from [61], K. W. Edmonds et al., *J. Appl. Phys.* 88, 3414 (2000). © 2000, American Institute of Physics.

is observed between 0.5 and 1 ML thickness, followed by a steep rise between 1 and 1.4 ML. No MCDAD signal is visible at 40 K at any coverage above the noise level.

As the coverage increases, the interactions between the clusters lead to a stabilization of the magnetization at 40 K. This, however, produces strong out-of-plane demagnetizing fields, and so the remanent magnetization of the sample is in-plane due to the coherent shape anisotropy of the film. At the highest coverage the remanence exceeds that of an Fe film of the same thickness grown *in-situ* with a conventional evaporator.

## 7. MAGNETISM IN EMBEDDED CLUSTERS

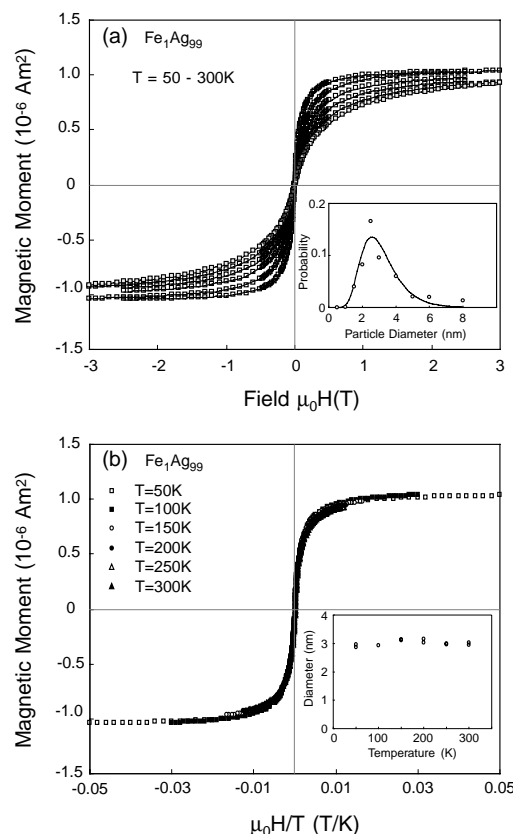

Co-depositing clusters and vapor from a conventional deposition source enables one to embed clusters with a known size distribution and a controlled volume fraction in a matrix of another material. The removal of the requirement to work *in-situ* allows a wide range of measurement techniques to be applied including conventional magnetometry.

### 7.1. Isolated Clusters—The Dilute Limit

A comprehensive magnetometry study of Fe and Co clusters deposited from the gas phase and embedded in co-deposited Ag films at very low volume fraction was carried out by Binns and Maher [131]. Magnetic isotherms measured in the plane of the surface, at temperatures 50–300 K, of unfiltered Fe clusters embedded with a 1% volume fraction in Ag are shown in Figure 13a (symbols). Each was fitted by a set of Langevin functions [Eq. (2)] with different moment values where the amplitude of each Langevin function was a fitting variable. Ten size bins were used in the range 0.5–8 nm and the average amplitude as a function of particle size (moment) after fitting all data sets is shown in the inset in Figure 13a. The calculated curves are displayed as lines and the fit is excellent in every case. The size distribution is the usual asymmetric shape and fitting it to a log-normal distribution (inset) gives a most probable cluster size of 2.57 nm with a standard deviation of 1.95 giving a median diameter of 3.0 nm. This distribution is similar to those obtained by direct STM imaging of deposited cluster films. It was pointed out by Allia et al. [132], however, that this procedure is hazardous. In an interacting system it is possible to obtain an excellent Langevin fit with an “apparent size” that is different from the real size and varies with temperature. Three conditions must be met to confirm ideal superparamagnetism with no interactions between the clusters:

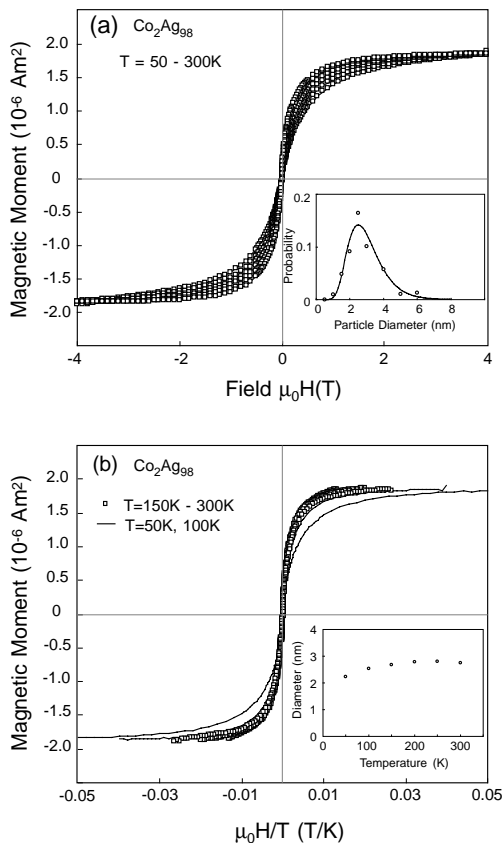

- The isotherms should display no hysteresis.
- The isotherms should scale with  $H/T$ .
- The fitted size distribution should be independent of temperature.

The lack of hysteresis is evident and the other two conditions are demonstrated in Figure 13b, which is the data in Figure 13a replotted against  $H/T$  and an inset that shows the invariance with temperature of the median size obtained from the Langevin fits. This sample thus displays perfect superparamagnetism above 50 K.

**Figure 13.** (a) Magnetization isotherms in the range 50–300 K of  $\text{Fe}_1\text{Ag}_{99}$  (open squares) compared to fits by Langevin functions (lines) with a size distribution represented by 10 size bins in the range 0.5–8 nm. The inset shows the average probability of each bin for the optimum fit to curves at temperatures  $> 50$  K ( $\circ$ ) and the corresponding log-normal distribution (line) with  $d_{\text{max}} = 2.57$  nm and  $\sigma = 1.95$ . (b) The same data plotted against  $H/T$  showing the scaling predicted by the Langevin functions. The inset shows the median size from the distributions as a function of temperature and demonstrates the invariance of the fitted size vs  $T$  required for an ideal superparamagnetic system. The magnetic isotherms measured in the plane of the surface at temperatures 50–300 K of unfiltered Co clusters embedded with a 2% volume fraction in Ag [131] are shown in Figure 14a (symbols) along with the Langevin fits using the procedure already described (lines). In this case the fitted median size displayed in the inset in Figure 14b is temperature-dependent below about 150 K. This could either be due to weak dipolar interactions at the slightly higher volume fraction [132] or to the higher anisotropy of the Co clusters relative to Fe requiring a higher temperature to reach the superparamagnetic limit. In either case the superparamagnetic limit is reached at a temperature  $\sim 150$  K. This is also demonstrated in Figure 14b in which the same data are plotted against  $H/T$  and only the 100 and 50 K curves are visibly separated from the rest. The size distribution obtained by Langevin fits as described above to the curves taken at 150 K and above along with the fitted log-normal distribution is shown in the inset in Figure 14a.

**Figure 14.** (a) Magnetization isotherms in the range 50–300 K of  $\text{Co}_2\text{Ag}_{98}$  (open squares) compared to fits by Langevin functions (lines) with a size distribution represented by 10 size bins in the range 0.5–8 nm. The inset shows the average probability of each bin for the optimum fit to curves at temperatures >150 K (○) and the corresponding log-normal distribution (line) with  $d_{\text{max}} = 2.45$  nm and  $\sigma = 1.81$ . (b) The same data plotted against  $H/T$  showing the scaling predicted by the Langevin functions for data in the range 150–300 K (open squares). The data at 100 and 50 K (line) show a departure from the scaling law. The inset shows the fitted median size as a function of temperature and demonstrates that the apparent size becomes temperature-invariant (the true size) above 150 K. For the Co clusters the most probable size is 2.45 nm with a standard deviation of 1.81 giving a median diameter of 2.8 nm.

At 2 K most of the clusters in the  $\text{Fe}_1\text{Ag}_{99}$  sample discussed above are below the blocking temperature and as shown in Figure 15a the magnetic isotherm develops hysteresis [131]. The remanence,  $M_r$ , of an assembly of blocked particles reveals the symmetry of the anisotropy axes and their distribution in space. For example uniaxial anisotropy axes randomly distributed over three dimensions give  $M_r/M_s = 0.5$  but if they are distributed over two dimensions (2D) in the plane of the applied field,  $M_r/M_s = 0.71$ . The equivalent values for cubic anisotropy axes are 0.82 distributed over 3D and 0.91 distributed over 2D. The measured remanence is  $\approx 0.4$  and is thus closest to the case for uniaxial anisotropy axes randomly distributed over 3D. In this case the magnetization between saturation and

**Figure 15.** (a) Magnetization isotherms at 2 K of  $\text{Fe}_1\text{Ag}_{99}$  sample: (●) field sweeping down, (○) field sweeping up. The inset shows the decay from saturation (●) compared to a calculation (line) assuming a random distribution of uniaxial anisotropy axes [Eq. (13)]. The best fit anisotropy constant is displayed in the inset. (b) As (a) but for  $\text{Co}_2\text{Ag}_{98}$ . Reprinted with permission from [132], C. Binns and M. J. Maher, *New J. Phys.* 4, 85.1 (2002). © 2002, IOP Publishing.

remanence is obtained at each field value by minimizing over all alignments of the anisotropy axes the intraparticle energies

$$E_\phi = KV \sin^2(\phi - \theta) - \mu_B \cos \phi \quad (13)$$

where  $K$  is the anisotropy constant,  $V$  is the particle volume, and  $\theta$  and  $\phi$  are the angles between the applied field and the anisotropy axis and particle magnetization vector respectively. The inset in Figure 15a compares the curve calculated thus with the data and it is evident that this simple model reproduces the data accurately. So in zero field the system is a collection of static, randomly aligned cluster giant moments each pointing along the local anisotropy axis. The anisotropy constant is a parameter of the fit and optimizes at  $K = 2.63 \times 10^5 \text{ J m}^{-3}$ , which is in reasonable agreement with the value of  $K = 2.3 \times 10^5 \text{ J m}^{-3}$  obtained by a SQUID measurement of a similar sample [133] and is about 5 times the bulk value. As discussed next a more detailed study of cluster anisotropy by Jamet et al. [75] showed that the magnetocrystalline term is a small component of the total measured value. A uniaxial anisotropy of the individual clusters is expected as it will be produced by any incomplete atomic shell. Only clusters containing magic numbers of atoms are expected to have a cubic anisotropy but even in this case it is likely to be lost due to other processes during deposition such as collision with the substrate.

The blocking temperature,  $T_b$ , of a cluster with a volume  $V$  and anisotropy constant  $K$  is given by

$$T_b = \frac{KV}{k_B \ln(\tau_{\text{exp}}/\tau_0)} \quad (14)$$

where  $\tau_{\text{exp}}$  is the measurement time ( $\sim 100$  sec for dc magnetometry) and  $\tau_0$  is the lifetime due to the natural gyro-magnetic frequency of the particles. A measurement of Fe nanocluster with a similar size distribution embedded in Ag yielded  $\tau_0 = 10^{-8}$  s [133] so for the Fe particles having the median size (3 nm) in the  $\text{Fe}_{10}\text{Ag}_{90}$  sample, with the anisotropy constant shown in Figure 15a, a value of  $T_b = 8.5$  K is obtained. At 2 K clusters with a diameter less than 1.4 nm, or about 5% of the distribution shown in the inset in Figure 13a, are unblocked explaining in part the observation of a remanence less than 0.5.

The magnetic isotherms were found to be almost isotropic but a slightly higher anisotropy constant was found by fitting Eq. (13) to the out-of-plane data. This was interpreted as a slight shape or stress anisotropy resulting from the deposition onto the surface. The coherent in-plane anisotropy of the cluster film was estimated to be  $\sim 9 \times 10^3 \text{ J m}^{-3}$  [131].

The isotherms at 2 K of the dilute Co cluster sample are shown in Figure 15b. Again the remanence is slightly less than 50% and assuming the clusters are randomly oriented over 3D and have a uniaxial anisotropy the approach to saturation can be modelled using Eq. (13). This is compared to the data in the inset in Figure 15b and the anisotropy constant obtained is over three times larger than that found in the Fe cluster assembly giving a blocking temperature of  $\sim 20$  K. The larger blocking temperature will require a higher temperature than Fe clusters to obtain superparamagnetism as already observed.

Jamet et al. [75] provided yet more detail on the isolated properties of embedded nanoparticles by using the  $\mu$ -SQUID technique (Section 3) to determine the three-dimensional switching field distribution of a single Co nanoparticle containing about 1000 atoms embedded in Nb. The data could be fitted by the Stoner–Wohlfarth model [6] with the anisotropy constants:  $K_1 = 2.2 \times 10^5 \text{ J m}^{-3}$  along the easy direction,  $K_2 = 0.9 \times 10^5 \text{ J m}^{-3}$  along the hard direction and a fourth order term, and  $K_4 = 0.1 \times 10^5 \text{ J m}^{-3}$ . By estimating the contributions from shape and magnetoelastic terms they concluded that the main source of anisotropy in the particle was the surface anisotropy term described by Néel [134] with the fourth order term corresponding to the magnetocrystalline anisotropy.

An XMCD study of Co clusters assembled at low volume fraction in Cu matrices was carried out by Eastham and Kirkman [18] who measured an orbital magnetic moment 2.2 times larger than the bulk value—a similar enhancement to that found in exposed Fe clusters (Section 5). By a careful analysis of the orbital to spin ratio as a function of the applied field, they were able to show that the atomic spin direction is determined only by the external field and the surface anisotropy, which again highlights the importance of this term in determining the cluster magnetization.

As pointed out earlier, one of the most important advantages of cluster assembly is the ability to prepare granular films of miscible materials and thus magnetic grains can be

studied in a magnetic matrix. Baker et al. [128] used MXCD to measure the orbital and spin moments in mass-selected Fe clusters coated with Co. As discussed in Section 3 XMCD can focus on the orbital and spin values within specific elements and they found that the Co coating increases the total magnetic moment within the Fe particles to a value similar to that found in free Fe clusters. This was due to a large increase in the spin moment as also observed in Fe–Co alloys and within a rigid band model is ascribed to an increase in the majority spin band population by electrons from the Co [135]. In the case of the cluster-assembled film there is not a well mixed alloy although there may be alloying at the interface [16]. In addition, no significant change was observed in the total Fe  $L$ -edge X-ray absorption (“white line”) intensity indicating that there is no significant change in the number of Fermi level  $d$ -band holes in the Fe. The increase in the spin moment was attributed to an increase in the Fe valence band exchange splitting produced by the interaction with the Co.

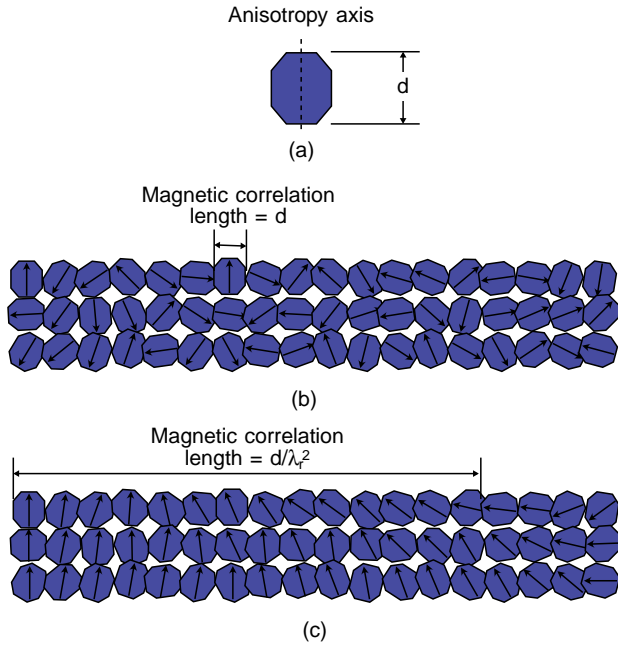

## 7.2. Interacting Cluster Films

Developing a detailed understanding of the effect of interactions between clusters embedded at higher volume fractions is important not only to satisfy scientific curiosity but also in order to fully exploit such systems in the development of high performance magnetic materials, for example high-moment films (see next section). In such applications the required volume fraction of nanoparticles is close to or above the percolation threshold and is well into the strong interaction regime. When the interparticle interactions become significant the system displays a rich variety of magnetic configurations resulting from competing energy terms. The dipolar interaction introduces frustration as it is impossible to produce an optimum alignment for every particle. In addition there is frustration resulting from the competition between the interparticle dipolar and exchange terms and the intraparticle anisotropy energy (magnetocrystalline, shape, magnetoelastic, etc.) that requires the magnetization vector to be aligned along specific axes in each particle.

A thorough investigation of Fe clusters assembled in Ag matrices at volume fractions from the dilute limit to pure cluster films with no matrix was carried out by Binns et al. [74]. Below the percolation threshold (volume fraction  $< 30\%$ ) a Curie–Weiss-like extension to superparamagnetism developed by Allia et al. [132] was used to analyze the magnetic isotherms. It was found that the films could be described in terms of cluster aggregates, in which the individual nanoclusters were exchange-coupled. For example in a film with a 10% volume fraction of Fe clusters, a typical aggregate would consist of 6–7 of the deposited nanoclusters. These aggregates would behave as a single particle and would interact with each other by dipolar forces.

With a further increase in volume fraction up to the pure cluster limit, the magnetic configuration in the film at 300 K becomes a correlated superspin glass [74, 131]. This state is illustrated in Figure 16c and results from the random anisotropy whose length scale is that of a single nanocluster. The exchange coupling between adjacent clusters tries to align their moments but perfect alignment is prevented

**Figure 16.** (a) Schematic representation of a magnetic nanoparticle with a uniaxial anisotropy axis (represented by a slight elongation). (b) and (c) A stack of particles with randomly oriented anisotropy axes. In (b)  $\lambda_r \geq 1$  and the magnetization vector points along the local anisotropy axis so the magnetic correlation length is a single particle diameter. In (c)  $\lambda_r < 1$  and the magnetic vectors are nearly aligned. The random perturbation from perfect alignment results in a finite magnetic correlation length that is a factor  $1/\lambda_r^2$  larger than a single particle. Reprinted with permission from [131], C. Binns and M. J. Maher, *New J. Phys.* 4, 85.1 (2002). © 2002, IOP Publishing.

by the random direction of the anisotropy axes of neighboring clusters. This produces a small randomized canting of adjacent spins resulting in a loss of magnetic order after a sufficient number of clusters. Thus there is a mesoscopic magnetic correlation length that is much greater than a single cluster diameter. At high volume fractions the magnetic isotherms were analyzed using a random anisotropy (RA) model developed by several authors in the last two decades [136–139]. In the RA formalism, the magnetic ground state in a granular film is determined by the relative strength of a random anisotropy field

$$H_r = \frac{2K_r}{M_s} \quad (15)$$

and an exchange field

$$H_{\text{ex}} = \frac{2A}{M_s R_a^2} \quad (16)$$

where  $K_r$  is the (randomly oriented) anisotropy of the grains,  $M_s$  is their saturation magnetization,  $A$  is the exchange constant for the interaction between the grains, and  $R_a$  is the nanometer sized region over which the local anisotropy axis is correlated (i.e., the characteristic grain

size). Their relative strength is given by the dimensionless parameter

$$\lambda_r = \frac{H_r}{H_{\text{ex}}} = \frac{K_r R_a^2}{A} \quad (17)$$

The model was developed to describe amorphous films in which a local, randomly oriented anisotropy is due to local atomic order. It is even better suited to providing a description of the magnetization in cluster-assembled films in which the distance  $R_a$  over which an anisotropy axis is correlated is well defined (i.e., the particle diameter). In addition, as pointed out by Löffler et al. [140], the exchange interaction at the boundaries between particles is weaker than the intraparticle atomic exchange further reinforcing the image of separate but interacting particles.

For  $\lambda_r > 1$  the magnetic correlation length at zero field is  $R_a$ , and the magnetic vector in each particle points along the local intraparticle anisotropy axis. Note that in an arrow representation this state would be identical to that in isolated noninteracting particles at absolute zero. This regime is illustrated in Figure 16b. With increasing interparticle exchange (or decreasing intraparticle anisotropy) the configuration becomes a correlated superspin glass (CSSG) in which the magnetization vector in neighboring particles is nearly aligned but the random deviation of the moments from perfect alignment produces a smooth rotation of the magnetization throughout the system with a magnetic correlation length that is a factor  $1/\lambda_r^2$  larger than the particle diameter. This regime is illustrated in Figure 16c. The disordered CSSG state is fragile and application of a small field produces a “ferromagnet with wandering axes” [137] with an approach to saturation that follows a  $1/\sqrt{H}$  dependence in three dimensions [137] and a  $1/H$  dependence in two dimensions [136]. These both change to a  $1/H^2$  dependence above a crossover field [139]  $H_{\text{co}} = 2A/M_s R_a^2$ .

Other studies of pure Fe and Ni cluster-assembled films have used the RA model to analyze magnetization data from cluster-assembled films [140–142]. The magnetic configuration could be described as a CSSG in all cases. This is an important find for technological applications as it shows that dense interacting cluster assemblies are magnetically soft.

Binns et al. [131] found that at 300 K, films with an Fe volume fraction  $>70\%$  formed CSSGs but at 2 K, for all volume fractions, Fe cluster assemblies coated with Ag were in the random magnetization state depicted in Figure 16b. Thus at a sufficiently low temperature the anisotropy dominates the exchange coupling and the magnetization at zero field in each nanocluster is forced to lie along the local anisotropy axis. This is the state predicted by the RA model for  $\lambda_r > 1$ . The increase in anisotropy at low temperature was ascribed to magnetoelastic stress induced by the different expansion coefficients of the Fe cluster film and the Ag capping layer. This analysis was supported by the observation that uncapped pure cluster samples transferred into the magnetometer in UHV, as described in Section 3, did not undergo the transition to the random cluster magnetization at low temperature and remained in the CSSG state all the way down to 2 K [74, 131]. A summary of the behavior of Fe cluster assemblies embedded in Ag is provided by the phase diagram shown in Figure 17 [74].

**Figure 17.** Magnetic phase diagram of Ag-capped Fe nanoclusters (3 nm diameter) assembled in Ag matrices.

## 8. APPLICATIONS OF CLUSTER-ASSEMBLED FILMS

In this section examples of technological applications that exploit the flexibility in the control of magnetic properties afforded by assembling films from nanoclusters will be described.

### 8.1. High-Saturation-Moment Materials

One of the important advantages of the cluster deposition technique in the creation of artificial materials is its ability to make granular mixtures of even the most miscible metals. For example a study using extended X-ray absorption fine structure (EXAFS) has shown [21] that for Co clusters embedded in Pt, alloying is limited to a single atomic layer at the interface leaving a pure core of Co within the grains. The same result was found for Co clusters embedded in a Nb matrix [143]. For Fe clusters embedded in a Co film, XMCD data show that the number of Fe 3d holes per atom is indistinguishable from the bulk demonstrating that the grains consist mainly of pure Fe with intermixing confined to the particle surfaces [16]. Creating granular mixtures of miscible materials is important for the creation of new magnetic materials.

A prized discovery would be a substance that had a saturation magnetization density greater than conventional  $\text{Fe}_{70}\text{Co}_{30}$  alloy (permendur)—the most magnetic material available today. This would be an important find for a wide range of technologies and most immediately for the magnetic recording industry. The conventional alloy has a magnetic moment per atom of  $2.45\mu_B$ , which is 10% greater than bulk Fe. Free Fe nanoparticles can have magnetic moments up to  $5.4\mu_B$  per atom in the case of  $\text{Fe}_{12}$  (see Fig. 7) but these reduce significantly when the clusters are deposited on a surface (see Fig. 10) and drop further toward the bulk value when the particles are brought into contact to make a film [14]. On the other hand it has been shown that coating the supported Fe nanoclusters with Co restores the magnetic moment back to the free cluster value [128]. The results are displayed in Figure 18, which shows the spin moment

**Figure 18.** Variation of the spin moment with cluster size in exposed Fe clusters on HOPG (filled squares), Co-coated Fe clusters on HOPG (open squares), and the calculated spin moments for free Fe clusters coated with Co [144]. Also shown is the spin moment measured by XMCD in a conventional Fe film deposited *in-situ* and the accepted spin moment for bulk Fe. Correcting the measured spin moments in the Co-coated clusters by the discrepancy gives the values shown by the filled circles.

in  $\mu_B/\text{atom}$  of exposed (filled squares) and Co-coated (open squares) Fe clusters on HOPG as a function of size. The data reveal that the enhanced spin moments measured in the exposed clusters relative to that in a conventional Fe film deposited *in-situ* are increased further by about 10% after coating with Co. Also shown in Figure 18 are the values of the spin moments in  $\text{Fe}_n\text{Co}_{1021-n}$  clusters, composed of a pure Fe core coated with Co, as a function of  $n$  calculated by Xie and Blackman [144] (open circles). These are higher than the measured values but as discussed in Section 6, even after accounting for the  $\langle T_z \rangle$  term, XMCD measurements of spin moments have systematic errors due to uncertainties in the number of valence band holes,  $n_h$ , and inaccuracies in applying the magneto-optical sum rules [63, 64] to solid state systems. In addition XMCD is insensitive to any spin polarization of the  $s$ - $p$  electrons, which is included in the calculation. An estimate of the systematic error in this particular experiment can be obtained by comparing the spin moment measured in a conventional Fe film under the same experimental conditions to the accepted bulk Fe spin moment. Shifting the measured values for the Co-coated Fe clusters by this difference yields the values shown by the filled circles, which agree well with the calculation. This procedure is, however, insecure since all the sources of error (e.g.,  $n_h$ ,  $s$ - $p$  spin polarization, etc.) are different in the clusters to the bulk. Clearly however, XMCD underestimates the spin moment and coating the Fe clusters with Co substantially increases their spin moment. The orbital moment averages  $0.16\mu_B$  over the size range shown [128] and adding this to the data gives a total magnetic moment of  $2.7\mu_B/\text{atom}$  in 100-atom Fe clusters coated with Co.

Thus embedded Fe cluster assemblies in Co matrices hold real promise for creating a new material with a record magnetization density. This depends to some extent on the value of the Co moment but with a high volume fraction of the Fe grains, the Co matrix itself will be in the form of

nanoscale grains in which moments as high as  $2.3\mu_B$  have been observed [145]. Interestingly the calculation by Xie and Blackman [144] revealed a further increase in the spin moment if a degree of Fe–Co intermixing at the interface was included. This suggests that a moderate heat treatment of the cluster-assembled Fe–Co films could yield higher moments. As pointed out in the previous section, dense interacting cluster assemblies are magnetically soft and thus would be valuable in applications such as write heads where a strong local controllable field is required.

## 8.2. High Anisotropy Binary Clusters

The ultimate limit of magnetic recording is defined by storage on individual single-domain particles. For example if these were 5 nm particles separated in both directions by 10 nm, the density would be 1000 Gbits/cm<sup>2</sup>, or about 1000 × the storage density in modern hard disk drives. Leaving aside the technical problem of making organized arrays of the particles over macroscopic areas or exactly how to read and write there is the more fundamental problem that transition metal particles of this size are superparamagnetic at room temperature. In order to realize this next level of technology it is necessary to create nanoparticles with a sufficiently high anisotropy to be blocked at room temperature. A promising avenue is the use of transition metal/rare-earth mixtures as reported by Negrier et al. [146] who made SmCo clusters by using a SmCo<sub>5</sub> target in their laser evaporation source. Measurements using X-ray photoelectron spectroscopy (XPS) of the deposited films showed that although the stoichiometry of the target was preserved, the Sm was in the form of Sm<sub>2</sub>O<sub>3</sub> while the Co was pure. The most likely arrangement is that the Sm oxide forms a skin around a pure Co core. Despite the lack of elemental mixing within the clusters, a significant increase in the coercivity was observed relative to pure Co clusters in a Ag matrix with a corresponding increase in the blocking temperature from 25 to 45 K. Further increases can be expected with improved control of the mixing within the cluster by, for example, using sources with two targets.

Any recording application using clusters requires that the clusters be organized into regular arrays over macroscopic length scales. Large-scale self-organization remains one of the holy grails of nanotechnology and several promising techniques have been demonstrated in the case of atomic deposition. Recently Perez et al. [147] demonstrated the formation of organized arrays using deposited Au nanoclusters on functionalized graphite substrates that had been patterned using a focused ion beam. A careful study of all the growth parameters showed that it was possible to obtain conditions where every cluster was at a defect site with none in between. Although it is impossible to obtain a condition where every defect contains a single cluster it is possible to have every defect site contain a small group of clusters. If these were magnetic they would be exchange coupled and act as a storage bit.

## 9. CONCLUSION

This chapter has tried to demonstrate the enormous benefit of studying magnetic nanoclusters in understanding the fundamental magnetic behavior of matter. Addressing this

borderland between the atom and the bulk requires the development of a deep understanding of the electronic and magnetic properties of materials and how they are influenced by atomic structure. It is also clear that films made from deposited clusters will form an important class of materials in future technologies.

## GLOSSARY

**Amorphous material** A solid material in which the atoms are not arranged on a crystal lattice but are distributed randomly, as in a snapshot of a liquid structure.

**Anisotropy boundary (or barrier)** The energy barrier separating two different alignments of the magnetization in a solid.

**Anisotropy energy** The energy associated with a specific alignment of the magnetization.

**Antiferromagnetic material** A material containing magnetically ordered atoms in which there are equal numbers of atoms with their magnetizations pointing in opposite directions so the material presents no external magnetic field.

**Atomic number** The number of protons in an atom of the element showing its position in the periodic table.

**bcc lattice** Body-centered cubic lattice. A crystal lattice consisting geometrically of a stack of cubes in which the atoms are arranged in the corners of the cubes with an additional atom at the center of each cube.

**Blocking temperature** The temperature below which a nanocluster has a static non-fluctuating magnetization.

**Bond length** The distance between atoms in a solid.

**Cohesive energy** The difference in energy between N atoms as isolated atoms and the same atoms bound in a cluster.

**Correlated super-spin glass (CSSG)** A magnetic configuration in a solid built out of nanoclusters in which the magnetization of neighboring clusters is approximately aligned but over a larger distance becomes uncorrelated.

**Curie temperature** The temperature above which the atoms in a ferromagnetic material become magnetically disordered.

**Density of states** The number of allowed (electron) states per unit energy interval.

**Dimer** Two atoms bonded into a pair.

**Dipolar interaction** The classical long-range interaction between magnetic dipoles (*see also* exchange interaction).

**Domain boundary** The boundary between two magnetic domains in a magnetic material.

**Electronic shell** The allowed electron states contained within a specific pair of allowed values of the principal ( $n$ ) and angular momentum ( $l$ ) quantum numbers. The number of electrons in a shell is determined by the number of allowed values of the remaining magnetic ( $m_l$ ) and spin ( $m_s$ ) quantum numbers within the specific ( $n, l$ ) pair.

**Extended X-ray absorption fine structure (EXAFS)** The ripples in X-ray absorption strength for photon energies greater than an X-ray absorption edge (*see* X-ray absorption edge) resulting from inter-atomic X-ray scattering.

**Exchange interaction** A short range (atomic scale) magnetic interaction between two atomic electrons arising from the difference in energy produced by reversing the spin quantum number of one of the electrons. The interaction has no classical analogue and at the range of atomic separations is much more powerful than the classical dipolar energy.

**fcc lattice** Face centered cubic lattice. A crystal lattice consisting geometrically of a stack of cubes in which the atoms are arranged in the corners of the cubes with additional atoms at the center of each of the faces of the cubes.

**Fermi level** The energy of the highest filled electron state in a solid.

**Ferrimagnetic material** Magnetic material containing magnetically ordered atoms with their magnetic moments pointing in different directions but in which there is a net imbalance of the magnetization in one direction.

**Ferromagnetic material** Magnetic material containing magnetically ordered atoms in which the magnetic moments of all the atoms within a magnetic domain are aligned.

**Fractal** Object with a structure that repeats on smaller and smaller scales and which can be defined to have a non-integer dimensionality.

**Giant magnetoresistance (GMR)** Anomalously large variation in electrical resistance as a function of applied magnetic field found in nanostructured magnetic materials.

**Hall Probe** An instrument using the Hall effect, i.e. the voltage developed across a current-carrying conductor on application of a magnetic field, to measure the magnetization of a material.

**Hartree-Fock (also tight binding)** A scheme for calculating electronic states by summing over atomic orbital basis sets.

**hcp** A crystal structure consisting geometrically of a stack of planes in which each has atoms ordered in a hexagonal structure.

**Helical undulators** An insertion device in an electron storage ring which induces a helical distortion in the electron orbit to produce circularly polarized synchrotron radiation.

**Hysteresis** Process in magnetic materials whereby the magnetization depends not only on the existing applied field but also on the magnetization history of the sample.

**Icosahedron** Twenty-sided body. Particularly stable structure often found in small atomic clusters.

**Inert (or rare) gas** One of the gases He, Ne, Ar, Kr, Xe, Rn containing only filled electronic shells making them particularly unreactive.

**Isomer** Alternative structure containing the same number of atoms.

**Laser ablation** Process where material is evaporated from a target by an incident high power laser.

**Macroscopic quantum tunneling** The process of quantum tunneling, i.e., the transition of a quantum particle through an energy barrier that is forbidden in a classical system, in objects that are much larger than a single atom.

**Magic number** A number of atoms in a cluster that forms a particularly stable structure.

**Magnetic anisotropy** The tendency of the magnetization in a magnetic material to be aligned along specific directions as a result of a minimum in the anisotropy energy.

**Magnetic correlation length** The distance over which the direction of magnetization in a magnetic material is aligned.

**Magnetic domain** Mesoscopic region in a magnetic material over which the atomic magnetic moments are aligned. A magnetic material tends to form domains since this produces a lower energy configuration than having all atoms in the sample magnetized in the same direction.

**Magnetic isotherms** The magnetization versus applied field curve for a magnetic material obtained at a specific temperature.

**Magnetic precession** The rotation of a magnetic moment in response to an applied magnetic field.

**Magnetocrystalline anisotropy** The magnetic anisotropy due to the crystal structure of a magnetic material producing a minimum in the anisotropy energy along certain crystallographic directions.

**Magnetoelastic etc anisotropy** The magnetic anisotropy arising from strain along a particular direction in the material.

**Magnetic circular dichroism in the angular distribution (MCDAD)** The variation in the intensity of photoemission along a particular direction arising from a change in the relative alignment of the sample magnetization and the angular momentum of the incident radiation.

**Mesoscopic** A length scale that is large compared to atomic dimensions but small compared to macroscopic sizes. A typical mesoscopic size is of the order of 1  $\mu\text{m}$ .

**Magnetic linear dichroism in the angular distribution (MLDAD)** The variation in the intensity of photoemission along a particular direction arising from a change in the relative alignment of the sample magnetization and the linear polarization of the incident radiation.

**Monolayer** A single layer of atoms adsorbed on a surface.

**Monomer** A single isolated atom.

**Monte Carlo simulation** A calculation scheme for systems of large numbers of particles where the evolution of the system is followed by allowing random steps of the particles and determining the lowest energy configuration at each step.

**Nanocluster (or cluster)** A small cluster of atoms typically containing 10–1000 atoms (1–3 nm diameter).

**Nanostructure** A generic name for a structure that is a few nm across. Includes nanoclusters, islands formed by depositing atoms on surfaces, monolayers, etc.

**Neel temperature** The temperature above which the magnetic moment of the atoms in an antiferromagnetic material become disordered.

**Orbital moment** The magnetic moment in an atom arising from the orbital motion of the atoms around the atomic nucleus.

**Paramagnetic material** Material displaying no magnetic order of its constituent atoms but which acquires a magnetization in the same direction as an applied magnetic field.

**Percolation threshold** The volume fraction of grains in a granular material at which there is at least one continuous

pathway through touching particles from one side of the sample to the other.

**Photoemission (or photoelectron spectroscopy)** The emission of electrons from a surface resulting from the application of ultra-violet light with a photon energy greater than the electron work function.

**Photon spin** The angular momentum of circularly polarized light.

**Quantum dots** Nanostructure whose dimensions are of the same order as the electron wavelength in all three directions. In such devices the electrons are bound to the structure as a whole with corresponding energy levels.

**Quantum wires** A very narrow strip whose width is of the same order as the electron wavelength in two dimensions but is macroscopic in the third dimension.

**Remanence** The magnetization remaining after a magnetic field has been applied to a ferromagnetic material and then removed.

**Rotational temperature** The temperature associated with the rotation of a nanocluster.

**Saturating (or saturation) field** The magnetic field required to produce magnetic saturation in a ferromagnetic material.

**Saturation** A state in a ferromagnetic material in which all the atomic magnetic moments are pointing in the same direction.

**Shape anisotropy** Magnetic Anisotropy produced resulting from any non-spherical shape of a sample.

**Single-domain particles** A piece of magnetic material that is too small (typically <100 nm) for the formation of domains to be energetically favorable. In such a particle the atomic magnetic moments are all aligned so there is magnetic saturation without an applied magnetic field. The particle magnetic moment direction in nanoclusters however may be fluctuating except at very low temperatures.

**Spin moment (or spin)** The magnetic moment in an atom arising from the intrinsic angular momentum (spin) of the electrons.

**Spin sublattice** The crystal lattice in an antiferromagnetic material containing atoms whose spin is in the same direction.

**Sputtering** Process where atoms are ejected from the surface of a solid as a result of bombardment by energetic ions.

**Superconducting quantum interference device (SQUID)** A device that measures the magnetization in a sample by measuring oscillation in the current flowing through a bridge of normal material between two superconductors. The device is the most sensitive magnetometer available.

**Scanning tunneling microscopy (or microscopy) (STM)** Device or process in which nanostructures on a surface are imaged by measuring the variation in a tunneling current between the surface and an atomically sharp tip brought to within a few atomic dimensions of the surface.

**Superparamagnetism** The magnetic behavior of a collection of single-domain particles above the blocking temperature of the individual particles. The magnetization of each particle fluctuates as a whole but the assembly can be magnetized in the same direction by an applied magnetic field.

**Synchrotron storage ring** Machine in which a high energy electron beam is constrained to move in an orbit. The electrons emit synchrotron radiation in the process that covers wavelengths from the infra-red to X-rays. The machines are used as source of intense radiation for experiments.

**Ultra-high vacuum (UHV)** A vacuum of the order of 10<sup>-10</sup> m bar or better that is required in order for a surface to remain atomically clean during an experiment.

**Valence shell** The most energetic electronic shell in an atom.

**Vibrational temperature** Temperature associated with the atomic vibration in a nanoparticle (see also rotational temperature).

**X-ray magnetic circular dichroism (XMCD)** The change in the spectral intensity of an X-ray absorption edge in response to changing the relative alignment between the sample magnetization and the photon spin of the incident X-rays.

**X-ray absorption edge** The vast change in X-ray absorption strength as the photon energy of X-rays incident on a sample is tuned through the energy difference between a core electron binding energy and the Fermi level.

## 1. INTRODUCTION

Nearly 40 years ago, heterogeneous films containing rare earth (R) and 3d transition metal components (T) first attracted the attention of the scientific community [1]. The current method of artificially creating complex magnetic systems came about as techniques for the preparation of R/T structures were developed. The presence of exchange interactions through adjacent surfaces of two magnetic substances with very dissimilar characteristics was neatly demonstrated in these structures. However, not all questions about the physics of new magnetic objects have been resolved because of limited technical capacity. In particular, the relationship between the thickness and structure of individual layers and the magnetic properties of R/T multilayered films has not been clarified nor has the role of interfaces. The application range of these materials has not been described.

Interest in R/T multilayered structures reappeared in the 1980s [2–4] and continues to increase to this day. This can be explained by the development of ion sputtering and

molecular beam epitaxy as thin films preparation methods, with a correspondingly high level of parameter control [5]. The research techniques have also been refined. Together with high-resolution electron microscopy [6], neutronography [7], and Mössbauer spectrometry, X-ray synchrotron radiation [8–12] and field ion microscopy [13] are usually used nowadays. Finally, multilayered R/T films have been used successfully in practice to increase the energy of hard magnetic materials [14], to reduce the magnetic saturation field in giant magnetostrictive materials [15], and to create the new materials for high-density magneto-optical data storage applications [16, 17].

This chapter is devoted to problems of R/T films such as layers and interfaces, atomic structure, magnetic structure, and the way magnetic structure changes under external magnetic field application or with changes in temperature. We also discuss the mechanism of the interlayer exchange interaction and perpendicular magnetic anisotropy. In addition, some data on hysteresis, magneto-optic, magnetotransport, and magnetostrictive properties are included; that is, we review the basic knowledge needed to understand possible technological applications for R/T films.

## 2. PREPARATION AND CHARACTERISTICS OF R/T MULTILAYERS

The atomic structure and fundamental magnetic characteristics of low-dimensional nanoscale subjects like R/T multilayers, such as spontaneous magnetization, Curie temperature, and crystalline magnetic anisotropy, are highly dependent on preparation conditions and geometry. This is the reason for both scientific and practical interest in R/T multilayers and

for the special attention given to the problem of parameter control in film technology.

## 2.1. Fabrication Technology

For scientific purposes, there are two R/T films preparation methods: ion sputtering and vacuum thermal evaporation of initial materials. Ion sputtering is the expulsion of the atoms from the target surface by inert gas ion bombardment. The target can be of either R or T composition. The formation and acceleration of inert gas ions, Ar as a rule, might take place in a direct electric field (DC sputtering) [4, 18] or in a radiofrequency electric field (rf sputtering) [19, 20]. It can be done in the presence of an additional magnetic field, which stimulates increasing electrical discharge, that is, magnetron sputtering [21, 22]. Comparatively high deposition rates (0.1–0.5 nm/s), high density, adhesion, and uniform thickness for large sample areas are the advantages of this method.

Vacuum thermal evaporation [23, 24] involves strong local heating, usually by a high-energy electron beam created by an electron beam gun. The film preparation occurs at ultrahigh vacuum of  $10^{-8}$ – $10^{-10}$  torr, called ultrahigh thermal evaporation or molecular beam epitaxy. However, the latter is not true for R/T multilayers; the epitaxial building of structure does not take place in alternating deposition of R and T layers, because of the great differences in atomic and structural parameters of rare earth and 3d transition metals. A comparatively low evaporation rate and minimal value of impurities in the deposited films are specific features of this method. Thermal evaporation allows us to achieve very low deposition rates (of 0.2–0.5 Å/s) and minimal contamination of the samples.

The two methods described above include a certain number of important technological parameters. Quantitatively the influence of these parameters on the quality of the nanoscale multilayers has been learned from experience in R–T thin films preparation. The possibility of direct transference of the parameters of thin film preparation to the case of multilayers is different for each experimental setup and, so far, there is no systematic study of the problem in the literature; one of the few examples is the analysis of the influence of the substrate electrical bias on the structural state of the Fe layer in Gd/Fe magnetron sputtered multilayers [25].

The technology of deposition very often depends on the purpose of R/T multilayer preparation. For basic study, especially in structural studies, the method of thermal evaporation seems more appropriate because it has the advantage of low contamination of the samples. For studies in the material science field, the ion sputtering process is more reasonable because it can be more easily adapted to industrial conditions. Apart from R and T targets, the vacuum systems for multilayer preparation usually offer additional possibilities for depositing other layers such as buffers of Cu [26], Mo [27], nonmagnetic spacers of Cu, Y [28, 29], Cu, Si [30], Pt, or Cr [31], or protecting layers of Si [32], Al [33], V [18], or Ag [34] to avoid oxidation. The last point is very important for R layers, which have a very high oxidation rate.

Substrates play an important role in thin film microstructure and property formation. At the same time, for nonepitaxially grown multilayers, like R/T structures, the substrate

material is less important. This is a consequence of the relatively high ( $\geq 100$  nm) total thickness of the samples and of the repeated alternation of different layers. In practice, monocrystalline Si or glass (for example, Corning glass) substrates of appropriate quality are utilized.

## 2.2. Structure of a R/T System in a View of Preparation Conditions and Thickness: Interfaces

The structural state is a key parameter for the formation of many physical properties of thin films as well as the magnetic properties between them [35, 36]. The type of atomic structure can be determined by the presence/absence of order in the positions of the atoms at precise distances compared with the atomic size. The presence of larger ordered formations is called microstructure. The components of the microstructure are the amorphous matrix part, crystalline grains, boundaries between the grains, space, and compositional defects. If the thickness of the film is relatively high ( $L > 10$  nm), the structural state first of all depends on the temperature regime of the deposition. However, in very thin films the thickness plays a key structural role. This is true both for uniform films and multilayers. For the latter, the characteristic size parameter is the thickness of each individual layer.

Transmission electron microscopy and X-ray diffraction are the most widespread methods for studying the structure of all kinds of thin films. Figure 1 shows the electron diffraction pattern and the microstructure images in a dark-field regime for a rf-sputtered Si/[Gd(7.5)/Co(3)]<sub>4</sub>/Si sample. This formula contains all the important information about the general structure of the multilayered film. It says that this sample has buffer and covered Si layers and Gd layers of thickness  $L_{\text{Gd}} = 7.5$  nm alternated with Co layers of thickness  $L_{\text{Co}} = 3$  nm. The structure  $L_{\text{Gd}} + L_{\text{Co}} = L_p$  is repeated four times, where  $L_p$  is a period of the structure.

The main feature of this electron diffraction pattern is two very diffused rings, corresponding to the Gd and Co components. The diffused state of the reflections testifies to the amorphous state of these metals. At the same time, one can define the most probable distances between the atoms (0.3 and 0.2 nm, respectively). Dark-field observation enables us to separate the images corresponding to different diffraction maxima, that is, related to mainly Gd or Co (Fig. 1a and 1b).

**Figure 1.** Electron diffraction patterns and dark-field microstructure images corresponding to different diffraction maximums for an Si/[Gd(7.5)/Co(3)]<sub>4</sub>/Si sample. The systematic interatomic distances are 0.3 and 0.2 nm.

The common feature for such different metals is the very small size (<2 nm) of the volumes of coherent dispersion, which look like bright points in the photographs.

Amorphization of the rare earth and 3d metals, which occurs as the thickness of the layers decreases, has been reported in many cases both for thermal evaporation [23, 32, 37–40] and ion sputtering methods [4, 21, 25, 41]. The details of the transformation from the amorphous to the nanocrystalline state of Gd/Fe, Tb/Fe, and Dy/Fe systems are shown below (Table 1). The amorphous state of these metals is observed for very small and slightly different layer thickness:  $L_R < 1.1$  nm and  $L_{Fe} < 0.8$  nm. Real transitions from one structure to another do not show up as jumps but take place in some interval of the layer thickness; thus the data shown above are only an estimate. There is a long transition zone between the crystalline and amorphous states. See, for example, [42] in which Mössbauer spectrometry was used to get information about structure of the [Tb/Fe]<sub>20</sub> multilayer through the analysis of the hyperfine field of the iron isotope <sup>57</sup>Fe. The percentage of crystalline body-centered cubic (bcc) phase in comparison with total Fe volume decreases with the decrease in the thickness of the layers. The features of this phase transition depend on the substrate temperature. At a thickness of about 2 nm complete amorphization takes place.

In nanoscale R/T multilayers, the decrease in layer thickness results in the transition from a crystalline to an amorphous state. The quantitative parameters of this transition depend to some extent on the preparation conditions, but the average thicknesses are 1.5–2 nm for R = Gd, Dy, and Tb and 1.5–2.5 nm for T = Fe and Co.

**Table 1.** R/T multilayer studies.

*Note:* Publications reporting R/T multilayer studies are listed in this table, taking into account the type of rare earth layer (R) (first column) and the structural state of the R layer. It is known that R thickness is an important parameter. In each particular case there is a certain thickness ( $L_T$ ) corresponding to the transition from the amorphous to the crystalline state.  $L_T$  depends on composition and fabrication conditions but usually it is about 2 nm. Therefore, we have divided all references into two large groups with respect to this parameter. It is clear from the table that this approach has an internal logic: group one ( $L_R < 2$  nm) has collected the data about R/T structures with thin Tb layers and perpendicular anisotropy interesting with respect to magnetic recording; group two ( $L_R > 2$  nm) has collected data with relatively thick Gd for model study.

The interfaces, zones between different layers, play a very important role in influencing macroscopic magnetic properties. Although there is great scientific interest in studying the interface problem, many questions about their structure and chemical state are still unanswered. The main point of discussion is the level of mixing of the different layers.

Low-angle X-ray diffraction is a powerful method for study of interface. This method provides the opportunity to work in a framework of Woolf–Bragg conditions for reflecting atomic planes, which are situated relatively far apart. In multilayers, the surfaces of the layers act as reflecting surfaces. Therefore, the appearance and position of the diffraction maximum of low-angle X-ray dispersion helps to define the presence of the periodic structure and its period. At the same time, the profile of the low-angle diffraction contains even more profound information about the state of the reflecting surfaces. Extracting this information usually includes a modeling process and the comparison of the calculated diffractogram with the experimental results [27].

Figure 2 shows an example of low-angle X-ray diffraction in Cu–K $\alpha$  radiation for the Cu/[Gd(7.5)/Co(3)]<sub>20</sub>/Cu. One can see up to five diffraction peaks; these confirm to the very high localization level of the layers. At the same time the total diffraction profile depends not only on the perfection of the interfaces but also on their relative volume in the total volume of the material. Because of this fact, there is a tendency for the number of maxima to be reduced as the period of the multilayered structure gets smaller [2, 130]. Nevertheless, the authors of [4] found, for the rf sputtered R/Fe multilayers (R = Gd, Tb, and Dy), that the presence of the layered structure was maintained up to the layer thickness of the atomic size scale, thus providing the experimental basis for their conclusion about the possibility of preventing mixing in the materials of the type mentioned above. The same conclusion was reached in [24], on the basis of numerical analysis of the low-angle X-ray diffraction profiles of thermal deposited Tb/Fe multilayers. These researchers found a good match between the experimental and the calculated curves, assuming wave-shaped interfaces and no mixing. However, many other publications reported significant diffusion between R and T layers on the basis of Auger electron spectroscopy measurements [23, 27, 43–46, 82, 94, 131]. This method allows definition of

**Figure 2.** Low-angle X-ray diffraction for the Cu/[Gd(7.5)/Co(3)]<sub>20</sub>/Cu film prepared by rf sputtering. Reprinted with permission from [93], V. O. Vas'kovskiy et al., *Phys. Met. Metall.* 86, 140 (1998). © 1998, MAIK “Nanka/Interperiodica.”

the element composition of the surfaces. In combination with the method of ion etching, it makes it possible to construct the composition profiles of the film samples. Figure 3, in accordance with [94], shows the example of such a profile of a two-layer Gd(50)/Co(21) film prepared by ion sputtering. The transition region between the Gd and Co layers is not sharp and has a thickness of about 10 nm as a consequence of interlayer diffusion. Two points have to be mentioned regarding this last example: first, the Auger electrons give information not only about the surface but also about the narrow zone near the surface; and second, the ion etching process very often results in formation of a different surface relief. Both the first and the second processes may imitate the mixing effect.

Another interesting fact is that there is asymmetry in the variation of the concentration changes related to the thickness of Gd and Co bilayers (Fig. 3). This can be explained, to some extent, by taking into account the higher oxygen concentration in the Gd layer. Another, and it seems more important, reason is the difference in the mobility of Gd and Co atoms. As a result of this, Co usually diffuses better than Gd into the neighbor layer (up to 3 nm). The same conclusion is reached in [131] and [27]. In the last case the low-angle diffraction data were taken using synchrotron radiation.

An even more detailed interface study was made using Mössbauer spectrometry [47]. These researchers investigated the state of Fe layers in Tb/Fe multilayers by introducing the isotope  $^{57}\text{Fe}$  as an additional 0.5 nm sublayer. If one deposits Fe on the Tb surface, mixing takes place. For Tb deposition onto the Fe surface there is a clear boundary between well-separated layers. Similar conclusions were drawn for the Gd/Co [27] and CoNi/Gd [132] systems. Theoretical analysis of low-angle diffraction shows higher levels of interface imperfection for Co deposited onto Gd than for Gd deposited onto Co.

Certain information about interfaces can be gathered by analyzing variations in the deposition parameters and by subsequent heat treatments of the multilayers. Many efforts have been made with the objective of fabricating multilayers with interfaces that are as narrow and as sharp as possible by, for example, utilization of the appropriate substrate temperature,  $T_s$ . In the majority of studies researchers were dealing with films deposited on a cooled substrate at temperatures  $T_s = 80$  K [130],  $T_s = 90$  K [32],  $T_s = 190$  K [133],

**Figure 3.** Composition depth profile taken by Auger spectroscopy of the Gd(50)/Co(21) bilayer: (1) Co; (2) Gd; (3) O. Film was deposited onto a glass substrate by ion sputtering. From [94] J. P. Andres et al., *J. Appl. Phys.* 87, 2483 (2000). © 2000, American Institute of Physics.

$T_s = 200$  K [2],  $T_s = 220$  K [48], and  $T_s = 240$  K [134]. There are data for room temperature deposition regimes [82, 135] and even deposition at elevated temperatures of  $T_s = 310$ – $370$  K [27] and  $T_s = 390$  K [46]. These experimental results are very difficult to compare because they are not systematic and the types of deposition equipment are very different with many additional parameters involved. There are interesting exceptions [42, 47] for which comparative studies of the samples were made for two deposition temperatures of 150 and 300 K. The result seems trivial; the higher the deposition temperature, the less separated the layers are. However, there is another study [136] in which the temperature  $T_s = 410$  K is declared to be optimal when one is trying to achieve smooth interfaces. The results of [49], based on the Tb/Fe multilayer study after heat treatments, are in accord with those of [136]. The authors found localization of the magnetic layers in an amorphous structure of a very thin layered system at the beginning of the heat treatments for annealing temperatures  $t_a < 370$  K. In other words, a process opposite to mixing took place. A similar conclusion was drawn in [137]. Interlayer diffusion takes place only at more elevated temperatures and results in the formation of an amorphous Tb–Fe unhomogeneous composition interface. In its amorphous state, a layered system is generally rather thermostable. It changes only at  $t_a > 520$  K and the crystallization of Tb, Fe, and Tb–Fe and as a result destruction of the multilayered structure take place at  $t_a \geq 770$  K [49].

Other methods of influencing the interfaces include the use of different substrates and buffer layers, electrical bias of the substrates, and implantation. The structural characteristics of Gd/Co films [27, 95] prepared by molecular beam epitaxy deposition onto an  $\text{Al}_2\text{O}_3$  substrate with a Mo buffer layer were compared with those deposited onto a Si substrate and a Si substrate with a SiN buffer layer. Low-angle X-ray diffraction analysis shows the maximum mobility of Co into Gd for the  $\text{Al}_2\text{O}_3$  substrate, resulting effectively in a reduction of the thickness of the pure Co layer by more than 50%. A difference in the diffusion level was observed for multilayers deposited onto Si substrate: it is higher in the presence of the buffer layer. The influence of the substrate on the properties of the multilayered films is achieved through substrate relief and formation of a special thermal regime during the deposition. In our view, this last factor could play the key role in the above experiment.

The influence of the voltage applied to the substrate (electric substrate bias) during the rf sputtering deposition [138] has also been studied by means of low-angle X-ray diffraction of Gd/Fe films. It was shown that the presence of a negative bias of  $-30$  V causes smoother interfaces and smaller crystalline grains. Possibly these two effects have a reciprocal relationship and the interface smoothing is the result of the increased microstructure dispersion.

Different effects were reported for the ion implantation treatment [50, 137, 139]. The simplest consists of layer mixing as a result of irradiation, for example, in a Gd/Co sample by Ar ions with energy of 150–300 keV (a dose of  $10^{16}$   $\text{cm}^{-2}$ ) [131]. It was found that in multilayered structures with small periods ( $< 10$  nm), such treatment can lead to complete layer mixing and amorphization of the nanosized layer structure. For samples with structure periods greater than 20 nm the

mixing and amorphization processes take place only partially. Clear structural changes do not appear after the use of lower energy/dose radiation for the Tb/Fe samples, but one can see measurable differences in magnetic properties before and after irradiation [51].

Rather delicate changes in the interface structure of Tb/Fe multilayers were observed after irradiation by different hard ions like Kr, Xe, Pb, and U [52, 53, 140]. Mössbauer spectroscopy was used to get information about structure. Two steps of structural change were reported [52, 140]. At the beginning of the treatment, if the ion beam power is low, there is an increase in the thickness of the iron layers, known as de-mixing, that is, the opposite process to the layer mixing described earlier. Let us remember that the same effect appears [49] at low temperature heat treatment of multilayers. The cause of changes in properties during low-energy ion bombardment may be a trivial heating of the material. In the second step, when the ion flow power increases, interlayer diffusion dominates, and the layered structure disappears. The differences between the structures of Tb on Fe compared with those of Fe on Tb interface increase as well [53].

All these results demonstrate the great variety of structural states of the multilayers and, especially, interfaces in R/T multilayers, which clearly depend on composition and method of preparation. One can develop a model that is appropriate for the experimental methods to be used in any specific study, but we emphasize the need for special analysis for each particular case.

### 3. MAGNETISM OF R/T MULTILAYERS

Multilayered R/T films have unique combinations of magnetic properties, corresponding to the different elements of their structure, because they are formed from very dissimilar magnetic materials. First are magnetoactive 3d transition metals, known as band magnets. The main carriers of magnetism in these magnets are 3d electrons, which are collectivized to a great extent and not related to a particular atom of crystalline lattice. In this case, magnetic ordering is short range and is achieved through direct exchange interaction. As a rule, these metals have ferromagnetic ordering, high Curie temperature, and high spontaneous magnetization.

Second, in rare earth metals, magnetism is caused by 4f electrons located in internal electron shells. This leads to localization of magnetic moments on atoms and to the absence of direct exchange interaction in the 4f electron system. Magnetic ordering occurs because of indirect exchange through the conduction electrons. This interaction is oscillating and acts over a long range. It causes low values of magnetic ordering temperatures and aids the formation of complex magnetic structures.

The third category of materials, namely alloys of rare earth and 3d elements, may easily appear in R/T structures because of interlayer mixing during preparation, after annealing [49] or ion irradiation [51]. In their crystalline state, R–T alloys do not form continuous solid solutions, because of differences in ion radii and occur as stable intermetallic compounds. High magnetic anisotropy and magnetostriction are distinctive features of some of them. As was

shown in Section 2, the actual R/T multilayers tend to amorphization. It might be supposed, therefore, that interfaces with fluctuating composition, if they appear, are amorphous.

Amorphous R–T alloys are well known. It is not very difficult to get them in an amorphous state in thin film geometry using special preparation technology, because of the differences in ion radii. Amorphous Gd–Co, Gd–Fe, and Tb–Fe films have been well investigated [141]. They were the starting point of interest in corresponding multilayered structures. High structural stability, the presence of magnetic ordering over a large range of temperatures, and monotonous change of the main magnetic characteristics according to composition are the important features of amorphous R–T films.

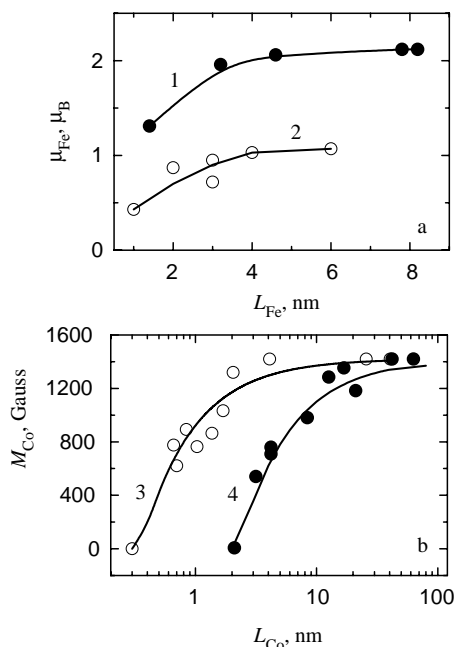

Thus, the magnetism and nonmagnetic properties which, in R/T multilayered systems, depend on the presence of magnetic order, connect with the combination and superposition of properties of R and T metals and their alloys. Another important feature is specific interlayer interactions. This section is devoted to the magnetism of R/T multilayers.

#### 3.1. Magnetic Properties of Nanocomponents

Research interest in R/T multilayered films is determined by practical needs. Therefore, layered structures containing strong magnetic components, namely metals in which magnetic ordering occurs at high temperatures, are of special interest. These are Fe and Co from the group of 3d metals and Gd, Tb [125], and Dy from the group of rare earth elements. As exceptions, it is possible to mention experiments using Ni [82], Sm [125–127], Nd [124], and R = any rare earth element [48, 56] (Table 1).

Fe and Co are the most widely used ferromagnetic materials and their properties are well known. However, in the thin film state some peculiar features may appear [29, 142, 143]. This is true, first of all, for atomic structure. As mentioned in Section 2, sufficiently thin films have a tendency to amorphization. It is known that the transition to the amorphous state has a relatively weak influence on Co magnetism. Cobalt retains high spontaneous magnetization and high Curie temperature,  $T_c$ . A different process takes place for iron. At amorphization the iron atomic magnetic moment decreases greatly and  $T_c$  drops. What is the reason for this phenomenon? In the amorphous state the average number of nearest neighbors is restricted to about 12 for any selected atom. It corresponds to the number of nearest neighbors in the bcc crystalline lattice. Thus, from the point of view of atomic structure, the amorphous structure is similar to that corresponding to the low-spin state of crystalline iron,  $\gamma$ -Fe.

Corresponding experimental data for layered structures were obtained by investigation of the samples containing only one sort of magnetic layer separated by nonmagnetic spacers, for example, Fe/Y multilayers [129, 144–147]. Yttrium does not have a magnetic moment, but its structural–chemical properties are similar to those of rare earth metals. Typical dependence of the average Fe atomic magnetic moment,  $\mu_{Fe}$ , on Fe layer thickness is shown in Figure 4a (curve 1). It was measured at room temperature in  $[\text{Fe}(L_{Fe})/\text{Y}(7.8)]_n$  multilayers prepared by molecular beam

**Figure 4.** Dependence of Fe average magnetic moment (a) and Co spontaneous magnetization (b) on magnetic layer thickness at room temperature for different structures: (1)  $[Fe(L_{Fe})/Y(7.8)]_n$ . epitaxy [129]. It is seen that a significant decrease in  $\mu_{Fe}$  takes place at  $L_{Fe} < 4$  nm. Naturally one might associate this tendency with amorphization of the magnetic layers and the increase in the low-magnetic Fe phase fraction. However, the authors of [129] point to another potential reason for  $\mu_{Fe}$  change, namely the elements of superparamagnetic behavior of Fe/Y multilayers at  $L_{Fe} < 1.4$  nm. It means that Fe layers have lost continuity. Thermal fluctuations of the magnetic moments of ultrathin particles, formed as a result of discontinuity, lead to a decrease in the average magnetization of the macroscopic sample from which the atomic magnetic moment is experimentally determined. Ultrathin particles, formed as a result of discontinuity, that is, granular ferromagnetic thin Fe films deposited on  $Al_2O_3$  substrates in ultrahigh vacuum, and low temperature ferromagnetic quenching effects in Fe(110) contacting nanoscale islands, were observed and studied in [142].

Although the Fe/Cr system is not a R/T system, we feel that it should be mentioned because of its enormous contribution in stimulating research. In the same way that exchange interaction between ferromagnetic films across nonmagnetic metallic Y spacers was considered for Gd [143, 148, 149] and Dy [150], this was also done for the Fe/Cr structures [151–153]. Interest in the basic physics of the exchange-coupled multilayers and especially in Fe/Cr multilayers was enhanced by the discovery of giant magnetoresistance in the antiferromagnetically coupled Fe/Cr system [154] (see Section 5.2). Although multilayered R/R systems were carefully studied as well, they are

less adaptable for technological applications. The interested reader may find all information about this system reviewed in [155].

In thin-layered films the reciprocal influence of layers plays an important role. The presence of adjacent layers may effect structural transformation in iron or influence magnetic properties in a specific way. The  $\mu_{Fe}(L_{Fe})$  dependence for  $[Fe(L_{Fe})/Ti(1)]_n$  is shown in Figure 4a (curve 2) as a typical example [156]. It can be seen that the dependence is far lower than that for  $[Fe(L_{Fe})/Y(7.8)]_n$  multilayers (curve 1), because it is connected with interlayer mixing and formation of an amorphous Fe–Ti alloy or intermetallic compounds like  $TiFe_2$  with reduced magnetization. At the same time, significant interlayer diffusion may be caused by peculiarities of the preparation method (rf ion sputtering or molecular beam epitaxy) and/or by properties of contiguous materials.

There are few data in the literature about the individual characteristics of Co when it forms part of a R/T structure. To a certain degree these are determined by the weak correlation, already discussed, between the atomic structure and magnetic properties of cobalt. However, this ferromagnetic material combines resistance to structural transition and sensitivity to the influence of the adjacent layers. It follows from the analysis of the properties of multilayered films containing both Co layers and nonmagnetic spacers. Figure 4b shows the dependence of the Co layer spontaneous magnetization,  $M_{Co}$ , on the thickness of the Co layer as a part of  $[Co(L_{Co})/Cu(2.5)]_{20}$  (curve 3) and  $[Co(L_{Co})/Si(2)]_{20}$  (curve 4) structures. In both cases, the decrease in the magnetic layer thickness leads to  $M_{Co}$  decay but it appears at different intervals of  $L_{Co}$ .

For Cu spacers, appreciable changes of magnetization occur at  $L_{Co} < 2$  nm whereas in nonmonocrystalline multilayers the disturbance of continuity (or granulation) plays a dominant role. It leads to a decrease in the magnetic ordering temperature and an increase in superparamagnetism [157]. In films with Si spacers the decrease of magnetization begins at higher thicknesses ( $L_{Co} \leq 20$  nm) and therefore at  $L_{Co} < 2$  nm layers are nonmagnetic. X-ray and electron diffractions do not detect the presence of Si compounds, which may cancel out the magnetically ordered state of Co. In connection with this process, the change of the electron structure of Co by electrons of Si spacers (charge transfer effect) is the most probable reason for the  $M_{Co}$  decrease. Perhaps this phenomenon takes place at the contact of Co and Si. The thickness of the transition region with changed electron structure may reach 1.5 nm. This phenomenon can also be observed in homogeneous, amorphous Co–Si films [158].

Let us now turn to rare earth metals. From the R elements mentioned above, gadolinium has a maximum Curie temperature of 293 K, and it is the only collinear ferromagnet at all temperature intervals below  $T_c$ . Tb and Dy display ferromagnetic ordering up to 215 and 85 K, respectively. Tb and Dy have helical magnetic structures over the temperature intervals of 215–230 and 85–179 K, respectively. This structure does not produce total magnetization. In addition, these metals have very different magnetic anisotropy. The spherical shape of the electron shell of Gd ions causes low crystalline magnetic anisotropy, but anisotropic Tb and Dy ions form high single-ion anisotropy. This peculiarity

is a reason for the practical interest in R/T multilayered films, with  $R = \text{Tb}$  as a medium, for perpendicular magnetic recording. However, Gd is more suitable for the analysis of magnetism of rare earth metals in the thin film state.

The majority of studies devoted to Gd thin layers have been carried out on single crystal (epitaxial) samples, both homogeneous Gd films [159, 160] and layered structures composed of Gd layers and nonmagnetic spacers [89, 90, 96, 143, 148, 149, 161–164]. The results of these investigations do not always agree. For example, an oscillation of the Gd magnetic moment with  $W$  thickness was detected for Gd/W multilayers in [161], with  $Y$  thickness in [143, 148], and it was not detected in [162]. It was shown [148, 149] that the sign of the exchange interaction between two Gd layers in a Gd/ $Y$  structure may oscillate, being positive or negative as a function of the thickness of the  $Y$  layer. The oscillation period is a function of the number of  $Y$  spacers in this case. Some properties, including the dependence of Curie temperature on Gd thickness, were measured reliably enough. Corresponding experimental data for multilayered films can be found in [162]; here the decrease of  $T_c$  with the reduction of  $L_{\text{Gd}}$  takes place. The study devoted to Dy thin layers in a Dy/ $Y$  system have been carried out in [150].

We should also mention the sensitivity of spontaneous magnetization to heat treatments. According to [160] annealing at temperatures up to 620 K increases the slope of  $M_s(T)$  dependence and the  $T_c$  rises substantially, by up to 15°. The authors of [160] connect this change in magnetic properties with the relaxation of microstrains of structural defects and macrostrains caused by the difference of crystalline lattice parameters in the film–substrate system. Thus, the fundamental characteristics of magnetic ordering in Gd films exhibit sensitivity to structural conditions. This unusual phenomenon is probably associated with the peculiarities of exchange interaction in rare earth metals, namely long-range and distance oscillation.

In multilayered R/T structures the epitaxial growth of the layers is impossible because of large differences in the parameters of the crystalline lattices of R and T metals. Moreover, both thin rare earth and 3d metal layers tend to amorphization (see Section 2.2). Naturally, one might suppose that the changes in the magnetic state are a consequence of the structural transformation of gadolinium. The corresponding experimental data for rf-sputtered Gd/Cu and Gd/Si films [97, 98] are shown in Figure 5: the dependence of a specific torque mechanical moment  $P$  on the temperature for the bulk sample (curve 1), for a single-layered Gd film of 720 nm (curve 2), and for a multilayered  $[\text{Gd}(L_{\text{Gd}})/\text{Cu}(1)]_n$  with different thicknesses of magnetic layers (curves 3 and 4). Let us keep in mind that  $P(H)$  dependency reflects the spontaneous magnetization behavior in the absence of structural anisotropy.

The comparison of  $P(H)$  curves provides the basis for concluding that even a very thick uniform film has a lower Curie temperature (of about 250 K) and smoother magnetization changes than the bulk sample. The transition into the thin film state by introduction of Cu sublayers is accompanied by an additional decrease of the Curie temperature and the appearance of a fold point in the 160 K zone. This behavior of the mechanical moment indicates the multiphase magnetic state of Gd layers and its dependence on

**Figure 5.** Temperature dependence of torque of a Gd bulk sample (1) and  $[\text{Gd}(L_{\text{Gd}})/\text{Cu}(1)]_n$  films with different magnetic layer thicknesses: (2) 780 nm; (3) 22.5 nm; and (4) 7.5 nm. Gd layer thickness,  $L_{\text{Gd}}$ . Very similar results were reported for  $[\text{Gd}(L_{\text{Gd}})/\text{Si}(1)]_n$  showing clear differences between Co and Gd. The properties of the latter are not very sensitive to the properties of adjacent magnetic layers.

Figure 6 shows the microstructure and diffractogram for  $[\text{Gd}(L_{\text{Gd}})/\text{Si}(1)]_n$  structures with various thicknesses of Gd layers. The absence of sharp lines (Fig. 6a) is a typical indication of the amorphous state of a thin Gd layer. The state of the samples with  $L_{\text{Gd}} = 15$  nm (Fig. 6b) is intermediate; there are both amorphous and crystalline parts as well as for the samples with  $L_{\text{Gd}} = 40$  nm (Fig. 6c). However, in the last case the crystalline  $\alpha$ -Gd phase is better separated and quantitatively dominates.

The results of the study of layered Gd films show a direct connection between the structure and effectiveness of the

**Figure 6.** Electron diffraction patterns and microstructure for  $[\text{Gd}(L_{\text{Gd}})/\text{Si}(1)]_n$  films with different magnetic layer thicknesses: (a) 7.5 nm; (b) 15 nm; and (c) 40 nm. exchange in the rare earth metals. Curie temperature decay and spin system frustration occur as consequences of the degradation of the crystalline structure. Space amorphization of the rare earth metals takes place over a wide interval of layer thicknesses by the mechanism of microdeformation accumulation. The coexistence of crystalline, amorphous, and a number of intermediate phases leads to multiphase magnetic states of rare earth layers.

Interlayer interfaces may play an important role in R/T magnetism. In Section 2 we described the discussion related to the role of interfaces. Once the idea of the existence of interfaces is accepted, it is logical to suppose that they have a structure of amorphous R–T alloys with a varied composition depending on the thickness. Amorphous R–T systems, especially Gd–Co, are well known in the physics of magnetically ordered materials. The key property of all systems with heavy rare earth ions is collinear ferrimagnetism. Moreover, in contrast with crystalline ferrimagnetic materials, the amorphous alloys show continuous change of the value of sublattice magnetizations as a function of composition.

Typical dependencies on temperature for spontaneous magnetization of amorphous  $Gd_xCo_{100-x}$  films were reported in [165]. The special selection of the composition helps to show the most interesting feature of magnetization behavior, that is, nonmonotonous changes of  $M_s(T)$ . The difference in temperature dependencies of magnetization of sublattices of gadolinium ( $M_{Gd}$ ) and cobalt ( $M_{Co}$ ) condition this behavior. At a certain point near the compensation temperature,  $T_{comp}$ , the magnetization absolute values are equalized ( $M_{Gd} = M_{Co}$ ) and a minimum of  $M_s(T)$  appears. The compensation temperature of amorphous ferrimagnetic materials is a monotonous function of composition.

Experimental values were compared with those calculated by the mean field theory of magnetization for  $Gd_{21}Co_{79}$  and  $Gd_{18}Co_{82}$  films [166]. Although, the theoretical description matches the experimental data well enough, it is necessary to make the correct allowances for a large number of parameters, for example, Co spin. Cobalt spin is sensitive to composition and decreases abruptly as the gadolinium concentration increases [167]. Co does not have a magnetic moment at Gd concentrations above 50 atomic %. It occurs because of the charge transfer effect described above. In this case the Co electron structure changes by Gd one. This feature, together with the charge transfer in Co/Si layers, suggests a high probability of charge transfer in Gd/Co multilayers.

### 3.2. Spontaneous Magnetization

In the earliest publications about R/T multilayered films, exchange interactions between layers were identified [2, 3, 136]. The character of the exchange interactions in R/T systems is very similar to that of homogeneous R–T materials between R and T subsystems. The magnetic moments of the Fe and Co layers are parallel to the magnetic moments of the light R element layers and antiparallel to the magnetic moments of the heavy rare earth element layers. This last case is most interesting because it corresponds in some way to a ferrimagnetic structure, where the magnetic moments of R and T layers play the role which,

in a classic ferrimagnet, would be played by the magnetic moments of the sublattices.

The spontaneous magnetizations  $M_s(T)$  of different ferrimagnetic multilayers, such as homogeneous R–T ferrimagnetic materials, have very different temperature dependencies [4, 38, 41, 91, 54]. For example, nonmonotonous dependencies of  $M_s(T)$  may either increase or decrease at different layer thicknesses, as a result of the behavior of partial R and T layer magnetizations and variations in their contributions to  $M_s$ . The minimum can be identified as a magnetic compensation state where the magnetic moments of the R and T subsystems are equal. However, in contrast with homogeneous R–T ferrimagnets,  $M_s(T)$  is significantly higher than zero for R/T multilayers. To explain this difference, one might suggest the higher level of volume heterogeneity of the R/T system due to the surface relief, for example.

The changes of layer thickness in ferrimagnetically ordered multilayers correspond to changes of the composition in homogeneous RT ferrimagnets. At the same time it is not the only factor influencing R/T spontaneous magnetization. If the layered structure contains iron, as mentioned in Section 3.1, amorphization and decreases of the atom magnetic moment may occur as a result of the reduction in the thickness of the layers. Some quantitative data on this subject are reported for  $[Gd/Fe]_n$  multilayers with equal thickness of the iron and gadolinium layers  $L_{Fe}$  and  $L_{Gd}$ , with a different period of the structure  $L_p = L_{Fe} + L_{Gd}$  [130]. The sharp decline in the magnetic moment  $\mu_{Fe}(L_p)$  appears for  $L_p < 15$  nm. The decrease in the contribution of the Fe layer to the spontaneous magnetization of the whole structure should result in the growth of the compensation temperature with an  $L_p$  decrease. The same tendency was observed for  $[Gd/Fe]_n$  films. The  $\mu_{Fe}(L_p)$  value [130] was calculated on the basis of spontaneous magnetization measurements made at temperature  $T = 4.2$  K, assuming independence from the thickness of the layers for the Gd magnetic moment on. It is a logical assumption, but there is a probability that Gd amorphization, which takes place with the reduction of the Gd layer thickness, is accompanied by noncollinear magnetic structure formation. The consequences of this transition are decreases in the level of the contribution of Gd subsystem and in the accuracy of the  $\mu_{Fe}$  definition. Another point to discuss is the exchange interaction feature. The temperature dependence of the spontaneous magnetization of Gd is a function of the exchange parameters: it has an “internal” Gd–Gd component and an “external” Gd–Fe exchange part. The exchange interaction between the layers, Gd–Fe, depends on the distance: it is at a maximum level near the interface and decays toward the center of the Gd layer. Therefore, the effectiveness of the exchange in Gd increases with the  $L_{Gd}$  decrease. As a result, in multilayers with thinner layers, magnetization declines less abruptly with temperature and  $T_{comp}$  is higher. The above-described mechanism and the  $\mu_{Fe}(L_p)$  dependence have similar tendencies of  $T_{comp}(L_p)$  change; therefore, their separation is not an easy task and has to be supported by additional theoretical analysis.

Let us now examine the role of exchange interaction between layers in multilayered structures using  $[Gd/Co]_n$

as a model. This system shows nonmonotonous temperature dependence of spontaneous magnetization at certain intervals of the layer thickness. Figure 7 shows compensation temperature dependencies on the value of the period of layered structure at a fixed ratio of  $L_{\text{Gd}}/L_{\text{Co}}$  [99, 100]. In both cases the compensation temperature increases as the period of the multilayered structure decreases. Because spontaneous magnetization of Co is not very sensitive to amorphization, the main reason for the increase in compensation temperature is probably an increase of the magnetic order in Gd due to growing exchange influence of Co. Here again additional comments are needed. The structural transitions of Gd may influence its contribution to the spontaneous magnetization and consequently the compensation temperature. The charge transfer may play a certain role as well. We mentioned in Section 3.1 that the charge transfer effect results in a decrease of the Co atomic magnetic moment. The charge is carried through the interface; therefore, its influence should become less important toward the center of the layer. To summarize, the magnetization of the Co layer can be nonuniform over the layer thickness. When the  $L_{\text{Co}}$  gets smaller, the relative role of the interfaces, where the magnetization is smaller, increases, and average magnetization corresponding to all parts of the Co component decays. The consequence of these peculiarities is that spontaneous magnetization depends on the structural state of the films or the preparation technology. The discrepancy between the experimental results reported in [99] and [100] can be explained by taking into account the fact that the authors used multilayers with very different thickness ratios,  $L_{\text{Gd}}/L_{\text{Co}}$  being 2.5 and 1.2, respectively.

Additional information about spontaneous magnetization can be derived from the study of structures with relatively thin layers. For example, the dependence of the specific magnetization,  $\sigma$ , of the systems  $[\text{Tb}(0.45)/\text{Fe}(L_{\text{Fe}})]$  and  $[\text{Dy}(0.5)/\text{Fe}(L_{\text{Fe}})]$  on the Fe layer thickness was reported in [168]. The shape of the  $\sigma(L_{\text{Fe}})$  curves is rather complicated. The measurements were performed at room temperature, that is, the state when Tb and Dy are not magnetically ordered. Apart from this, thin Fe layers are in an amorphous state and can be nonferromagnetic as well. Therefore, in the  $L_{\text{Fe}} < 0.7$  nm region, we observe the presence of detectable magnetization connected with formation of the amorphous Tb-Fe and Dy-Fe alloys due to mixing of the adjacent layers. The magnetization changes for thin Fe layers depend on the variations in composition of the mixed interfaces.

**Figure 7.** The dependence of compensation temperature on the period of  $[\text{Gd}/\text{Co}]_n$  films. Reprinted with permission from [99], A. V. Svalov et al., *J. Alloys Compd.* 327, 5 (2001). © 2001, Elsevier Science.

Changes in the  $\sigma$  sign values mean changes in the relative magnetizations of each sublattice in the ferrimagnetic R-Fe structure. In the  $L_{\text{Fe}} \sim 1$  nm region two curves have a fold and plateau, these being the manifestation of the appearance of Fe amorphous layers with minimum magnetization and increasing thickness. Consequently, we conclude that the thickness of the interface of the variable composition from the Fe side can be up to 0.5 nm. The sharp growth of magnetization immediately after the plateau is the consequence of the Fe crystallization and its transition into a high-spin state. The critical thickness of high-spin state transition depends on the composition adjacent to the iron layers.

Together with the magnetic layer thickness, nonmagnetic spacers introduced between R and T metals can be considered as an effective instrument for influencing spontaneous magnetization of the R/T structures. It is clear that nonmagnetic spacers should decrease the interlayer exchange and transform the  $M_s(T)$  dependence. The following publications on the use of nonmagnetic spacers are of interest: [28, 143, 148] for Y and Cu, [30] for Si and Cu, and [31] for Cr and Pt with Gd/Co as a model structure. The Gd/Co system is characterized by having the strongest interlayer interactions. The compensation temperature was found to be very sensitive to the state of the interface quantitative parameter. Figure 8 shows examples of the  $T_{\text{comp}}$  dependencies on the thickness of Cu and Si spacers. One may compare these data taken for  $[\text{Gd}(7.5)/\text{X}/\text{Co}(3)/\text{X}]_{20}$  films with very interesting results for  $[\text{Gd}(3)/\text{X}/\text{Co}(3)/\text{X}]_n$  multilayers for Y and Cu spacers [28]. We observed a decrease in the compensation temperature as the thickness of spacers  $L_s$  increased as a result of the weakening of the ordering exchange influence of Co on Gd and the decrease in the gadolinium magnetization.

This general tendency for change in the compensation temperature can also be accompanied by a significant quantitative difference of the  $T_{\text{comp}}(L_s)$  behavior for spacers of different composition. The spacer can work as a passive element, simply changing the distance between magnetic layers, but most probably the increase in thickness of nonmagnetic spacers plays an active role at the interval of 0 to 1 nm. The active parts of nonmagnetic spacers have an island structure and the  $L_s$  increase actually corresponds to a decrease in the area of direct contact between magnetic layers. Thus, the particular morphology and relief of each component of the multilayer may be important parameters. The

**Figure 8.** The dependence of compensation temperature on X spacer thickness for  $[\text{Gd}(7.5)/\text{X}/\text{Co}(3)/\text{X}]_{20}$  films: (1) Cu; (2) Si; experimental data, circles; result of calculation, lines.

effectiveness of the interlayer exchange interaction, which is achieved most probably by an indirect mechanism, should depend on the conductivity of nonmagnetic spacers. Neither the direct nor the indirect mechanism has yet been systematically studied.

Nonmagnetic spacers may play an active role and influence the adjacent layers. For example, the authors of [28] associated the tendency for rapid reduction of the compensation temperature in multilayered structures with the introduction of additional Cu layers and the consequent formation of a nonmagnetic part of the Gd–Cu alloy. The effective thickness of nonmagnetic layers is increased compared with the calculated Cu layer thickness. However, such an abrupt compensation temperature decline (Fig. 8, curve 1) was not observed in another study. Even more curious, one might think that the heat treatment ought to result in the Gd and Cu mixing and a decrease in the compensation temperature, but the data of [101] show an increase in  $T_{\text{comp}}$  in the case under consideration. The results of the Si spacer introduction are less uncertain (Fig. 8, curve 2). The high Si effectiveness may be attributed to the phenomenon of charge transfer from Si to Co. Silicon brings down the magnetization of Co in the area near the surface and weakens the exchange interaction more than would be the case if it were just simply increasing the distance between interacting layers.

In concluding this section, we can say that spontaneous magnetization of R/T multilayers with heavy rare earth elements acts in accord with the general principles of ferrimagnetism, but localization of the negative exchange interaction in the contact zone results in spontaneous magnetization being highly sensitive to the geometrical, structural, and compositional characteristics of the multilayered films.

### 3.3. Magnetic Structure of R/T Multilayers in a Magnetic Field

The general features of R/T multilayer magnetism are determined by the exchange interactions between R and T magnetic systems forming pseudo-ferrimagnetic structures. One effective way of getting information about these exchange interactions is to study their magnetization processes. This study is especially attractive in the case of R/T films because it is possible to modify the properties in relatively low fields. The magnetic phase transitions induced by the external magnetic field is one of the important indications of collinear ferrimagnetism. The transitions from the collinear to the noncollinear phase [102–107] were found in different R/T multilayers by magnetometry [169], magnetoresistance measurements [170], magneto-optic effects [108], Mössbauer spectroscopy [171], and resonant X-ray magnetic scattering [109].

The distinctive feature of a magnetic phase transition is a change in the slope of the magnetization curve or hysteresis loop  $M(H)$  (see example for  $[\text{Gd}(10)/\text{Co}(10)]_{50}$  in Fig. 9 [110]). One may see break points, which correspond to the appearance of noncollinear structures in both the positive and negative fields. Even more pronounced transformations are seen on the magnetoresistive curve  $\Delta R(H)$  (Fig. 9). The measurements of the magnetoresistance were done in parallel geometry, that is, with the current flowing parallel to the direction of the applied magnetic field.

**Figure 9.** The dependence of magnetization  $M$  and longitudinal magnetoresistance  $\Delta R$  on the magnetic field for  $[\text{Gd}(10)/\text{Co}(10)]_{50}$  films at 5 K. Reprinted with permission from [110], H. Nagura et al., *J. Magn. Mater.* 240, 183 (2002). © 2002, Elsevier Science.

The break points of the magnetization curves can only be easily detected in a low temperature region ( $\sim 4.2$  K). At higher temperatures the paraprocess in gadolinium plays a “masking” role. Figure 10 shows the hysteresis loop of  $[\text{Gd}(7.5)/\text{Si}(0.5)/\text{Co}(3)/\text{Si}(0.5)]_{20}$ , measured at 97 K [111]. Against the background of the monotonous magnetization changes, the break points of the  $M(H)$  curve, which are related to the noncollinear structure formation, are almost invisible. In this case the magnetoresistance and magneto-optical effects are more helpful as indicators of the phase transitions. The difference between the magnetic hysteresis loop  $M(H)$  and the magneto-optical  $F(H)$  loop (Fig. 10) confirms this conclusion. The higher sensitivity of the  $\Delta R(H)$  and  $F(H)$  curves in the break point visualization is due to the fact that the magnetoresistance anisotropy and the plane of the light polarization rotation (Kerr effect) are much higher for 3d than for rare earth metals. Therefore, as the paraprocess takes place mainly in the R subsystem it makes only a very small contribution to the  $\Delta R$  and  $F$  values.

Mössbauer spectroscopy is usually associated with the introduction of the  $^{57}\text{Fe}$  isotope into the system being studied. It is very productive, therefore, for the R/Fe multilayers and gives information about the state of Fe layers [32, 42, 171] such as the  $T$ - $H$  phase diagram for Gd/Fe systems with various layer thicknesses [32]. In the coordinate plane of “temperature–magnetic field strength,” it represents the areas where the different magnetic phases exist in

**Figure 10.** Field dependence of the magnetization  $M$  and Kerr rotation  $F$  for  $[\text{Gd}(7.5)/\text{Si}(0.5)/\text{Co}(3)/\text{Si}(0.5)]_{20}$  at  $T = 97$  K. Reprinted with permission from [111], D. N. Merenkov et al., *Low Temp. Phys.* 27, 137 (2001). © 2001, Fizika Nizkih Temperature.

the structure with a compensation temperature of  $\sim 200$  K. These areas are separated by the curve that defines the critical field of the phase transition for each temperature. The areas corresponding to the collinear structures are situated below this curve, where the magnetic moment of Gd layers is parallel to the field for  $T < T_{\text{comp}}$ , and for  $T > T_{\text{comp}}$  the external field direction and the magnetic moment of Fe are also parallel. Above the critical field curve lies the area of the angular phase, this phase is described as *twisted*.

The term *twisted magnetic phase* was not introduced by accident, but specifically to emphasize a special feature of noncollinear magnetic structure in layered materials. In contrast to uniform ferrimagnets, in multilayers the negative exchange interaction between magnetic elements is spread nonuniformly through the multilayer volume: the highest value corresponds to the interfaces and it decays very fast toward the center of the magnetic layer. As a result there is a spatial nonuniformity in noncollinear structures, in which the angle between the local magnetization and an external field decreases from the separating interface toward the center of the layer. Very weak self-exchange interaction and the dependence of the magnetization of R layers on the thickness produce additional complications. The latter is conditioned by the magnetic action of the 3d layer in the area near the interface on the Gd in this area. As a result, the twisted magnetic structure is formed basically in R layers and is characterized by the angular and amplitude dependence of the magnetization. This model was first developed theoretically [172] and then confirmed by resonance X-ray magnetic dispersion [24, 109].

Magnetic phase transitions can be stimulated not only by magnetic field variation but also in a fixed field by temperature variation (see as an example the measured and calculated  $T$ - $H$  diagram for  $[\text{Gd}(8.4)/\text{Fe}(4.2)]_n$  in [32]). The temperature dependencies of R/T multilayers magnetization are peculiar in this case. Figure 11 shows  $M(T)$  dependencies

**Figure 11.** Experimental (a) and calculated (b) temperature dependencies of the magnetization of  $[\text{Gd}(7.5)/\text{Si}(1)/\text{Co}(3)/\text{Si}(1)]_{20}$ . The curves are recorded in the fields  $H = (1)$  and  $(4)$  200 Oe,  $(2)$  and  $(5)$  500 Oe,  $(3)$  1000 Oe, and  $(6)$  750 Oe. Reprinted with permission from [112], G. S. Patrin et al., *JETP Lett.* 75, 159 (2002). © 2002, IAPC “Nauka/Interperiodica.”

for a  $[\text{Gd}(7.5)/\text{Si}(1)/\text{Co}(3)/\text{Si}(1)]_{20}$  multilayered structure, with in-plane measurements made for the magnetic field of 200–1000 Oe [112]. All curves have local maxima. Their origin seems to be associated with the existence of a noncollinear magnetic structure and the increase of the magnetization within its frame. The low values of critical fields are related to weak interlayer exchange in the R/T structure because of the presence of the nonmagnetic Si spacer. The increase in the magnetic field strength results in the extension of the temperature interval where the anomalous critical points appear basically by extension in the low temperature region. On the high temperature side, the positions of the anomalous critical points are limited by the Gd transition to the paramagnetic state.

R/T multilayers show the disturbance of the collinear structure in the magnetic field, that is, the most general property of all low anisotropy ferrimagnets. Special features of multilayered structures are the low field of the magnetic phase transitions and space nonuniformity of the twisted magnetic phase.

### 3.4. Phenomenological Models

Although results of many experiments on the magnetic properties of R/T multilayers have been published recently, their microscopic theory remains to be developed. The situation is easy to understand, because of the influence of factors such as their complicated structural/chemical state and the strong role of technological factors when it comes to the repetition and comparison of experimental data. Meanwhile phenomenological models of interlayer exchange based on mean field theory have been developed.

The simplest model supposes nonuniform layer mixing; for Co/Dy see, for example, [37]. According to this model there is a sine-shaped modulation of the composition over the thickness from pure Co to pure Dy. To calculate spontaneous magnetization, the film has to be sectioned into thin sublayers of corresponding composition of amorphous Dy–Co for each one. The calculation corresponding to all layers enables us to calculate the temperature dependencies of the spontaneous magnetization  $M_s(T)$  for different periods of the layered structure. Using the Co/Dy system as a model, Shan et al. [37] demonstrated the nonmonotonous behavior of the calculated dependencies and achieved reasonable agreement with experiments. But, at the same time, this approach should be considered as something of a simplification, because it does not allow adequate description of the field behavior of the magnetic structure.

Mixing of the layers is the key assumption of a more complicated theory [173] where the R/T layered structure is treated on the base of a cubic lattice with partial mixing of the different types of atoms in the interface area. In a Heisenberg model framework, using Monte Carlo simulations, it was shown that the temperature dependence of spontaneous magnetization, compensation, and Curie temperatures may depend on the layer thickness and the interface state. The theoretical and experimental results for Tb/Fe structures are in satisfactory agreement, when one takes into consideration the concentration dependencies of the atomic exchange parameters and variation of the Tb atomic magnetic moment.

In contrast, the well-defined layers approach is used in [174] with the iteration method to find the equilibrium magnetization distribution with temperature and applied field as parameters. The film structure is divided into thin sublayers with uniform magnetization in each one as oriented in the plane of the sublayer. The transfer from one sublayer to the next is characterized by changes to the value and orientation of magnetization in a discrete way. Both the first and second sublayers depend on the kind of atoms under consideration (R or T) and the presence of an effective field in each sublayer. In the absence of magnetic anisotropy and self-demagnetization, the effective field in each sublayer consists of the sum of the external field and the exchange fields of the adjacent sublayers. The exchange fields between layers of the same composition are positive and those of different compositions are negative. The aim is to construct the configuration of the magnetic moments to minimize the energy in the external field and the exchange energy of the system.

The search for equilibrium magnetic configuration is carried out by the iteration method. In the initial state there is random orientation of the magnetic moments of all layers. The first iteration consists of fixing of the magnetic moment of a randomly selected sublayer parallel to the effective field and calculation of its value at a certain temperature. The temperature dependence of the magnetization is described by the Brillouin function. Then the whole procedure is repeated for the fixed moment of the first sublayer and repeated until we have achieved parallel orientation of the magnetic moments and local effective fields in all sublayers and their corresponding values at the temperature under consideration. This state corresponds to the minimum of free energy.

In the localized layer model [44, 172, 175] efforts have been made to use an analytical approach to describe R/T structures according to molecular field theory. The spontaneous magnetization at  $T = 4.2$  K and temperature dependence of the  $M_s$  were calculated for Gd/Fe multilayers with different periods of the layered structure. The agreement with experimental data is close enough, given the condition of a sharp decay of the magnetic moment of Fe atoms in the films with less than a 15 nm period. This condition seems to be related to the Fe transition to the amorphous state.

Among the studies based on the sharp interface approach, we have listed a theoretical study [176]. Here the exchange interaction is assumed not only to be effective at the interface but also to be spread through the volume by exponential decay. Therefore, the authors use an additional model parameter, the characteristic length of the exchange interaction ( $l_{ex}$ ). Temperature dependencies of the spontaneous magnetization for Tb/Co multilayers with different layer thickness and different compensation temperatures have been calculated according to mean field theory. The best agreement of the theory with an experiment was found at  $l_{ex} = 0.5$  nm.

In another nonuniform interlayer exchange model [30, 93, 99, 113], assumptions are made about exponential law for the exchange interaction and the iteration method is used for definition of the equilibrium magnetic structure. Figure 12 (curve 1) shows the temperature dependence of spontaneous magnetization for the  $[Gd(7.5)/Co(3)]_{20}$  structure calculated by this method. The result of  $M_s(T)$

**Figure 12.** Temperature dependence of the magnetization for a  $[Gd(7.5)/Co(3)]_{20}$  film: circles, experimental results; (1) calculated by the model of nonuniform exchange interaction between layers; and (2) by the model of partial mixing layers. calculations for the mixed layers model, but without taking interlayer exchange into account, is shown in Figure 12 (curve 2) for comparison. The first model describes the experimental data (points) better. The studies [30, 93, 99, 113] take into account the influence of different neighbors on magnetic properties of the R and T layers. As a result changes in the compensation temperature of the Gd/Co films with nonmagnetic spacers were calculated (Fig. 10) and anomalies in the temperature dependencies of the magnetization were explained (Fig. 11b).

In summary, there are several phenomenological models of R/T magnetism. The majority of them give a satisfactory description of the temperature dependence of spontaneous magnetization and magnetization behavior in the magnetic field. It is difficult to say which one is the best, because all of them operate by adjusting some theoretical parameters, but we can state the general principle, which helps achieve adequate description of the magnetic properties of R/T multilayers, namely, the presence of long range, nonuniform exchange between R and T layers and the reciprocal dependence of the atomic and electronic structures of the adjacent layers.

#### 4. MAGNETIC ANISOTROPY

Why do R/T multilayers attract so much attention in the scientific community? The answer is simple: because they may have perpendicular magnetic anisotropy (PMA) [2]. PMA is uniaxial magnetic anisotropy with an easy magnetization axis perpendicular to the plane of the film; that is, the orientation of the magnetization vector is perpendicular to the plane of the layered structure, even without application of an external magnetic field. Because of this property R/T multilayers are considered as a potentially interesting medium for perpendicular recording, including magneto-optical perpendicular recording [177]. Other interesting magnetic anisotropy features of these materials are very high PMA value [41], localization of most anisotropy parts in areas near to the surface of the magnetic layers [62], and the characteristics of the shape anisotropy of R/T multilayered structures [115].

#### 4.1. Structural Origins of Perpendicular Magnetic Anisotropy

Macroscopic magnetic anisotropy is the manifestation of structural anisotropy, which appears in one way or another in all magnetically ordered systems. The main kinds of structural anisotropy, which may drive magnetic anisotropy are crystalline lattice, preferred orientation of the axes of like-atom pairs, anisotropy elastic deformation, nonuniform distribution of the defects over the grain boundaries, ordered distribution of microscopic structural formations possessing shape anisotropy, and shape anisotropy of the macroscopic objects.

All of the structural features mentioned above can appear in thin films. However, such small subjects have an additional very specific feature, namely, surface anisotropy. This occurs when atoms located near the surface are in a specific position. The surface atoms have asymmetrically arranged nearest neighbors. The volume fraction of these atoms and role of the surface anisotropy increase with a decrease in the thickness of the layer. In multilayered systems, the atoms near the interfaces are in the same situation. Therefore, in the majority of publications related to the study of R/T anisotropy, the most attention has been devoted to the structure of the interfaces.

We discussed the size parameters of interfaces in Section 1, but more detailed data on the atomic structure of the interfaces are needed to understand the nature of their magnetic anisotropy. One of the sources of such information is the method of extended X-ray absorption fine structure (EXAFS). On the basis of data collected by the EXAFS method for Tb/Fe, the atomic distribution anisotropy in the interfaces can be quantified [178–180]. The main effect is interlayer diffusion with a preference direction perpendicular to the interface plane. As a result there is asymmetry for nearest neighbors around any selected atom: on the side of the terbium layer there are more Tb atoms among the nearest neighbors and there are more iron atoms on the Fe side.

Structural anisotropy is connected with a gradient of chemical components, oriented perpendicular to the multilayer plane. By analogy with perpendicular magnetic anisotropy, this is called perpendicular structural anisotropy (PSA). The PSA unit,  $K_{\text{psa}}$ , is the relative difference of probabilities for two atoms of the same kind to be nearest neighbors in the directions parallel and perpendicular to the film plane [180].

Figure 13 shows the experimental and calculated  $K_{\text{psa}}$  dependencies for iron atoms on the period,  $L_p$ , of the Tb/Fe layered structure if the thickness of the iron and terbium layers is the same,  $L_{\text{Tb}} \approx L_{\text{Fe}}$ . This dependence is non-monotonous with a maximum corresponding to the period value of 1–2 nm. This result is confirmed by experimental study of PMA. For example, one can compare the dependencies for the anisotropy constant,  $K_u$ , on the thickness of 3d layers in R/T structures of various compositions [37]. All  $K_u(L_T)$  dependencies have a maximum. Their position is variable on the  $L_T$  axis depending on the components, but always in the interval from 0.4 to 1 nm, the same as the position of the structural anisotropy maximum. At the same time linear decay of  $K_u$  was reported [57] for Tb/Fe structure in the interval of  $L_p$  from 0.6 to 5 nm. Although the

**Figure 13.** Comparison of experimental (circles) and calculated (lines) perpendicular structural anisotropy obtained from Fe EXAFS and simulation, respectively. relationship between PSA and PMA is not contested, PSA is mentioned in other studies [4, 39, 55, 181, 182]. The PMA value was also found to be almost independent of the substrate; that is, mechanical tensions which sometimes arise on the substrate–film boundary have very little effect [181].

#### 4.2. Mechanisms of Magnetic Anisotropy

The fact that perpendicular magnetic anisotropy in R/T multilayers depends on the structural magnetic anisotropy does not define the mechanism of magnetic anisotropy. The atomic structure of the interlayer interfaces described above has given rise to two different explanations of the principal governing PMA mechanisms. The first is two-ion anisotropy as a result of different dipole interactions of neighbor atoms (the Neel–Taniguchi and Yamamoto model). The second is single-ion anisotropy, which may occur because of spin–orbital interaction in metals that have anisotropic electron shells. Most research tends to favor the second theory. One of the arguments supporting the second point of view is easy to accept: strong PMA appears only in multilayers that contain anisotropic electron shell ions [58, 83, 84, 183]. The data on the anisotropy of Dy/Fe, Dy/Co, Tb/Co, Gd/Fe, and Gd/Co systems can be found in [37]. In multilayers with anisotropic Dy and Tb ions the perpendicular anisotropy constant is 1 order of magnitude higher than that corresponding to the spherical Gd ion. The authors of the Nd/Fe, Pr/Fe, and Gd/Fe study [38] came to the same conclusion.

However, nonspherical electron shell shape, that is, a nonzero orbital ion moment, is not in itself a sufficient condition for the formation of PMA. For instance, the comparative study of Fe/Nd and Fe/Tm multilayers [136] resulted in the fact that PMA was found only in the Fe/Nd multilayer although Tm is also a nonspherical ion.. The complete analysis of all R/Fe spectrum multilayers (R = Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, or Lu) can be found in [56]. Only nonmagnetic Y, La, Yb, Lu, and Gd with zero orbital moment do not lead to single ion anisotropy formation. For other elements there is no prohibition, but PMA was found only in multilayers containing Pr, Nd, Tb, and Dy. Finally, not only is anisotropy of the electron shell important, but also the configuration of the crystalline field of the neighbor ions is important. Perhaps the atomic structure of the interfaces forming the crystalline field depends

slightly on the kind of rare earth atoms, but these variations are small and difficult to detect.

An even more surprising conclusion was drawn recently [69] on the basis of X-ray magnetic dichroism analysis of Tb/Fe multilayers where transformation of the Tb electronic structure was observed as a consequence of a decrease in the layer thickness. It consists of the loss of orbital moment by Tb ions automatically prohibiting their taking part in single ion anisotropy formation. In the Dy/Co study [181], the anisotropy dipole interaction of the atomic magnetic moments approach is used to describe PMA, in the same way as for Gd–Co amorphous films [184, 185]. However, in the multilayered structures the anisotropy carriers are localized in the interfaces, which leads to an almost incredibly high value of the parameter that defines the pair distribution anisotropy.

### 4.3. Influence of Various Factors on the Magnetic Anisotropy

To clarify the nature of the magnetic anisotropy in R/T multilayers, continued detailed investigation of the atomic structure of both magnetic layers and interfaces is needed. The lack of direct experimental data has stimulated many indirect studies of the influence of different factors on the PMA.

As a result of the temperature dependence of the Dy/Co multilayer magnetic anisotropy study [54], the PMA value at  $T = 4.2$  K was found to be many times stronger than that for  $T = 300$  K. The  $K_u$  temperature dependence correlates with  $M_{Dy}^2$  temperature behavior. This seems to support the single-ion theory of the PMA mechanism. Many attempts have been made to clarify the connection between different characteristics of interfaces and PMA, but it is not easy to make a comparative analysis of different authors' data because of differences in preparation and experimental methods.

The Mössbauer effect has been very useful for obtaining information about the magnetic anisotropy of R/T multilayers. In particular, it was shown that in Nd/Fe multilayers, magnetic anisotropy increases as the interface thickness decreases [186]. The decrease of PMA due to interface roughness was described in [68, 187]. In addition, the conclusion connecting PMA with a very wide mixed interface in the Tb/Fe system was reached [188]. In Dy/Co multilayers, the maximum PMA value was found at 0.6 nm for both Dy and Co layers. In this condition, the ratio of the interface size and the total volume is maximum [54, 87, 189].

It must be kept in mind that the interface structure may depend on the deposition order of the layers. The delicate experiments for the magnetic anisotropy study for two-layered Tb/Fe and three-layered Tb/Fe/Ag films [59–61, 190, 191] were carried out in this context. The interface was considered to be the major source of PMA for Tb deposition onto the Fe layer. The interfaces are sharp and, in this case, Fe has a crystalline structure. Fe deposition onto the Tb layer creates rough interfaces and initiates the amorphization of the layers [92]. The influence of different interfaces on PMA was investigated in the [Tb/Fe/Y]<sub>10</sub>, [Y/Fe/Tb]<sub>10</sub>, and [Tb/Fe]<sub>10</sub> systems [62]. The Y layer was introduced to exclude the Tb on Fe and Fe on Tb boundaries. All systems had more or less pronounced PMA. At temperatures below 100 K, stronger anisotropy was detected for Tb on Fe than

for Fe on Tb. In the 250 to 300 K temperature range, Fe on Tb related anisotropy was higher. A possible explanation might include the differences in magnetism for the two types of boundaries. At low temperatures strong single ion Tb anisotropy corresponding to the sharp interface dominates. At temperatures higher than that of Tb magnetic ordering (219 K) it decreases, but weaker anisotropy related to mixed boundaries starts to be important. The mixed boundary actually consists of a ferrimagnetic alloy of Tb–Fe with high Neel temperature. The length of this boundary results in low PSA and correspondingly small PMA. Comparison of PMA values at room temperature revealed the lowest  $K_u$  value for Tb on Fe, an intermediate value for Fe on Tb, and the highest for the two types of boundaries together because, apart from the one-ion anisotropy in Tb/Fe samples, dipole interaction between Fe layers through the Tb layer may take place. This mechanism was suggested as an explanation for the CeH<sub>2</sub>/Fe system anisotropy [193].

The magnetic layers themselves may play a certain role in the formation of magnetic anisotropy. The main point here is the influence of the thickness on the magnetic properties of each layer in multilayered structures. For example, the increase of magnetization and consequently of the demagnetizing field is the result of increased layer thickness in Tb/Fe multilayers [41] together with a decrease in PMA [67]. At the same time, amorphization of the relatively thin layers appears. At room temperature both Fe and Tb lose their magnetic order whereas a decrease in magnetic phase volume leads to a corresponding decrease in the PMA value. Similar ideas were considered for R/Fe (R = Pr, Nd, and Tb) system analysis [48].

There are data about the presence of PMA only in those Tb/Fe structures that do not have pure terbium [43, 44, 194]. When pure Tb layers have been included in a multilayered structure, PMA has been detected at temperatures below 220 K, that is, after the Tb transition in the ferromagnetic state. It is on this basis that the conclusion about PMA induction in the interfaces in the presence of the exchange interaction between Fe layers through the Tb layers has been reached. A similar result has been reported in a study by transmission electron microscopy of pure Tb segregation with Tb layer thickness of more than 1 nm [64]. The occurrence of segregation coincides with PMA disappearance at room temperature. However, there are also data about the presence of PMA in Tb/Fe multilayers with  $L_{Tb} = 2$  nm [65].

One interesting feature of the structural transition taking place in R/T structures as the layer thickness changes is the iron crystallization and, as a consequence, an increase in PMA, which is caused by the formation of a sharp interface between the layers [42]. Comparing the multilayer properties formed at two different substrate temperatures of 150 and 300 K, these authors found that iron crystallization took place at 300 K with thinner layers and it was precisely these samples, with a minimum thickness of crystalline Fe, which had the maximum PMA value. The increase of the perpendicular magnetic anisotropy value after heat treatments of Tb/Fe has been explained in other research by the very sharp interface formation [49, 63]. The temperatures and thickness of the layers related to structural changes of multilayers vary from one publication to another because of dependence on varying preparation methods.

Let us now return to the results of the R/T study at different temperatures. We have discussed the possibility of a significant increase in PMA values at low temperatures, but this is true only for structures with relatively thin layers, where the interfaces play the main role. At greater thicknesses the temperature decrease may cause an opposite effect, even so far as to change the magnetization orientation to the film plane from perpendicular into parallel. Such a reorientation of the spins is brought about by a change in the correlation between the induced perpendicular anisotropy and shape anisotropy. The existence of the reorientation itself and the reorientation temperature both depend on the average chemical composition of the multilayer (correlation of the thickness of the layers) and period of the layered structure [41]. The dependence on the multilayer period to a certain extent can be explained by changes of the interlayer exchange interaction whose role increases with a decrease of the period of the layered structure. Similar results were reported in [195], although in [63, 196] the authors found no dependence of the magnetization orientation on the thickness of the Fe and Tb layers at low temperatures.

An additional important factor influencing PMA is the number of periods,  $n$ , in multilayer structure [55, 66]. For  $[\text{Tb}(0.42)/\text{Fe}(0.75)]_n$  magnetization is oriented in the plane of the layered structure if  $n$  varies from 1 to 30. Increasing the number of layers ( $n$ ) up to 35 causes PMA to occur, but its value shows only very small changes for further increase in  $n$ . For the  $[\text{Tb}(0.95)/\text{Fe}(1.15)]_n$  structure, PMA appears at  $n \geq 5$ , but the authors do not discuss the possible origin of these variations [55, 66]. We might suppose that the temperature regime of deposition plays an important role because it may vary over the extended period of total deposition time needed for structures with high  $n$  value.

#### 4.4. Enhanced Magnetostatic Effect

The majority of the results discussed are related to R/T multilayers with perpendicular magnetic anisotropy. The most important condition of PMA formation is the presence of layers with anisotropic rare earth ions in a multilayered structure. Gd is irrelevant in this case. It makes Gd/T multilayers less attractive for magnetic recording applications. However, due to high Curie temperature and collinear ferromagnetism, Gd/T can be very useful as a model system for studying R/T structures [93, 114, 174, 197, 198]. Specifically, study of the magnetic anisotropy of a layered ferrimagnetic  $[\text{Gd}(7.5)/\text{Co}(3)]_{20}$  structure was undertaken in a magnetic compensation region of 200 to 300 K including the compensation temperature ( $T_{\text{comp}} \approx 240$  K) and no perpendicular anisotropy was detected [115]. In accordance with shape anisotropy, the magnetization was oriented in the plane of the films, but the actual shape anisotropy constant was much higher than  $2\pi M_s^2$ , where  $M_s$  is the spontaneous magnetization of the ferrimagnetic structure. Figure 14 shows  $K(T)$  and  $2\pi M_s^2(T)$  dependencies in the magnetic compensation region. This discrepancy disappears if we take into account an additional contribution in magnetostatic energy related to the rising of the magnetic charges in the interface areas. Because of a negative exchange interaction between Co and Gd, the surface density of these charges is defined as a sum

**Figure 14.** Temperature dependencies of magnetic anisotropy constants measured by a torquemeter (1) and calculated as  $K_s = 2\pi M_s^2$  (2), respectively. Reprinted with permission from [115], V. O. Vas'kovskiy et al., *J. Magn. Magn. Mater.* 203, 295 (1999). © 1999, Elsevier Science.

of the normal components of the magnetizations of the layers, but not as a normal component of total magnetization of the ferrimagnetic Gd/Co structure. A similar enhanced magnetostatic effect was also observed in  $\text{Gd}_{15}\text{Fe}_{85}/\text{Gd}_{40}\text{Co}_{60}$  amorphous multilayers [199].

## 5. ATTENDANT PROPERTIES

Magnetoordered substances possess a number of physical properties that are not directly related to the set of inherent magnetic properties, but become available because of the existence of spontaneous magnetization. Usually, they are revealed during magnetization and consist of changes in size (magnetostriction) or electrical resistance (magnetoresistance effect) of the samples or of changes in the characteristics of the refracted or reflected light (magneto-optical effects), the absorption of the electromagnetic field energy (magnetic resonance), etc. Thus, generally there is a possibility of driving the nonmagnetic parameters of these materials and of products made from them using a magnetic field. Very often properties that are precisely attendant on magnetism define the importance of the material for technological applications. The values of the effects described above, as well as those of spontaneous magnetization, are defined to a considerable extent by the chemical composition but may also reflect the structural state. Furthermore, many features of nonmagnetic properties depend on the type of magnetic structure and on features of their magnetic anisotropy. In this section we review very briefly these related phenomena in R/T multilayers.

### 5.1. Magnetostriction

The elastic deformation, which, in the presence of magnetic ordering, occurs in a crystal lattice or in an amorphous structure of a solid-state body, reflects the existence of the exchange and the magnetic interactions between elemental carriers of magnetism. As a result the volume and shape of macroscopic subjects are changed. We say that volume and, accordingly, linear magnetostrictions take place. Linear spontaneous magnetostriction is important for applications, because the elongation or shortening of the magnetic sample

in a certain direction depends on the spontaneous magnetization orientation. The magnetization process takes place by rotation of the magnetization vector in the whole sample or only in part of it, and this causes a rotation of the total or local deformation axis resulting in changes in the sample size in the direction of the applied field. Deformation caused in this way is defined as magnetostriction. Magnetostriction is an even effect; that is the deformation does not depend on the sign of the magnetization.

Very high, giant magnetostriction is a characteristic feature of many rare earth magnets. As for single-ion magnetic anisotropy, it is caused by rare earth ions. The magnetization rotation caused by spin-orbital interaction is accompanied by a change in the orientation of the electron orbits of these ions in an intercrystalline field and deformation of the atomic structure and of the sample as a whole. Among the crystalline magnets with giant magnetostriction, a  $\text{TbFe}_2$  crystalline intermetallic compound is well known. In the thin film state it is usually amorphous but shows relatively high magnetostriction. The main disadvantage in terms of practical applications for this material and for materials of similar composition is their low magnetic susceptibility. Many efforts have been made to decrease magnetic anisotropy while keeping the high magnetostriction of R-based materials. Among other possibilities is that of creating multilayered thin film structures with optimal magnetoelastic properties, for instance, trying to improve the magnetic susceptibility of a Tb-Fe film by introducing soft magnetic material sublayers with high magnetization (like Fe) [200]. The best results were achieved in a  $[\text{Tb}_{0.4}\text{Fe}_{0.6}(4.5)/\text{Fe}(6.5)]_n$  system with strong exchange interactions between the elements of the layered structure. After heat treatment at 550 K the magnetostriction in the low field of 200 Oe is 1 order of magnitude higher than that corresponding to single-layer films of the same composition, and this sounds very promising.

A similar effect of introducing Fe sublayers has been reported for  $\text{Tb}_{34.2}\text{Fe}_{65.8}$  films [201]. Figure 15 shows the dependence of magnetostriction,  $\lambda$ , on the strength of the magnetic field  $H$  for single-layer Tb-Fe films and for  $[\text{Tb}_{34.22}\text{Fe}_{65.8}(L_{\text{Tb}})/\text{Fe}(10)]_n$  with different thicknesses of Tb-Fe layers. The authors believe that creation of the layered structure results in a decrease in the strong perpendicular anisotropy, which is typical of single-layer films of this composition and as a consequence facilitates the in-plane magnetization process. The authors have also pointed out that the multilayers have a ferrimagnetic structure that transits in a noncollinear phase in the field of about 1 kOe. The magnetostriction curves  $\lambda(H)$  reflect in some way the magnetization process, opening the possibility of using it as a tool for the R/T multilayer study. The same opinion is expressed in relation to the Gd/Fe ferromagnetic resonance study [116], in which the magnetoelastic deformations were found to depend on the deposition methods. Specifically multilayers prepared by DC sputtering have higher magnetostriction than those prepared by rf sputtering. This can be explained by the presence of sharp interfaces in the first type of films.

**Figure 15.** Elastic coupling coefficients (magnetostriction) of  $[\text{Tb-Fe}(X \text{ nm})/\text{Fe}(10 \text{ nm})]_n$  multilayers with various Tb-Fe thicknesses: (a)  $X = 15$ , (b) 20, (c) 25, and (d) 30 nm and (e) a Tb-Fe single layer film measured in the longitudinal direction of the magnetic field. ## 5.2. Magnetoresistance

Magnetoresistance is the change in electric resistance,  $R$ , of a ferromagnetic conductor caused by a magnetic field. This is a galvanomagnetic effect. In magnetically ordered materials it reflects a magnetic contribution to the conductive electron scattering, which depends on the value and orientation of the spontaneous magnetization. Therefore, one may separate the two components. In uniform magnets only the component related to the magnetization orientation is of practical interest, that is, anisotropic magnetoresistance. The magnetic field causes magnetization rotation and changes the electrical resistance of the sample, and thus the effect of the anisotropy of the magnetoresistance takes place. As for magnetostriction, magnetoresistance is an even effect.

Some time ago, a new type of magnetoresistive effect, *giant magnetoresistance* (GMR), was discovered in multilayered and granular magnetic structures [154, 202]. It consists of the change in electrical resistance at a variation of mutual orientation of magnetizations in heterogeneous magnetic structures with ultrathin elements. Let us emphasize that for both magnetoresistance and giant magnetoresistance we are dealing with direct current flowing over the ferromagnetic conductor. The discovery of GMR in Fe/Cr systems was preceded by the discovery and study of exchange coupling between magnetic layers across a nonmagnetic metallic layer [151, 153, 202] (see Section 3.1). The GMR effect occurs in a Fe/Cr system at a certain Cr thickness when antiferromagnetic coupling takes place and adjacent Fe layers have the opposite orientation to the spontaneous magnetization. When an external magnetic field aligns magnetizations in parallel configuration, the multilayer resistance decreases. Although GMR of Fe/Cr is induced by antiferromagnetic coupling, it was shown that antiferromagnetic coupling is not a necessary condition of GMR which can be caused, for example, by hysteresis effects [203, 204]. GMR is due to propagation of spin-polarized conductive electrons through the ferromagnetic films, divided by sublayer or spin-dependent scattering at the interfaces.

In R/T multilayers both the first effect, magnetoresistance, and the second, giant magnetoresistance, take place. R and T layers are not identical in terms of anisotropic magnetoresistance [91, 130, 170] because, compared with

rare earth metals, 3d metals have much higher anisotropic magnetoresistance. Because of the high specific resistance in R layers, the electric current flowing in a multilayer is pushed out from the R to the T layers as well. Therefore, the magnetoresistance of a R/T system reflects mainly the magnetoresistance of its T layers. It was shown in Section 3.3 that this feature is successfully used for registration and study of the magnetic phase transitions induced by a magnetic field [100, 110, 117]. Moreover, magnetoresistance analysis may yield certain information about the atomic structure [118].

The word *giant* is not very appropriate for describing the spin-dependent resistance of R/T multilayers because the value of the effect is small, even compared with ordinary anisotropic magnetoresistance. The small value of the effect makes it difficult to study when the geometry of the experiment determines that the electric current and the applied field are parallel to the plane of the film (CIP geometry). If the electric current flows perpendicular to the plane of the film (CPP geometry) and an external field is applied in the plane of the multilayered structure [202] and, therefore, magnetization occurs in the plane of the sample, the GMR is easier to measure because anisotropic magnetoresistance is absent. It is absent because magnetization and the electric current are perpendicular all the time. There is an opinion that resistance changes in the field take place because of deformations of the ferrimagnetic structure caused by the magnetic moments of R and T layers [110]. Figure 16 shows an example of  $R(H)$  dependence for a Gd/Co structure. High fields used in this, as in many other similar studies, cause a paraprocess in the gadolinium subsystem. Changes of the spontaneous magnetization of Gd should influence the  $R(H)$  behavior.

The low value of magnetoresistance is a great disadvantage for R/T multilayers in technological applications and makes them noncompetitive with many other magnetoresistive materials. At the same time, it is possible to use R/T structures as a part of more complicated systems showing GMR. Figure 17 shows the magnetometrical and magnetoresistive hysteresis loops for a  $[\text{Tb}(1)/\text{Co}(1)]_{16}/\text{Co}(5)/\text{Cu}(2.5)/\text{Co}(5)$  sample [70]. Here the multilayered  $[\text{Tb}(1)/\text{Co}(1)]_{16}$  element with in-plane magnetic anisotropy and a high coercive field acts as a pinning layer. The  $[\text{Tb}(1)/\text{Co}(1)]_{16}$  structure and the adjacent Co layer are

**Figure 16.** Resistance changes  $\Delta R$  in CPP geometry for a  $[\text{Co}(10) \text{ nm}/\text{Gd}(10 \text{ nm})]_{50}$  multilayer as a function of the applied magnetic field measured at 4.2 K. The initial resistance before applying the magnetic field is defined as  $\Delta R = 0$ . Reprinted with permission from [110], H. Nagura et al., *J. Magn. Magn. Mater.* 240, 183 (2002). © 2002, Elsevier Science.

**Figure 17.** Magnetometrical (a) and magnetoresistive (b) hysteresis loops for the  $[\text{Tb}(1)/\text{Co}(1)]_{16}/\text{Co}(5)/\text{Cu}(2.5)/\text{Co}(5)$  spin-valve structure.

connected to each other by exchange interaction and the multilayered structure provides the stability of the Co layer in the external field. At the same time, another Co layer, separated from the first by a Cu spacer, has the possibility of remagnetization in a small magnetic field. As a result, mutual magnetization of the cobalt layers may be changed by an external magnetic field, that is, GMR, which, in this particular case, could be better described as the *spin-valve* effect, occurs. The term spin-valve relates to a case where the possibility of separate remagnetization of the layers is caused not by the negative exchange interaction between the layers, but by the difference in the magnetic anisotropy or the coercive field of the layers [203, 205].

### 5.3. Magneto-optical Kerr Effect

Magneto-optical effects are certain changes of optical properties of a medium caused by application of the external magnetic field. In magnetically ordered materials they have special peculiarities due to the existence of spontaneous magnetization. From both basic and practical points of view, the most interesting are the Faraday and Kerr effects. They consist of the rotation of plane polarization at light refraction through (Faraday) or reflection from (Kerr) the magnet. In metals, the light penetration depth is limited by a skin effect and does not exceed 100 nm. Therefore, for multilayers only the magneto-optical Kerr effect (MOKE) is really interesting. The suitably smooth surface of multilayers is an advantage in this case. Different effects are produced depending on the direction and angle of the light incidence. The polar effect corresponds to geometry when magnetization points along the surface; a normal effect results in the rotation of the plane of polarization as a function of the perpendicular component of the magnetization. The longitudinal effect describes the plane polarization rotation for the light inclination onto the surface of the sample when the position of the magnetization is in the plane of the sample. The longitudinal effect can also be used for perpendicular polarization. It is proportional to the magnetization component in the plane of the light incidence. The transverse orientation effect in which the magnetization is perpendicular to the plane of incidence produces little contrast in a visible image [206].

There are a number of reasons for interest in the Kerr effect as observed in R/T multilayers [16, 20, 71, 72, 88, 92, 119, 178, 206–212]. The first is the comparison of the optical properties of multilayers with single-layer analogues

material. The authors of [207] have studied the Kerr rotation spectra for uniform amorphous and multilayered Gd/Fe films. The value of the effect is similar in both samples, but the layered structure opens the way for an additional technological possibility of controlling the magnetic and magneto-optical properties [190] useful for applications such as magnetic recording. Both high anisotropic Tb/Fe and low anisotropic Gd/Co films are interesting for the technique of super high resolution [16, 73] (see Section 5.4) as well as for other applications. The second line of interest is based on the Kerr effect using the magnetization process study method [88, 178]. The magneto-optical effect, in contrast to magnetostriction and magnetoresistance, is an odd effect; that is, it contains information about the sign of magnetization. As we mentioned in Section 3.3, the magneto-optical hysteresis loops are more informative than magnetometric loops for studying phase transitions. One may explain this finding by taking into account the fact that T metals have higher plane polarization rotation values than R metals. Figure 10 shows an example of a magneto-optical hysteresis loop observed via the longitudinal Kerr effect for perpendicular polarization. Direct domain structure observation is possible through the Kerr effect, although the number of publications related to R/T multilayers is small [66, 74, 92, 213]. Structural investigations can also be undertaken via the Kerr effect [20, 119]. Elegant, quick, and appropriate ways of detecting different types of coupling in layered magnetic structures by means of the MOKE were presented as the basis for the magnetic domain study [204, 214].

#### 5.4. R/T Structures and Magneto-optical Recording

Can you imagine our community without audio and video recorders, CD-ROMs, etc.? They are part of our lives. The two basic methods of recording are magnetic and optical. Here we describe very briefly the general principles of magneto-optical recording and the role of R/T materials.

The principle behind any recording is representation of numbers by the state of a bistable physical system; therefore, in the recording process we are dealing with binary numbers. Any number in a binary system can be written as a specific sequence of the elements equivalent to "1" or "0." In the magneto-optical recording medium we have a rather complicated multilayer structure of different layers, not all of which are magnetic. At the beginning, the homogeneously magnetized medium stores no information. We can then write onto it the required sequence of digits by a process of thermomagnetic writing, that is, cooling in or without a local magnetic field after local heating by a short laser pulse to a temperature close to the Curie temperature. Any zone with initial magnetization direction may represent the information unit "1." If a field biased in the opposite orientation is present during cooling, a magnetic domain is formed with opposite magnetization orientation to the initial magnetization. This represents the information unit "0." The size of the domain is determined by the temperature and by the profile of the temperature-dependent coercivity, that is, the magnetic properties of the magnetic film used. The stability of this information unit depends on the type

of the domain wall between the homogeneous part of the disc and the information unit, on the magnetization, and on the anisotropy energy. The reading process is performed by using the magneto-optical Kerr effect at typical wavelengths of 780 and 820 nm. To obtain the maximum signal, the magnetization should be perpendicular to the film plane (perpendicular recording) [212].

The quality and stability of the writing and subsequent reading depend strongly on the material properties of the magneto-optical films. PMA is required to keep the magnetization of the domains normal to the plane of the film/disc. Therefore, the energy of the demagnetizing field must be compensated for by the energy of the perpendicular anisotropy. This condition can be fulfilled when the magnetization is sufficiently small. It is achieved in modern devices by use of amorphous thin films consisting of R and T metals, coupled antiferromagnetically. The film thickness is on the order of 50 to 100 nm.  $Tb_{25}Fe_{75}$  is the most usual composition. In closely related compounds Tb and Fe are partially substituted for by other R metals (Dy and Gd) and T metals (Co and Ni), respectively. As mentioned in Section 3.1, different temperature dependencies of the magnetic T and R sublattices of the films normally have a compensation point, where the magnetizations of R and T cancel each other out, and the total magnetization is zero. The compensation point can be chosen close to room temperature by appropriate composition selection. As a consequence of a very small magnetization, the coercivity becomes very large at the compensation temperature and a very high field would be required for changes of the magnetic moments. As a result, a domain structure written at a temperature of about 500 K, close to Curie temperature, is very stable against external fields at room temperatures.

In addition to the magnetic layer for magneto-optical processing, the recording disc incorporates a nonmagnetic antireflecting coating, which reduces the polarization component of directly reflected light. To increase the signal-to-noise ratio a magneto-optical double layer ( $Tb_{11}Fe_{64}Co_{25}/Tb_{24}Fe_{65}Co_{11}$ ) [215] or trilayers or quadrilayers with an additional reflecting layer [216] can be used. To increase data access time, the erasing process can be incorporated into a so-called direct overwrite cycle [217]. One solution applies exchange-coupled double layers (ECDLs) as storage media [218]. These ECDLs can be used for magnetic super-resolution [16, 73], where one of the layers works as a magneto-optical mask for the super-resolution. It allows an increase in the density of information recording.

One may see from our very short description that a magneto-optical recording medium contains a number of different magnetic and nonmagnetic layers. From this point of view they are similar to R/T multilayers. The composition of magnetic layers in a magneto-optical structure includes R and T elements. R/T multilayers may have suitable magneto-optical and magnetic properties for them to be used in real devices. The basic principles of magneto-optical recording have many points in common with the physics of R/T multilayers. We can say, therefore, that R/T systems could be considered as a model structure or potential candidates for magneto-optical recording.

## 5.5. Magnetic Resonance

Magnetic resonance consists of the intensive absorption of high-frequency field energy by a magnet when the frequency of the oscillations of the external field and oscillations of the magnetic moment of the magnet are equal. In magnetically ordered materials this resonance frequency is defined by the effective field, which reflects all interactions related to magnetization. The components of the effective field are the demagnetizing field, the anisotropy field, and exchange (including interlayer) interactions. This explains a potential interest in ferromagnetic resonance as a method to study R/T magnetism.

There are just a few publications on R/T structures. Let us mention the ferrimagnetic Tb/Fe [59], Gd/Fe [116], and Gd/Co [99, 120, 121] multilayers. Interesting results were reported for a  $[\text{Gd}(7.5)/\text{Si}(L_{\text{Si}})/\text{Co}(3)/\text{Si}(L_{\text{Si}})]$  study at various temperatures. The magnetic compensation appeared in this structure in the range of 100 to 300 K. The compensation temperature depends on the thickness of the Si sublayer  $L_{\text{Si}}$ . To describe ferromagnetic resonance in uniform two-sublattice ferrimagnets, the effective magnetomechanic ratio,  $\gamma_{\text{eff}}$ , is used. This is defined as the difference between magnetizations of the sublattices divided by the difference of the specific mechanical moments of these sublattices. In practice, it is more convenient to use its normalized value, known as the effective  $g$ -factor,  $g_{\text{eff}}$ , instead of using  $\gamma_{\text{eff}}$ . Figure 18 shows the temperature dependencies of  $g_{\text{eff}}$  calculated on the basis of experimental resonance field data for the samples with  $L_{\text{Si}} = 0.3$  nm (curve 1) and  $L_{\text{Si}} = 0.5$  nm (curve 2). Dashed vertical lines mark  $T_{\text{comp}}$ . The character of the  $g_{\text{eff}}(T)$  changes near the compensation temperature and is different at high and low temperatures. There is a break point in the curve corresponding to  $T_{\text{comp}}$ . This can be interpreted in terms of sequential changes in the states of compensation of the magnetic moments and mechanical moments of the Gd and Co layers as the temperature increases. Therefore, there is a general possibility of using phenomenological ferromagnetic resonance theory to interpret the resonance properties of layered ferrimagnetic structures.

**Figure 18.** Temperature dependence of an effective  $g$ -factor for  $[\text{Gd}(7.5)/\text{Si}/\text{Co}(3)/\text{Si}]_{20}$  films with different Si spacer thickness: (1) 0.3 nm; (2) 0.5 nm. Dashed lines indicate the compensation temperatures of the films.

## 6. CONCLUSIONS

Multilayered structures consisting of rare earth and 3d metal layers have been intensively studied for the last 15 years. Different technologies for their preparation such as ultrahigh vacuum thermal evaporation and ion sputtering have been developed. Independently of the preparation method, these subjects may be described as a system of magnetic layers connected by exchange interaction. It is precisely this type of interaction, together with the individual properties of the different layers, that defines the R/T system magnetism.

Rare earth (Tb, Gd, and Dy) and 3d (Fe and Co) metals are those used most frequently for the sublayers that define the negative exchange interaction and ferrimagnetic ordering in a system of magnetic layers. The characteristic feature of the temperature dependence of spontaneous magnetization is the existence of magnetic compensation. The quantitative characteristics of the spontaneous magnetization and compensation temperature depend on many parameters, including the sublayer thickness ratio, period of the layered structure, structural state, and the presence of nonmagnetic spacers. The main structural features of R/T multilayers are amorphization, which appears at a relatively low thickness of layers, and the existence of interface areas. The morphology of the interfaces depends on the preparation technology, order of the layer deposition, and subsequent treatments.

R/T multilayers with anisotropic Tb or Dy ions show strong perpendicular anisotropy, which has a single ion nature and is caused by anisotropy of the atomic structure of the interfaces. An enhanced self-demagnetization effect takes place in all ferrimagnetic multilayers. It occurs because of formation of demagnetizing fields in the interfaces. The characteristic feature of the magnetization process of R/T structures is a magnetic phase transition and a twisted structure.

A number of phenomenological models were developed to describe R/T spontaneous magnetization and changes of the spontaneous magnetization in the external magnetic field. It seems that the most suitable is the model of nonuniform interlayer exchange with reciprocal influence of the sublayers, and charge transfer.

Some nonmagnetic properties such as magnetostriction, magnetoresistance, the magneto-optic Kerr effect, and magnetic resonance have been studied with the objective of using R/T multilayers in the future both as a tool for magnetization process research and as a basis for technological applications.

We have a relatively clear picture of the nature of magnetism in R/T multilayers today. Major progress in this field of modern physics depends very much on progress in the technology of preparation, but meanwhile valuable work can be done by extending the range of magnetic and nonmagnetic components in layered structures, by precise study of the properties attendant on magnetic ordering, by increasing the reproduction level, and by special study of the compatibility of these materials with the aim of increasing their technological applications and improving miniaturization.

## GLOSSARY

**Atomic structure** The presence/absence of order in the positions of the atoms at precise distances compared with the atomic size.

**Interfaces** Zones between different layers of multilayered structures.

**Ion sputtering** The expulsion of the atoms from the target surface by inert gas ions bombardment.

**Magnetism in rare earth metals** Caused by 4f electrons located in internal electron shells. This leads to localization of magnetic moments on atoms and to the absence of direct exchange interaction in the 4f electron system. Magnetic ordering occurs because of indirect exchange through the conduction electrons. This interaction is oscillating and acts over a long range. It causes low values of magnetic ordering temperatures and aids in the formation of complex magnetic structures.

**Nanoscale rare earth/transition metal (R/T) multilayers**  $NM/[R(a)T(b)]_n/NM$  samples. This formula contains all the important information about the general structure of the multilayered film. It says that this film has buffer and covered nonmagnetic (NM) layers and rare earth (R) layers of thickness  $L_R = a$  nm alternated with transition layers (T) of thickness  $L_T = b$  nm. The structure  $L_R + L_T = L_p$  is repeated  $n$  times, where  $L_p$  is a period of the structure.

**R/T ferrimagnetic structure** The magnetic moments of R and T layers play the role which, in a classic ferrimagnet, would be played by R and T, the magnetic moments of the sublattices.

**Twisted magnetic phases** Special feature of a noncollinear magnetic structure in layered materials. In contrast to uniform ferrimagnets, in multilayers the negative exchange interaction between magnetic elements is spread nonuniformly through the multilayer volume. As a result there is a spatial nonuniformity in noncollinear structures, in which the angle between the local magnetization and an external field changes from the separating interface toward the center of the layer.

**Ultrahigh vacuum thermal evaporation or molecular beam epitaxy (MBE)** Film preparation at ultrahigh vacuum of  $10^{-8}$ – $10^{-10}$  torr, involving strong local heating of the target, as a rule by a high-energy electron beam created by an electron beam gun.

## ACKNOWLEDGMENTS

We gratefully thank Jane Kalim for her help with the manuscript and Professor Blanca Hernando for the encouragement to write this chapter. This work was partially supported by Award Rec-005 of USA Civilian Research & Development Foundation for the Independent States of the Former Soviet Union (CRDF), MCyT and Universidad de Oviedo in the framework of the “Ramon y Cajal” program, and by the Spanish CICYT under Grants MAT2000-1047 and MAT2001-0082-C04-01. The authors would like to express their gratitude for all authors (J. Teillet, A. Fnidiki, D. García, A. Hernando, M. Vázquez, A. V. Gorbunov, J. P. Andrés, J. L. Sacedon, J. Colino, J. M. Riveiro, Z. S. Zhang, Y. T. Wang, F. Pan,

# Magnetoimpedance in Nanocrystalline Alloys

B. Hernando, P. Gorria, M. L. Sánchez, V. M. Prida, G. V. Kurlyandskaya  
*Universidad de Oviedo, Calvo Sotelo, Oviedo, Spain*

## CONTENTS

1. Impedance
  2. Magnetoimpedance
  3. Soft Magnetic Nanocrystalline Alloys
  4. Magnetoimpedance Effect in Nanocrystalline Alloys
- Glossary  
References

## 1. IMPEDANCE

Our interest in impedance is due to the change of this magnitude in a magnetic material under the application of some external parameters like stress, torsion, magnetic fields, and so on. Impedance is not only sensitive to the magnetic properties of a material, but also to its structure. Therefore, it is a good parameter that allows the study of the properties of nanostructured magnetic materials.

Our magnetic nanostructured sample is submitted to an ac drive current passing through it. The drive current frequency is  $f$ . The sample is now part of an ac circuit, and according to the well-known Ohm's law, a voltage is induced between the ends of the sample with the same frequency of the drive current, and its value is proportional to the drive current. The proportionality is established by using the complex impedance  $Z$ .

$$V_{ac} = I_{ac}Z \quad (1)$$

The induced voltage can be measured by an oscilloscope.

The impedance  $Z$  depends on the drive current frequency, and can be separated into its real and imaginary components ( $Z = Z' + jZ''$ ).

Let us consider the current distribution in the sample's section. When the drive current frequency increases, the current will be mainly concentrated close to the surface of the sample [1] due to the skin effect. The exact solution to the problem generally depends on the shape of the conducting sample and the drive current. To obtain the solution, the Maxwell equations have to be applied.

The Maxwell equations can be easily solved for the case of a sample with cylindrical symmetry. Our wire-shaped sample has a conductivity  $\sigma$  and circular permeability  $\mu_\phi$ . The magnetic field induced by the drive current is circular,  $B_\phi = \mu_\phi H_\phi$ . The impedance can then be derived in this case by solving Maxwell equations [2]:

$$Z = \frac{1}{2}R_{dc}ka \left[ \frac{J_0(ka)}{J_1(ka)} \right] \quad (2)$$

with  $k = (1 + j)(a/\delta)$  and  $\delta = (c/2\pi)(\sigma\mu_\phi f)^{-1/2}$ , where  $j = \sqrt{-1}$ , and  $J_0$  and  $J_1$  are Bessel functions of the first and second kind,  $R_{dc}$  is the resistance of the wire at  $f = 0$ , and  $\delta$  is the skin penetration depth.

The impedance depends on the properties of the material through the skin penetration depth, where  $\sigma$  and  $\mu_\phi$  appear. The magnetic and structural properties of the material are characterized by these parameters. The action of other external properties, such as a magnetic field, would change these parameters through the change of the magnetic domain configuration or structure. The ac frequency also affects the skin effect: the higher the frequency, the smaller  $\delta$  is, and the narrower the outer shell of the sample is, through which the current flows.

In the case of a sample with no circular cross section, the resolution of the Maxwell equations is difficult, although the impedance shows the same dependence on the skin penetration depth, and the behavior of the impedance can be explained qualitatively through the interaction of all of the involved parameters.

## 2. MAGNETOIMPEDANCE

In the last ten years, there has been a considerable interest in transport phenomena due to their possibilities for use in technological applications, such as magnetic recording and magnetic sensors. One of them is the magnetoimpedance (MI) effect concerning large variations in the impedance (both real and imaginary components) of a soft ferromagnetic conductor when submitted to a static magnetic field, with a high-frequency drive current flowing through it. This

effect was discovered in FeCoSiB amorphous wires [3–6] and ribbons [7]. The MI effect has been observed in other different Co-rich amorphous ribbons, microwires, and thin films [8–26], and also in nanocrystalline Fe-rich wires, ribbons, and thin films [17, 26–56].

As mentioned above, the MI effect has a classical electromagnetic origin, and can be explained by solving the Maxwell equations and Landau–Lifshitz equation of motion [1] for a magnetic conductor when a high-frequency driving current flows along it. The MI effect is a consequence of the impedance  $Z$ , dependence on the applied bias field  $H$ , and the drive frequency  $f$  due to the skin effect.  $Z$  can be expressed in terms of real (resistive) and imaginary (reactive) components as  $Z(f, H) = Z'(f, H) + jZ''(f, H)$ .

In the MI measurements, an ac drive current flows through the sample. The current amplitude is kept constant during the measurements. An axial magnetic field is applied in the axial direction by a pair of Helmholtz coils. The ac current induces a voltage between the ends of the sample that is measured by a digital oscilloscope and that is proportional to the impedance.

The magnetoimpedance ratio is obtained with respect to a maximum field  $H_{\max}$  at which the sample is saturated. A 45 Oe field is high enough to saturate a 10 cm long sample.

$$\Delta Z/Z(\%) = 100 \times \frac{Z(H) - Z(H_{\max})}{Z(H_{\max})} \quad (3)$$

The MI rate behavior depends on the drive current amplitude and frequency, and on other parameters, such as magnetic permeability, magnetostriction, induced anisotropy, and so on. When the axial field is applied, the transversal permeability which appears on the skin penetration depth  $\delta$  decreases, making  $\delta$  increase, and changing the current distribution in the sample section. This produces a change in impedance [57].

The MI depends on several parameters, and can also give information about them, as will be explained in the following sections. The magnetostriction coefficient seems to play an important role since the highest values are obtained at an almost negligible magnetostriction. This is related to the magnetic softness of the sample, as well as to a high permeability value.

The magnetoimpedance phenomenon appears at a frequency at which the  $\delta$  is on the order of the sample thickness, at about  $10^4$  Hz in the case of 130  $\mu\text{m}$  diameter wires, and at a somewhat higher frequency for 20  $\mu\text{m}$  thick ribbons. The MI spectrum shows a maximum at a certain frequency, and then decreases, for all type of samples.

### 3. SOFT MAGNETIC NANOCRYSTALLINE ALLOYS

This section is subdivided into four parts, and constitutes a general introduction to the nanocrystalline soft ferromagnetic alloys. The most remarkable aspects related to the preparation methods used to synthesize these compounds, the different treatments applied in order to improve their magnetic response, as well as some generalities concerning the structural and magnetic evolution during the nanocrystallization process are explained.

### 3.1. Introduction

The term “soft magnetic nanocrystalline alloy” is commonly applied to a singular type of material that exhibits a superb soft magnetic response due to its ultralow values of the magnetic anisotropy (excellent research reviews on this topic are, for example, those by Herzer [58] and McHenry et al. [59]). These kinds of alloys are usually obtained by devitrification of Fe-rich metallic glasses, and in the last decade, they have been the subject of an enormous research effort due to their promising applications in a large variety of technological devices.

On the other hand, these materials have also opened new and unexplored fields of basic research in magnetism, as well as in solid-state physics in general because the competition between two or more magnetic phases, amorphous and nanocrystalline, coexisting in the same system, gives rise to a very rich scenario for the study of complex magnetic interactions [60].

During the last three decades, nanostructured materials have attracted huge attention, not only because of their unusual structural, electrical, magnetic, and optical properties, different from corresponding noncrystalline precursor alloys, but because they have conditions and techniques of preparation different from the bulk materials as well. Fine-grain structures can be obtained by heat treating an amorphous alloy precursor with a noncrystalline structure. Amorphous alloys inherently have a uniform distribution of constituent elements. The last is a condition suitable for the formation of nanostructured materials, making the glassy alloys promising precursors for controlling the nanoscale structure because of the high degree of freedom for a topological and chemical structure that persists in these amorphous materials [61]. Currently, minority elements are added in a glass-forming amorphous alloy to promote massive nucleation through the addition of insoluble atoms such as Cu, and to inhibit grain growth by adding refractory and stable species such as Nb, Ta, and so on. The addition of these elements has a key effect on the improvement of material properties, such as mechanical strength or corrosion resistance [62].

In the late 1980s and early 1990s, Yoshizawa et al. [63], Herzer [64], and Suzuki et al. [65] obtained, for the first time, these kinds of alloys in a nanocrystalline state, and published their unique soft magnetic behavior results. The interest in these alloys, as already mentioned, lies in the very soft magnetic properties shown, especially in the low-frequency range (megahertz), surpassing the magnetic response shown by their precursor alloys in the amorphous state. These properties include high saturation magnetic polarization (up to 2–2.1 T), quasivanishing macroscopical anisotropy, nearly zero saturation magnetostriction ( $\lambda_s \approx 10^{-7}$ ), and therefore, high magnetic permeability ( $\mu \approx 10^5$ ). All of these features combined with the reduction of magnetic losses, in the low-frequency range, originating by an appreciable decrease of the electrical resistivity and coercive field ( $H_c < 1$  A/m) values, shown in the nanocrystalline state, make them good candidates for technological applications such as power transformers, common-mode choke coils, flux-gate magnetometers, or magnetoelastic microsensors and transducers [59].

The composition of these nanocrystalline soft magnetic compounds is based on the Fe–*M* metallic glasses (where *M* is a metalloid such as B, Si, Al, P, or Ge), largely studied in the 1970s and 1980s, but with the addition of a small amount (less than 15at%) of transition metals (TM) such as Zr, Nb, Cu, Hf, V, Ta, and so on [58, 59, 63–67]. There are four families of such alloys.

1. Fe–TM–Cu–Si–B alloys: TM is Nb, Ta, V, and so on, the percentage of metalloid atoms is around 20–25at%, the amount of TM is rather low (around 3at%), and the percentage of Fe is not higher of 75at%. These alloys show the lowest values for the coercive field (less than 1 A/m), but due to the high amount of metalloids, and the fact that the magnetic nanocrystalline phase is FeSi, the saturation magnetic polarization  $J_s$  never exceeds 1.3–1.4 T. The better magnetic response is obtained with TM = Nb, the so-called FINEMET alloys.
2. Fe–TM–B–(Cu) alloys: In this case, TM is Zr, Hf, or Nb, the percentage of metalloids is lower than in the previous group (2–10at%), and the amount of Fe is over 85at%. The nanocrystalline phase is now nearly pure  $\alpha$ -Fe, giving rise to high values of  $J_s$  (up to 1.7 T), but the coercivity is about one order of magnitude higher than in group 1) above, reaching values of several amperes per meter, due to the slightly higher saturation magnetostriction. The most studied compounds of this group are FeZrB(Cu) alloys, commonly known as NANOPERM alloys.
3. Fe–Co–TM–B–(Cu) alloys: The composition of these alloys is similar to those of group 2), but Fe atoms are substituted for Co ones in several concentrations, reaching values of  $J_s$  above 2 T, as for an Fe<sub>44</sub>Co<sub>44</sub>Zr<sub>7</sub>B<sub>4</sub>Cu<sub>1</sub> alloy. However, the coercivity never decreases below 20 A/m because the ferromagnetic nanocrystalline phase, actually FeCo, has larger anisotropy values due to the presence of Co atoms. These alloys are called HITPERM.
4. Other alloys: There is a huge number of ferromagnetic nanocrystalline alloys in which other metalloids, such as Al, P, or Ge, substitute B and/or Si or, also, Ni is included in the composition, substituting Fe and/or Co atoms, but up to now, none of these has shown better soft magnetic properties than the compounds included in the previous three groups.

If the so-called nanocrystalline regime is pursued, these alloys have to be submitted to appropriate heat treatments in order to provide enough thermal energy to favor the structural transition from a disordered metastable glassy structure to a stable and more ordered crystalline one. In other words, the crystallization of the initial amorphous state takes place when the alloy is annealed. The crystallization process takes place in two differentiated steps [68, 69]. In the first step, the ferromagnetic Fe or FeSi crystalline phase, with an average grain size of about 10–15 nm, is formed. At this moment, the system is composed of a mixed structure of Fe(Si) nanograins embedded in a remaining amorphous matrix or intergranular region, which becomes more and more inhomogeneous as this first crystallization step continues. Once the first crystallization process has finished,

the second step leads to the crystallization of the remaining amorphous matrix, enriched in B and TM, into Fe–B or FeTM(B) phases (with much higher values for the magnetic anisotropy), and the growing of the Fe(Si) nanograins above 20 nm. These two processes overlap in most cases, when Fe–metalloid alloys are submitted to heat treatments [70], and occur for temperatures above 400 °C; hence, the nanocrystalline state is never reached, and the soft magnetic properties shown in an amorphous state do not improve during the crystallization process. However, the addition of a small amount of Cu, which acts as a nucleation center for crystallites, accelerates the first step, and takes place at lower temperatures (below 500 °C). On the other hand, the effect of the addition of other transition metals, such as those mentioned above, retards the second crystallization step up to temperatures above 700 °C, and prevents grain growth. In between both steps, the structure of these materials consists of a large amount of Fe or FeSi nanosized grains (around 70–80% of the sample) surrounded by the remaining amorphous ferromagnetic matrix (less than 30%) [71]. The origin of the excellent soft magnetic properties displayed in this state lies in the nanometer grain size of the Fe(Si) phase, which is lower than the exchange correlation length. As is well known, this critical dimension plays a definite role in magnetic interactions. This behavior has been largely explained in the framework of the random anisotropy model [72] by Herzer [58, 64]. Another reason contributes to this magnetic softening: say, some of these systems, especially those of group 1), exhibit near-zero average magnetostriction due to the opposite sign of this parameter for the Fe(Si) nanocrystals and for the amorphous matrix, so no macroscopic magnetoelastic anisotropy is present in the samples.

### 3.2. Preparation: Composition and Geometry (Thin Films, Ribbons, Wires, and Microwires)

As mentioned above, the magnetoimpedance phenomenon consists of the change of total impedance of a ferromagnetic conductor under the application of a magnetic field [7–14]. Therefore, by definition, the MI effect is expected in the sample only under the conditions of the ferromagnetic state, that is, below the Curie temperature, and if it is large enough to show the ferromagnetic behavior. What is large enough? Some time ago, we could answer the question about critical size of the ferromagnetic sample only on the basis of theoretical predictions. But new experimental methods like the micro SQUID setup [73] are available now to study the magnetization behavior of an individual magnetic cluster, for instance, of 1000 atoms, which is about 3 nm in size in the case of cobalt [74]. Magnetic nanostructures are subjects of special interest due to many possible potential applications. One may distinguish between tiny separate nanosized elements showing interesting properties and macroscopic objects having nanosize structural units. The nanosize clusters [73, 74], polycrystalline materials with grains of nanosize [26, 28, 37, 44, 49, 51, 53, 56, 63, 64, 75–78], or multilayers with layers of nanoscale thickness [16, 48, 79–82] are examples of such new structures.

Although the term “as small as possible” seems most popular for modern applications, there are theoretical and

technological limits on the size of the elements involved in the functionality for each particular case. Here, we wish to show that, for an MI element, the size limit of the ferromagnetic state lies far below the critical size for the appearance of a strong MI effect.

As mentioned in the Introduction, the MI effect in a uniform ferromagnetic conductor is based on the impedance dependence on the classic skin penetration depth  $\delta = (\rho\pi f\mu)^{1/2}$  for the flowing ac current of angular frequency  $\omega = 2\pi f$ .

The impedance of a ferromagnetic sheet of thickness  $d$ , width  $b$ , and length  $L$  under the condition  $b \gg d \gg \delta$  can be written as [12]

$$Z \approx L(1 + j) \frac{(4\pi\rho f\mu)^{1/2}}{4b} \quad (4)$$

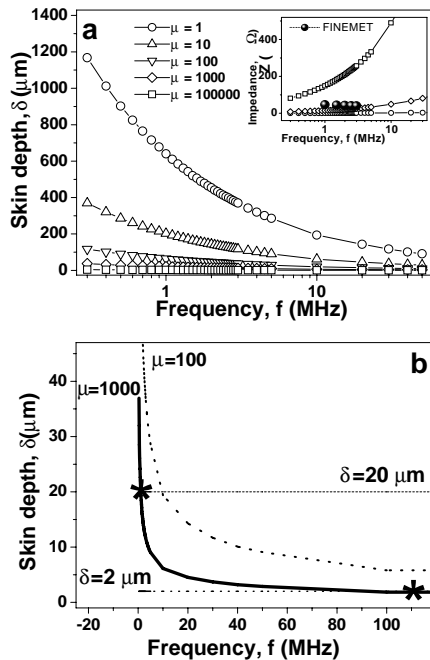

where  $\rho (= 1/\sigma)$  is the electrical resistivity, and  $\mu$  is the low-frequency transverse magnetic permeability. Figure 1 shows the frequency dependence of the skin depth and the impedance for different values of the transverse magnetic permeability. The geometrical parameters of the sheets were:  $L = 10$  cm,  $b = 0.8$  mm,  $d = 20$   $\mu\text{m}$ , that is, the  $b \gg d$  condition was satisfied. We are interested in comparing the results of the MI measurements for a nanocrystalline sample (FINEMET ribbons, for example), with an approximation taken in the framework of the classical model (Eq. (2) [1]) for samples of the same geometry. The same parameters for approximation were taken as for experimental samples. The resistivity  $\rho = 1.5$   $\mu\Omega \cdot \text{m}$  was measured using the four-point method for a dc current of 10 mA. One may see that an increase of the exciting current frequency

results in a decrease of the calculated penetration depth and an increase of the total impedance. But there is a strong dependence of  $\delta$  and  $Z$  values on the magnetic state of the sample: the higher the effective magnetic permeability, the less, for the same frequency, the penetration depth and the higher the impedance variation are. The inset in Figure 1a shows the impedance dependence on the exciting frequency for selected values of the permeability. The calculated data are compared with the results of MI measurements for FINEMET nanocrystalline ribbons of the same geometry; they are in the reasonable agreement.

The second condition,  $d \gg \delta$ , for the frequency range under consideration can be satisfied only for the sheets with very high transverse permeability ( $\mu = 1000$  in Fig. 1b). The dashed line  $\delta = 20$   $\mu\text{m}$  corresponds to the thickness of our nanocrystalline ribbon. When do the skin effect, and consequently the MI effect, appear? When  $\delta$  is less than half the thickness of the sample. Therefore, if we are interested in a small size of the sample, the size condition of the skin effect results in a strong increase of the operating frequency. This is, of course, an undesired complication. Let us illustrate these ideas for the sample with a very high, but realistic effective permeability of  $\mu = 1000$ . Figure 1b shows that, for the 20  $\mu\text{m}$  thick element, the skin/MI effect appears at  $f \cong 0.8$  MHz, but for the 2  $\mu\text{m}$  element, the operating frequency is about 110 MHz. Two “stars” in Figure 1b prompt this question: “size or frequency?” A high operating frequency on the order of 100 MHz required another level of the electronic part of the device (higher price, complicated circuit, etc.). Therefore, one has to decide up to which size the complication of the sensing process and price of the device can be compensated by the miniaturization. Another important point to mention is that the higher the effective permeability of the magnetic material is, the lower the operating frequency we need for the same size of sensitive element.

The size of the sensitive element based on the ribbon geometry material is not acceptable for many applications. Therefore, there were many theoretical and experimental studies of the MI effect in thin-film geometries [1, 12, 16, 79, 80, 82]. But just a few results were reported for nanocrystalline thin films on the strong dependence of the properties on the technology of preparation [48]. Nie et al. [83] reported that MI of the Mumetal sheets depends very much on the thickness of the samples, being maximum for a thickness of 1 mm and negligible for a 12.5  $\mu\text{m}$  thick sheet. This means that, for nanocrystalline materials, apart from the usual dependence of the MI on the geometry of the sample, there are many additional parameters related to nanocrystallization and induced anisotropy features in thin samples.

The nanocrystalline materials can be obtained from a metallic glass with the shape of ribbons, wires, or microwires, as described below. Metallic glasses are obtained using a rapid solidification technique. The composition is first chosen and mixed. Afterwards, it is pressed and sintered in an  $\text{H}_2$  atmosphere, in order to eliminate oxygen and avoid oxidation during the melting process. The next step is to melt the alloy in an induction furnace at 1500  $^\circ\text{C}$ . The alloys will be used to produce metallic glasses with different shapes. All rapidly quenching techniques are based on a melted alloy falling over a moving surface, and cooling down at about  $10^6$  K/s.

**Figure 1.** Calculated frequency dependencies of classic penetration depth and the impedance of a conductive sheet with different values of the effective permeability. The measurements of a nanocrystalline FINEMET  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$  ribbon (inset) are in agreement with the model estimation.

### 3.2.1. Ribbons

The technique employed first by Duwez [84] is used to obtain ribbon-shaped samples. The melt-spinning technique consists of the injection of the melted alloy over a Cu wheel, which is spinning at a high speed. The Cu is a good thermal conductor, and produces cooling of the alloy at a rate of about  $10^6$  K/s.

The prepared solid alloy, by using this method, is introduced in the quartz melting pot, which has a hole of about tenths of a millimeter at the bottom. The alloy is molten with an induction furnace at 1300 °C and in an Ar atmosphere. The furnace works at 2500 kHz. As the sample contains 80% of metals, the Foucault currents produce the heating and melting of the sample. A higher Ar pressure is applied to produce the expelling of the alloy over the spinning wheel. The thickness, width, and characteristics of the ribbon depend on the speed of the wheel, the Ar pressure, the orifice diameter of the melting pot, its distance and inclination with respect to the wheel, and the alloy temperature at the expelling time. The ribbons obtained with this technique have a thickness on the order of several tenths of microns, and widths between 1 and 3 mm.

### 3.2.2. Wires

Samples with a circular section can be obtained by the melt-spinning technique. The production technique was initially developed by Masumoto et al. [85]. The molten alloy is obtained in the same way as explained above. The method consists of injecting the melting alloy in a flow of water, which is turning at a high speed. The water is introduced in a hollow toroid that is spinning, making the water turn and keeping it inside due to the centrifugal force. A rapid transfer of heat freezes the atoms when the metal hits the water, obtaining an amorphous solid. The cooling speed is about  $10^6$  K/s. The cooling of the alloy takes place from the outer surface of the alloy, which acquires a cylindrical shape when it falls into the water. Wires with diameters between 100 and 150  $\mu\text{m}$  can be obtained by this procedure.

### 3.2.3. Microwires

The microwires have a ferromagnetic nucleus and a glass cover. They are obtained by the Taylor–Ulitsky technique, which has been modified in the last 40 years [86]. The alloy is introduced in a Pyrex tube, that will be melted with the alloy [87]. The alloy is melted by the furnace as explained above in the other techniques, and the Pyrex is melted due to the contact with the molten alloy. The molten alloy with a glass layer is cooled when it passes a flow of cooling material (water, oil, etc.), and it is collected in a coil that produces an axial stress on the microwire. The microwire diameter varies with the following parameters: furnace potency, distance of the alloy to the furnace, and speed of the coil collecting the sample. The diameters of the nuclei vary from 1 to 25  $\mu\text{m}$ , and the glass coat has a thickness between 1 and 10  $\mu\text{m}$ . The internal stresses are much stronger than the conventional amorphous wires as a consequence of the presence of the glass coating which, coupled with the magnetostriction, can give rise to strong magnetoelastic anisotropy which determines the magnetization process. Amorphous and nanocrystalline microwires may show a magnetoimpedance effect in a very

high range of the frequency from kilohertz up to hundreds of megahertz [88, 89].

Nanocrystalline materials have been obtained from an amorphous alloy. Nanocrystals of sizes ranging from 5 to 10 nm and compositions of AlRu, SiRu, NiTi, or CuEr have been obtained in this way. Amorphous alloys of FeB also have been produced using this technique, in order to induce crystals with sizes in the 10 nm range after a suitable annealing technique.

Nanocrystals have been obtained in the Fe<sub>73.5</sub>Si<sub>13.5</sub>B<sub>9</sub>Cu<sub>1</sub>Nb<sub>3</sub> alloy by Yoshizawa et al. [63]. This alloy is produced as an amorphous ribbon, obtaining a nanocrystallized state after an additional treatment above the crystallization temperature. Ultrafine grains of the  $\alpha$ -FeSi phase and sizes between 10–20 nm are obtained after a suitable treatment. The interest of this composition lies in the high magnetic permeability and soft magnetic properties when the grain size is about 10–20 nm [64]. The magnetic softness is a dramatic function of the grain size.

In order to determine the nanocrystalline structure of the material obtained with any geometry, an additional annealing treatment is needed [90]. This annealing can be performed in a conventional furnace, heating the sample above the crystallization temperature. The annealing has also been successfully performed by using the current annealing technique, which consists of the application of a dc current across the sample. The temperature increases in the sample due to the Joule effect, reaching the desired temperature in a very quick way, although a dc magnetic field is induced, and is not homogeneous inside the sample.

### 3.2.4. Thin Films and Multilayers

Magnetic materials in a thin-film shape can be prepared by different methods, such as thermal deposition on a cold substrate, electrodeposition, laser ablation, or sputtering. Sputtering can be provided using alternating or direct current in the inert gas atmosphere (Ar or Kr). The ions of the inert gas move from the substrate (anode) to the target (cathode). As a result of the ion bombardment, some atoms of the target are set free, and then are deposited onto the substrate. If the rate of deposition is high enough (on the order of 0.1 nm/s) and cooling of the substrate is used (by water, liquid nitrogen, or even liquid helium), the deposited film shows an amorphous structure. Apart from the composition of the target, the deposition rate, and the temperature/type of the substrate, the thickness of the film can be a critical parameter in order to obtain an amorphous or nanocrystalline state in as-deposited films. The same as for nanocrystalline ribbons, it is much easier to prepare thin films in a nanocrystalline state using sputtering deposition, followed by conventional or field annealing for nanocrystallization [48]. The thickest single-layer samples usually do not exceed the 5  $\mu\text{m}$  limit, even if deposited onto Si because of the separation of the sample on the substrate.

In any sputtering system, it is very important to ensure the homogeneity of the deposited samples from the point of view of the composition and thickness. There are many methods to control these parameters and to avoid strong deviations [91–94]. Homogeneity can even be a more critical parameter in the case of the MI thin-film element because it

includes not only the magnetic film itself, but also the electrical contacts and other parts of the imprinted circuit. Up to now, we have been addressing a single-layer MI thin-film element. A very sensitive magnetoimpedance recently has been reported to appear in multilayered structures of two very soft magnetic layers separated by a highly conductive layer [12, 48, 82, 95–97]. In such a complicated structure, the homogeneity of the sample properties is very important in order to avoid critical stresses in a three-dimensional structure. The sensitivity of the magnetoimpedance in single-layer Co-rich thin films typically does not exceed 10%/Oe [98], but it can be on the order of 30%/Oe in the case of a Co-based sandwich with a Cu conductive lead, where a large impedance change appears at lower frequencies. The condition of a strong skin effect is not required in “soft ferromagnetic/conductor/soft ferromagnetic” sandwiches. For a sufficiently large width of the MI sandwich, the contribution of the outer magnetic layers to the total impedance is defined by the external inductance. In this case, the impedance shows linear variation with effective magnetic permeability and frequency. Although there have been many optimistic discussions with respect to the potential of the MI sandwiches to be employed in developing magnetic heads for high-density magnetic recording, finally it seems that they are better suited sensor applications as very sensitive detectors of a small magnetic field. An additional advantage of a thin-film MI structure consists of the possibility to use the thin-plate permanent magnet attached to the substrate to generate the bias magnetic field to achieve a better response.

The MI sandwich is composed of an inner conductive lead of a nonmagnetic material (Cu, Ag, Au) and two outer layers of amorphous or nanocrystalline very soft magnetic material. In order to enhance the value of the effect, two magnetic layers and a conductive layer are deposited in the shape of a closed-loop structure. The unidirectional magnetic anisotropy in each magnetic layer of the MI sandwich is formed in the transverse direction, that is, perpendicular to the conductive lead, but in the plane of the magnetic films. It can be done by application of a constant magnetic field, usually on the order of 100 Oe, during the deposition. The MI effect in MI sandwiches is much stronger compared with that in a single-layered thin film of the same thickness. This can be explained taking into account the very weak influence of stray fields in an MI closed-loop structure, being actually part of the more general fact that all mechanisms involved in the magnetization process contribute to the magnetoimpedance effect [99].

The new types of magnetic sensors on the basis of the MI effect in sandwiched thin-film structures were developed recently to be employed as direction, revolution, and position sensors [100]. They show no hysteresis, good linearity, reasonable temperature stability, and very high sensitivity with a detection resolution of  $10^{-3}$  Oe, that is, higher than any other type of thin-film sensor like an element based on magnetoresistance or the Hall effect. A self-oscillation circuit technology is very useful for construction of the MI-element-based sensor in order to avoid parasitic displacement currents and reflected signals. In oscillation circuits like the Colpitts oscillator, the MI element is employed as inductance, and the MI effect is amplified in a resonant circuit due to a simultaneous change of

both the impedance and the current amplitude [101, 102]. Another example of possible technological applications of the impedance sandwiches is strain sensor, which detects the change in impedance with applied strain in magnetostrictive thin films [103, 104]. Reported in this case are gauge factors ten times larger than those of semiconductor strain gauges.

### 3.3. Postpreparation Treatments

Once the samples are prepared in any of the geometries mentioned in the previous section, two kind of heat treatments, with different main objectives, are used, with the aim of reaching the optimal magnetic state of the particular alloy: first, to nanocrystallize the samples, and second, to obtain a particular anisotropy distribution combining heat treatments with the application of a magnetic field, tensile, and or torsional stresses. These two aspects are explained in the following paragraphs.

- **Nanocrystallization treatments:** The nanocrystalline state is obtained when the as-prepared amorphous samples are conveniently annealed. Conventional heat treatments are performed using a furnace under controlled atmosphere (Ar, He, or vacuum) to prevent oxidation of the samples. The range of the annealing temperatures is in between 450 and 600 °C, and time periods on the order of several minutes or hours [58, 59]. There is another way to heat the samples that consists of passing an electrical current along the sample, particularly used in the case of ribbon or wire geometries. This method, called flash annealing, current annealing, or Joule heating, is based on the Joule effect [105], and allows us to obtain the sample in a nanocrystalline state in a quicker way (10–100 s) [106, 107].
- **Induction of anisotropies:** Magnetic anisotropy in nanocrystalline soft magnetic materials for MI applications can be induced by traditional methods like annealing in a magnetic dc or ac field [78] or stress annealing [75, 76]. Many parameters play an important role in the magnetic anisotropy, and consequently, MI response formation. For example, for FeCuNbSiB ribbons, the Si content could be critical for the field annealing, leading to a decrease or increase of the magnetoimpedance ratio [100]. All treatments below the Curie point usually need to be provided in a magnetic field higher than the saturation one. The temperature, time of exposure, rate of heating and cooling, and specific stress for stress annealing are the important parameters. Both the stress and field annealing can be done in two different ways: annealing of as-cast samples under field or stress, or using previously nanocrystallized samples, and then submitting them to a stress or field annealing. Since the magnetoimpedance depends on the permeability, there are many possibilities for modifying the GMI responses. Apart from the objective of nanocrystallization in order to achieve extra soft magnetic material, one may take into account the value of the transverse induced magnetic anisotropy [44, 80]; the anisotropy distribution [44] and thermal or time stability may be the parameters of interest both for the

study of technological applications and magnetization processes. Magnetic anisotropy in nanocrystalline soft magnetic materials for MI applications can be induced by traditional methods like annealing in a magnetic field [44, 75, 76]. Usually, it is a dc field applied in the direction of the ribbon or wire axis or in a perpendicular direction [37]. There were attempts to use low- and high-frequency ac [77] fields as well. It is known that ac field annealing leads to a magnetic structure formation with no stabilization of the domain walls, which is a very favorable feature for the MI conditions of the magnetization. Stress annealing is another effective method of anisotropy formation. It was found that, not only can simple uniaxial magnetic anisotropy be formed as a result of stress annealing, but also, a very complicated high-order anisotropy, which results in interesting and unwanted hysteresis of the MI. As mentioned, many parameters play an important role in magnetic anisotropy formation. For example, for FeCuNbSiB ribbons, the Si content could be critical for field annealing to decrease or increase the MI ratio, as well as the cooling conditions [77, 78]. All treatments below the Curie point usually need to be provided in a magnetic field higher than the saturation one, and kept at room temperature during the cooling process. The temperature, time of exposure, specific stress for stress annealing, and rate of heating and cooling are very important, not only as each parameter itself, but also, they have a mutual influence, and should be checked together in many cases. Both stress and field annealing could be done in two different ways: annealing of as-cast samples under field or stress, or using previously nanocrystallized samples, and then submitting them to stress or field annealing [37].

### 3.4. Structural Evolution

The conditions that allow the formation of these nanostructured materials depend on the crystallization temperatures, the thermodynamic quantities such as the crystal-interfacial energy and the free-energy driving force for homogeneous versus heterogeneous crystal nucleation, the small or large crystal nucleation frequency at sufficiently low growth rates, and the volume change during the crystallization.

It was mentioned previously that the crystallization of these materials takes place in two differentiated steps, which are clearly separated. Figure 2 constitutes a schematic approach to the crystallization process of these kinds of alloys. In the upper plot, two different curves are shown, a differential thermal analysis (DTA) scan, together with a resistivity versus temperature  $\rho(T)$  curve for a typical FINEMET alloy. Three different pictures representing the internal structure of the alloys in three characteristic structural situations (amorphous, nanocrystalline, and fully crystallized states) are included as insets, in order to clarify the whole picture. Among this, and in the lower part of Figure 2, the X-ray diffraction patterns and hysteresis loops that correspond to the three different structural are also presented. The two exothermic peaks of the DTA curve and the two minima of the  $\rho(T)$  curve situated around 550 and 700 °C

**Figure 2.** Schematic view of the crystallization process for a typical FINEMET alloy, showing the thermal evolution of the electrical resistivity, a DTA curve, as well as X-ray diffraction patterns and hysteresis loops at three characteristic structural stages.

correspond to the beginning of both crystallization steps. In between both peaks, the system is in a nanocrystalline state, that is, a mixture of small grains, of a few nanometers in average size, embedded in the remaining amorphous matrix. The most common experimental technique used to evaluate the degree of crystallization in a given material is obviously X-ray powder diffraction [69] because it is available in most of the research laboratories. This technique allows us to confirm the amorphous state of the as-prepared sample (only broad haloes are present in the diffraction patterns, instead of the characteristic sharp peaks corresponding to the Bragg reflections), as well as the evolution of the structure during the heat treatments. In this way, the values of the most important structural parameters, such as lattice constant and average grain size, can be obtained from the position of the peaks and their widths, respectively. Also, neutron diffraction is a valuable technique that gives information on the whole sample (not only from the surface, as is the case for X-rays), and also permits *in situ* structural studies of the nanocrystallization kinetics [108]. But these diffraction techniques are not the unique ones that help in the structural evolution study, Mössbauer spectroscopy give detailed and quantitative information on the amount of Fe atoms in each different environment, as well as details of the hyperfine magnetic parameters [69, 109, 110]. Also, electron

microscopies give information about the average grain sizes of the nanocrystallites, and their distribution along the sample surface [62]. Finally, it is worth noting that a relatively new technique, atomic force microscopy, allows us to obtain high-resolution topographic 3-D images of the alloy surface [111], as can be seen in Figure 3a and b for a FINEMET-type alloy in an amorphous and a nanocrystalline state, respectively.

The crystallization process of this kind of material can be summarized as follows. In the first step, the soft magnetic Fe or FeSi crystalline phase, with an average grain size around 10–15 nm, is formed, leading to a mixed structure of nanograins embedded in the remaining amorphous matrix or intergranular region, which is becoming more and more inhomogeneous when first crystallization occurs. The composition and structure of the nanograins depend on the alloy composition as well.

- For FINEMET alloys, the structure of the nanograins is a BCC–FeSi solid solution (when the amount of Si is less than 12at%) or a  $\text{DO}_3$ –FeSi (for percentages of Si above 12at%).
- For NANOPERM alloys, the structure is BCC–Fe.
- For HITPERM alloys, the structure varies, depending on the percentage of Co, and can be a BCC–FeCo ordered ( $\alpha$ ) for a nearly equal content of Fe and Co (Co atoms occupy fixed Fe positions) or a disordered ( $\alpha'$ ) solid solution for a low Co content (Co atoms occupy Fe atoms randomly).

Once the first step is finished, the second step leads to the crystallization of the remaining amorphous matrix into Fe–B or FeMT(B) phases (with high values for the magnetic anisotropy; see the evolution of the hysteresis loops in Fig. 2), and the growing of the Fe(Si) phase. These two processes overlap in most cases, when FeSiB alloys are submitted to heat treatments, and occur for temperatures above 400 °C; thus, the nanocrystalline state is never reached, and the soft magnetic properties shown in an amorphous state do not improve during the crystallization process. However, the addition of a small amount of Cu, which acts as a nucleation center for crystallites, accelerates the first step, and it takes place at lower temperatures (below 500 °C); meanwhile, the addition of other transition metals, such as those mentioned above, retards the second crystallization step up to temperatures above 700 °C, and prevents grain growth. In between both steps, the structure of these materials consists of a large amount of Fe or FeSi nanosized grains (around 70–80% of the sample), surrounded by the remaining amorphous ferromagnetic matrix (less than 30%).

**Figure 3.** Atomic force microscopy 3-D images of a FINEMET alloy, a: in an amorphous (as-prepared) and b in a nanocrystalline state.

### 3.5. Magnetic Behavior

As shown above, nanocrystalline alloys consist of particles or grains with sizes ranging in the nanometer scale up to 20–30 nm embedded in the amorphous matrix-forming nanocomposite. The precipitation of these nanocrystalline particles from the amorphous matrix improves the tensile strength and ductility of the alloy due to the strong reduction of the anisotropy induced by residual internal stresses and, as a consequence of that, the softening of the magnetic properties in the nanostructured state.

Metallic Fe–TM–metalloid-based amorphous and nanostructured materials produced by rapid solidification of the melt are the most important ones from a commercial point of view because their soft magnetic properties make these nanocrystalline materials very suitable for use as high-frequency electronic components in magnetic devices or magnetic sensors [9, 62, 112–115].

Fe-based amorphous ferromagnetic metallic glasses show a larger magnetization than those based on Co, and much larger than those containing Ni. However, iron-rich amorphous alloys generally have fairly high magnetostriction ( $\lambda_s \approx 20 \times 10^{-6}$ ), limiting their magnetic permeability. The formation of a nanocrystalline Fe-rich alloy can lead to a drastic reduction in magnetostriction and coercivity due to the well-coupled Fe nanocrystallites by exchange interaction, thus favoring easy magnetization and, simultaneously, high permeability. These nanocrystalline alloys are composed primarily of crystalline Fe grains, having at least one dimension on the order of a few nanometers, that are embedded in a residual amorphous matrix. Thus, such materials provide an excellent context in which to study the principles of magnetism in nanometer structures [112, 113].

In particular, the so-called soft ferromagnetic alloys (characterized by high values of saturation polarization and low values for the coercive force and core losses) have been the most widely studied, and the typical composition in atomic percent is about 70–80% of Fe and 20–30% of metalloid atoms, such as B, Si, P, and so on [62, 113, 114]. The origin of the soft magnetic properties lies in the weak magnetic anisotropy presented by these materials in the amorphous state. When the alloys are submitted to temperatures above 450–600 °C, crystallization of the system takes place, leading to magnetic hardening of the material due to the appearance of different crystalline phases with high values of the magnetocrystalline anisotropy.

However, the addition of a small amount (5–10at%) of transition metals such as Nb, Zr, Cu, Ta, and so on drastically changes the crystallization kinetics. First, the crystallization temperature increases slightly, and second, there is a large interval of temperatures (up to 200 °C) in which the average grain size of the principal crystalline phase remains below 15–20 nm lower than the typical exchange correlation length for these systems, which is about  $l \approx 35$  nm. The magnetic response of the nanostructured material is, at this point, even better than in an amorphous state [61, 71, 116] and nowadays, typical compositions of prototype Fe-rich nanocrystalline alloys such as  $\text{Fe}_{73.5}(\text{SiB})_{22.5}\text{Cu}_1\text{Nb}_3$  (FINEMET alloys) or  $\text{Fe}_{100-x}(\text{ZrB})_x$  (NANOPERM alloys) are the softest magnetic materials known, with attractive soft magnetic properties, including

values of the coercive force  $H_C$  below  $1 \text{ A} \cdot \text{m}^{-1}$ , vanishing magnetostriction ( $\lambda_s \approx 10^{-7}$ ) due to the balancing between the opposite contribution of this parameter from the Fe(Si) nanocrystals and from the residual amorphous matrix, magnetic permeability  $\mu$  higher than  $10^5$ , and polarization saturation values  $J_s$  over  $1 \text{ T}$  [63, 117, 118].

The change in the surface magnetic domain structure from the as-cast state to the nanocrystalline one, during the annealing of the ferromagnetic samples, can be investigated by using the Bitter technique, where the colloidal ferrofluid is attracted by the Bloch wall's gradient field, thus revealing the intersection of every Bloch wall with the sample surface [19]. Photographs a)–c) in Figure 4 show the evolution of the magnetic domain structure for the  $\text{Fe}_{73.5}\text{Si}_{16.5}\text{B}_6\text{Cu}_1\text{Nb}_3$  ribbons from the as-cast state a) to the different annealed states. In all photographs, the longitudinal ribbon axis lies along the horizontal direction. Hence, photograph 4a) reveals an island domain structure on the bright surface of the as-cast sample. The observed islands domain in a) correspond to closure domains resulting from compressive internal stresses, in which the anisotropy direction lies perpendicular to the ribbon plane, and whose narrow laminar widths are between  $4.1\text{--}5.8 \mu\text{m}$ . These experimental measured values are in good agreement with the theoretical one, around  $4.3 \mu\text{m}$ , calculated for the corresponding Landau–Lifshitz domain width [120].

When the annealing temperature is increased up to  $425\text{--}475 \text{ }^\circ\text{C}$ , the internal stresses are nearly removed, and nanocrystallization begins to take place, with a mean grain diameter around  $12 \text{ nm}$ . It can be observed that a stripe domain structure appears in these annealed samples, with a measured domain width around  $5.5\text{--}6.8 \mu\text{m}$  for the ribbon annealed at  $425 \text{ }^\circ\text{C}$  [Fig. 4b)], which exhibits a magnetic hardening, and which diminishes to  $2.7 \mu\text{m}$  for the ribbon annealed at  $475 \text{ }^\circ\text{C}$  [Fig. 4c)], when the nanocrystallization begins. The latest domain width value measured is in very good agreement with that calculated from the random anisotropy model ( $2.8 \mu\text{m}$ ) [72]. In this late state, all of the

**Figure 4.** Pattern domain of  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{16.5}\text{B}_6$  amorphous and nanocrystalline ribbons. a) As-cast sample. b), c) Annealed at  $425$  and  $475 \text{ }^\circ\text{C}$ , respectively. The scale shows a  $0.1 \text{ mm}$  division. Reprinted with permission from [54], M. Tejedor et al., *J. Non-Cryst. Solids* 287, 396 (2001). © 2001, Elsevier Science.

anisotropies start to vanish, and the magnetization vector tends to align parallel to the ribbon plane, increasing the transversal magnetic permeability, and therefore improving the magnetic properties of the sample. At higher annealing temperatures, the pattern domain exhibits a much more fine stripe structure, where the easy axis of magnetization may lie between the longitudinal and transverse directions, as can be observed through other techniques [81, 38]. The transverse-induced anisotropy in a nanocrystalline FeSiB–CuNb alloy could mainly be due to the magnetoelastic anisotropy exerted through annealing, by the FeSi nanocrystallites, that induces a transverse anisotropy via magnetoelastic interaction with tensile back stresses created by the inelastically deformed residual amorphous matrix [37, 44, 54, 121, 122]. If this transverse anisotropy is sufficiently large, the domains will orient themselves along the anisotropy axis. Hence, this uniaxial anisotropy can control the magnetization in the ribbon domains, and therefore the high-frequency response of these soft nanocrystalline materials.

Figure 5 shows the variation of both magnetostriction and conductivity with the annealing temperature for the  $\text{Fe}_{73.5}\text{Si}_{16.5}\text{B}_6\text{Cu}_1\text{Nb}_3$  [FINEMET (B6)] ribbons. It is important to note that near-zero magnetostriction can be achieved in Fe-rich alloys by nanostructuring. In nanocrystalline alloys, the sum of the volume-weighted magnetostrictions of the nanocrystalline grain phase and of the amorphous grain boundary phase can result in a net vanishing magnetostriction, even when the precursor amorphous alloy shows strong magnetostriction. In FINEMET nanocrystalline systems, the positive magnetostriction of the residual amorphous phase ( $\lambda_s \text{ amorph} = 20 \times 10^{-6}$ ) is balanced by the negative magnetostriction of the growing  $\alpha\text{-Fe(Si)}$  nanocrystalline phase ( $\lambda_s \text{ FeSi} = -6 \times 10^{-6}$ ) [62, 64, 113, 123].

In our particular composition, FINEMET (B6), a compensated or zero magnetostriction value is obtained after heating at a temperature of about  $565 \text{ }^\circ\text{C}$ , measured by the small angle magnetization rotation technique [124].

Heating at higher temperatures gives rise to slightly negative values of magnetostriction, which also lead to the modification of the domain structure that, in this case, results in the appearance of transversal domains [54].

On the other hand, it is clear that the conductivity can also influence the impedance and magnetic permeability

**Figure 5.** Evolution of conductivity  $\sigma$  and saturation magnetostriction  $\lambda_s$  with annealing temperature for  $\text{Fe}_{73.5}\text{Nb}_3\text{Cu}_1\text{Si}_{16.5}\text{B}_6$  ribbons. Lines are guides for the eye.

of the sample, and therefore its high-frequency response [125, 126]. As can be observed in Figure 5, not only is  $\lambda_s$  modified during the successive annealing, but also  $\sigma$ , where  $\sigma$  increased from about 5000 ( $\Omega \cdot \text{cm}$ )<sup>-1</sup> in the as-quenched state to about 6800 ( $\Omega \cdot \text{cm}$ )<sup>-1</sup> at the higher annealing temperature of about 575–580 °C.

This strong increase in the conductivity of the nanocrystalline ribbons ( $\sigma_{\text{nanocryst}}$  is on the order of 15% higher than  $\sigma_{\text{amorph}}$ ) reduces the skin depth, which contributes to an increase of the impedance of the sample, because this fact favors the appearance of both macroscopic eddy currents as well as the microscopic-induced currents due to the free transverse domain wall displacements [125, 127, 128].

#### 4. MAGNETOIMPEDANCE EFFECT IN NANOCRYSTALLINE ALLOYS

Another interesting feature, recently discovered in these kinds of nanostructured materials in the form of FeCuNb-SiB ribbons, wires, microwires, and films, or similar compositions, is the so-called magnetoimpedance effect, which consists of a strong decrease of the electrical impedance  $Z$  of the ferromagnetic sample when submitted to an external static magnetic field, as was mentioned above [11, 21, 26–39, 41–44, 48–56, 129–136].

In the case of FINEMET materials, and using the classical eddy-current theory, it was found that large MI was associated with the reduction in resistivity during the crystallization of the samples, together with a vanishing magnetostriction [11, 28–34, 39]. The first fact can be explained by taking into account that a decrease in the electrical resistivity implies an increase of the eddy-current losses, and hence the MI maximum. Moreover, if we consider the approach of the existence in the material of current lines distorted and dragged by magnetic domain walls oriented perpendicular to the current direction, we may take into account the effects of microeddy currents generated by the free displacement of the domain walls on the effective magnetic permeability for these soft ferromagnetic nanocrystalline materials. Therefore, we cannot neglect the influence of microeddy currents on the MI effect [11].

There is a clear relationship among the reduction of the resistivity of the samples, the vanishing of the residual anisotropies accompanied by the strong reduction of the saturation magnetostriction, and the maximum of the magnetic permeability and MI effect response as the crystallization process advances. In fact, and as shown in Figure 6, the maximum MI value is obtained for the ribbon annealed at 575 °C when the value of  $\rho$  is 15% lower than the corresponding one for the amorphous precursor, and the transverse magnetic permeability is maximum [39, 41]. Similar results are found in samples with other geometries and compositions [21, 28, 37, 48, 77].

These results are in agreement with the evolution of the surface magnetic domain structure of the annealed samples and the behavior of the electrical conductivity and magnetostriction shown above. The ribbon of FINEMET (B6) annealed at 575 °C, which exhibits the maximum MI effect, is the one that presents the smallest magnetostriction value ( $\lambda_s \approx -3.6 \times 10^{-7}$ ), which involves vanishing residual anisotropies, and the appearance of a transverse anisotropy

**Figure 6.** Field dependence of the magnetoimpedance ratio for some annealed Fe<sub>73.5</sub>Cu<sub>1</sub>Nb<sub>3</sub>Si<sub>16.5</sub>B<sub>6</sub> ferromagnetic ribbons at a frequency of 500 kHz.

induced by the magnetoelastic interaction between the FeSi nanocrystallites formed with tensile stresses of the residual amorphous matrix, resulting in a transversal magnetic permeability maximum.

All that, accompanied by a strong reduction in the resistivity of about 15% with respect to the as-cast state, which favors the appearance of both macroscopic eddy currents and the microscopic ones due to the free transverse domain wall displacements, gives rise to a drastic increase of the MI effect at low frequencies of the passing current across these nanostructured materials.

#### 4.1. Research Tool

The magnetoimpedance effect can be employed as a research tool to study magnetic properties of amorphous and nanocrystalline materials. It is not only important for the development of new technological applications, but also in the field of basic research in order to provide information about other interesting magnetic parameters of the materials. Due to its dependence on several soft magnetic properties, like anisotropy field, magnetostriction, and magnetization processes, the behavior of these properties can be inferred from the magnetoimpedance dependence on frequency and magnetic field and its value.

##### 4.1.1. Magnetostriction Coefficient

The MI effect shows a characteristic behavior with the applied magnetic field. In the case of as-quenched or annealed samples, the magnetoimpedance rate shows a monotonous decrease from a maximum value at  $H = 0$  Oe, as in the case of nanocrystalline samples that have been annealed at a certain temperature in order to obtain their softest magnetic properties. When the sample has a transverse-induced anisotropy, the impedance curve versus the applied field shows a peak at a field on the order of the anisotropy field of the sample [137]. This fact can be used to determine the anisotropy field of the samples, which can provide us with valuable information, for example, to determine magnetostriction coefficients, as explained in the next paragraph.

Figure 7 shows the behavior of magnetoimpedance as a function of the applied magnetic field, together with the hysteresis loop for a stress-annealed amorphous ribbon. The behavior of nanocrystalline-annealed samples, with an

**Figure 7.** Magnetoimpedance ratio at 1 MHz versus the applied magnetic field and hysteresis loop obtained at 50 Hz of a  $\text{Co}_{66.5}\text{Fe}_{3.5}\text{Si}_{12}\text{B}_{18}$  amorphous ribbon subjected to an annealing treatment of 340 °C, followed by a stress annealing at 340 °C with a 300 MPa applied tensile stress.

induced transverse anisotropy, is exactly the same. It can be seen how the anisotropy field can be obtained by the maximum of magnetoimpedance.

One of the properties that can be deduced from the MI behavior is the saturation magnetostriction coefficient. The magnetostriction can be obtained from the MI effect due to the MI dependence on the applied stress.  $\lambda_s$  has a linear dependence on applied stress [138]

$$\lambda_s = \lambda_s(0) - k\sigma \quad (5)$$

The impedance behavior as a function of the applied bias field depends on the anisotropy field, which can be changed by the application of tensile stresses. A peak of MI appears at the anisotropy field, and its position can be determined.

Let us consider the case of a soft magnetic sample with a negative magnetostriction and no induced anisotropy. In the unstressed state of the sample, the impedance drops continuously with the increasing bias field. The application of tensile stresses on this sample would increase the magnetoelastic anisotropy field, and the MI peak would appear at a higher field. This would be the case for nanocrystallized samples, which have a negative saturation magnetostriction coefficient that usually occurs when the sample has been annealed above around 550 °C, depending on the composition.

When the saturation magnetostriction coefficient is positive, the behavior of the magnetic sample is somewhat different. The value of the anisotropy field could not be determined because the MI effect would have a maximum at  $H = 0$ . But if the positive magnetostriction sample has an induced anisotropy, it will have a peak at  $H_k$  in the unstressed state, and further application of tensile stresses, which would decrease the anisotropy field, would lead to a smaller value of the anisotropy field, which can be determined [139].

The anisotropy field does not vary linearly with stress, but it can be fitted as a second-order polynomial of the form

$$H_k = a\sigma^2 + b\sigma + c \quad (6)$$

where  $a$ ,  $b$ , and  $c$  are constants. There is a relationship between the magnetostriction and the anisotropy field:

$$\lambda_s = \frac{\mu_0 M_s}{3} \left( \frac{dH_k}{d\sigma} \right) \quad (7)$$

It can be easily verified that the saturation magnetostriction is a linear function of stress, as shown in Eq. (5). From Eqs. (7) and (5), we can obtain

$$\lambda_s(0) = \frac{\mu_0 M_s b}{3} \quad (8)$$

which is the unstressed value of the saturation magnetostriction coefficient, and

$$k = \frac{d\lambda_s}{d\sigma} = \frac{2\mu_0 M_s a}{3} \quad (9)$$

which is the measured slope.

Using this procedure, we can find the  $\lambda_s(0)$  values of all types of samples, with positive and negative magnetostriction, with an accuracy similar to the well-known SAMR (small angle magnetization rotation) method [124, 140]. This method can be applied to all types of samples, but in the case of nanocrystallized samples, the application of stresses might produce the breaking of the sample due to its fragility.

Although this method is accurate, some specific problems can be found. The  $\Delta Z/Z - H$  curves may be broad and not symmetric, it being difficult to correctly estimate the position of the impedance peak.

#### 4.1.2. Nanocrystalline State

The MI effect shows a great variation in its value due to structural changes in the magnetic nanocrystalline samples. A correlation between magnetoimpedance and microstructure as a function of the average grain size can be established. The average grain size of the FeSi crystallites in these samples is about 10–15 nm in the studied range of annealing temperatures. Other materials with similar compositions have similar values of grain sizes [141]. The grain size increases strongly after annealing at temperatures of 600 °C, approximately, when new crystalline phases nucleate as well.

Figure 8 shows the dependence of the MI ratio as a function of the annealing temperature in  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{16.5}\text{B}_6$  ribbons. The highest value of the MI ratio, close to 60%, is reached for an annealing temperature of 575 °C, which corresponds to the softest behavior of this material due to the grain size.

The MI temperature dependence allows us to investigate the nanocrystalline state of annealed samples by measuring the magnetoimpedance. This behavior has been seen in ribbon- and wire-shaped nanocrystalline materials [27], showing that the MI rate response depends on the sample structure, and the sample shape influence is not as important. The highest MI rate is obtained when the nanocrystalline sample reaches its softest magnetic behavior, that is, when the FeSi crystallites have grain sizes of about 10 nm.

**Figure 8.** Magnetoimpedance ratio as a function of the annealing temperature of the nanocrystalline  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{16.5}\text{B}_6$  ribbons.

#### 4.1.3. Permeability Measurement

The real and imaginary components of impedance can be obtained by using a lock-in amplifier, which separates the out-of-phase components. The magnetoimpedance ratio and sensitivities for both components of impedance can be calculated in the same way, as  $\Delta Z'/Z'(\%)$  and  $\Delta Z''/Z''(\%)$  for the resistance, and reactance, respectively. The total impedance would be written as  $Z^* = Z' + jZ''$ , where  $j = (-1)^{1/2}$ .

When dealing with a magnetic system, it is often advantageous to use the complex inductance formalism, and deal with  $L^*$  instead of  $Z^*$  since it is directly related to the value of permeability. The transformation from impedance to permeability (through inductance) can be simply written as

$$\mu^* = kL^* = -\left(\frac{kj}{\omega}\right)Z^* \quad (10)$$

where  $\omega = 2\pi f$  is the angular frequency.

Note that, due to the form of this transformation, the real component of permeability  $\mu'$  depends on the imaginary part of impedance, and conversely, the imaginary part of permeability  $\mu''$  is obtained from the real part of impedance. The geometrical constant  $k$  can be evaluated in the case of a wire-shaped sample by assuming, as a first approximation, a wire homogeneously magnetized in the circumferential direction. By defining the induction  $L$  as the ratio of magnetic flux  $\Phi$  to the current intensity  $i$ ,  $L = \partial\Phi/\partial i$  [142].

Figure 9 shows the case of a wire with composition  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{16.5}\text{B}_6$  that has been annealed at different temperatures in the range 400–640 °C during 1 h in an Ar atmosphere. The wires have a length of 8.5 cm and a diameter of 120  $\mu\text{m}$ . The figure shows the behavior of permeability, evaluated as explained above, versus the applied axial magnetic field. The magnetic softening of the sample can be inferred from the permeability behavior. At low annealing temperatures, up to around 500 °C, the permeability shows low values, but the largest permeability at  $H = 0$  Oe is obtained at 550 °C. The annealing at higher temperatures leads to a further magnetic hardening of the sample. The softest magnetic properties, including the lowest coercive force, are achieved for annealing temperatures close to 550 °C, where the nanostructured FeSi phase precipitates.

**Figure 9.** Permeability obtained from the impedance measurements in nanocrystallized wires versus the applied magnetic field.

This phase has a mean grain size of about 10 nm. Finally, an important magnetic hardening occurs for temperatures above 600 °C, mainly as a consequence of the precipitation of new Fe–B phases [141]. As the applied magnetic field is increased, the transverse permeability decreases, due to the magnetization of the sample in the axial direction.

The behavior of permeability as a function of frequency and other parameters can then be obtained from Eq. (10) for all types of samples, without taking into account the geometrical constant  $k$ . Figure 10 collects the permeabilities of nanocrystallized ribbons in arbitrary units as a function of the drive current frequency. For low frequencies (up to  $10^4$  Hz), the permeabilities for all of the samples have the same value. For higher frequencies, the nanostructure of the ribbons influences the permeabilities, making them change. The 460 °C annealed ribbon has the lowest permeability in all of the studied frequency range. When the annealing temperature is increased, the permeability increases. Up to  $4 \times 10^4$  Hz, the 575 °C annealed sample has the largest permeability. For higher frequencies up to  $10^5$  Hz, the highest value corresponds to the 550 °C annealed ribbon. A further increase of the annealing temperature leads to a hardening of the magnetic behavior of nanocrystalline samples, and to a decrease in permeability, as can be observed in the above-mentioned figure.

**Figure 10.** Permeability obtained from magnetoimpedance measurements for annealed  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{16.5}\text{B}_6$  ribbons as a function of the annealing temperature for three selected drive current frequencies.

#### 4.1.4. Magnetization Processes

The MI effect behavior depends on the magnetization processes that take place in the sample when the ac current is flowing through it, and is subjected to external influences that modify its magnetization. The magnetoimpedance rate spectra give us information about the magnetization processes that take place at different frequencies. The different domain structures of as-quenched and nanocrystalline samples are responsible for their distinguishable MI effects [38]. At low frequencies, the magnetization processes take place by domain wall displacements, but at higher frequencies, the domain walls are not able to follow the ac magnetic field, and the magnetization processes are due to moment rotations. The relaxation frequency  $f_x$  is the frequency which separates the two main areas of different magnetization processes. The MI spectrum shows a maximum in this area, and  $f_x$  can be easily obtained.

The value of  $f_x$  has been recently seen to be dependent on the magnetostriction coefficient [143]. This matter is still undergoing research, but could show in the future why the MI effect has larger values when the saturation magnetostriction coefficient is small and negative. The relaxation frequency decreases with an increase of the magnetostriction coefficient for all types of samples, both nanocrystalline and amorphous ones. Figure 11 shows this dependence for a nanocrystalline sample, and a comparison to an amorphous one. The high magnetostriction value and low permeability of the FeCuNbSiB ribbon in the as-quenched state explain that the MI effect is not observed until partial devitrification and a softer magnetic behavior are achieved by annealing. Although all treatments for the amorphous ribbon resulted in a decrease of the relaxation frequency as a function of the magnetostriction coefficient (see arrows in the curves), the opposite tendency is observed for the nanocrystalline ribbons: the relaxation frequency becomes higher after the treatments. And the representation of the relaxation frequency as a function of the magnetostriction coefficient shows the same behavior in all of the samples: it is a monotonous decay. The same behavior has been previously observed in other amorphous ribbons [143].

**Figure 11.** Relaxation frequency  $f_x$  relationship with the magnetostriction coefficient of nanocrystalline ribbons, and comparison to amorphous ribbons. The arrows guide the eye and indicate the scales.

#### 4.2. Technological Applications

The earliest work on applications based on the MI effect was devoted to a magnetic field sensor employing amorphous ribbons [144–147]. Active research recently has been done on the development of miniaturized sensors based in MI [12]. The special advantage of the MI effect as detected in amorphous wires in comparison with other magnetic phenomena is that even small fields (below  $100 \text{ A} \cdot \text{m}^{-1}$ ) can produce a strong impedance variation. In fact, they look very competitive in comparison with magnetic field sensors based on magnetoresistance or the Hall effect. The main applications are related to the influence of the magnetic field. In particular, current sensors and proximity sensors are actually sensor devices measuring the magnetic field.

The MI effect strongly depends on the magnetic softness of the sample, including both higher induction and permeability, and for special environmental conditions, materials capable of operating at higher temperatures. As previously mentioned, large circular (wire shape) or transversal (ribbon shape) permeability and a small resistivity and magnetostrictive coefficient are required to observe the MI effect. The magnetic permeability is determined by the chemical composition, crystal structure, microstructure, and shape of the sample. Alloys with small magnetocrystalline anisotropies and magnetostrictions give rise to particularly soft magnetic materials. Amorphous and nanocrystalline magnetic materials are now competitive with SiFe bulk alloys and Fe–Co alloys, and their soft magnetic properties exceed those of the bulk alloys based on Fe, Co, and Fe–Co [59].

The first MI measurements in nanostructured materials were performed in FeSiBCuNb wires devitrified from an amorphous precursor by annealing at different temperatures [28, 148]. Optimum soft magnetic behavior was achieved after annealing at about  $550 \text{ }^\circ\text{C}$ . Meanwhile, the maximum impedance variation appears for the softest nanocrystalline wire; a larger MI ratio is observed after annealing at a higher temperature (near  $600 \text{ }^\circ\text{C}$ ), where the resistivity clearly decreases as a consequence of crystallization [13]. We should also remark that the MI effect in nanocrystalline materials (wire or ribbon morphology) [28, 39] does not reach values as large as for amorphous Co-rich alloys. This must be associated with the smaller values of the circular or transversal permeability in that nanocrystalline material. It could be possible that the nanocrystalline sample is softer when it is axially magnetized, but what is required in the MI effect is a very large circular or transversal permeability, which involves a circular or transversal and very weak magnetic anisotropy.

#### 4.3. Unique Properties of Nanocrystalline Alloys for Special Applications

Giant magnetoimpedance has attracted significant attention in the last years due to possible technological applications in position sensors, rotary encoders, and direction sensors for navigation, current sensors, biomedical and environmental controllers, nondestructive control sensors, and reading heads [7, 12, 44, 48, 80, 101, 135, 145–153]. It is possible to modify and adapt the magnetoimpedance responses of appropriate material for each particular application performing specific treatments. Although many of the proposed

applications can be realized using very different materials for the same type of application, there are a few of them where amorphous materials are useless due to particular conditions.

Recently, high-temperature magnetic measurements were reported, opening the possibility to study both the basic problems of the exchange-coupling process in nanocrystalline materials and the conditions of possible high-temperature applications of the magnetic materials [154, 155]. Why do we need sensors for high-temperature applications? It is easy to answer this question by reference to the everyday needs of our life surrounded by modern technology: it would be much easier to control the space and aircraft engines and other technical blocks, nuclear and power station functionality, metallurgical production, and many other potentially dangerous processes in order to avoid a catastrophe or simply little controlled actions. The high-temperature sensing has different basic problems. The first one is the temperature dependence of the saturation magnetization and the Curie point existence [156, 157]. It is very difficult to find a magnetic material at elevated temperatures, which can be used at the same time for sensing processes. We say that temperatures from 0 to 180 °C correspond, in most general estimations, to the normal functionality interval. There are many amorphous materials with a measurable MI response at room temperature in which MI effect totally disappears at 180 °C because of a low Curie temperature (for example, in  $\text{Fe}_3\text{Co}_{64}\text{Cr}_3\text{Si}_{15}\text{B}_{12}$  ribbons with a Curie temperature of 160 °C and a crystallization temperature of 570 °C [158, 159]). Another problem is structural stability. The amorphous state is a metastable one. The closer we are to the crystallization temperature (around 500 °C for many amorphous materials), the less stable are the structural features of the amorphous sensitive element. Especially important, if we take into account those facts, is the presence of *proper induced magnetic anisotropy*, which shows even faster temperature degradation compared with the changes of structural parameters [160, 161].

A high-temperature giant magnetoimpedance effect was reported for  $\text{Fe}_{73.0}\text{Cu}_{1.0}\text{Nb}_{2.5}\text{V}_{1.0}\text{Si}_{13.5}\text{B}_{9.0}$  nanocrystalline ribbons with measuring temperatures up to 550 °C [135]. A maximum relative change of the impedance of about 60% of the MI ratio with a sensitivity of about 20%/Oe in a small field appears at about 320 °C. Let us emphasize that the maximum sensitivity of magnetic sensors based on a giant magnetoresistance effect does not exceed 2%/Oe in CoCu multilayers at room temperature. The MI effect of  $\text{Fe}_{73.0}\text{Cu}_{1.0}\text{Nb}_{2.5}\text{V}_{1.0}\text{Si}_{13.5}\text{B}_{9.0}$  nanocrystalline ribbons still exists at 500 °C (being 5%). The authors explain these outstanding properties by the thermal evolution of the magnetic softness and magnetic anisotropy of the nanocrystalline sample: as the temperature rises, a combination of stress release and magnetocrystalline anisotropy decrease in the amorphous phase further softens the ribbon magnetically, increasing its MI. There were additional attempts to study the MI effect in amorphous and nanocrystalline thin films and MI sandwiches of similar composition ( $\text{Fe}_{71.5}\text{Cu}_1\text{Cr}_{2.5}\text{V}_4\text{Si}_{12}\text{B}_9$ ) [150, 154]. The MI ratio reaches its maximum of about 140% at a very low characteristic frequency of 4 MHz in FeCu-CrVSiB/Ag/FeCuCrVSiB, but the temperature measurements for nanocrystalline films are missing at the moment.

#### 4.4. Recent Progress of the Magnetoimpedance Effect in Nanocrystalline Materials

In this section, an updated overview covering the very recent works based in the MI effect in nanocrystalline alloys is given.

The principles of remote-interrogated stress sensors based on high-frequency magnetic materials showing the inverse magnetostrictive or magnetoimpedance effects has been reported by Ludwig et al. [162].  $\text{Fe}_{50}\text{Co}_{50}/\text{Co}_{80}\text{B}_{20}$  amorphous/nanocrystalline multilayers have been prepared, showing ferromagnetic resonance frequencies up to 5 GHz and good magnetoelastic properties in the gigahertz range. The high-frequency remote interrogation allows the reduction of the sensor antenna size and measurements using high bandwidths.

The MI effect in powder samples of Fe-based nanocrystalline  $\text{Fe}_{73}\text{Cu}_1\text{Nb}_{1.5}\text{V}_2\text{Si}_{13.5}\text{B}_9$  has been reported for the first time [163]. The magnetic permeability of the powder materials may not be as high as that of thin films or ribbons and the coercivity may not be as small, but they can be conveniently pressed into different shapes such as cylinders and rings, offering less brittleness than nanocrystalline ribbons and wires, and many possible high-frequency applications.

A systematic study of the high-temperature MI effect in nanocrystalline  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$  ribbons with different annealing temperatures has been presented [164]. The discussion is given on the basis of a random anisotropy model [165], to explain the relationship between the thermal dependence of the MI and the magnetic coupling between grains.

A small GMI effect was found in nanocrystalline  $\text{Fe}_{79.5}\text{P}_{12}\text{C}_6\text{Mo}_{0.5}\text{Cu}_{0.5}\text{Si}_{1.5}$  ribbons obtained by annealing the precursor amorphous at temperatures ranging from 350 to 500 °C [166].

A review of the amorphous alloy preparation, measurement system, and various annealing techniques used in the MI enhancement can be found in [167].

The effects of Cr substitution, the type of thermal treatments (in a conventional furnace and by current annealing), and the sample length in MI have been reported in  $\text{Fe}_{73.5-x}\text{Cr}_x\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$  ( $x = 0$  and 10) nanocrystalline wires [168], and a similar study of the MI effect with annealing temperature was done in glass-covered CoB-SiMn microwires [169]. The domain structure and induced anisotropy influences on the MI are both discussed.

Two other recent works contribute to the study of the evolution of the MI effect in some nanocrystalline ribbons, previously submitted to different annealing treatments in an as-cast state: stress annealing on  $\text{Fe}_{88.02}\text{Zr}_{4.69}\text{Nb}_{2.31}\text{B}_{4.98}$  ribbons [170], and current annealing on  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{V}_2\text{Si}_{15.5}\text{B}_7$  [171]. The MI behavior is explained in both papers by taking into account the role of the induced magnetic anisotropy, saturation magnetostriction coefficient, and the microstructural changes developed with the thermal treatments.

A correlation among the structural, electrical, and magnetic properties, together with the MI effect response in some heat-treated FINEMET types of different composition and FeZrB ribbons, is given in [172]. High values of the MI ratio up to 130% have been achieved, at a drive frequency of 5 MHz, by subjecting FeZrB ribbons to a current annealing treatment.

Table 1 displays a brief summary of some of the investigations mentioned through this chapter, indicating the studied material composition and its main properties related to the MI effect, with the respective references.

Finally, we can conclude that these compounds could be excellent candidates for the design and development of new magnetic sensors and high-frequency devices based on nanocrystalline alloys.

**Table 1.** MI Effect in Nanostructured Medium.

Composition	Properties/remarks	Ref.
$\text{Fe}_{4.3}\text{Co}_{68.2}\text{Si}_{12.5}\text{B}_{15}$ $\text{Co}_{68.15}\text{Fe}_{4.35}\text{Si}_{12.55}\text{B}_{15}$	Low magnetostriction alloys. Induced anisotropy. MI and magnetoinductive effects.	[4, 12, 17]

$\text{Fe}_{91}\text{Zr}_7\text{B}_2$	MI in current-annealed nanocrystalline ribbons	[172]

## GLOSSARY

**Amorphous alloy** Alloy with no long range atomic order.

**Magnetic anisotropy** The magnetic properties depend on the direction in which they are measured.

**Magnetic domain** Volume of material in which all atomic magnetic moments are aligned in the same direction.

**Magnetic permeability** The ability of a material to support a magnetic flux density.

**Magnetoimpedance** Impedance change in a ferromagnetic sample when submitted to a magnetic field.

**Magnetostriction** Deformation of a magnetic substance due to its magnetic state.

**Nanocrystalline alloy** Alloy containing crystalline nanograins embeded in an amorphous matrix.
