## 1. INTRODUCTION

Recent progress in microfabrication techniques has made it possible to realize low dimensional electronic systems in semiconductor structures. The motion of electrons inside microfabricated structures (whose size is comparable to the Fermi wavelength) is quantized. This is known as the quantum size effect. This effect was first observed in two-dimensional electronic systems confined in the Si/SiO<sub>2</sub> surface of metal-oxide semiconductor transistors, followed by experiments with semiconductor heterostructures such as GaAs/GaAlAs systems. One can also realize electronic systems of low dimensions, such as a one-dimensional quantum wire and a zero-dimension quantum dot, using electrostatic confinement potentials inside the surface. Owing to the quantum size effect, the discreteness of energy levels becomes apparent. Moreover, it is obvious that in such small structures, the Coulomb interaction between electrons is enhanced. In an analogy with an atom, which is a small system with a few electrons occupying discrete energy levels and interacting with each other by Coulomb repulsion, semiconductor quantum dots are sometimes called “artificial atoms.” They differ from real atoms in several ways. For example, they are larger than the atomic size and the confining potential is different from the  $1/r$  potential of real atoms.

Confinement of electrons can be achieved in two ways. One way is by confining them in the depletion region of

a semiconductor. Here, we confine electrons in the depletion region, which can be modeled by a parabolic potential [1–8]. The second way is by confining the electrons using compound semiconductor heterostructures, such as GaAs/AlGaAs. Here, the size of the confining structure can be on the order of 10 nm [9–14]. In the second way, the electron density inside a dot can be tuned, that is, the number of electrons in a dot can be counted [15].

In comparison with metallic particles, quantum dots fabricated on the semiconductor heterojunctions are clean and highly symmetric. Further, they can be made sufficiently small that the dot size is comparable to the Fermi wavelength. Two types of quantum dots, the lateral dot and the vertical dot, have been used in transport experiments. A lateral-dot device can be made in a two-dimensional electron system by fabricating metal electrodes on the surface of semiconductor heterostructures, for example AlGaAs/InGaAs/AlGaAs, as shown in Figure 1 [16]. Metals are deposited in a particular pattern to form Schottky electrodes above the two-dimensional electron system, where anti-bias voltage is applied so that electrons are confined inside the small region surrounded by the electrodes. Electrons can move by tunneling only through two paths, which are pinched off by these electrodes. The tunneling rate can be controlled by adjusting the gate voltage.

A vertical-dot device is also useful in experiments on transport through a quantum dot. Mesa-shaped structures are carved out of a semiconductor double-barrier structure in order to obtain a quantum dot sandwiched between two tunneling barriers, as shown in Figure 2 [17]. Electrons inside the dot are confined by the heterostructure potential barrier perpendicular to the layers. On the other hand, parallel to these layers, the depletion-layer potential originating from the gate electrode fabricated on the side of the dot confines these electrons using a parabolic potential. The vertical dot has two advantages over the lateral dot. One is that the number of electrons inside the dot can be adjusted, since the electrons are essentially independent from those outside. The other advantage is that the electronic states can be determined using a simple calculation because the shape of the region where electrons dwell is almost cylindrical due to the confining potential.

**Figure 1.** Transmission electron micrograph (TEM) image of a lateral dot structure used in the experiment involving the Kondo effect. Three electrodes (right one and left upper and lower ones) adjust the tunneling barriers between the dot and the leads, while the electrode at the center of the left side modifies the gate voltage. We review some recent work on quantum dots featuring spin-related phenomena, for example Kondo effects [18], in which the magnetic moment of electrons is elicited in localized sites coupled to metallic reservoirs. We note that electron–electron interaction is important in describing these spin-related phenomena. Before spin-related phenomena in quantum dots are discussed, let us consider the history of research on small metallic particles, including the Kubo effect of electrons.

## 2. HISTORICAL BACKGROUND ON METAL NANOSTRUCTURES

### 2.1. Ultrafine Particles

Particles about 1–100 nm in size are called ultrafine particles. Electronic states confined in an ultrafine particle have discrete Eigen energies whose level spacing is about 1–100 K. The electronic properties of ultrafine particles (e.g., specific heat and spin susceptibility) are different from those of bulk metal owing to this discreteness of energy levels.

**Figure 2.** TEM image of a vertical quantum dot used in the Kondo-effect experiment. Reprinted with permission from [17], S. Sasaki et al., *Nature* 405, 764 (2000). © 2000, Macmillan Magazines Ltd.

A prominent feature of the electronic properties of ultrafine particles is single electron tunneling, which was first posited in the 1950s [19, 20]. At sufficiently low temperatures, where the charging energy (typically 100–1,000 K) is much higher than the thermal energy, the number of electrons inside the particle is constant. In electron transport across the particle, electrons go into and out of the particle one by one, which results in steplike  $I$ – $V$  characteristics. Differential conductance is often plotted in the  $V_g$ – $V_{SD}$  plane, where  $V_g$  and  $V_{SD}$  are the gate and source-drain voltage, respectively. The resulting diagram, which is sometimes called “Coulomb diamonds,” is a series of diamonds inside which no current flows due to the Coulomb blockade, as shown in Figure 3 [21]. When the dot region is superconducting, a Cooper pair can be manipulated by the bias voltage [22]. Note that these effects, which are due to the high charging energy of an island of electrons, can be distinguished from the Coulomb blockade effect, in which the electric current is suppressed by high charging energy via a capacitor with low capacitance.

The difference in electronic properties depending on whether the number of electrons in the particle is even or odd is caused by the Kubo effect [23, 24]. For example, spin susceptibility shows anomalies at sufficiently low temperatures, where the thermal energy is less than the level spacing. When the number of electrons is odd, the highest occupied single-particle level of the multielectron ground state has only one electron, and thus the state has a free spin of  $\hbar/2$ . Therefore, spin susceptibility obeys Curie’s law and diverges in proportion to the inverse of the temperature. On the other hand, when the number of electrons is even, all the energy levels of the ground state are occupied with two electrons with opposite spins. In this case, charge excitation is needed so that the fine particle has a finite magnetization, which requires energy equal to the level spacing. When the

**Figure 3.** An example of Coulomb diamonds. Differential conductance is plotted in  $V_g$ – $V_{SD}$  plane. Reprinted with permission from [21], L. P. Kouwenhoven et al., *Science* 278, 1788 (1997). © 1997, American Association for the Advancement of Science.

system is in thermal equilibrium, the spin susceptibility starts to decrease at the temperature where the thermal energy is equal to the level spacing.

The report on the Kubo effect [23] is the first study to emphasize the importance of the odd/even difference of the electron number inside nanoscale structures. Later, we shall see that the same phenomena appear in transport through the quantum dot. Recently, metallic fine particles have provoked the interest of chemists from the viewpoint of chemical functionalizing using ligands in order to obtain nanoscale optical and electronic devices [25].

## 2.2. Kondo Effect

One of the puzzles of low-temperature physics has been the anomaly in the resistance of metals with magnetic impurities [26], which was first noted in the 1930s [27]. At low temperatures, elastic scattering brings about residual resistance, which remains finite at  $T = 0$  and is independent of temperature, while there is no contribution of inelastic scattering to resistance when the temperature is near zero. Thus, resistance is expected to decrease as the temperature goes down, followed by a saturation in residual resistance. Experimentally, however, resistance takes a minimum, then increases with decreasing temperature. After some thirty years, the cause of this phenomenon was reported by Kondo [28]. Resistance was calculated perturbatively up to the second order of Born approximation with respect to the interaction between conduction electrons in metals and the localized spin of a magnetic impurity. Conduction electrons are scattered by the localized spin through exchange interaction. A temperature called the Kondo temperature ( $T_K$ ) has been identified, below which the higher-order terms of perturbation cause a large scattering amplitude of conduction electrons and thus enhance resistance. This effect is now known as the Kondo effect. The Kondo effect describes the interplay between a quantum spin and conduction electrons with energy under the Fermi energy  $E_F$ . In fact, the Kondo temperature is related to the strength of exchange interaction ( $J_K$ ) and the electron density of states at the Fermi energy [ $N(E_F)$ ] as  $k_B T_K \propto \exp[-1/J_K N(E_F)]$ .

## 3. KONDO RESONANCE IN A QUANTUM DOT

### 3.1. Spectroscopy

Electron phenomena in semiconductor quantum-dot structures have drawn much attention [29–52]. Quantum dots can be regarded as “artificial atoms” whose ground and excited states can be probed electrically using single-electron tunneling spectroscopy [53–55].

When a small bias  $V$  is applied across the dot between the source and the drain contacts, the ground states of a few electrons inside the quantum dot can be investigated directly by observing the  $I$ – $V$  characteristics of the current through the dot as the voltage  $V_g$  is varied. When no current flows (that is, a Coulomb blockade is apparent), the number of electrons is specified by integer  $N$ . On the other hand, when current flows the number of electrons can oscillate between  $N$  and  $N + 1$ . By raising the gate voltage,  $N$  can

be increased from zero, so a series of sharp current peaks due to the charging of the dot, which are called Coulomb oscillations [56], can be observed, as shown in Figure 4 [57]. For a large dot containing a large number of electrons, as in the above case of metallic particles, the Coulomb oscillations are periodic because the charging effect can be treated in a mean-field manner, and the single-electron charging energy is determined by classical theory using only the total dot capacitance.

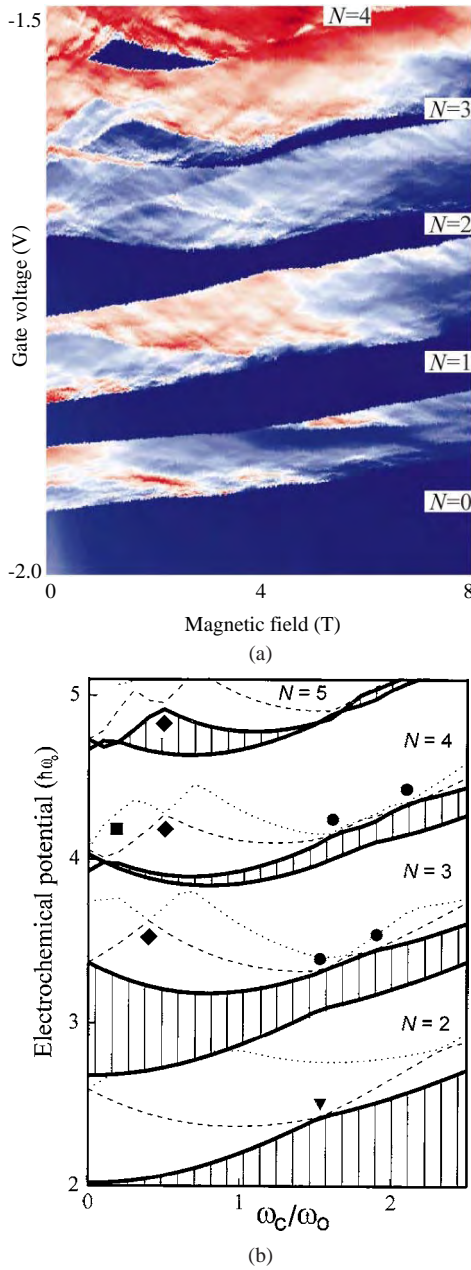

For a dot containing only a few electrons, however, quantum effects reflecting both the discrete energy levels formed inside the dot and the electron–electron interactions become more important as the dot size is reduced. This leads to Coulomb oscillations that are no longer periodic. One can modify the energy levels by tuning parameters such as the magnetic-field strength. The electron–electron correlation effect is enhanced when the crossing of two energy levels occurs. This effect is shown in the observed spectrum shown in Figure 5 [21].

### 3.2. Kondo Effect of an Odd Number of Electrons in a Dot

Semiconductor quantum dots provide a new type of Kondo effect [58–79]. Quantum dots containing a few electrons, which are coupled with two conducting leads via tunneling barriers, act as a single artificial “impurity,” and the Kondo effect *enhances* the conductance *through* the impurity [80–96]. Assume that there are no degenerate energy levels of electrons inside the quantum dot. If the dot has an even number of electrons, its total magnetic moment is zero since

**Figure 4.** Conductance of a lateral quantum dot as a function of the gate voltage plotted for various temperatures. Around the Coulomb oscillation peaks, conductance grows with decreasing temperature. As to the Coulomb blockade regions, conductance continues to decrease outside the peaks, while it exhibits saturation inside the peaks. The temperature dependence is logarithmic, as is shown in the inset. These conditions are caused by the Kondo effect. Reprinted with permission from [57], D. Goldhaber-Gordon et al., *Phys. Rev. Lett.* 81, 5225 (1998). © 1998, American Physical Society.

**Figure 5.** Energy spectrum obtained from tunneling current spectroscopy with the corresponding calculated energy spectrum. Reprinted with permission from [21], L. P. Kouwenhoven et al., *Science* 278, 1788 (1997). © 1997, American Association for the Advancement of Science.

the occupied states have a pair of electrons with both up and down spins. If the number of electrons is odd, on the other hand, the situation is the same except for the highest occupied state with an unpaired electron, which makes the total magnetic moment equal to  $\hbar/2$ .

Figure 6 shows a schematic illustration of a quantum dot with an odd number of electrons, coupled to two electrodes (which are referred to as source and drain) via tunneling barriers. The energy level of the highest occupied state ( $\varepsilon$ ), which can be controlled by the gate voltage, is shown inside the dot, as well as the Fermi energy of the electrodes ( $E_F$ ).

**Figure 6.** Schematic illustration of a quantum dot with odd number of electrons.

The tunneling rates to the electrodes are denoted as  $\Gamma_L$  and  $\Gamma_R$ , the sum of which gives the width of the resonance peak of conductance as a function of the gate voltage ( $\Gamma = \Gamma_L + \Gamma_R$ ). Let  $U$  be the charging energy of the dot. Consider the case where  $\varepsilon < E_F < \varepsilon + U$ ,  $|E_F - \varepsilon| > \Gamma$ , and  $|\varepsilon + U - E_F| > \Gamma$ . The transport property of an electron through the dot is significantly altered when the temperature is sufficiently low, so that the discreteness of the energy levels is clear. At higher temperatures, an electron from one electrode, say the left one, cannot enter the dot because otherwise its energy would be higher than the Fermi energy due to the charging energy. Thus, tunneling through the dot is inhibited (by the Coulomb blockade), and the number of electrons remains odd. In this case, the profile of the conductance is a series of peaks (Coulomb oscillation), as depicted by the dotted line in Figure 7. Peaks occur when the Fermi energy is equal to the addition energy, which is the energy required to add one electron to the dot.

On the other hand, if one decreases the temperature below the Kondo temperature ( $T_K$ ), conduction electrons in the electrodes start to couple with the electron at the highest occupied state inside the dot in order to form a singlet bound state (the Kondo effect), resulting in the screening of the magnetic moment of the dot and the coherent transmission of electrons through the dot [97]. This mechanism modifies the conductance at the gate voltage where an odd number of electrons remains inside the dot at higher temperature. Within this range, the conductance grows with decreasing temperature and finally reaches its maximum  $G = (2e^2/\hbar)(4\Gamma_L\Gamma_R/\Gamma^2)f(T/T_K)$  [98, 99], where  $f(T/T_K)$  has logarithmic dependence ( $\log T^{-1}$ ) at  $T \sim T_K$  and approaches unity as  $T \ll T_K$ . It should be noted that the Kondo temperature depends on the gate voltage as

**Figure 7.** Conductance profile of quantum dot. Coulomb peaks are plotted by dotted lines. As the temperature decreases, conductance grows in the Coulomb blockade region where there are an odd number of electrons inside the dot, while conductance remains the same in the region of even number of electrons.

$k_B T_K \sim (\sqrt{\Gamma U}/2) \exp[-\pi \delta \varepsilon (U - \delta \varepsilon)/\Gamma U]$ , where  $\delta \varepsilon = \varepsilon - E_F$ . Correspondence with the conventional Kondo effect can be seen as follows: When the energy level of the dot is near the Fermi energy ( $\varepsilon \ll U$ ),  $k_B T_K \propto \exp(-\pi \delta \varepsilon/\Gamma)$ . Let  $t$  be the transfer integral between the dot state and the lead. Then, the tunneling rate is given by Fermi's golden rule:  $\Gamma \propto t^2 N(E_F)$ . An electron with a spin antiparallel to the spin in the dot state can transit virtually to and back from the unoccupied state, which causes an antiferromagnetic exchange interaction:  $J_K = t^2/\delta \varepsilon$ . Thus,  $k_B T_K \propto \exp[-\pi/J_K N(E_F)]$ , as stated above.

The temperature dependence of the conductance differs with the gate voltage. Conductance grows around the Coulomb peaks, while it hardly changes inside these peaks. This feature can be seen in Figure 7, with broken and solid lines. This effect has been observed experimentally [16, 57, 100–103]. These experiments using lateral quantum dots have several features in common. Zero-bias ( $V_{SD} = 0$ ) conductance in the Coulomb-blockade regions increases with decreasing temperature, and this conductance depends logarithmically on the temperature, as suggested by the Kondo effect. Conductance disappears when  $V_{SD}$  is applied; the Kondo effect no longer applies because of the enhancement of inelastic scattering. The peak structure appearing in the conductance as a function of  $V_{SD}$  splits in the presence of magnetic fields, as described by the Zeeman effect.

The effect of microwave radiation was also investigated, both theoretically [104] and experimentally [105], on the transport properties through quantum dots in the Kondo regime. With increasing power of the microwave of the frequency between 10 GHz and 50 GHz, the Kondo anomaly in conductance tends to disappear. This phenomenon is ascribed to dephasing of the spin states inside the quantum dot, which is introduced by external irradiation.

### 3.3. Kondo Effect of an Even Number of Electrons in a Dot

Thus far, we have assumed that the energy levels are not degenerate. We shall see that a new type of Kondo effect occurs when the electronic states inside the dot that contribute to the transport are degenerate.

In the previous section, we saw that the energy levels inside the dot can be adjusted by varying the strength of the applied magnetic field, and that two levels with different spatial symmetry can cross. Let us consider the case where the number of electrons is even. In this case, the total magnetic moment is zero, and the Kondo effect on transport phenomena would ordinarily not be expected to appear. In fact, it does appear, however, if one can adjust the strength of the magnetic field so that multiple states are involved in the transport. The key to realizing this situation is for two electrons at the highest occupied level to form a singlet state ( $S^0$ ) and three triplet states ( $S^1_0, S^1_1, S^1_{-1}$ ).

The degeneracy of a few electron states can be realized by coupling to a heat bath [106, 107] and also by an external magnetic field [108–113]. There are two types of magnetic-field effects. The first is due to the Zeeman effect, which was realized in an experiment using carbon nanotubes with a  $g$  factor larger than that of semiconductor heterostructures

[114, 115]. The second is due to the deformation of multielectron wave functions, yielding spin-singlet-spin-triplet transitions in a parabolic dot [116] and parity oscillation in a square-well dot [117].

## 4. RELATED TOPICS

### 4.1. Interacting Electrons in Double Dots

Tunneling transfer  $t_{cd}$  between adjacent dots plays an important role in coupled quantum dots, where the effect of Coulomb interaction between electrons is enhanced by a sufficiently small  $t_{cd}$  [118, 119]. When this happens, the ground state of two electrons in double dots has an antiferromagnetic correlation as in a Mott insulator [120–123].

Ono et al. [124] observed what they called a “spin blockade” effect [125, 126] due to Pauli's exclusion principle in the  $I$ - $V$  characteristics of a vertical double-dot system. In this experiment, the energy difference between the spin-singlet state and the three spin-triplet states formed inside the dot is much larger than that between two dots. In such a situation, a spin blockade occurs only in one bias direction, while an electron always resides in one dot.

Due to couplings to a heat bath, the spin-singlet state and spin-triplet states of two electrons can be degenerate, as in a dot with a certain strength of external magnetic field, yielding a resonance similar to that of the Kondo effect [127–139]. Kikoin and Avishai proposed that Kondo resonance could be observed in a double-dot system connected to reservoirs by applying asymmetric gate voltage [140]. If electrons are confined by a heterostructure of compound semiconductors, strongly correlated electron states of double dots can have a quasisresonance between multielectron states belonging to the same sector, classified by the discrete symmetries of the dots [141].

### 4.2. Tunneling Effects Related to Antiferromagnetic Correlated States

In an array of coupled quantum dots in which electrons can tunnel through the barriers of a heterostructure between adjacent quantum dots, we can expect electrons to have various phases [142–148]. When the density of electrons in a quantum-dot chain is lower than that in a chain of half-filled electrons, the system acts as a metal of correlated electrons with no antiferromagnetic order, as in a Tomonaga–Luttinger liquid, of an infinite chain. On the other hand, when the chain is half filled, a Mott–Hubbard gap opens, and the system becomes a Mott insulator with an antiferromagnetic spin correlation, where the upper Hubbard band is empty and the lower Hubbard band is fully occupied by electrons.

If an array of very small quantum dots of GaAs is embedded in bulk AlGaAs, a field effect caused by a depletion region or an external electric field causes parabolic confinement over the array. Hubbard-gap tunneling, which can be thought of as quasisresonance, is expected in these quantum-dot chains [149]. The Tomonaga–Luttinger liquid and a Mott insulator can be thought of as a single system when the overall parabolic potential confines electrons with a density

less than that of half-filled electrons. When an overall confining potential is imposed, the density of electrons in the center becomes higher. When the density of electrons in this region approaches that of half-filled, a Mott insulating state is produced, resulting in a quasi-Hubbard gap in the center of the chain. There is a metallic electron located to the left of the Mott-insulating electrons in the center of the chain in the multielectron state  $|L\rangle$ , and there is a metallic electron located to the right of the Mott-insulating electrons in the multielectron state  $|R\rangle$ . The ground state of our quantum-dot chain can be written as the bonding state of these multielectron states:  $(|L\rangle + |R\rangle)/\sqrt{2}$ , in which an electron tunnels between the right-hand side and the left-hand side, where the tunneling effect depends on the number of electrons confined in the quantum-dot chain [150]. Note that our system has multiple electrons whose wave functions are totally asymmetric and  $|L\rangle$  and  $|R\rangle$  are really multielectron states [151].

### 4.3. A Dot Coupled to Various Leads

Resonant Andreev tunneling in quantum dots coupled to a superconducting lead and a metallic lead has been investigated when the Kondo effect plays a great role [152–158]. It was found that the interplay between Kondo resonance and two-particle tunneling causes an anomalous feature in  $I$ - $V$  characteristics, which depends on the relative strength of the gap energy to the Kondo temperature. Transport through a quantum dot coupled to two superconducting leads was also investigated [159, 160].

Let us turn to a quantum dot coupled to ferromagnetic leads. When both leads have the same orientation of magnetic moments, the existence of a spin-dependent renormalization of the localized levels in a quantum dot was shown theoretically [161]. When a quantum dot is connected to two ferromagnetic leads whose magnetic moments are oriented at an angle with respect to each other, the current has been calculated using Keldysh–Green’s function and has been shown to be dependent on the angle [162].

### 4.4. Composite Quantum Structures in a Magnetic Field

Tunneling conductance through disconnected double dots threaded by an Aharonov–Bohm (AB) flux has been calculated in a wide temperature range [163–165]. Various types of AB oscillations appear depending on the temperature and the potential depth of the dots. Especially, AB oscillations have strong higher-harmonics components as a function of the magnetic flux when the potential of the dots is deep.

Let us turn our attention to a quantum dot embedded in a mesoscopic ring [166]. It is shown that the persistent current accompanied by the Kondo resonance is large in comparison with the current flowing either when the dot is at a single-particle resonance or along a simple ring of the same length. The possibility of detection of the Kondo effect by means of a persistent-current measurement is proposed [167–170]. The transmission phase shift of a quantum dot in an AB ring was discussed in the context of the Kondo effect [171]. It was proposed that this system should allow the direct observation of the well-known scattering phase

shift of  $\pi/2$  expected at zero temperature for an electron forming a Kondo singlet. The influence by the spin fluctuations on the persistent current was also investigated [172].

Simon and Affleck discussed the persistent currents induced by the AB effect in a closed ring that either embeds or is directly side-coupled to a quantum dot at Kondo resonance [173]. They mentioned that the persistent current is very sensitive to the ratio between the length of the ring and the size of the Kondo screening cloud, as suggested by a scaling theory of the Kondo effect.

### 4.5. The 0.7 Anomaly in Transport Through a Quantum Point Contact

In 1988, it was found that the conductance through a quantum point contact, that is, a narrow constriction whose size is comparable to the Fermi wavelength of the conducting electron, is quantized in units of  $2e^2/h$  [174, 175]. A single-particle description is useful in explaining the quantized conductance through a quantum point contact [176]. Besides these conductance plateaus, Thomas et al. observed an extra structure close to  $0.7(2e^2/h)$  [177–184]. The peak of the differential conductance at the bias zero suggests that the 0.7 structure is caused by the formation of Kondo-like spin states. Therefore, the description of a localized state coupled to a heat bath can be used in explaining the extra structure. Meir et al. analyzed an Anderson model, which explains the observed gate-voltage, temperature, magnetic-field, and bias-voltage dependences [185].

## GLOSSARY

**Addition energy** The energy required in an addition of an electron to a dot.

**Aharonov–Bohm effect** The effect of a gauge potential on quantum motion without any electromagnetic field.

**Anderson model** A lattice fermion model in which electrons interact with each other only at a single site.

**Andreev reflection** A phenomenon in which one of the electrons consisting a Cooper pair only reflects at a superconductor-normal junction.

**Charging energy** Energy of excess charge in a capacitor.

**Cooper pair** Paired electrons which carries a superconducting current.

**Coulomb blockade** Suppression of a tunneling current through a small junction around zero bias voltage due to the large charging energy.

**Coulomb oscillation** A periodic structure in conductance through a dot.

**Curie’s law** Power-law decay of spin susceptibility with decreasing temperatures.

**Depletion region** A semiconductor region accompanied with an imbalance of carriers and impurities.

**Exchange interaction** The effective interaction between adjacent spins.

**Fermi’s golden rule** A general formula which gives the quantum transition probability.

**Fermi wavelength** The length determined by the inverse of wave number of an electron at the Fermi surface.

**g factor** The coefficient measuring the strength of the Zeeman effect.

**Half-filled** A state of electrons on a lattice where each site has a single electron on the average.

**Heat bath** A completely thermalized system in which electrons have continuous density of states.

**Hubbard band** Two sets of states forming bands separated from each other by a Hubbard gap.

**Hubbard gap** A gap of the single-particle density of states due to electron–electron interaction when electrons are on a lattice.

**Keldysh Green’s function** A non-equilibrium Green’s function.

**Mean field** An approximation method ignoring fluctuations around the average value.

**Mott insulator** An insulator because of the existence of a Hubbard gap.

**Parity** The symmetry accompanied with a mirror-reflection transformation.

**Pauli’s exclusion principle** The law of physics stating that any quantum states cannot be occupied by two or more quantum particles which obey the Fermi statistics, e.g., electrons.

**Persistent current** Non-dissipative current due to mesoscopic effects.

**Quantum dots** A zero-dimensional quantum system which has a discrete spectrum of energy eigenstates.

**Quantum point contact** A nanometer-size waveguide in which ballistic electrons go.

**Quantum size effect** The effect of confinement of electrons which is coherent over a mesoscopic structure.

**Quasiresonance** Resonant tunneling between multiparticle states belonging the same sector classified by the discrete symmetries of the system.

**Schottky electrodes** A contact between a semiconductor and a metal where currents are rectified.

**Semiconductor heterostructures** A material’s interface composed of two different species of atoms epitaxially grown on a substrate.

**Singlet** A nonmagnetic two-spin state.

**Spin susceptibility** The degree of response of a spin to an applied magnetic field.

**Tomonaga–Luttinger liquid** A metallic state of one-dimensional electrons characterized by the absence of the Fermi surface (actually, points) due to electron–electron interaction.

**Transfer integral** An energy measuring the mobility between two states.

**Triplet** A two-spin state with magnetic moment  $\hbar$ .

**Zeeman effect** The energy splitting of spin states due to an applied magnetic field.

## 1. INTRODUCTION

This chapter will describe some recent attempts in nanofabrication aiming to exploit the use of lasers and scanning probe instruments in conjunction. More than reviewing fully established techniques, we aim to introduce the reader to ideas and technologies which, although in part still in their infancy, represent the essence of the “bottom up” nanotechnological fabrication process.

Why is the “bottom up” approach important? Building matter or devices starting from single atoms or molecules has been recognized from the very beginning of the attempts toward nanotechnology as the conceptually ideal methodology, in spite of the fact that this approach is intrinsically slow and perhaps inadequate to parallel mass fabrication. Not all that is valuable is necessarily addressed to a large market, however; all pieces of fine arts, and in general all achievements of knowledge, for example, are unique examples of “bottom up” methodology that have a universally

recognized intrinsic high value. But there are also many high value technological products that are built in a limited number, like high performance nuclear magnetic resonance imagers for clinical use, or machineries for specific productions. In the nanoscopic realm, where humanity has no direct perception, art may not be an important issue; bottom up nanotechnologies, however, will help in achieving a deeper understanding in materials science, an advancement of human knowledge of high intrinsic value. They will also soon enable us to fabricate unique high value devices in the fields of nanomedicine and surgery, of neural prostheses, of sensing, beyond supplying prototypes for nanoelectronics and more and more sophisticated devices for nanoscopic mass productions. Thus, although the present industrial approach to micro- and nanofabrication of highly integrated electronic circuits still relies completely on the high throughput, parallel, “top-down” approach represented by optical lithography, as early as in 1992 a paradoxical but significant statement was made by pioneers in nanoscience: that “lithography in nanofabrication is like building the Golden Gate bridge by carving it out of a single block of steel” [1]. On the other hand, an equally paradoxical and important statement is often made today, that “if technology is represented by computers and cellular phones, or more simply by motor cars or washing machines, then in nanotechnology we are today at the pickaxe stage.” The most used “pickaxe” is the scanning probe instrument, or microscope (SPM), whose nanometric controllable tip is also employed to carve and drill surfaces [2], or to accumulate small amounts of material in nanometrically resolved spots, like in silicon nanooxidation lithography [3], or even to move around and put together little “bricks” represented by atoms [4], molecules [5], or self-assembled nanostructures (such as fullerenes and nanotubes of different sorts) [6, 7].

If we are to continue with the analogy, scientists often perform their bottom up nanoassemblage with the pickaxe in their hands and a very limited supply of bricks (atoms or molecules) somewhere close to their working location. When they finish the supply, although they have learned a lot on the art of “nanomasonry” (a huge value in itself), they have not completed the building, unless it is so elementary to be of little practical use. Unfortunately we do not have

a nanoscopic truck to carry more atomic components easily, but we shall see in the following that lasers may contribute to carry or produce new bricks.

Thus, in order to tackle real technological challenges, bottom up nanotechnology needs to turn into something more than the mere use of a nanometric “pickaxe.” There are of course many other challenges beyond easy and unlimited delivery of atomic or molecular components; for example, in order to meet the requirement of faster bottom up assembly, scientists hire a large team of pickaxe workers, or in other words develop arrays of scanning probes controlled by computer, which will perform their building tasks in parallel [8]. Very recent developments have achieved arrays of  $32 \times 32$  scanning force cantilevers, capable of printing 40 nm size spots, which can be used to encode information with a density of 1 Gb/mm<sup>2</sup>. Further, not always do we necessarily need to use simple bricks to assemble our nanodevices. Sometimes it is convenient to put together preassembled elements, like the fullerenes that we already mentioned, but also more complex ones. In the nanoworld the preassembly step is often conveniently performed by chemistry or biology, which therefore have received increasing attention recently [9–13]. Positioning of complex “smart” molecules, capable of performing specific tasks, in nanometrically predetermined locations on the surface of a microelectronic chip is thus one important goal that is pursued by several research groups [14–16] in spite of the difficulties of dealing with delicate soft matter that easily loses its smart properties. Again, as we shall see, lasers have recently given an important contribution to “soft” deposition techniques, the bases of which are therefore described in Sections 3 and 4.

One further, very important requirement of any bottom up assembling technique is the ability to see, characterize, and test what we have produced. Scanning probe instruments of course are almost ideal instruments to this aim. Here we find that the pickaxe analogy no longer holds. These rather simple manipulation tools turn into sophisticated sensors not only of the morphology of what we have done, but also of its stiffness, its external force fields, its electrical conductivity, and even, through its optical and spectroscopic characteristics, its physical chemical state. Once more we have a hint that lasers, as intense sources of well manageable light, may have something to do with such characterizations, well beyond their common use in sensing the deflection of scanning force cantilevers. We refer here to the exciting very recent area of near-field optics and spectroscopy, pursued both by tapered optical fibers, as in “conventional” scanning near-field optical microscopes [17] and by the exploitation of the near-field scattered by metallic tips, [18, 19] for spectroscopic characterizations [20, 21].

Lasers as a nanotechnological tool, and in particular deep ultraviolet (UV) lasers, are being commonly used nowadays for optical lithography in the 100 nm range, allowing fast parallel processing of large surfaces through the multistep procedures of lithography. This type of technology is based on location specific degradation of a polymeric resist, its removal followed by the subsequent deposition of a uniform layer of the desired material, and finally the removal of the unwanted portions by means of the removal of the remaining resist. It is a complex procedure that allows parallel deposition of the same material in different locations,

the procedure to be repeated for each material for a total of 20 or 30 times in modern industrial technology. But the use of lasers in nanotechnology can be much more than this.

First of all they are successfully used as a tool to vaporize materials to be deposited [22]; laser fabrication of layered thin films has gained enormous importance in recent times, the current literature being extremely rich. Pulsed laser ablation or desorption in particular has been used for deposition of intact delicate materials such as polymers and organic or biological molecules. They may thus represent an important and convenient source of vapor phase material, particularly suitable in micro- and nanotechnology because, due to ease of focusing, they can act upon very small amounts of valuable materials. Desorption (i.e., the transfer in vapor phase of atoms and molecules adsorbed on a surface without affecting the surface structure) and ablation, or bulk evaporation of the material with strong damage of the surface, will be shortly described in Section 2, with some insight into the threshold of plasma ignition for ablated materials and into integrity of vaporized large molecules.

Second, lasers are used to ionize vapor phase molecules, both directly, acting on neutral vapors (in which case the ionization process can be made extremely material selective, by exploiting resonance enhanced multiple photon ionization, described in Section 3) or indirectly by proton adduction following extensive molecular fragmentation [as in the case of the matrix assisted laser desorption ionization (MALDI) technique, described in Section 4]. Ionization can then be used to direct molecular ions at will; use of an electric field applied to the SPM tips, or of very fine movable masks driven by the piezo actuators of the SPM, can produce nanometric patterning when coupled to laser ablation/ionization. Recent work performed in this direction will be reported in Section 9. In this respect laser radiation and the applied electric fields may well play the role of the molecular carrier, or “truck,” that we wished to have. In perspective, we can foresee that nanofabrication strategies based on supplying a burst of laser ionized gaseous material finely directed at the SPM tip, where a voltage pulse steers selected ions to hit the device surface, would be most appealing due to its flexibility (almost any material can be vaporized and ionized) and speed (pulsed lasers can be operated at high repetition rates).

Furthermore, in conjunction with the fine tips of SPMs, lasers can supply resolution beyond the diffraction limit in optical lithography, exploiting the near EM field scattered by the nanometric tip, that we have already briefly mentioned with respect to characterization rather than fabrication. This near-field enhancement of the incident radiation, which will be described in Section 5, has typical dimensions of the order of the tip apex rather than of the wavelength of the incident light; it can then be exploited to reach the ionization threshold, or for field induced desorption, surface melting, and even manipulation [23, 24] all limited to the nanometric region close to the tip apex. As we have mentioned, the same process can also be used in the characterization step: the enhancement of Raman spectral intensities due to EM field enhancement caused by surface nanostructures (often called SERS, surface enhanced Raman scattering), also occurs in the proximity of the SPM tip; it is thus possible to obtain Raman spectra from regions of the surface

that have comparable dimensions to that of the facing tip apex, easily nanometer sized [20]. This means that we are in principle capable of characterizing spectroscopically single molecules or small clusters immediately after performing a nanostructured deposition.

Finally, laser induced thermal effects can also be extremely important in localized nanostructuring of surfaces. We shall thus spend some time in Section 6 to show some possible models of thermal expansion and to highlight the important parameters that affect this process. It is commonly recognized that a laser pulse focused at the scanning tunneling microscope tip will cause a thermal expansion of the tip; this is normally considered a drawback of laser-SPM techniques. It can, however, also be used to mechanically affect the surface and, more subtly, to couple the heating effect due to light absorption to the additional heating caused by the exponential increase of the tunneling current, to thermally desorb single atoms or molecules from the tip. Furthermore, thermal recrystallization of the substrate surface may occur under strong laser irradiance, leading to a variation of the electric field distribution between tip and surface. Field enhancement effects may arise both from the tip and from the recrystallized surface, causing atoms or molecules to be moved to or from the surface.

As mentioned at the beginning, laser assisted SPM nanofabrication is not a fully established technique yet. In spite of early attempts soon after the invention of the STM, these methodologies are not as widely used as other nanotechniques. Beyond the obvious fact that bottom up methods are less interesting for the present electronic industry, this is probably due partly to the high cost and complexity of the experimental apparatus, reducing the number of research groups active on the subject, but even more to the high number of parameters playing a role at the STM gap. This caused early experiments to be unreliable, not easy to reproduce, and even less to interpret. With the progress of theory, mainly on thermal effects and field enhancement, the role of each important parameter is becoming more clear, so that interest is being revived and fascinating possibilities can be seen.

This chapter will only deal with laser assisted SPM nanostructuring, referring the reader to the excellent recent review by Grafstrom for the important fields of optically assisted scanning probe microscopy and scanning probe assisted spectroscopy, where most exciting achievements have also been obtained recently [25].

## 2. PULSED LASER DESORPTION AND ABLATION

Pulsed lasers have been used for many years to remove material from a sample and transfer it onto a substrate with or without the assistance of electric fields. There are thousands of publications on this mature subject, regarding all classes of materials and applications, from polymers like PTFE, PMMA, or polycarbonate [26, 27], to composites as magnetic [28] and piezoelectric materials [29], from organic semiconductors [30] to biological macromolecules [31, 32], from hard coatings of diamondlike carbon [33] to single wall carbon nanotubes films encapsulated in amorphous carbon [34], and of course to metals and semiconducting materials

[35, 36], quoting only a very small selection of recent work. Useful recent reviews of the subject are those by Haglund [22], Voevodin and Donley [33], and Zhigilei et al. [37], particularly insofar as modeling of the MALDI technique is concerned. The fundamentals of the subject can be found in the books by von Allmen [38] and Lubman [39].

When a laser beam interacts with a solid, light absorbing surface, energy is transferred from the radiation field into the solid. Dissipation of this energy leads to heating of the solid, which can be so strong as to cause melting and vaporization of material. For example, continuous wave lasers are industrially used to drill and cut metals, wood, or textiles or to weld metals. Further, the evaporated material can absorb the incident radiation, mainly by multiple photon absorption, and become strongly ionized. Above a threshold irradiance (or power density, measured in  $\text{W}/\text{cm}^2$ ), easily reached by pulsed lasers, plasma ignition is normally observed. The physical processes involved are too complicated and interdependent to be treated in any depth here; we shall only spend some time on two aspects of desorption and ablation that are particularly relevant to organic and biological molecules, that is, maintenance of molecular integrity through selective breakage of the adsorption bonds, and plasma ignition threshold. The MALDI technique, of particular relevance for biological molecules, will be described in the following section.

Let us consider a molecular species adsorbed on a solid surface, in the common case in which the total adsorption energy is higher than the internal binding energy of the weakest bond. If laser irradiation goes on for a long time, the temperature can increase to values where adsorbed molecules are dissociated as the amount of energy transferred from the surface to the internal degrees of freedom of the molecule exceeds the covalent molecular binding energies. The process is analogous to heating molecules on a flame, simply producing molecular dissociation. However, while the phonons in the heated solid may easily exchange energy with the low frequency modes of the adsorption weak interactions, being entirely off resonance with the higher frequency modes of the intramolecular covalent bonds, they experience a “bottleneck” in exciting the molecular vibrational modes [40]. Therefore, use of a short laser pulse tuned away from the molecular absorption band will help in desorbing intact molecules by concentrating the energy input in times much shorter than the time necessary to overcome the bottleneck. If  $\tau$  is the excitation duration, this can be expressed by

$$\tau < 1/k$$

where  $k = \nu \exp(-\xi)$  is the rate constant for energy transfer between the weak adsorption mode of low frequency  $\nu$  and the internal molecular vibrations, and the adiabaticity parameter  $\xi = 2\pi T/T'$  (with  $T$  and  $T'$  the characteristic times of motions of the adsorption mode and of the intramolecular vibrational mode respectively) is a measure of the difficulty of energy exchange between adsorption and covalent modes. If  $D$  is the weak bond energy to the surface, the condition for desorption of intact molecules is

$$\tau < (h/D) \exp \xi$$

where  $h$  is Planck's constant.

The important parameters are thus the heating rate  $1/\tau$  which, to the aim of obtaining vapor phase intact molecules, must be as high as possible, the decoupling between modes (or adiabaticity)  $\xi$ , which should also be large, and the adsorption energy  $D$ , which should be as low as possible. Typical values for  $\xi$ , according to Zare and Levine [40], are around 10, which, considering binding energies of about 0.12 eV (a typical adsorption energy), requires heating rates of the order of  $10^{11}$  or  $10^{12}$  K/s. It has been proved experimentally since the mid 1980s that indeed nanosecond laser excitation yields desorption of intact  $\text{CH}_3\text{OH}$  and  $\text{C}_2\text{H}_4$  [41, 42] whereas at much lower heating rates there is complete fragmentation. Other examples of intact desorption of fairly labile molecules concern, for example, amino acids [43, 44].

We have described so far the so-called desorption process. Increasing the power density of the light impinging on the surface will lead to disruption of the surface and ejection of material, which is commonly termed ablation. Ablation is normally associated with a large amount of ejected material that is visually observable and because of its shape has been named the “plume.” The plume has a variable degree of ionization and, unlike desorption, requires a threshold power density that is of the order of  $10^7$ – $10^9$  W/cm<sup>2</sup>. Interestingly, the threshold energies are orders of magnitude higher than the cohesive energy of the outermost monolayer (estimated in the range of 0.1–1 mJ), suggesting that a large amount of energy is dissipated into relaxation processes not leading to material ejection. As we have already mentioned laser ablation at high laser irradiances can produce a plasma. When plasma ignition occurs, molecules within the plasma are in large part destroyed, although the sudden sublimation of the area immediately surrounding the plasma region is rich in intact molecules as has been observed by measuring the biological activity of enzymes ablated in these conditions [45]. It should also be noted that plasma ignition strongly increases the total ablation rate, including that of intact molecules, at least in a limited irradiance range.

The plasma ignition threshold is influenced by several factors; the main ones are the material ionization potential, the absorption coefficient, and the particle number density [46]. It is found that the plasma ignition takes place more easily for low ionization potential materials and for high particle density. High absorbances favor plasma ignition up to the point where the gas becomes opaque to radiation. Further, plasma ignition was found to be easier with long wavelength lasers than with UV lasers. Typical fluence thresholds for plasma ignition with organic molecules are between 0.1 and 1 J/cm<sup>2</sup>.

A review on the characterization of laser ablation plasmas can be found in [47].

### 3. RESONANCE ENHANCED MULTIPLE PHOTON IONIZATION

Atoms and molecules in the gaseous phase can be ionized by laser excitation up to a nonbound electronic state. Normally ionization thresholds lie at energies of several eV so that photons in the UV to deep UV are needed to reach such energies. It is possible, however, to reach the same excitation levels by simultaneous or sequential absorption of

two or more photons of lower energies, following one of the schemes of Figure 1. The fundamentals of multiple photon excitation can be found in several books [48–50] mainly about its important application in mass spectrometry.

The probability that an atom or molecule is excited to the upper level by a two frequency field  $\underline{E}(\omega_1, \omega_2) = 1/2[\underline{e}_1 E_1 \exp(i(\underline{k}_1 \underline{r} - \omega_1 t)) + \underline{e}_2 E_2 \exp(i(\underline{k}_2 \underline{r} - \omega_2 t))] + \text{complex conjugate}$ , if the energy difference between initial and final state is equal to the sum of the energies of the two photons (which is always true when the total energy of the two photons is above the ionization threshold) and neglecting line broadening, is given by

$$W_{gf} = [2(h/2\pi)^4]^{-1} |A_{gf}|^2 E_1^2 E_2^2$$

where the transition matrix element between states  $g$  (ground) and  $f$  (final) is given by

$$A_{gf} = \sum_n \{ [\underline{p} \cdot \underline{e}_1]_{gn} [\underline{p} \cdot \underline{e}_2]_{nf} / (\omega_{ng} - \omega_1) + [\underline{p} \cdot \underline{e}_2]_{gn} [\underline{p} \cdot \underline{e}_1]_{nf} / (\omega_{ng} - \omega_2) \} \quad (1)$$

where  $p$  is the electric dipole operator and where the sum runs over all intermediate states  $n$  [51, 52].

If the energy of one photon matches an energy level of the atom or molecule (resonance condition), then we see from Eq. (1) that the probability of the two photon process is greatly enhanced. This has also another important consequence, that the resonant ionization process is extremely species selective, particularly so in the case of atoms that have very narrow resonances. Further, since the transition from the excited state to the ionization continuum is unstructured, ionization has a spectral dependence that reflects only the intermediate state. Measuring the ion current as a function of the excitation wavelength thus gives us the spectral fingerprint of the ionized molecules. The intensity dependence of simultaneous and sequential absorption is quite different. If no real resonances are present, the excitation rate depends on the probability that two photons are available at the molecule at strictly the same time

**Figure 1.** Three possible multiple photon excitation ways to the ionization continuum. The resonance enhancement mechanism is often termed multistep excitation, while multiphoton excitation (right) occurs with simultaneous absorption of photons via a virtual state when the irradiance is very high.

(in the theoretical description of the process the two photon absorption occurs via a virtual intermediate state, arising from the photon-matter interaction, which has very short lifetime). If, on the other hand, one photon is resonant with an intermediate permanent energy level, the second photon has to be available within its lifetime. Thus we may expect an intensity dependence of the form  $I^n$  with  $n = 2$  for a two photon process without resonance and  $n = 1$  in case of resonance with a very long lived intermediate state. In  $\text{UF}_5$ , for example,  $n$  is 1.2 for resonant excitation and about 2 off resonance [53]. A further advantage of multiple photon excitation, when dealing with narrow resonances (atoms or cold molecules), is that by arranging that the two photons being absorbed travel in opposite directions, Doppler broadening effects can be eliminated [54]. This is mainly useful for isotope separation purposes, but it can in principle be also exploited for the selection of specific molecular conformations that have only slightly different excitation wavelengths.

Molecular vibroelectronic energy levels are arranged in ladderlike schemes, along which excitation “climbs” (resonantly or nonresonantly) until either dissociation or ionization is reached. If the dissociation threshold is lower than the ionization level, depending on the lifetime of the dissociative state, a percentage of fragments will be formed, which can again absorb radiation along their vibrational states “ladder” and then dissociate and ionize and so on until, for very high photon densities, complete atomization of the molecule is achieved. This is described by the “ladder switching” model of Boesl and co-workers [55] (excitation switches from the energy ladder of the parent molecule to that of the primary ion and so on). Ladder climbing up to energies above the ionization level of the parent molecule and ladder switching to the fragments ionization are often competitive processes. With laser pulses longer than the dissociative state lifetime, the ladder switching process tends to dominate, increasing fragment ions with respect to parent ions; use of picosecond or femtosecond pulses limits excitation to the ladder climbing process and, if the dissociative state lifetime is not too short, it can be effective in optimizing the yield of unfragmented ions. The comparison of the effects of nanosecond and pico- or femtosecond pulses is reviewed in a recent paper by Ledingham and Singhal [56]. Although it is not the purpose of this chapter to go into the details of the fragmentation process that may follow multiple photon excitation, we want to underline here that fine tuning of the experimental parameters (wavelength, intensity, pulse length) can indeed supply a soft ionization methodology by controlling the fragmentation rate, from complete atomization to molecular integrity.

By this method it was shown, from the late 1970's onward, that molecular ions of molecules such as benzene [57], amines [58, 59],  $\text{UF}_5$  [60], sugars and polymers [61], amino acids, and peptides [62], to mention only a few, could be obtained. The technique was obviously applied mainly to mass spectrometry, and in particular to time-of-flight mass spectrometry exploiting nanosecond pulsed laser excitation. Very high mass resolution, of the order of 10,000, was achieved by introducing in the flight tube devices to compensate the kinetic energy spread of the ions produced (reflectron devices) [63].

With regard to the issue of spatial control and resolution of the ionization process, which can be very relevant to micro- and nanotechnologies, we note that although resonance enhanced ionization is extremely species selective (isotopic separation is also effected by this method), nonresonant multiphoton excitation, due to its higher dependence on intensity, can be in principle more efficiently localized in space.

#### 4. MATRIX ASSISTED LASER DESORPTION IONIZATION

In spite of the “softness” of the multiple photon ionization method (MPI), it was not possible to obtain the mass spectra of intact complex biological molecules until the MALDI technique was developed by Karas et al. in 1987 [64]. Due to the importance of biomolecules in nanotechnology we shall thus briefly describe this technique which produces controlled ionization of unfragmented large biomolecules like DNA [65], enzymes, and antibodies [66, 67]. The underlying idea in this technique is to exploit a different molecular species, to be mixed in large excess (of the order of  $10^3$  M) with the biomolecule of interest, to couple the laser energy into the sample. The absorption band of this matrix must have minimal overlap with the absorption of biomolecules (which is dominated by the absorption of aromatic amino acids of proteins and of nitrobases of nucleic acids and thus is limited to the region below 300 nm). Strong excitation of the matrix by short laser pulses will not directly affect biomolecules but will lead to evaporation of the sample with minimal energy transfer to the analyte biomolecules. Minimization of the energy transfer relies on the rapid adiabatic expansion in the vacuum environment, so that excitation of matrix molecules will have too short a time to be transferred efficiently into the analyte. Detailed descriptions of the vaporization process and maintenance of molecular integrity can be found in the early paper by Vertes and Levine [68], and in a more recent review by Zhigilei and co-workers [37]. Vaporization alone would not supply ionized analytes, however. If excitation of the matrix molecules is strong enough to cause ionization, subsequent absorption, dissociation, and further ionization/dissociation of the fragments, as described by the ladder switching model mentioned in the previous paragraph, we will end up with plenty of small fragment ions and protons. These are easily captured by the uneven charge distribution on the surface of protein molecules, causing a net charge on the molecule that can be exploited for mass selection purposes or, more generally, to direct molecules on the desired locations.

While the integrity of organic molecules is commonly checked by mass spectrometry, loss of small fragments from the bulk of a large macromolecule is not easily detected, unless very high resolution spectrometers are used. Furthermore, since conformation plays a crucial role in the biological functionality of biomolecules, a check of their mass integrity is not enough to decide that they have not been damaged. Moreover, if deposition is effected, denaturation may occur as a consequence of dissipation of kinetic energy on impact onto the deposition substrate. However, measurement of both enzyme and antibodies activity deposited by

such a method on glass or metal surfaces was demonstrated in the author's laboratory [45, 69].

The main drawback of this technique is that, together with the ions we are interested in, it yields a large amount of ionized fragments. These are small enough to be confined to an entirely different region of the mass spectrum with respect to the heavy biomolecules. For deposition purposes, however, it implies the need for some sort of mass filter to avoid contamination with the matrix fragments. Due to the commercial interest of MALDI based mass spectrometers, a large number of possible matrix molecules have been investigated [70–72], some of which minimize fragmentation.

A recent development of this technique allows atmospheric pressure analysis of samples by coupling the mass analyzer to the atmospheric ambient through a thin capillary [73, 74].

## 5. PROXIMITY ENHANCEMENT OF THE ELECTROMAGNETIC (EM) FIELD

Much interest has been devoted in recent times to electromagnetic field enhancement in the near field of nanoscopic objects, and in particular of metal tips, analogous to the mechanism responsible for SERS [75, 76]. The area of near-field optics developed with the aim of extending optical microscopy and the related fields of spectroscopy and lithography beyond the diffraction limit. Furthermore it was also applied to the recent technological achievement of optical trapping (optical tweezers), as the high spatial confinement of near-field emission allows manipulation of loose matter on the molecular scale [23, 77]. The basic idea underlying near-field optics is that the charges oscillating in an assembly of atoms under the influence of external radiation will in turn reradiate, or scatter, an oscillating field, which results in a strong enhancement of the radiation intensity in regions comparable to the size of the atom assembly [78]. It was found experimentally that silver nanoparticles were most efficient in enhancing the Raman scattered intensity, although most surfaces with an appropriate degree of roughness show enhanced scattering. Several models were therefore developed.

The electromagnetic model, which was first developed, considers the large EM fields that are produced when the incident light frequency is in resonance with collective excitation frequencies of the surface charges (surface plasmons). For a nanometric spherical object whose dimensions are much less than the incident light wavelength, the real part of the dielectric constant associated with the  $n$ th surface collective excitation mode is  $\varepsilon(\omega_n) = -(n+1)/n$  [79], and considering that the polarization of the sphere is [80]

$$\underline{\mathbf{P}} = \alpha \underline{\mathbf{E}} = 3/4\pi(\varepsilon - 1)/(\varepsilon + 2)\underline{\mathbf{E}}$$

the surface mode with  $n = 1$  yields a resonance in the polarization of the sphere. A resonance is also observed when the real part of the dielectric constant is  $\varepsilon(\omega) = -2$ .

Objects other than spheres are usually described by the model for an ellipsoid of volume  $V$ , which changes this equation into

$$\underline{\mathbf{P}} = \underline{\mathbf{E}}V(\varepsilon - 1)/[1 + \eta_i(\varepsilon - 1)]$$

where  $\eta_i$  is the depolarization form factor  $\eta = (ab^2/2) \int_0^\infty ds / [(s + a^2)^{3/2}(s + b^2)]$  with  $a$  and  $b$  the spheroid semiaxes.

We can see that excitation of plasmons may lead to strongly increased polarization and scattered intensity, and that the enhancement depends on the dielectric function and the elongation of the scattering nanostructure.

A further source of field enhancement, even in absence of resonances, is given by the concentration of field lines with the strong curvature typical of SPM conductive tips. This effect, often called the “lightning rod” effect, adds to the resonance effects to reach calculated field enhancement factors  $g$ ,  $10 < g < 1000$ .

A different way of modeling the field enhancement is to consider the SPM tip as both a receiving and an emitting antenna at optical frequencies [81]. This approach also yields the dependence of the field enhancement on the main parameters affecting the electromagnetic interaction: the polarization and incidence angle dependence, the dielectric constant of the tip and substrate material, the tip aspect ratio, and the tip to substrate distance. It is found that the field enhancement is greatest for incidence close to the substrate (i.e., almost perpendicular to the tip axis) and polarization parallel to the tip, for high conductivity metals of both tip and sample (silver tip on gold surface gives enhancements five times greater than on a glass surface), for high tip aspect ratio, and for short tip to sample distances. The same model calculates the temperature increase of the substrate surface subject to EM emission from the tip antenna. The authors of the model obtain

$$\Delta T_0 = \pi^{1/2} I_0 (1 - r) g w_0 / 8\lambda$$

where  $g = I_{\text{loc}}/I_0 =$  field enhancement,  $w_0$  is the near-field spot size (at  $1/e$  of the maximum),  $r$  is the sample reflectivity at normal incidence, and  $\lambda$  is the thermal conductivity of the sample.

The sample surface temperature calculation is important to the aim of laser-SPM assisted surface nanostructuring, as temperatures as high as the metal melting or boiling point could be achieved. In the case considered by these authors, where the calculated near-field spot size is 60 nm,  $g = 525$ ,  $r = 0.64$ ,  $\lambda = 2.44$  W/cm K, to reach the melting temperature of gold (1338 K) a threshold laser irradiance of 13 MW/cm<sup>2</sup> would be necessary. As we shall see, this is consistent with that reported by other authors. The problem of calculating the heat transferred from the laser enhanced near field to a sample and its diffusion in thick and thin films on a dielectric was studied in detail by Geshev and co-workers using a finite-difference numerical method [82]. The results they obtain in terms of temperature rise in a thin metal film are similar to those of Lu and co-workers (i.e., hundreds or thousands of degrees for irradiances in the order of 10 MW/cm<sup>2</sup>). This is certainly an easily accessible power density range that, if suitable control of all the experimental parameters is reached, would allow controlled material transfer to and from the sample with molecular size resolution.

## 6. THERMAL EXPANSION IN THE LASER FIELD

When a laser beam is focused at the tip/substrate gap, the focal volume being much larger than the gap, both the tip and the substrate partially absorb the laser radiation so that their temperatures rise considerably and thermal expansion of both occurs. This in turn reduces the gap distance and exponentially increases the tunneling current. These phenomena are always observed in laser-SPM experiments.

In order to understand the basic mechanisms and the important parameters and to evaluate the expected order of magnitude of expansion we shall briefly outline in the following some of the existing theories. Grafstrom and co-workers investigated the thermal expansion of a tip subject to a periodically modulated laser beam [83]; they solve the differential equation for the temperature modulation generated by a heat flow that is composed of a periodically modulated input and of an output toward the tip holder that is considered at constant temperature. No heat flows out of the tip apex. Setting the modulating frequency to zero, they find for the temperature rise of the apex

$$T_{\text{apex}} = 2PA/(\lambda\pi^2 w \tan \phi) + PA \tan \phi(1 - lc)/\lambda\pi^2 R^2$$

and on integrating the temperature variation on the whole tip,  $\Delta z_{\text{therm}} = \sigma \int_{0,l} T(z) dz$

$$\Delta z_{\text{therm}} = (\sigma PA \tan \phi / \lambda \pi^2) [(\ln(l_c/w) + 1/2) / \tan^2 \phi + l^2 / 2R^2] \quad \text{for the tip}$$

where  $\sigma$  is the coefficient of thermal expansion,  $P$  is the laser power,  $A$  is the absorption coefficient of the material,  $\phi$  is the half angle of the tip cone,  $w$  is the illuminated tip length (spot radius),  $\lambda$  is the heat conductivity,  $l_c$  is the tip cone length,  $l$  is the total tip length, and  $R$  is the radius of the cylindrical tip shaft, although we are mainly interested in pulsed laser irradiation, this result shows the important aspects of tip expansion: the first term is related to the conical part of the tip, while the second depicts thermal expansion of the cylindrical tip shaft. Furthermore, for narrow tip angles, the  $\tan^2 \phi$  denominator means that thermal expansion is dominated by the cone, as the thermal diffusion through the narrow conical region is slow and the temperature rises considerably. The authors also calculate the sample thermal expansion

$$\Delta z_{\text{therm}} = [\sigma PA / (2\pi\lambda)] \ln(2t/w) \quad \text{for the sample}$$

$t$  is the sample or substrate thickness.

Comparison of the latter equation to that for a small angle tip shows that sample expansion is negligible with respect to tip expansion, due to three-dimensional heat flow in the bulk.

In the assumption of pulsed irradiation, a different, simpler model [84] neglects thermal diffusivity along the tip axis and simply assumes that the heat content of a portion or slice of the conical tip diffuses uniformly into the whole slice; slices further away from the apex, however, are wider and therefore heat and expand less. The temperature increase of the  $i$ th slice is

$$\Delta T(i) = J_{\text{laser}} A s_i / (c_v V_i \rho)$$

while its thermal expansion is

$$\Delta z_{\text{therm}}(i) = \sigma \Delta T(i) \Delta l_i$$

The thin regions closer to the apex thus heat much more than those away from it. Integration of the thermal expansions of all the slices between the apex and the tip length  $l$  gives

$$\Delta z_{\text{therm}} = [(2\sigma A J_{\text{laser}} / \pi w^2) / c_v \rho \pi] \int_{0,l} dz / (R + z \tan \phi)$$

where  $J_{\text{laser}}$  is the energy of a laser pulse,  $R$  is the tip apex radius,  $c_v$  is the specific heat of the tip material,  $\rho$  is the material density,  $s_i$  is the cross section of the  $i$ th slice, and  $V_i$  is the  $i$ th slice volume.

The typical expansions, in good agreement with experimental findings in spite of the model simplicity, range from approximately 5 Å at 1 μJ to 15 Å at 30 μJ.

In both models the tip aperture angle is the critical factor; the slimmer the tip apex, the higher the temperature being reached.

A third, simple model by Ukraintsev and Yates obtains the temperature increase of the tip considering only the tip volume corresponding to the thermal diffusion length [85]. From  $\Delta T = Q / c_v m_{\text{tip}}$  (where  $Q$  is the heat absorbed by the tip from the laser pulse and  $m_{\text{tip}}$  is the mass of the tip portion affected by the temperature increase), defining the volume and cross section area of the tip within the thermal diffusion length from the apex as

$$V_{\text{th}} = 2\pi(1 - \cos \phi) \lambda_{\text{th}}^3 / 3 \quad \text{and} \quad A_{\text{th}} = \lambda_{\text{th}}^2 \phi$$

and considering that only a fraction of the laser beam hits the tip, which has a reflectivity  $r$ , the absorbed heat is

$$Q = J_{\text{laser}}(1 - r) A_{\text{th}} / \pi D^2$$

Ukraintsev and Yates obtain

$$\Delta T_{\text{tip}} = 6\phi J_{\text{laser}}(1 - r) / [\pi^2 \lambda_{\text{th}} D^2 c_v \rho (1 - \cos \phi)]$$

and

$$\begin{aligned} \Delta z_{\text{therm}} &= \sigma h_{\text{exp}} \Delta T_{\text{tip}} \\ &= \sigma h_{\text{exp}} 6\phi J_{\text{laser}}(1 - r) / [(1 - \cos \phi) \pi^2 \lambda_{\text{th}} D^2 C_v \rho] \end{aligned}$$

where  $h_{\text{exp}}$  is the portion of the tip subject to  $z$ -expansion (not all the tip portion affected by the focused beam expands but only the thinnest portion, where expansion occurs primarily in the tip axis direction),  $h_{\text{exp}} = \eta \lambda_{\text{th}}$ ,  $1 < \eta < 3$  being the tip geometry factor.  $D$  is the laser beam diameter in the focal region and  $\lambda_{\text{th}} = \lambda t_{\text{pulse}}$  is the thermal diffusion length.

To have a feeling of the orders of magnitude of temperature increase and expansion in typical experimental conditions [ $D = 250 \mu\text{m}$ ,  $\phi = 15^\circ$ ,  $t_{\text{pulse}} = 8 \text{ ns}$ ,  $\sigma = 0.7 \text{ cm}^2/\text{s}$ ,  $c_v = 0.14 \text{ J/g K}$ ,  $\rho = 19.4 \text{ g/cm}^3$  (tungsten),  $r = 0.5$ ,  $\lambda_{\text{th}} = 0.75 \mu\text{m}$ ] a 1 μJ pulse causes a temperature increase of 18 K and a tip expansion, for a geometry factor  $\eta = 2$  of 1.2 Å.

A further model by Geshev and co-workers [86] is based on the transformation of the Poisson problem for the temperature distribution into the Laplace problem for the

modified temperature and on its solution by the boundary element method. This work shows that the temperature rise in a tungsten tip is 10–100 times that of the substrate, that is, of the order of 100 degrees for irradiances of 10 MW/cm<sup>2</sup>, corresponding to focused pulse energies of the order of hundreds of  $\mu$ J, while for silver, due to its lower absorption and its higher thermal conductivity, substrate and tip temperatures can rise by similar amounts. As we have seen in the previous section, due to enhanced field absorption, a thin metal layer on a low thermal conductivity substrate can raise its maximum temperature by several hundred degrees. Particularly when applied to small metal islands on a dielectric substrate, this model supplies extremely high temperatures of local structures, which may be responsible for melting or evaporation of nanometric features, opening the way to controlled nanometric machining.

As a conclusion we observe that all models supply the same order of magnitude for the evaluation of thermal expansion, in the range of several nanometers for irradiances of the order of tens of MW/cm<sup>2</sup>. Furthermore, all models show that expansion depends on the tip material and even more on the tip conicity; the sharper the cone, the lower the heat dissipation and thus the higher the temperature increase and the expansion. As we shall see in the following, even if thermal expansion is dominant over field enhancement effects, it may still be used to effect high resolution patterning, adding one more possibility to the set of available tools for bottom up nanotechnologies.

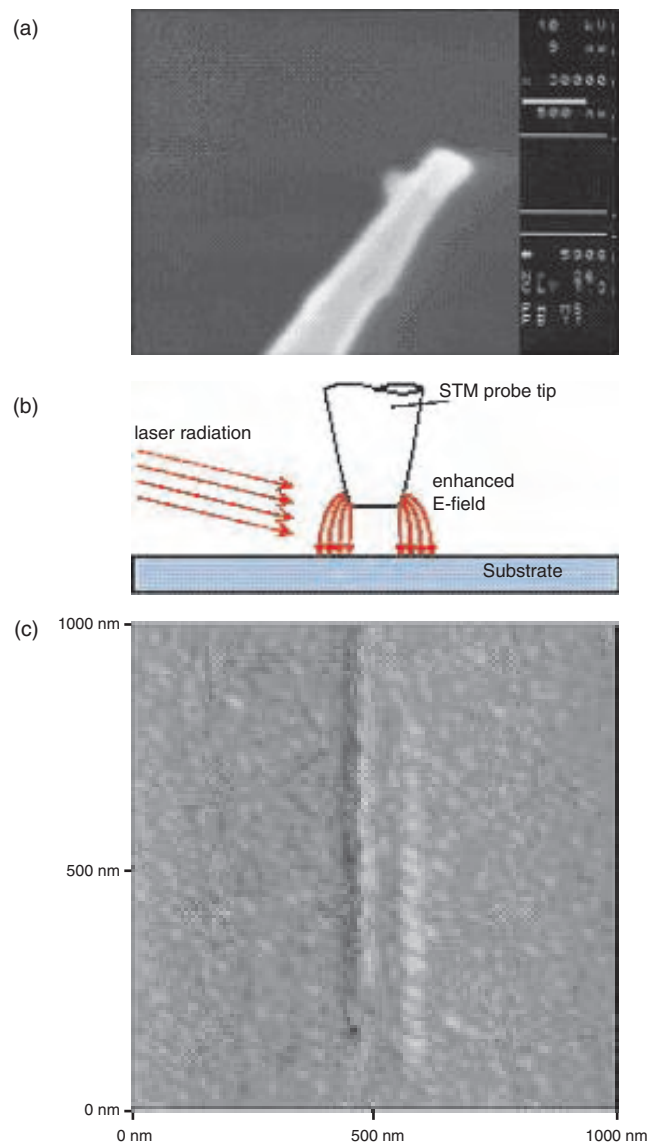

## 7. NANOPATTERNING OF METALLIC LAYERS

Illumination of a SPM tip–surface nanometric gap by a laser pulse normally gives rise to a fast variation of the tunneling current [87–89], very often accompanied by the formation of nanostructures on the surface. Most experiments concern the creation of pits and trenches in the metal layer, while some also produce hillocks. Several mechanisms can contribute to nanostructuring of metal layers, which makes modeling of the experiments quite complicated. The main phenomena involved are thermal expansion of the illuminated tip and localized field enhancement due to the tip. Either of these can in principle be the dominant effect in creating nanostructures, depending on the fine details of the experiment.

The first experiments on laser/STM metal layer nanostructuring were performed by Gorbunov and Pompe at Dresden in 1993–94 [90]. They were based on the expectation that the laser EM field would be strongly enhanced in the proximity of the sharp tip. They used polished silver STM tips because silver has the highest electrodynamic resonance in the electric polarization of a small particle [79]. Radiation of 800 nm from a mode locked Ti:sapphire laser was mildly focused (30 cm focal length) on the STM tip gap and switched on for 100 ms. The substrate was a gold film evaporated on glass. The film, consisting of 10 nm grains, was recrystallized by laser pulses until 100 nm crystallites were created. The STM tip was then positioned on the flat top of the largest ones and 100 W/cm<sup>2</sup> laser radiation was applied for 5 ms, producing 20–40 nm sized hillocks.

These hillocks could also be erased by application of the recrystallizing laser pulses (200 W/cm<sup>2</sup> for 100 ms). No interpretation of the mechanism of mound formation was given at the time, but it was noted that the same hillocks could be produced by applying voltage pulses.

Shortly after these experiments Jersch and co-workers performed similar work at Munster, again based on the idea of exploiting the enhancement of the electromagnetic radiation in the near field of the tip [91–93]. They used 5 ns, 532 nm, Nd-YAG laser pulses impinging on bare tungsten tips to produce holes and trenches or on silver coated tungsten tips to produce mounds. Figure 2 shows the mechanism of surface nanostructuring in the particular case of a flat apex tungsten tip and the resulting nanostructure as evidenced by STM imaging. According to the

**Figure 2.** Nanostructuring using a tungsten STM tip with a flat top (a) and a double structure obtained with this tip on a gold layer (c). (b) shows the fabrication mechanism. Reprinted with permission from [92], J. Jersch et al., *Appl. Phys. A* 66, 29 (1998). © 1998, Springer-Verlag.

authors, this particular result is an indication of the fact that nanostructuring is not the effect of thermal expansion, which would produce one single wide trace on sweeping the tip across the surface, but rather of the “lightning rod” enhancement at the tip corners. However, the size of the trace does not exactly match that of the tip shown, leaving some doubt about the mechanism. Figure 3 shows mounds created on using silver coated tungsten tips on a gold substrate, both as isolated features and as quasi-continuous line. The latter shows also the effect of increasing size with increasing irradiance from 13 to 20 MW/cm<sup>2</sup>. A threshold intensity was necessary to produce mound of 10 MW/cm<sup>2</sup> for silver and silver coated tungsten and 30 MW/cm<sup>2</sup> for Pt/Ir tips. Mound material was proven to be different from the substrate material (gold, on mica) by observing different tunneling spectroscopy characteristics. Thermal expansion of the tip was not considered a possible mechanism on the observation that focusing of the laser beam on the tip above the apex did not produce any structure. As we have seen in Section 5, however, this was probably a wrong assumption as the high thermal loss through the thick shaft toward the tip holder prevents substantial heating. Figure 4 shows a set of parallel grooves carved in a gold layer by sweeping a tungsten tip across the surface with a pulse energy of 15 MW/cm<sup>2</sup>, slightly above the threshold. For groove spacing less than the gold grain size, it is observed that grains are removed. The enhanced field induced mechanism was shown to be a possible explanation for such grain extrusion. With intensities much higher than the threshold, the structures showed very different features, possibly explained by field evaporation. Figure 4b also shows a convex structure obtained on polycarbonate using a Si tip. Threshold intensity

was much lower in this case, only 2 MW/cm<sup>2</sup>, and this structure was explained by polymer softening due to absorption from the enhanced field. No definite explanation was attempted on the mechanisms of pit formation with tungsten or Pt–Ir tips and mound formation with silver or silver coated tips.

A remarkable observation throughout all these experiments is that the tips did not show any sign of wear or distortion after thousands of laser shots. A further remarkable fact is that nanostructuring is strongly polarization dependent, the strongest effect being observed with the polarization vector parallel to the tip axis.

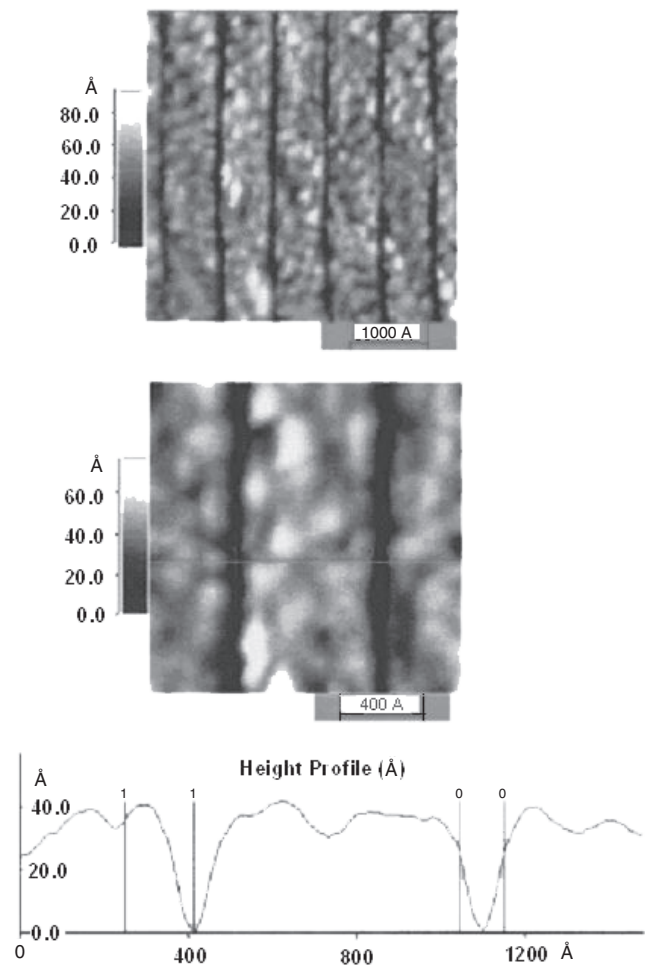

The most recent experiments, by Huang and co-workers at the National University of Singapore, created nm resolution pits and carved lines into approximately 30 nm thick gold and copper layers, using 30 nm radius atomic force microscope (AFM) silicon tips in contact mode and 7 ns green light pulses from the second harmonic of a Nd-YAG laser [94, 95]. Formation of the structures requires a threshold intensity of the laser pulse that is of the order of 7.5 MW/cm<sup>2</sup>, above which the depth of these structures becomes linear with the laser intensity with a coefficient of about 1 nm/(MW/cm<sup>2</sup>) for copper and about twice this figure for gold. Typical widths of the pits are a few tens of nm. (Fig. 5). The depth increases also with the number of laser pulses, but it saturates above approximately 10 pulses. On slowly scanning the AFM tip while the laser is operated at 10 Hz, neat trenches are created with a depth similar to that

**Figure 5.** AFM topographic image and the height profiles of nanoholes created by one laser pulse with irradiance of 9 (left) and 11 (right)  $\text{MW}/\text{cm}^2$ , respectively, on a gold on silicon film with an AFM boron doped silicon tip. of single pulse pits, in spite of the fact that the laser shoots several times within the dimension of the structure. Figure 6 reports such patterning in a gold layer, showing a maximum linewidth of about 10 nm and trench depth of about 3.5 nm. The authors believe that the dominant mechanism is metal melting and evaporation due to the temperature increase of the surface caused by absorption of the strongly enhanced EM field in the tip proximity. The calculated field energy enhancement factor is of the order of 15 to 30 but it is not clear how the incidence angle of the enhanced field should be calculated. The authors estimate that a field enhancement of 1.5 and 2.5 would bring the temperature to the melting point of Cu and Au, respectively, while enhancements by a factor 8 and 10 are necessary to reach their boiling points. They exclude hard mechanical contact due to thermal expansion of the tip on the basis of the observation that the tip shape remains unaffected after thousands of laser pulses. However, their calculation of the temperature increase of the tip is in the range 350–800 °C, corresponding to a thermal expansion of 2–5 nm, of the same order as the pit depth. According to most models, the full expansion of the tip is reached approximately at the end of the laser pulse, when the increased field absorption may have already caused melting of the surface. The decrease of the tip to surface distance caused by thermal expansion may contribute to further field enhancement in the later part of the laser pulse.

The authors also underline that direct surface heating by the laser pulse is essential to obtain nanostructures. Their calculation of the surface heating due to a  $10 \text{ MW}/\text{cm}^2$  beam incident at a  $10^\circ$  angle on the metal film deposited on an insulating substrate amounts to only about 80 °C. Experimentally, for the smoothest films, with roughness below

**Figure 6.** AFM topographic images and height profile of multiple nanolines created by laser pulses with intensity of  $7.5 \text{ MW}/\text{cm}^2$ . Reprinted with permission from [94], S. M. Huang et al., *J. Vac. Sci. Technol. B* 20, 1118 (2002). © 2002, American Institute of Physics.

1 nm, no single pulse carving occurs even at the highest laser intensities, which causes significant distortion of the tip. After several laser shots, the surface roughness increases and nanostructuring occurs at an average roughness of 2 nm, which the authors believe to substantially increase absorption and decrease thermal conductivity. The importance of surface heating is also confirmed by the fact that no nanostructuring is obtained on the highly reflective Al films. Thus the description of the structuring mechanism given by the authors is compatible with the experimental evidence, but the relative roles played by mechanical indentation and enhanced field absorption remain unclear.

The thermal expansion of a Pt–Ir STM tip due to laser pulse heating was experimentally measured by Boneberg and co-workers [96]. From the transient increase in tunneling current caused by pulsed laser heating of a tip that is retracted known distances from a reference tunneling distance, they obtain a thermal expansion of the tip of the order of a few angstroms for energy densities at least 10 times smaller than the threshold for nanostructure formation. They also obtain unequivocal experimental evidence that the expansion is strongly dependent on the polarization

of the incident light, parallel and perpendicular orientation of the polarization vector with respect to the tip axis being the angles at which absorption by the ellipsoidal tip end occurs. This is also confirmed on shifting the laser focus position on a thicker, cylindrical part of the tip, where neither expansion nor polarization effects are observed. Furthermore the transient behavior of the tunneling current occurs on a time scale that is much longer than the laser pulse, ruling out any direct effect of the light pulse, such as photoelectric emission or enhanced field electron emission. These experimental findings agree with those of Huang et al. and confirm that at nanometric distances thermal expansion of the tip cannot be neglected. Interestingly Boneberg and co-workers, using an STM Pt–Ir tip positioned within tunneling distance on a 150 nm thick gold film and again green light pulses from a Nd-YAG source ( $400 \text{ mJ/cm}^2 = 57 \text{ MW/cm}^2$ ), obtain hillocks on the gold surface rather than pits. Their interpretation of the mechanism of nanostructuring is almost opposite compared to that of Huang and co-workers: although they do not exclude a contribution from enhanced field absorption, these authors believe that the main factor responsible is mechanical contact and adhesion of the gold layer to the Pt–Ir tip. This interpretation is confirmed by their measurement of quantized conductance, obtained in the slow retraction phase following the laser pulse, where the current decreases in steps of  $2e^2/h$  as expected [97]. The same interpretation of mechanical adhesion is also given by other authors who obtain dips and hillocks simply on establishing a contact with the surface [98].

Another assessment of the importance of thermal expansion comes from Huber and co-workers who measured the thermal expansion of a tungsten STM tip by the deflection of an AFM cantilever in near contact with it [99]. They obtain values as high as 16 nm for tungsten, although with energy density 3 times higher than in the work of Boneberg et al. and more than 20 times higher than in the experiments of Huang et al. All these values of thermal expansion are therefore roughly equivalent.

While both enhanced field and thermal expansion mechanisms are undoubtedly active, there is thus at present no definite answer to the question of which is the dominant one and in what exact experimental configuration. The experiments of Huang et al. and Boneberg et al. are not identical (different tip material, one STM and one AFM, different laser pulse energies), so that it is difficult to make proper comparisons.

Recently Boneberg and co-workers, who had demonstrated the importance of thermal expansion in the interpretation of carvings, have also demonstrated the potential of locally enhanced fields for surface nanostructuring, using isolated polystyrene spheres dispersed on silicon or glass surfaces [100]. In their work, using spheres of different sizes, they show that local melting of the surface occurs just beneath the spheres illuminated by a laser beam.

If thermal expansion were the only mechanism, then there would probably be little interest in the use of lasers coupled to SPMs for carving, which could be more simply performed by control of the piezo vertical voltage. There is, however, no doubt that the tip integrity and the fact that there is little outspread material (as compared both to common tip

collision damages and to the carved volume itself) around the beautifully neat carvings reported by Huang et al. are good reasons to carry on further investigation. For example it would be interesting to check if the maintenance of tip is due melting of the surface, decreasing the forces experienced by the tip on dipping into the molten surface.

## 8. SMALL CLUSTER AND SINGLE ATOM DEPOSITIONS ON FLAT SURFACES

The first pioneer work on this deposition technique dates back to 1990 and is due to Yau and co-workers at the University of Urbana, IL [101, 102]. They photodissociated and photoionized a gaseous metal compound, trimethylaluminum (TMA), in order to obtain  $\text{Al}^+$  single ions in the STM tunneling gap region. The applied electric field between tip and surface drives  $\text{Al}^+$  ions to the surface, where they are imaged by the STM. The experiment was performed at a pressure of  $10^{-8}$  Pa on atomically flat highly oriented pyrolytic graphite. In order to obtain three photon dissociation of TMA and four photon ionization of Al atoms, exploiting the  $4300 \text{ \AA}$  resonance of the Al excitation, the laser intensity is very high, of the order of  $100 \text{ MW/cm}^2$ . The authors checked that no deposition occurs in the absence of TMA in the vacuum vessel and also that deposition is only rarely observed when the laser is detuned by only  $5 \text{ \AA}$  from the resonant excitation wavelength of Al. Deposits are well evident in the STM images and the atomic structure of graphite, also well detected by STM, is used for an accurate calibration of their dimensions (Fig. 7). The thickness of the deposit is strongly dependent on the applied electric field, ranging from 2 to  $53 \text{ \AA}$  (i.e., from a “monolayer” of four to five atoms to a thick mound of hundreds of atoms); the horizontal dimensions range from approximately 1 to 16 nm.

**Figure 7.** STM image ( $27 \text{ \AA} \times 27 \text{ \AA}$ ) of an Al deposit consisting of four components produced by one laser pulse at a tip bias of 1 V. The vertical span of the gray scale is  $2 \text{ \AA}$ . The crystal lattice of graphite is clearly visible. White arrows indicate the endpoints of the line profile ( $28.5 \text{ \AA}$ ), the maximum variation of which is  $1.4 \text{ \AA}$ . Reprinted with permission from [101], S. T. Yau et al., *Appl. Phys. Lett.* 57, 2913 (1990). © 1990, American Institute of Physics.

In the thinnest depositions, discrete round structures can be observed, their dimensions being compatible with that of single Al atoms. Although the amount of deposited material was too small to attempt electronic spectroscopy measurements in order to determine its elemental composition, the authors presume its different nature, in comparison with the graphite substrate, from the recorded  $I$ - $V$  curves that are linear over the deposition (typical of metals) and show a bandgap over clean graphite.

The authors also showed that holes created in the highly oriented pyrolytic graphite surface by voltage pulse application could easily be filled by aluminum deposited in such way; they could even erase their depositions by further laser pulses, although no explanation of this latter observation can be given.

In this work, on the basis of the experimental observation that no surface modification is obtained in the absence of TMA or with nonresonant radiation, no account of thermal expansion phenomena is given, which may sound strange nowadays, particularly considering a  $100 \text{ MW/cm}^2$  intensity. The authors explicitly state that in order to avoid tip ablation, which may produce extended deposition, they focus the laser beam ahead of the tip, but no quantitative estimate of the radiation intensity at the tip is given. If the power density there is too low to produce appreciable thermal expansion, it may still be enough for enhanced field dissociation/ionization processes; but then it is not clear why such large energy pulses should be used.

This work aroused a large interest since it was the first (and even today one of the few) attempt to add material to a surface in a controlled fashion, with truly nanometric resolution and with a virtually infinite source of material. The metal compound (TMA) was carefully chosen, having the atomic resonance used for the enhanced multiphoton ionization within the wide molecular absorption band used for photodissociation of the molecule, so that a single wavelength is necessary. However, it is obvious that, with fairly straightforward variations of the experiment (using more wavelengths, according to Fig. 1), the methodology could be of very general use. There are indeed many gaseous metal compounds (e.g., metal carbonyls) that can be used and in fact are used to deposit metals in electron or ion beam assisted deposition.

A few years later Ukraintsev and Yates at the University of Pittsburgh [85] obtained very repeatable single atom deposition on an atomically flat Si surface using 7 ns, 532 nm laser pulses to heat a W tip up to the point of evaporating its apex atoms (Fig 8). Several atoms were deposited while the STM was performing one scan line (the laser repetition rate was 10 Hz and the line scan time 1 s). Thus, in the scan lines that immediately followed it was possible to image the deposited atoms. The authors ascribe their results to low atomic coordination of the apex atoms (apex diameter of 25 nm) and also to a “chemical” interaction of the tip with the silicon surface, which is supposed to decrease the W atom binding energy. The experiment is performed in ultra-high vacuum. Although the calculated laser induced direct heating only accounts for about 100 °K, a further 350 °K temperature increase would be due to Nottingham heating, or heating of the apex bound to the strong increase of the tunneling current that is observed when thermal expansion

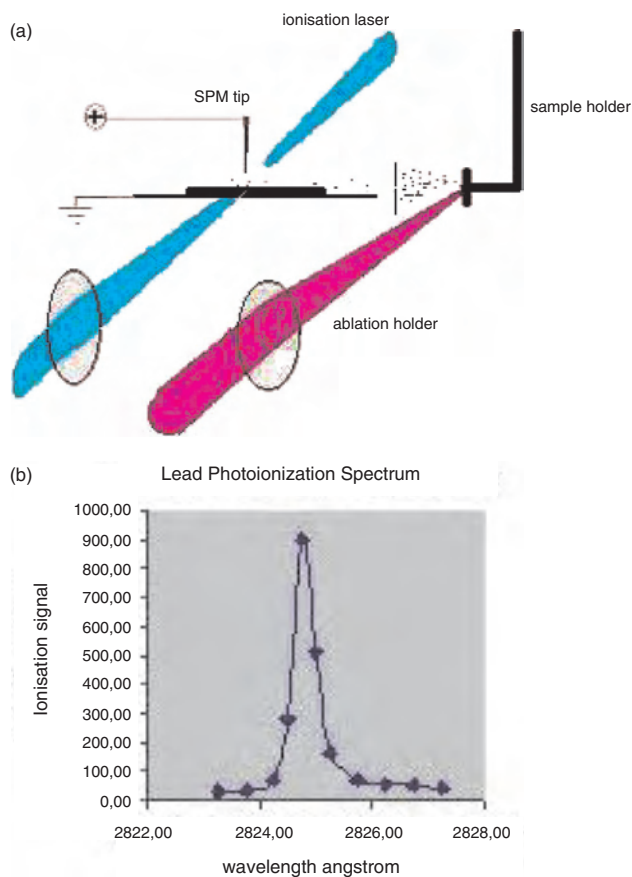

**Figure 8.** Laser induced single W atom transfer. Laser irradiance  $3 \text{ MW/cm}^2$  at 532 nm; sample bias =  $-1.3 \text{ V}$ . (a) STM image before atom transfer. The Si lattice structure and some impurities useful for identification of the deposition location are observable. (b) STM image during transfer: scan direction is left to right and bottom to top, laser shoots every 42 nm of one horizontal scan only, and the deposited atoms are already detected by the scan lines that follow immediately. (c) STM image of the whole deposition area after atom transfer. Reprinted with permission from [85], V. A. Ukraintsev and J. T. Yates, *J. Appl. Phys.* 80, 2561 (1996). © 1996, American Institute of Physics.

causes a tip approach of 8 Å. No tip damage was observed, however, and the transient tunneling current was limited to  $15 \mu\text{A}$  at most. The dependence of the transient tunneling current on both the laser intensity and on the tip to sample bias voltage showed that the thermal expansion cannot be the only mechanism to govern the current.

Very recently in the author’s laboratory at ENEA, Rome, some deposition experiments have been performed aimed at much lower resolution but in the sure knowledge that no thermal expansion consequences could be produced on the surface (i.e., keeping the tip hundreds of nanometers away from it). For such low resolution work no crystalline flat surface was required and the vacuum was in the range  $10^{-5} \text{ Pa}$ . These experiments aimed to establish an even more general technique (not necessarily relying on gaseous compounds) and therefore used one laser to vaporize solid material and a second laser, finely tuned on an electronic resonance of the atomic species as in the work of Yau and co-workers, to effect ionization (Fig. 9a). Lead was used in the first experiments, again because of its convenient spectroscopic properties, its resonant intermediate level being a little higher in energy than one-half the ionization threshold. The ionization charge signal was collected across the STM tip-sample gap as a function of the ionizing wavelength, showing the very narrow line, typical of atomic transitions, reported in Figure 9b. No charges are created and collected if the radiation is detuned by as little as  $1 \text{ \AA}$  from the lowest lead electronic resonance. The vaporizing laser is a pulsed Nd-YAG source at 1064 nm (8 ns) supplying an intensity at the solid lead surface of  $50 \text{ MW/cm}^2$ ; ionization is performed by an

**Figure 9.** (a) Scheme of the laser ablation/ionization apparatus. The ablation laser is focused on the sample that produces a burst of vapor phase atoms or molecules in high vacuum. These are collimated toward the tip-sample gap where a suitably delayed and tuned laser beam causes resonant enhanced two photon ionization. The tip is biased with 1 V. (b) The charge signal collected at the tip-sample gap when the burst of laser vaporized lead atoms is resonantly ionized by two photons, vs laser wavelength. Detuning by  $0.5 \text{ \AA}$  from the intermediate atomic energy level excitation causes ionization to drop to nearly zero. This signal is not observed when either of the two lasers is turned off.

excimer laser pumped, frequency doubled dye laser, supplying approximately  $5 \text{ MW/cm}^2$  at the STM gap with a suitable delay to account for the transit time from the neutral atoms source to the STM tip apex (15 mm ca.). We check that no deposition and no charge signal are present when either of the two lasers is absent. Figure 10 reports three different lead spots deposited on a gold coated silicon wafer surface, keeping the tip at three different distances from the surface. As expected, the spot becomes progressively smaller on approaching the tip; it is interesting that the dimensions of these deposits are much smaller than the focal region of the laser beam ( $200 \mu\text{m}$ ) and have fairly well defined edges, suggesting that ions must be produced in a region of the order of the tip apex size (a few tens of nm), rather than in the whole focal volume. However, whether this is the effect of the enhanced EM field at the tip proximity or merely of the effective electric field driving the ions to the surface (which might be strongly influenced by the first deposited clusters) is still difficult to decide. The scanning electron microscope analysis of the surface reveals that deposition is influenced

**Figure 10.** STM image of three lead spots obtained by resonance enhanced multiphoton ionization of laser ablated lead on holding the STM tip at different distances from the substrate. Spot size increases with increasing distance but it is always incomparably smaller than the beam focal dimension ( $200 \mu\text{m}$ ).

by the local electric field intensity that is determined by surface asperities. For example, the edges of submicrometer scratches produced by polishing powders on metals act as attractors for ionized material [32]; it is thus conceivable that any deposition protruding above the surface will focus new ions on itself.

Depositions can also be performed while scanning the tip in a raster fashion, in order to coat very small areas uniformly. A first attempt in this direction is reported in Figure 11, which shows a STM image recorded immediately after decorating the gold surface with lead ions. The tip was held 1200 nm away from the surface. Tip bias was +1 V; scan size was  $3 \mu\text{m} \times 3 \mu\text{m}$ . The deposition was effected with 300 laser shots over 1 min. The underlying gold structure of the original surface is observable; within the deposition, a large crater with outburst of material due to an unwanted crash of the tip into the sample is also visible.

Similar results were obtained with the amino acid tryptophan and tryptophan containing di- and tripeptides,

**Figure 11.** Painting a gold surface with a square of photoionized lead atoms by a scanning polarized tungsten tip (STM image). The consequences of an accidental collision of the tip into the deposit are observable. The underlying evaporated gold structure is also visible.

vaporized from a frozen aqueous solution under high vacuum and resonantly ionized by two photons at 286 nm. A time of flight mass analysis of these ionized biological materials shows that tryptophan reaches the deposition surface without measurable fragmentation, while peptide dissociation is of the order of 10% (Fig. 12). Separation of the ablation step from the two photon ionization step also allows measurement of the kinetic energy distribution of the vaporized material in the different phases of ablation, by measuring the collected ions signal as a function of the delay

**Figure 12.** Time of flight mass spectra of laser ablated (at 355 nm) and two photon ionized (at 286 nm) tryptophan and dipeptides, showing that deposited molecules are only minimally dissociated.

between the two laser pulses, which are focused at a fixed distance of about 15 mm from one another. Hansen measured the time of flight distribution of the masses detected following ablation of several polymers [103]. He found that in all cases at least two different waves of material are produced, the fastest ones being largely dissociated. For each component he extracted a velocity distribution, which was well fitted by an offset Maxwell–Boltzmann distribution, with an offset velocity of about  $5 \times 10^6$  cm/s and a transverse translational temperature of about 10,000 K. In the case of tryptophan and peptides only one component was measured in the ENEA laboratories, with the fastest part being made of unfragmented material while the late arrivals, ejected by the slowly cooling sample, show dissociation of the order of 20 to 50%. The desorption (or ablation) and ionization technique thus allows a very detailed characterization and control of the material to be deposited. It should also be observed that other spectroscopic characterizations of the vaporized jet of material, beyond photoionization spectra, are possible. Also, if entrained in a supersonic beam of monoatomic gases, molecules in specific conformational states could even be selectively ionized, and thus deposited, exploiting the strong narrowing of ro-vibronic lines at the low temperatures achieved in the supersonic expansion.

Although of very general applicability, this technique has some important drawbacks, particularly at the submicrometer scale. Most important of all, contamination from neutrals is observed on very large areas of the sample. Although careful skimming of the atomic or molecular beam can be easily introduced in the experiment, contamination will always occur on a surface area that is larger than our desired deposition. For thermally resistant materials, heating the substrate may reduce the problem. A second problem arises with neutral atom contamination of the STM tip, on which metal dendrites easily grow during the experiment. Such dendrites reduce the spatial resolution of the technique and often cause problems in subsequent imaging. It was found, however, that this can be minimized by frequent application of voltage pulses to the tip.

## 9. LASER-SCANNING PROBE MICROSCOPE (SPM) ASSISTED SHADOW MASK DEPOSITION

Shadow masks, or stencils, are commonly used in microtechnologies to produce patterned depositions by evaporation of metals through their open features. Normally they are clamped in close contact with the surface to be patterned. If they are moved with high resolution, controlling the distance from the surface so that they neither scratch it nor lift too much away, then this may become a neat bottom up fabrication method. Atomic force microscopes are of course the best suited instruments to control soft contact with the surface. A recent work by the IBM Ruschlikon and University of Cambridge groups used a modified AFM cantilever and an evaporation source to directly write Cu features on a flat substrate in ultrahigh vacuum (UHV) [104]. This methodology has the great advantage of being simple. It allows high resolution, it has no need for resists and surface chemistry,

and it even allows parallel writing of different features. Basically, what is needed is small apertures through the AFM cantilevers or movable shadow masks. Using focused ion beams, 50 nm apertures can be opened, but even smaller features can be written by increasing the angle between the vapor beam and the opened channel in the cantilever. A further advantage of this method is that written features can immediately be read and possibly modified by the AFM. Figure 13 shows some of the features created. Obviously pulsed lasers are an extremely convenient source of vaporization in UHV as they can supply small bursts of vapor in the immediate vicinity of the cantilever from a spatially well defined source, thus implying less stringent demands for collimation of the beam. As we have seen, the use of selective resonant ionization also allows high purity in the deposited materials, while laser soft ionization techniques allow delicate biological materials to be deposited. Very high resolution patterns of biologically functional monolayers have been obtained recently in the author's laboratory by means of e-beam lithography and laser deposition [105]. The following step has been to use piezoelectrically moved micro- and nanostencils to produce both metallic and biological material patterns. Figure 14 shows a micrometric square deposition of chromium, obtained through a movable micrometric stencil a few micrometer away from the surface. The second part of the figure shows a nanometric pattern of the enzyme horseradish peroxidase, softly vaporized, ionized, and shadowed by a nanostencil in close contact with the silicon wafer surface.

**Figure 13.** AFM images of Cu wire structures created by the nanostencil technique with thermal evaporation from a 60 mm distant source. Reprinted with permission from [104], R. Luthi et al., *Appl. Phys. Lett.* 75, 1314 (1999). © 1999, American Institute of Physics.

**Figure 14.** Deposition of chromium (left) and of the enzyme horseradish peroxidase (right) through movable stencils. Note the difference between a suspended stencil (left) and one in close contact with the surface (right). Depositions are 30 nm thick (chromium) and 4.5 nm thick (peroxidase).

## 10. CONCLUSIONS

We have shown that laser-SPM techniques, which are paradigmatic examples of bottom up nanoassembling, have produced in the last decade structures that range from single atoms to hundreds of nanometers. To the author's view laser-SPM coupling will become increasingly important mainly for two issues: unlimited supply of ionized material at the junction and high resolution heating, molecular transfer, or ionization, due to enhancement of the near field. Progress in this field has not been as fast as in other nanotechnological work, like silicon nanooxidation [3], because of the high number of parameters involved. Although too little experience has been gained so far on the subject, we have seen for example that the choice of the correct laser beam polarization, the tip material, and the tip shape may influence drastically both field enhancement and thermal expansion. Modeling of the involved processes has improved recently and will certainly improve even more in the near future, allowing more accurate planning of the experiments and almost certainly much better repeatability. Controlled evaporation of material from the sample surface due to a nanometrically localized EM field and ejection of single atoms from the tip are the most valuable results for ultrahigh resolution fabrication that, however, need better control by a deeper theoretical understanding of the processes.

Multiphoton ionization of gaseous precursors has also supplied atomic resolution deposits, while lower resolution but no dependence on tip thermal expansion has been obtained on holding the tip hundreds of nanometers away from the surface by pulsed laser vaporization and ionization in separate steps. Soft ionization techniques coupled to SPM localization seem ideal for the deposition of functional biological and organic material with nanometric resolution, and the first steps in this direction are being taken. In fact, nanometric resolution patterning of monolayers of

functional biological molecules has been obtained in conjunction with e-beam lithography, while somewhat lower resolution with both metals and biomolecules is achieved by movable shadow masks that need no other processing. First attempts of deposition of unfragmented amino acids and peptides, as well as of metals, in the localized SPM tip field are also being made, for the moment at lower resolution. For biomolecular work, these methods will have to compete with the beautiful technique of “dip pen” nanolithography, which recently succeeded in writing nanometric features of functional biomolecules by flowing a solution of a suitable chemical intermediate along the tip onto the substrate [14]. A problem posed by this latter method is that of reloading the tip with the “ink.” In perspective, controlled laser vaporization and ionization could accomplish this task, both with biomolecules and with metals, in a high vacuum environment. A disadvantage of the laser ionization technique (we have seen that excessive tip contamination leads to loss of resolution in deposition and of imaging capabilities) if suitably controlled may thus turn into a further powerful nanofabrication tool. And of course optical trapping of molecules within a focused laser beam could be a viable alternative to refill the tip.

Fascinating perspectives can also be foreseen with optical trapping in the tip enhanced radiation near field, where in principle modulation of the laser irradiance may lead to nanometrically controlled pick and release of nanoparticles or molecules. Although we have not discussed it as a fabrication technology, only one experimental attempt having been made so far in this direction [24], this methodology seems highly promising, and it may become soon a true fabrication tool, particularly for work in solution with large molecules.

We have not addressed in this short chapter the beautiful and exciting recent results on molecular resolution imaging or spectroscopic characterization obtained exploiting scanning near-field optical microscopes or fluorescence excited by SPM near-field enhancement, which are not properly nanofabrication techniques. These techniques, however, will stimulate the field of light assisted scanning probe nanofabrication, because of both buildup of experience on near-field optics and deeper and more general characterization of the fabricated nanostructures at the molecular level.

Nanotechnology is a multidisciplinary branch: beyond sophisticated engineering, it uses quantum solid state physics and surface science, but also chemistry and biology. Many processes in these fields are photoactivated. Single molecule scale photochemistry and photobiology seem nowadays not so far, so that soon the way may be opened to a wealth of achievements of hardly imaginable dimensions.

## GLOSSARY

**Atomic force microscope (AFM)** One instrument of the family of scanning probe microscopes based on the deflection of an elastic cantilever with a thin tip attached to it that interacts with the electronic cloud of the sample. Interaction causes weak deflection toward the sample at long distance range and strong repulsion at short distances.

**Highly oriented pyrolytic graphite (HOPG)** A form of crystalline graphite with very long range order, particularly

easy to cleave along crystalline planes so that freshly exposed atomically perfect flat surfaces are easily obtained.

**Multiple photon ionization (MPI)** Ionization of atoms or molecules by simultaneous or sequential absorption of two or more photons, whose energies are individually lower than the ionization threshold.

**NMR imaging** A tomographic imaging technique based on the nuclear magnetic resonance signal from the elementary magnets (spins) of hydrogen atoms contained in water and fats present in living tissues. Unlike X-rays tomography it does not use harmful ionizing radiation.

**Polymethylmethacrylate (Perspex) (PMMA)** Beyond being an ubiquitous lightweight transparent material, optically similar to glass, it is also a commonly used polymeric resist in electron beam lithography techniques.

**Polytetrafluoroethylene (Teflon) (PTFE)** Widely used polymer particularly suited for coating purposes where high temperature resistance and low friction are important.

**Scanning near-field optical microscope (SNOM)** One instrument of the family of scanning probe microscopes based on the detection of “optical tunneling” (evanescent wave) to or from a suitably tapered optical waveguide brought to nanometric distances from the sample.

**Scanning tunneling microscope (STM)** One instrument of the family of scanning probe microscopes based on the detection of the tunneling current between tip and sample brought to within one nm from each other. Since the tunneling current depends exponentially on distance only one atom of the tip practically contributes to the current so that the resolution is extremely high.

**Surface enhanced Raman scattering (SERS)** Inelastic scattering of radiation enhanced by nanometric corrugations of the surface.

**Ultrahigh vacuum (UHV)** Vacuum in the range of less than  $10^{-8}$  mbar.

## 1. INTRODUCTION

Nuclear fusion is the power source of luminous stars. The final goal of laser fusion research is to make an artificial microstar on the earth as an alternative clean energy source to maintain a healthy global environment. Although laser fusion research started later than magnetic fusion research, laser fusion has an attractive feature, that is, separability of the system and a simple, compact reactor due to high reaction efficiency [1–3]. The center plasma of laser fusion is very small even for the actual reactor size ( $\sim 200 \mu\text{m}$  in diameter) and of very high density ( $\sim 2000$  times solid density) which is achieved by keeping a highly spherical implosion process. The ignition temperature is  $\sim 10^7$  K, which is far from the conventional nanotechnology region, but the fine structured plasma should be well controlled to ignite fusion reaction. Therefore, laser fusion research should be overlap with the nanotechnology research field. The implosion process for the fusion reactor stands on laser and target technology. Laser is a quite low entropy photon flux; therefore most laser devices have precise structure related to nanotechnology. On the other hand, laser plasma generates high quality (for example monochromic [4]) X-rays,  $\gamma$ -rays, high temperature ions, electrons, positrons, etc., which depend on the combination of a tailored irradiating laser and an irradiated target. These features can be summarized such as an input of nanotechnology to the target and laser makes an output of another nanotechnology through laser plasma as shown in Figure 1.

## 2. LASER FUSION TARGET FABRICATION TECHNIQUE

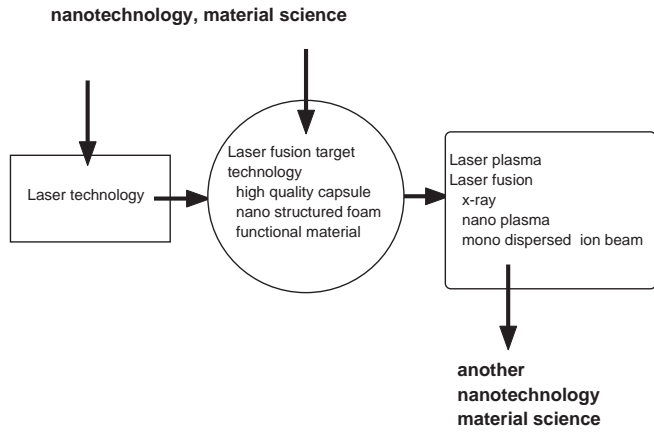

Capsule fabrication is the most important technology in fabrication of laser fusion targets. The capsules of laser fusion have roles as fuel containers and ablaters to compress the fuel (Fig. 2). Previous capsules were composed of glass and designed with the large aspect ratio of capsule diameter/thickness [5]. The capsules exhibited high neutron yield [6, 7], but the compression density was not sufficiently high due to shock heating and X-ray preheating effects from high atomic number silicon. Therefore, recent design have a relatively thick capsule composed of light atoms such as carbon to obtain high fuel compression. Capsule size has been designed to be 5 mm in diameter for a future reactor and 0.5–2 mm for current fundamental experiments depending on laser power. In the case of fundamental experiments, some capsules contain probe atoms to estimate fuel density or fuel temperature.

For an indirect driven system such as the National Ignition Facility (NIF), targets consist of a capsule and a hohlraum. The laser directly irradiates the inner surface of the hohlraum and the inner fuel capsule is compressed by X-rays from the hohlraum. There are three candidate materials of the capsules: beryllium, polyimide, and glow discharge polymer (GDP) for NIF targets. These specifications are summarized including the range of values for all targets and the variation in value allowed in a specific target of that group (Table 1). The NIF specification is shown in Table 2 [8, 9], where the out-of-roundness in mode 2 must be less than 500 nm and that in mode 10 should be less than 4 nm. In the direct driven system, the high power laser light directly irradiates the capsule; therefore it is no longer necessary and the material component is different than the indirect driven system.

### 2.1. Plastic Capsule Fabrication

#### 2.1.1. Coating Method

GDP capsules [10] have been fabricated and used in the United States and France to supply fundamental experiments as summarized in Table 1. The capsule scale depends on the laser power. GDP capsules are prepared using

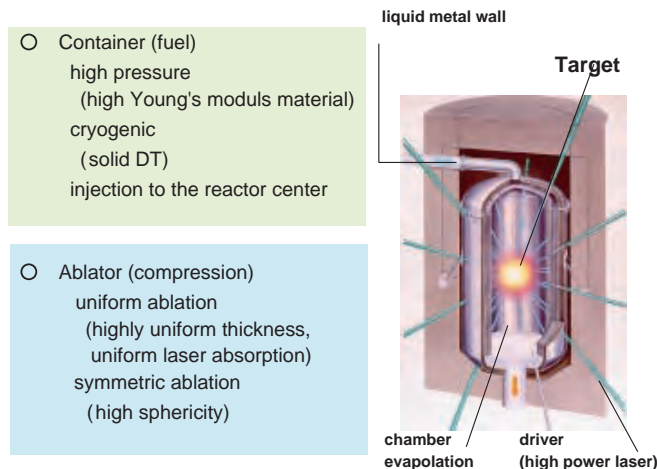

**Figure 1.** Relation between laser fusion target and nanotechnology.

the depolymerizable mandrel technique (Fig. 3). Poly( $\alpha$ -methylstyrene) (PAMS) mandrels were coated with GDP. After the coating of GDP, the PAMS mandrel is thermally decomposed via depolymerization and the remaining GDP capsule is used as a target. The thickness control is difficult for thick capsules ( $\sim 200 \mu\text{m}$ ). These dimensions are well beyond those currently fabricated on a routine basis [11, 12].

In French laser fusion experiments using laser integration line and the future megajoule laser systems, the coatings are prepared by GDP with *trans*-2-butene and hydrogen. Theobald et al. presented the first microshells obtained at the CEA with a GDP coater. Amorphous hydrogenated carbon shells of  $175 \mu\text{m}$  with 1 or 2.4 mm diameter have been prepared. The measured roughness at high modes is lower than 10 nm for a  $30 \times 30 \mu\text{m}$  characterization area [13, 14].

Thin walled polymer shells are required for cryogenic laser experiments with the OMEGA laser system at Rochester University [15]. These capsules need to be about  $900 \mu\text{m}$  in diameter and as thin as possible ( $\sim 1\text{--}2 \mu\text{m}$ ), while having enough strength to be filled with a equivalent deuterium–tritium mixture (DT) as fast as possible to about 1000 atm. They have found that by optimizing the coating parameters in the GDP deposition system, they can routinely make robust,  $\sim 1.5 \mu\text{m}$  thick,  $900 \mu\text{m}$  diameter GDP

**Figure 2.** Roles of laser fusion target as container and ablator.

**Table 1.** Various specs of GDP capsules for high power laser implosion experiments.

Laser system	Laser power	Capsule diameter	Capsule thickness
NIF	1.8 MJ	2 mm	200 $\mu\text{m}$
Omega (CRYO)	40 kJ	900 $\mu\text{m}$	as thin as possible
LIL	60 kJ	1 mm	
LMJ	1.8 MJ	2.4 mm	175 $\mu\text{m}$
Gekko XII	25 kJ	500 $\mu\text{m}^a$	7 $\mu\text{m}^a$

<sup>a</sup> A polystyrene capsule has been used and a GDP capsule has not been used.

shells with buckle strength of over 0.3 atm. Shells as thin as  $0.5 \mu\text{m}$  have been made. This is twice the strength of shells made prior to the optimization and it is comparable to values quoted for polyimide shells. In addition, these shells were found to be approximately three times more permeable and over 20% denser than previously made GDP shells. The combination of higher strength and permeability is ideal for direct drive cryogenic targets at OMEGA.

The composition and chemical structure of GDP capsules have been studied by Nikroo et al. [16, 17]. The investigation was carried out using combustion and Fourier transform infrared (FTIR) analysis. The strongest coatings were obtained when the polymer had the lowest hydrogen content or hydrogen/carbon (H/C) ratio ( $\sim 0.9$ ), whereas the weakest coating had the highest hydrogen content or H/C ratio ( $\sim 1.3$ ). Good agreement was observed between composition results obtained from combustion and FTIR analysis, where the strongest coating had less terminal methyl groups and more double bonds or olefinic structures. Strong GDP coatings that were aged in air reacted more with oxygen and moisture than standard GDP coatings. In addition to the more olefinic structures, there may also be more free-radical sites present in strong GDP coatings, which leads to a greater oxygen uptake.

Polyimide capsules are being developed for implosion experiments. Vapor-deposited polyimide capsules for the NIF were developed [18–22] by improving the capsule surface finish through better understanding of the origin of surface roughness created during the deposition processes and implementation of a postdeposition vapor smoothing procedure to imidation. They have determined that the most important factors during the deposition process that impact surface finish include mandrel quality, monomer mixing,

**Table 2.** The allowed long wavelength deviation from sphericity for low modes of the outer surface and ablator and fuel thickness.

Mode	Outer radius (nm)	Ablator thickness (nm)	Fuel thickness (nm)
1	—	50	400
2	500	75	400
3	400	75	400
4	120	75	400
5	50	25	400
6	25	17	120
7	10	10	80
8	6	8	70
9	5	7	50
10	4	6	40

**Figure 3.** Fabrication of GDP capsule using poly(2-methylstyrene) mandrel.

self-shadowing, and abrasion. They showed that the high rate deposition (above  $10 \mu\text{m/h}$ ) is effective at reducing roughness, which is due to the shorter total time of shell agitation in a bouncer pan. By adjusting the coating conditions, coating up to  $160 \mu\text{m}$  thick was reproducibly fabricated with  $300 \text{ nm}$  root mean square (rms) roughness. Solvent vapor smoothing using dimethyl sulfoxide, a new technique also developed at Lawrence Livermore National Laboratory, improves the surface to  $30 \text{ nm rms}$ .

The processing conditions for vapor-depositing polyimide shells were studied to improve the surface finish, the tensile properties, and the gas permeability for inertial confinement fusion application [23, 24]. The vapor-deposited polyimide possessed distinct properties from solution-cast Kapton, resulting perhaps from being physically or chemically cross-linked. The vapor-deposited polyimide was characterized as semicrystalline with molecular chains parallel to the shell's surface. Varying the imidization conditions (i.e., using different atmospheres, heating rates, and heating durations) increased the permeability while maintaining the Young's modulus. Plastically deforming the shells under biaxial stress increased the permeability up to 1000-fold, which could be reversed when shells were heated to  $350 \text{ }^\circ\text{C}$ . Analyses using X-ray diffraction, infrared spectroscopy, and solubility tests indicated that these modifications in properties may have arisen from changes in the crystallinity, cross-linking, and molecular weight. The low-mode (2 to 20) surface roughness was reduced when the shells were slightly inflated; the high-mode roughness (coating-induced bumps) was increased when the substrate was heated to a temperature of  $90$  to  $140 \text{ }^\circ\text{C}$ .

### 2.1.2. Emulsion Technique

The emulsion technique to prepare capsules is well known by polymer scientists [25, 26], but vacuole formation during microencapsulation is a serious problem for laser fusion targets [27]. Highly spherical and uniformly thick capsules without a vacuole have been developed in the field of laser fusion targets. In particular, the polystyrene capsule [28] provided the highest density implosion, 600 times that of solid density [29, 30]. In a future power plants, high repetition implosion is required in the reactor. For mass production of shells with monodispersed diameter and uniform thickness, a droplet generator (Fig. 4) was utilized to prepare emulsions [31].

However, the process in which a uniform wall is formed was not clearly known. Norimatsu et al. [32, 33] and Gresho

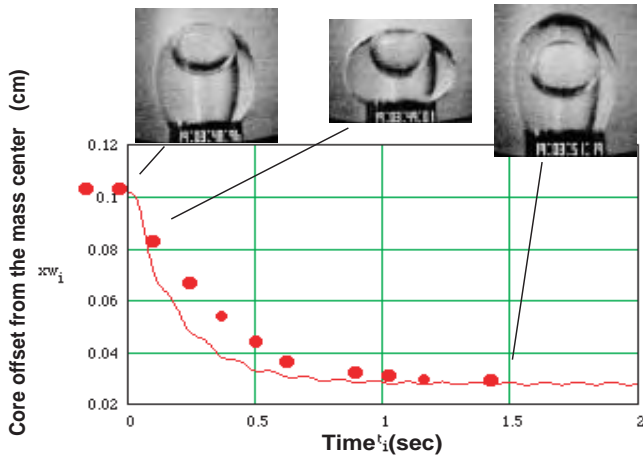

**Figure 4.** Monodispersed sized emulsion generator (left), polystyrene capsules from the emulsion (upper right), and various capsule size range (lower right).

[34] proposed a model (Fig. 5) to numerically simulate the emulsion process to improve the shell fabrication process. When some external force such as collisions with the stirring propeller deforms a water/oil/water ( $W_1/O/W_2$ ) emulsion, the deformation force is transferred to the inner water core through the oil phase. If the force is inversely proportional to the thickness of the oil phase, a centering force appears and the core moves toward the center of the emulsion. Because some important assumptions were made in the model, they compared the model with an experiment, where equipment was established to mechanically deform a  $W_1/O/W_2$  emulsion by a vertically vibrating rod instead of the deformation during stirring. Experimental results obtained using a mechanical driver are shown in Figure 6. The densities of  $W_1$  and  $O$  measured before making the compound emulsion were  $0.998$  and  $1.024 \text{ g/cc}$ , respectively. Their values were estimated to be  $0.999$  and  $1.017 \text{ g/cc}$  during the centering experiment because of diffusions of 1, 2-dichloroethane into the  $W_1$  and  $W_2$ . The viscosity of  $O$  was  $0.1 \text{ P}$  ( $\pm 15\%$ ). Their model calculations could explain experimental results obtained by emulsions with the large

**Figure 5.** A schematic view of an emulsion (left) and the core  $W_1$  phase of the emulsion centered by the deformation of emulsion due to the sloshing (right).

**Figure 6.** Comparison of the centering process of a compound emulsion with the Norimatsu model. The oscillation is in sloshing mode. The vertical axis is the offset of the core in mm and the horizontal axis is the time in seconds. In the set of photographs, the left and middle photographs show the first vertically lengthened phase and the first compressed phase, respectively. The right photograph shows the final equilibrium position in the lengthened phase. Time origins for experiment and simulation are arbitrary.

and small core oscillating in sloshing mode. However, the centering speed of the small core was faster than calculations. The recommended aspect ratio  $\lambda$  (=inner radius of O/outer radius of O) was  $0.5 < \lambda < 0.8$ .

The mass transfer of the solvents was experimentally measured in the oil, water, and distillate phases during the curing process of highly spheric monodispersed 4-mm-diameter polystyrene capsules of uniform thickness (Fig. 7) [35]. It was determined that the water solubility of the solvents is crucial in the solvent selection in order to prepare the capsules by this method. The curing process started from the

**Figure 7.** At the early time of the emulsion curing process ( $\sim 30$  min), the distillate ratio of 1, 2-dichloroethane/benzene was higher than that at the later time (above). This means that the curing was not governed by the boiling point (benzene:  $\sim 80^\circ\text{C}$ , 1, 2-dichloroethane:  $\sim 83^\circ\text{C}$ ) but rather the solubility in water (benzene: 0.2 g/100 g, 1, 2-dichloroethane: 1.0 g/100 g at  $50^\circ\text{C}$ ).

water/oil/water emulsions, where the boiling temperature and the densities of the oil were well matched by mixing benzene and 1, 2-dichloroethane. The masses of the solvents were measured for the oil phases and the distillate and then calculated for the water phase. The analysis of the solvents in the water phase indicated that the process was governed by the kinetics of the dissolving from the oil phase to the outer water phase rather than by the vapor pressure of the solvents in the early stage before the oil phase lost its fluidity. The time at losing the centering motion of the emulsion core was measured experimentally and gave a procedure of the highly spheric PAMS mandrel [36–38].

The surface finish of the final shells was examined using atomic force microscopy (AFM) and scanning electron microscopy (SEM). A clear dependence of the spectrum of final GDP shell on the quality of the initial PAMS mandrel was observed. These shells with various thicknesses have very similar power spectra, indicating little coating deterioration of shell surface finish due to GDP coating processes [39].

Surface ripples of mode 10 in IFE shells were a serious problem for NIF ignition. PAMS spherical shells made by microencapsulation show a surface roughness ( $\sim 30$  nm) within the mode range 7–20 (Fig. 8). The roughness mode number corresponds with theoretical models of Marangoni convection cells formed during the curing of the initial wet shells. The roughness was removed by reducing the curing rate so that the concentration gradient across the wall was less than the threshold of Marangoni convection [40].

Takagi et al. developed a new method for making spherical PAMS mandrels, where a small amount ( $< 0.1$  wt%) of high-molecular-weight poly(acrylic acid) (PAA) was utilized instead of poly(vinyl alcohol) in the suspending medium, which substantially increases the interfacial tension during curing and yields extremely round capsules. The poly(acrylic acid) is also beneficial for centering of the core water, leading to exceptionally concentric capsules. However, fully cured capsules made by this method displayed a significant level of high frequency surface debris that became especially problematic when the mandrels were subsequently overcoated with GDP. To overcome this problem, they examined the use of poly(acrylic acid) in conjunction with poly(vinyl alcohol) in order to reduce these surface features

**Figure 8.** The PAMS capsule showed a surface roughness  $\sim 30$  nm within mode 7–20. The roughness mode number corresponds with theoretical modes of Marangoni convection cells formed during the curing of emulsion.

and explored numerous variations of concentration and timing of the poly(vinyl alcohol) addition. The conditions were optimized for the initial use of poly(acrylic acid) for centering and symmetry of the mandrel, followed by exchange to poly(vinyl alcohol) solution. GDP shells made from these mandrels satisfy the ignition capsule design requirements [41, 42].

The capsule characteristics mainly depend on the number of average molecular weight, molecular weight dispersion, and finally the atomic composition. It was shown that the surface quality of the capsule is directly connected to the polydispersity index. The best results have been obtained using polystyrene which exhibited a dispersity index inferior to 1.20.

Thin-walled shells with polystyrene or its copolymers were fabricated using a conventional emulsion technique [43]. The wall thickness of the resultant shells was found to be 3  $\mu\text{m}$  for the 1 mm diameter. The reduced thickness was due to the low concentration oil of polystyrene derivatives and the high temperature water phase.

Recently high quality polyimide capsules have been fabricated using an emulsion technique (Fig. 9), while the previous emulsion method succeeded only for conventional soluble and noncrystalline polymers such as polystyrene and poly(methyl methacrylate). The polyimide capsule is one of the leading designs for IFE experiments and is prepared using a chemical vapor deposition process [18–24], which requires expensive apparatus. By curing an emulsion containing nonvolatile *N, N*-dimethylacetamide, 0.5–5 mm capsules of highly spheric poly(amic acid) were fabricated [44]. Although the sphericity of the capsule (>99%) obtained by the emulsion method was slightly lower than the highest millimeter-sized polystyrene capsule, its surface was smooth without irregular deviation. The curing for high sphericity capsules required stabilization and deformation, which were governed by several conditions such as the concentration of PAA, the viscosity of the emulsion matrix, the stirring speed, and the temperature. The PAA capsule was imidized by a chemical process.

Metal particle (20–30 nm) doped polystyrene capsules were fabricated using an emulsion technique. The capsule will be applied to suppress Rayleigh–Taylor instability [45]. Another polystyrene hollow pellet with a high atomic number atom boundary irradiator is fabricated for inertial confinement fusion experiments. The pellet adsorbs high *Z* micro- or nanoparticles on its inner surface to emit characteristic X-rays of the high *Z* materials. A triphasic

**Figure 9.** A polyimide capsule was obtained using the emulsion technique via a soluble precursor of the poly(amic acid) capsule and the chemical imidation process.

emulsion of  $W_1/O/W_2$  is used for the fabrication processes. The  $W_1$  is a high *Z* microparticle (alumina) mixture in water. After drying, high *Z* microparticles 300 nm in diameter remain on the inner surface of the pellet [46].

### 2.1.3. Other Problems with Capsule Treatment

Stephens et al. reported unique capsule fabrication using a heated drop tower. Polystyrene capsules in the 1 to 1.5 mm diameter range were prepared employing solid polystyrene pellet feed [47].

The capsules need to be characterized in detail. A wall mapping apparatus and a sphere mapping apparatus were investigated to determine thickness along the same paths as the surface profiles [48]. In the system, a capsule was mounted on a horizontally rotating vacuum chuck. Sphere mapping was done using AFM, while wall mapping was monitored using optical fiber connected to a light source to illuminate the capsule. Both mapping circles were on the equatorial face of the capsule.

The economic viability of target fabrication is a crucial issue for the feasibility of future IFE power plants. Current targets produced for IFE ignition experiments are estimated to cost about \$2500 each. Design studies of cost-effective power production from IFE have found a cost requirement of about \$0.25 each. While a four orders of magnitude cost reduction may seem at first to be a significant challenge, there are many factors that suggest this is an achievable goal. Goodin et al. summarized the major steps in cost reduction that will be taken to economically supply targets for IFE power plant fueling [49].

Target delivery to the reactor center is important problem. In order for the driver to properly ignite the target, the target and laser beams must come together at the center of the reactor chamber with precise timing ( $\pm 10$  ms) and positioning ( $\pm 10$   $\mu\text{m}$ ). The cryogenic target must not melt [50, 51]. A preliminary injection system was constructed at the Institute of Laser Engineering (ILE) in Osaka to ascertain the initial perturbations in the injection speed and the direction (Fig. 10). The system is composed of two sets of coils. Each consists of three pairs of two coils triggered by a 120 degree delay in the phase. The coils in the first and second stage are powered with 300 V, 1980  $\mu\text{F}$  and 840 V,

**Figure 10.** Tracking system developed at ILE Osaka and the typical signal obtained from a 5 mm polystyrene shell at  $v = 40$  m/s.

366  $\mu\text{F}$  capacitors, respectively. This system can launch a 98 mm long, 12.5 mm diameter, 0.5 mm thick aluminum sabot with a 5 mm diameter polystyrene shell inside at a speed of 10 m/s.

## 2.2. Inorganic Capsule Fabrication

Glass microspheres were the principal fuel container for laser fusion targets. In particular, high-aspect-ratio targets produced thermonuclear neutron yields exceeding  $10^{12}$  with the 12-beam green GEKKO XII laser [6, 7]. Two methods were developed for the specific purpose of supplying high-quality glass microspheres: liquid droplet and the sol-gel methods. The liquid droplet method involves the formation of highly uniform droplets of aqueous glass solutions by breaking up a capillary jet flow of the solution. The droplets are subsequently dried and fused to form the desired hollow glass microspheres. In the sol-gel method, a solution of glass-forming oxides is dried to form gel. After crushing and sieving to a suitable particle size, the gel particle drops through a high-temperature furnace to form a glass microsphere. The two methods are complementary in many aspects. Reference [52] summarizes both methods briefly.

Recent developments in making glass shells from metal doped GDP deposited by plasma polymerization (where metal is Si or Ti) have significantly expanded the diameter and wall thickness obtainable by the process. Further, the wall uniformity of glass shells made by the process is generally superior to those made by the traditional drop-tower approach. Hoppe enabled pressurization of a glass shell with argon by taking advantage of permeability properties of the glass before it is converted to full density where it becomes essentially impermeable to most gases [53].

## 2.3. Cryogenic Solid Hydrogen Layering

Cryogenic targets with solid deuterium/tritium layers are very important in laser fusion and have occupied a large area in target development. The hollow, spherical solid density fuel can be efficiently imploded due to the initially higher density and lower isentropy compared with gaseous fuel with the same mass. This means such targets reduce the energy to compress it to a high density and high temperature. A cryogenic target system with low density plastic foam was developed 10 years ago [54, 55] and supplied for the fundamental experiments [56], while very recently the first results from a cryogenic target without foam have been supplied for implosion experiments at Rochester University [57].

It is difficult to form a uniform layer because of gravity and polycrystallization during the solidification process. Many techniques have been proposed and studied to overcome the difficulties. The first cryogenic target was fabricated by cooling a fuel-filled glass sphere with direct thermal conduction through a supporting copper fiber [58]. The second technique, fast isothermal freezing, did not use the supporting fiber which disturbs the implosion symmetry [59–62].

The  $\beta$ -heating technique uses  $\beta$ -decay-induced redistribution of a DT-filled fuel container to be cooled uniformly below the freezing point. Because the DT fuel generates heat due to  $\beta$  decay, the temperature of the inner surface of the thicker area is higher than that of the thinner area

when it is cooled uniformly. The solid DT at the thicker area is redistributed to the thinner areas through a sublimation–condensation process. The maximum rate at which the redistribution occurs was given by  $d\delta/dt = -\delta/\theta_{\text{TC}}$ , where  $\delta = \text{DT ice thickness in excess of that for a uniform layer}$  and  $\theta_{\text{TC}} = \text{a time constant } \sim 1500 \text{ s}$  [63]. The apparatus was summarized in the [64], and  $\theta_{\text{TC}}$  was reported depending on the  $^3\text{He}$  content (the age of  $^3\text{T}$  [63]).

Norimatsu et al. developed a plasma layering technique in which a nonuniform solid fuel layer is redistributed into a uniform one, with a glow discharge initiated in the void by an external intense microwave field. Reactor sized frozen deuterium was demonstrated with the redistribution time constant of  $\sim 80 \text{ s}$  [31, 66, 67]. Mapoles et al. reported a technique to generate a heat flux across the fuel surface by applying an electric field to the DT layer in the center of the shells. The vapor has a small but significant conductivity due to ionization caused by  $\beta$  decay of tritium in the vapor and the solid [68].

The IR heating method is also a powerful candidate for future reactor use. Pumping the IR collision induced vibration–rotation band in solid  $\text{D}_2$  ( $3.15 \mu\text{m}$ ) and (HD, heated deuterium-hydride  $2.57 \mu\text{m}$ ) redistributes the solid depending on IR intensity profile [69]. HD layers 150–250  $\mu\text{m}$  thick formed near the triple point have a surface roughness rms between 1 and 3  $\mu\text{m}$  and become rougher with decreasing temperature. When solid DT in an isothermally cooled shell is heated, the solid DT layer becomes uniform through a process similar to  $\beta$ -heating. Solid growth dynamics have a significant impact on the quality of the resultant layer. The solid layers slowly grown from the melt were much smoother [70]. Koziowski et al. reported results of modeling and experiments on infrared HD layers in hohlraums [71]. A 2 mm diameter, 40  $\mu\text{m}$  thick shell with 100–400  $\mu\text{m}$  thick HD ice inside a NIF scale gold hohlraum is heated by pumping the HD vibrational bands. Models indicate control of the low-mode layer shape by adjusting the infrared distribution along the hohlraum walls. They have experimentally demonstrated control of the layer symmetry perpendicular to the hohlraum axis.

The cryogenic foam target consists of a low-density, plastic foam shell to sustain liquid fuel and an outer thin film to prevent the fuel from boiling off (Fig. 11). The uniformity

**Figure 11.** Cross section of foam shell obtained from macromonomeric acrylate with multifunctional groups.

of the liquid fuel layer is confirmed by that of the foam shell. The carbon in the foam material was considered to be an acceptably low-content impurity for the fusion plasma. A recent target design by Phillips et al. indicated that the impurity of carbon is preferable to absorb laser efficiently [72].

Layering indirect drive targets with the capsule already assembled in the hohlraum would be advantageous. One way to accomplish this is to layer targets in controlled temperature tubes while they are being staged for feeding to the injection system. Successful layering requires maintaining a specially tailored temperature profile on the hohlraum surface. Tritium decay heat removal from the filled capsule depends upon the thermal properties of the tube material, the capsule material, and other materials filling the hohlraum. Pulsifer et al. evaluated various techniques for achieving adequate thermal control during the in-hohlraum layering process. Results provided feedback to target designers on design techniques which will be important in order to make in-hohlraum layering possible [73].

All the cryogenic targets mentioned previously were supported, for example, by a stork. Technologies based on using freestanding targets (FST) are important for the next step fuel production. In each production step (fuel filling, fuel layering, and target delivery) the research has been intensively explored at the Lebedev Physical Institute. The layering apparatus can form 30–100  $\mu\text{m}$   $\text{H}_2$  and  $\text{D}_2$  solid layers on the inner surface of millimeter sized polystyrene shells. Layering time was less than 30 sec. Based on their advances, the FST technologies are now at the stage of extension on a reactor target design for the IFE power plant [74–76].

To form the smooth cryogenic layer inside laser targets a new approach is in progress which shares basic principles of fabrication of finely dispersed compounds (solid solutions) with little doping that slows crystalline grain growth. This approach has been demonstrated experimentally with a  $\text{H}_2/\text{HD}$  mixture where the amount of HD is less than 1%. As a result the transparent solid layer has been formed inside 500  $\mu\text{m}$  glass shells. The layer keeps its transparency at cycling heat treating in the range of 5 to 16–20 K [77].

Concerning cryogenic targets, cooling-induced deformation of fuel capsules was experimentally characterized in detail by Endo et al. In the experiments, polystyrene shells were cooled using liquid nitrogen and observed with an optical microscope. Pictures of each shell were recorded at various temperatures, and they were compared with each other. As a result of precise error estimation, it was found that any polystyrene shell showed deformation in varying degrees. It has been found that thinner shells deform more remarkably than thicker shells [78, 79].

## 2.4. Porous Foam Fabrication

Foam targets have been used not only for the cryogenic target [54–56] but also for the study of laser shock [80, 81] and laser–plasma interactions [82–84], for which the foam fabrication technique has also been investigated over a wide range of element compositions, densities, and microstructures.

Ultra-low-density foams provide a plasma under the cutoff density ( $n_{cr}$ ) which allows the penetration and interaction of laser light with the frequency of  $\omega_L$ , and the relation is [85]

$$\omega_L = [(e^2 n_{cr}) / (\epsilon_0 m_e)]^{1/2} \quad (1)$$

where  $e$ ,  $\epsilon_0$ , and  $m_e$  are the elementary charge, vacuum permittivity, and electron mass, respectively.

In addition to the ultra-low-density foams, recent laser–plasma experiments have required finer structures such as submicro- and nanostructures, for example, the high-power laser-induced D–D reaction indicated a size effect of the atomic cluster where the maximum nuclear yield was given at the cluster size of 6 nm [86]. Therefore, a variety of micro- and nanostructures of the foam materials are important in controlling the laser plasma.

Poly(4-methyl-1-pentene) (denoted as PMP) foams [82, 87–96] have been investigated for the following reasons: (1) they contain no oxygen which interferes with X-ray diagnostics, (2) they have the potential for heavy atom doping, and (3) they can be fabricated by dissolving the polymer by heat, cooling to coagulation, and removal of the solvent. See Table 3.

Generally, the removal of the solvent from a gel to the corresponding foam has been carried out by the freeze-drying method or the supercritical fluid extraction (SFE) method; either way a neat density polymer should be obtained. Ultra-low-density foams were prepared by the freeze-drying method to give a density of 2.5  $\text{mg}/\text{cm}^3$  [87–90], and their structure, for example for a PMP foam prepared from durene/naphthalene solution, was  $\sim 20 \mu\text{m}$  in size.

Recently, the coagulant effect for microstructures was observed in PMP foam from its gel of hexanol derivatives via supercritical fluid  $\text{CO}_2$ . The obtained ultra-low-density PMP foams have various microstructures depending on coagulant alcohols (Fig. 12). Although alcohols do not dissolve PMP, they have an alkyl group that interacts with the main and side chains of PMP [96].

The silicon doped CH foams were prepared by a thermally induced phase-inversion technique, with PMP, durene/naphthalene, and  $\text{SiO}_2$  as the foam skeleton material, the solvent/nonsolvent, and the doping materials, respectively. Foam density was 5–80  $\text{mg}/\text{cm}^3$ , and the weight percentage of Si was less than 10% [92].

One method of production of low-density polymeric foams is to dissolve a multifunctional monomer and initiator in a solvent and to polymerize by means of free-radical polymerization. The gel produced is precipitated in a non-solvent and subsequent SFE drying produces a low-density

**Table 3.** Characteristics of low-density foam of poly(4-methyl-1-pentene) prepared from alcoholic gel.

Coagulant	Foam density ( $\text{mg}/\text{cm}^3$ )	Disk size at the cutoff ( $\mu\text{m}$ )	Wavelength density ( $\mu\text{m}$ )
1-Hexanol	12	$\sim 10$	0.55
2-Methyl-1-pentanol	5.0	$\sim 3$	0.84
2-Ethyl-1-butanol	2.0	$\sim 6$	1.3

**Figure 12.** Scanning electron microscope image of poly(4-methyl-1-pentene) foam prepared from (a) 1-hexanol, (b) 2-methyl-1-pentanol, and (c) 2-ethyl-1-butanol.

microporous foam, which has a finer structure than that prepared by the freeze-drying process [93].

The cross-linked acrylic polymer exhibited fine structure of  $\sim 200$  nm [97–99] and was widely used as foam capsules with a gas barrier and foam-coated cryogenic targets (Fig. 11). The metal doping was done using lead and titanium [97]. Other cross-linked polymers provide fine foam, for example, phenol resin [100] and copolymer containing divinylbenzene. Resolsinol/formaldehyde foam, a kind of phenol resin foam, exhibited fine structure and opacity for laser light [101].

A middle density, foam layer coating was proposed to protect direct-drive, cryogenic targets from melting due to surface heating by residual gas in a laser fusion reactor. A  $100 \mu\text{m}$  thick,  $50 \text{ mg/cm}^3$  foam layer can prevent melting of the solid DT layer injected into the latest heat of Pb vapor. A thermal insulator coating on the target surface, or a sabot-in-chamber scheme, is necessary to protect the direct-drive, cryogenic target [102, 103].

To characterize foam, SEM and optical interferometric techniques are used. The latter method is limited by scattering caused by the foam structure. Foam parameters were estimated using model calculations to enable adequate foam shell characterization for a baseline capsule [104].

## 2.5. Cluster Target

Vapor atomic clusters and large molecules are attractive as targets for intense ultrashort pulse lasers. For example, Ditmire et al. reported D–D fusion at high pressure and low temperature gas jet, where  $10^2$ – $10^6$  molecules of  $\text{D}_2$  were coupled through van der Waals interaction [86, 105]. Such a system has a high atomic density similar to solids, but the average density is low: as a consequence the absorption of laser light is more than 90%. The efficiently absorbed laser light stripped almost all electrons, and the following ion acceleration is called a Coulomb explosion, reaching kinetic energy as high as 1 MeV. The neutron yield of the D–D fusion reached  $10^4$ .

Another difference of the cluster target from gas and solid is well-ordered molecular orientation. This phenomenon

provides fundamental prospects to design not only neutron generation but also generation of bright X-rays [106–109], high energy ions [110], etc.

## 2.6. Other Techniques

Due to the recent progress in ultra-high-intensity lasers, the “fast ignition” scenario enables heating of ultra-high-density plasma [111, 112]. The target structure is shown in Figure 13 where a gold cone is inserted in a spherical poly(d8-styrene) capsule. The gold cone was fabricated by electrochemical gilding on a brass mandrel.

To fabricate the cryogenic gold cone guided target, a foam technique is useful because the required cooling uniformity is not as important as that for beta layering and IR heating. The fuel will be loaded into the void through a gas feeder pipe at a cryogenic temperature although normal targets are loaded by diffusion across the wall at room temperature. This technique can significantly reduce the inventory of tritium in a future target factory. The liquefied fuel penetrates into the foam leaving a void inside (Fig. 14) [113].

To examine hydrodynamic instability during high power laser irradiation, targets with perturbed surfaces have been prepared by, for example, the thermal-press method [114], Fourier laser machining, the laser interference ablation technique, etc.

Nanoadhesion of metal foils was achieved to provide a precise thickness ( $\sim 20 \mu\text{m}$ ) of an adhered step target for ultrahigh pressure, laser shock experiments [115]. The technique involves two processes: single molecule coating on the metal surface and fastening the two surfaces together. For the two  $20 \mu\text{m}$  aluminum targets of single foil and adhered foils, a negligible difference in laser shock speed was observed in comparison with laser energy and target thickness (Fig. 15).

## 3. LASER FUSION TARGET MATERIALS

### 3.1. Light Atom Materials

A beryllium capsule has been designed and has multi-mode hydrodynamic instability in implosion simulations. In comparison with a CH capsule, the instability of a beryllium capsule is much less sensitive to DT ice roughness

**Figure 13.** Right: The implosion target for efficient heating of the highly compressed plasma. A gold cone is attached to a poly(d8-styrene) capsule. Left: An X-ray image of the implosion.

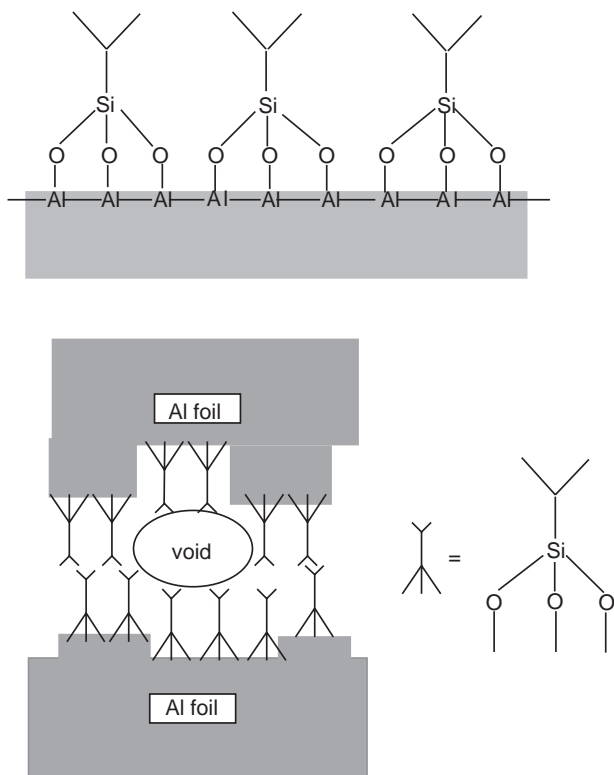

**Figure 14.** Structure of cryogenic foam target with gold cone guide. Gaseous DT is filled into the target using the gas feeder shown in the figure.

[116, 117]. Capsule fabrication of micrometer sized beryllium metal and its alloy has been investigating at Los Alamos National Laboratory [118]. Chemical vapor deposition of beryllium was done by using dialkylberyllium derivatives [119], bis(cyclopentadienyl)beryllium [120].

Amorphous beryllium has a grain structure, and a model study was done taking into account the possible effect of beryllium grain sound speed anisotropy in capsule implosions, where effects of crystallographic texture on sound velocity propagation in polycrystalline beryllium were discussed [121].

Recently light atom hydride was fabricated as low-density foam. Beryllium-containing materials were foamed to be

**Figure 15.** Schematic structure of single molecular membrane glue. Left: ideal modified surface with isopropylsiloxo groups on the aluminum surface. Right: possible mechanism of adhesion.

less than 0.1 g/cc in density and pore sizes of  $\sim 10 \mu\text{m}$  could be used. Such structures could be obtained in the course of thermal transformation of beryllium hydride (deuteride) [122, 123] as well as mixtures of beryllium hydride and lithium hydride. Heavy elements can be admixed to the low-density beryllium and their distribution can be controlled over layer thickness.

### 3.2. Photovoltaic Target to Prevent Laser Shine-Through

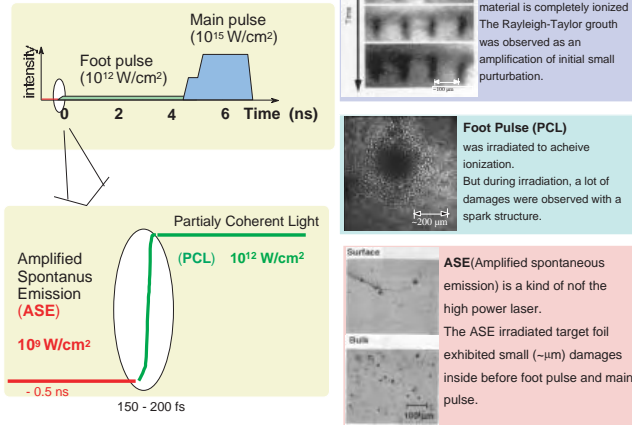

In the direct-driven ICF implosions, where laser light directly irradiates the target, hydrodynamic instabilities such as Rayleigh–Taylor instability during the implosion are seeded by initial imprint due to laser irradiation nonuniformity, along with the original target surface roughness. These perturbations are accompanied by rippled shock propagation before the shock breaks out the inner surface, and they grow due primarily to the Rayleigh–Taylor instability after the shock breakout. The perturbations grown on the outer surface are then fed through on the inner surface. These, together with inner surface roughness, will grow again during the spark and the main fuel, which could quench the ignition and burn. The precise structures of the fuel capsule have been designed and fabricated based on the strategy mentioned previously, and a number of experiments on the rippled shock waves, initial imprint, and Rayleigh–Taylor instability in direct drive as well as indirect drive have been done [124].

There is another problem in which the previous scenario does not take into account, called the laser shine-through effect. Recent experiments indicated that sparklike damages are nucleated inside the capsule layer during the very early phase of the laser pulse. The damages are considered to be due to penetration of laser light into the transparent capsule materials such as GDP and polystyrene before the laser intensity reaches high intensity to ionize the capsule materials. A similar damage pattern and damage threshold are well known in high-power laser optical materials, such as potassium dihydrogenphosphate and silica glasses, in which the damage threshold values are  $1 \times 10^{10}$ – $3 \times 10^{11} \text{ W/cm}^2$  [125, 126]. This damage inside the laser optical materials has been characterized to be traces of self-focusing of the laser beam, where both the nonlinear growth of small scale beam break-up and the whole-beam self-focusing alter the focusing properties of the system (Fig. 16).

Organic material is one of the promising materials to be engineered for this purpose due to its feasibility based on advanced synthetic chemistry. Such organic functional materials will provide us not only functionality of the IFE target to suppress initial perturbations but also an efficient yield of IFE because they consist of low  $Z$  atoms. Experiments [127, 128] showed a uniform laser ablation in a polystyrene film coated with a photovoltaic perylene/phthalocyanine [129] bilayer when an incident took place at an intensity range of  $10^9$ – $10^{10} \text{ W/cm}^2$  ( $\lambda = 1064 \text{ nm}$ ) as shown in Figure 17b. Without the bilayer coating, the laser pulse formed spiky structures in the polystyrene film as self-focusing traces of the laser pulse, while for the coated film, the uniform surface ablation trace without the spiky interior structures was observed (Fig. 17a).

Irradiation of High Power Laser

-Amplification of initial perturbation-

**Figure 16.** Pulse shape of high power laser (left) and the perturbation growth of the capsule surface and damage generation in the capsule during laser irradiation.

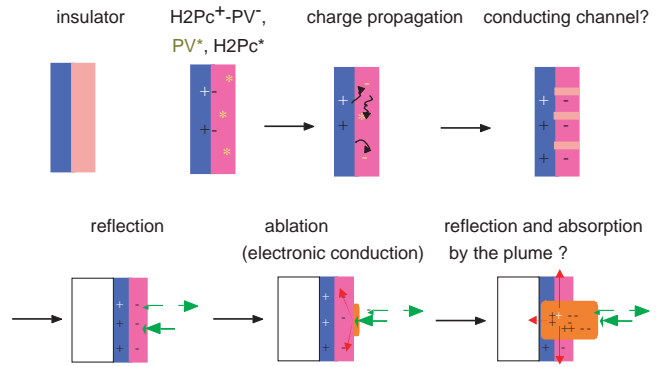

In the case of a laser incidence of 532 nm where the coating material exhibits no reflection, such a difference depending on the coating was not observed [130]. These phenomena were coupled with the reflection and conduction properties via the photovoltaic effect and agreed with the required ablation to reduce the initial damage and to achieve high-density compression of the fuel capsule for inertial fusion energy. The property indicates a functionality of organic materials, where a possible scenario is presented in Figure 18.

3.3. Magnetic Materials

The next step of direct driven implosion experiments demands high symmetrical irradiation for which a nonsupported pellet is useful. Sakagami et al. reported the first description concerned with fundamental studies of magnetic suspension of a target: how one can coat the ferromagnetic thin film over the pellet, how a magnetically suspended pellet behaves in low temperature, and how the optical forces damp unexpected horizontal oscillation of them [131]. Yoshida et al. designed and tested a magnetic suspension system (“MINO” series) to suspend a Ni coated plastic capsule without mechanical contact [132]. MINO-2 is composed

**Figure 17.** Laser ablation trace of polystyrene film (4 μm thickness); 1060 nm input beam in a 1.1 ns (full width half maximum) pulse with a 1/e<sup>2</sup> beam diameter of 750 μm.

**Figure 18.** Mechanism of uniform laser ablation utilizing organic photovoltaic materials.

of four compact units: the gas puff unit to detach a Ni coated capsule into the detective area, the capsule detection unit within 5 μm accuracy, the pellet control unit to achieve less than 5 μm vertical vibration amplitude, and the pellet suspension unit not to obstruct laser irradiation using a small solid angle electromagnet (Fig. 19). Recently they succeeded in suspension of Ni coated capsules in a hohlraum.

In the fusion reactor chamber, the irradiation frequency is ~4 Hz, which requires an injection system for capsule delivery to the reactor center. Survival of the cryogenic target during acceleration and during its transit across the high-temperature target chamber is also an issue. A combination of thermal analyses, modeling, materials property measurements, and demonstration tests with representative injection equipment is being employed to demonstrate IFE plant fueling [133].

A prototype of the facility for a reactor target repetitive production and injection with the rate of 1–6 Hz has been designed by Osipov et al. [134]. The most important elements of the design are the unit for the protective sabot-and-target cryogenic assembly, and the double-stage accelerator combining the coil gun for target preacceleration and the gas gun for target final acceleration up to 200 m/sec. This approach contributes to a considerable reduction of the dimensions of the injector, increasing the reproducibility of the injection velocity as well as increasing the reliability of the device operation without mechanical and heat target damage.

**Figure 19.** Schematic diagram of magnetic suspension system for laser fusion target “MINO-2,” where a nickel coated polystyrene capsule was magnetically centered within 5 μm accuracy.

**Figure 20.** Magnetic hysteresis of the hardest molecular based magnet of MnEtOPP/TCNE at 2 K and its chemical structure.

For both capsule levitation and injection, coating of magnetic material is a promising technique. Actually, in the MINO system, conventional metals have been used as magnetic material. A light atom magnet is preferable as a coating material for the same reason that one avoids X-ray generation. Fourteen years ago, two organic magnets were discovered of which one exhibits very low critical temperature ( $T_c$ ) with well-characterized spin source and the other with high  $T_c$  with unknown organic spin source. The field has been investigated as molecular-based magnet, which unfortunately has not provided high  $T_c$  with a well-characterized spin source. The IFE target with solid DT is used at cryogenic temperature; therefore a molecular-based magnet with low  $T_c$  is applicable as a magnetic material for levitation. For example, manganese(tetraethoxyphenylporphyrin)/tetracyanoethylene (MnEtOPP/TCNE,  $\text{C}_{58}\text{H}_{44}\text{MnN}_8\text{O}_4$ , Fig. 20) and its derivatives contains about 1% metal ion, but it has an extremely high coercive force (20,000 Oe) [135].

#### 4. SUMMARY

We have summarized the present status of the research field of laser fusion target fabrication, especially capsule fabrication, low-density foam fabrication, cryogenic hydrogen layering, and related materials. The present field will be developed with further investigation of material chemistry, cryogenic technology, and nanotechnology. In addition to these improvement, the demands from laser plasma physics and fusion reactor technologies are also important and will contribute to the present field.

#### GLOSSARY

**Cryogenic target** A target with hollow, spherical solid density fuel is called as the cryogenic target and known to be more efficiently imploded than a target with a gaseous fuel with the same mass because of its higher initial density and lower isentrope in the compression process.

**Inertial fusion energy (IFE)** A future energy source to generate electric power. Fuel (typically deuterium and tritium) is instantaneously heated to a high-temperature and high-density plasma by laser or heavy ion beams to complete nuclear reactions before it expands.

**Laser fusion target** Used to feed fuel to the burning position of the IFE power plant. The typical target is a plastic capsule filled with hollow, solid deuterium-tritium fuel. The design and fabrication of the target is one of the key technologies of the Laser Fusion Energy.

**Ultralow density foam** A key material of the fusion targets. The usage of the foam includes supporting the liquid deuterium-tritium fuel, protective coating on the target against thermal radiation in the reactor and supporting the fuel capsule in a cavity target. Foams whose electron density is less than  $10^{20}/\text{cc}$  is especially called ultralow density foam and laser light can deeply penetrate into the foam plasma.

## 1. LASER INDUCED SURFACE NANOSTRUCTURING

Laser processing has a wide range of industrial applications from macroprocessing-like welding to ultraprecision machining using laser lithography technologies. Laser induced surface nanostructuring is a type of ultraprecision machining and deals with the surface phenomenon whose size is on the order of laser wavelength, that is, from hundreds of nanometers to 10  $\mu\text{m}$ . Laser induced surface nanostructuring is being actively studied in the United States, Europe, and Japan. In this chapter, the authors systematically explain in detail their interesting reports.

In the past 37 years, the surface structuring of various materials from a micrometer to nanometer size that is induced by laser irradiation has been observed. Most of the primary research was done by Birnbaum [1], who studied the ruby laser irradiated damage of a semiconductor and observed the damage morphology. The parallel straight line pattern was then discovered and therefore the research was likely the initial one for surface structuring by a laser.

The target materials dealt with until now were metals (Al alloy, brass,  $\text{Ni}_x\text{P}_{1-x}$ , iron, etc.) [2–8], semiconductors (Si, Ge, GaAs, etc.) [1, 3, 9–13], polymers [14–29], and recently, multilayer materials [30–33], inorganic materials [34–39], superconductor [40], fullerite [41], and diamond crystals and microclusters [42]. The main interest of the researchers was how the structures were formed on the irradiated surface. Some researchers observed laser induced periodic surface structures (LIPSS) on the irradiated material like a silicon single-crystal surface using  $\text{CO}_2$ , Nd:YAG, and excimer lasers. They explained the cause of the formation of the periodic structure focusing on the relationship between the optical characteristics of the laser beam such as the incident wavelength and polarization and the periodic surface ripples with spacing and direction. These structures were formed with the morphology of several hundreds of nanometers to tens of micrometer size.

On the other hand, many investigations of cone and column type micronanostructuring by laser ablation have also been carried out. The target materials used were silicon (Si) [43–51], a polymer (polyimide, etc.) [52–58], oxides ( $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ,  $\text{ZrO}_2$ ) [59–62], nitride ( $\text{Si}_3\text{N}_4$ ) [61], and metal (Co, Ti, W, etc.) [63–70] to examine the microcones and microcolumns. Two lasers such as a KrF (248 nm) excimer laser and a Ti:sapphire (800 nm) laser have been utilized for the laser ablation of the Si substrate, and the influence of the ambient gas species such as  $\text{SF}_6$ ,  $\text{Cl}_2$ , and air was examined. The formation of micro-nano-sized protuberances was considered by many different mechanisms such as the shielding effect of the particulate impurities [53, 54] and the solvent [53, 54, 59, 60], the debris particles [61], capillary waves [43–45], catalyst-free VLS (vapor-liquid-solid) [46–50], etc., depending on the materials.

Finally, a coherent array with hundreds of nm-sized protuberances was discovered by the authors for single crystal tungsten substrates [71–74]. The influence of laser fluence, wavelength, polarization, surface crystal structure, etc., was examined. This study will be discussed later.

In this chapter, the various surface micro–nano-scale structuring processes are described and the phenomena and the formation mechanisms are also discussed. In particular, the authors deal with in detail the effect of the surface modification parameters on both the process and the product by using a pulsed laser ablation technique. This chapter is composed of three interesting topics that include laser induced periodic surface structures, cone and column type surface structuring, and nanometer-sized protuberance coherent array.

## 2. LASER INDUCED PERIODIC SURFACE STRUCTURES

It is well known that laser ablation induces some interesting phenomena on an irradiated surface. For instance, the surface structuring by laser ablation includes the phenomenon of a LIPSS. Some researchers observed a kind of fringe, grating, and ripple pattern on the irradiated material surface. They discussed these phenomena focusing on the relationship between the optical characteristics of the laser beam and periodic surface ripples with spacing and direction. Based on their discussions, the periodic ripples were related to the number of laser shots. The first pulse caused only a rough surface while subsequent pulses created periodic ripples [69]. The ripples depended on the incident wavelength, polarization, and the angle of incidence. The ripple spacing was calculated from Rayleigh's diffraction condition [2, 3, 5, 9–11],

$$\Lambda = \frac{\lambda}{(1 \pm \sin \theta)} \quad (1)$$

where  $\Lambda$  is the ripple spacing,  $\lambda$  is the laser wavelength, and  $\theta$  is the angle of incidence relative to the surface normal.

Some other researchers considered it from the polarization ( $p$ -polarized incident beam) of the incident laser beam [3, 5, 9–11]. In this case, the ripple direction should be perpendicular to the polarization of the normal incident beam and parallel to the plane of the incident beam at  $\theta \geq 45^\circ$  [9]. The ripple spacing of the incident beam at  $\theta \geq 45^\circ$  was calculated from  $\lambda/\cos \theta$  [9]. When the laser beam was circularly polarized, no ripples were observed [10]. In a recent report about inorganic materials irradiated by an ArF excimer laser, the influence of polarization on the patterns was not confirmed. This research was planned to modify the geometric surfaces of the inorganic materials. In the case of a single crystalline  $\text{CaF}_2$ , the structure of the laser-irradiation marking depended on the crystal surface structure [35, 36]. The LIPSS induced on metallic surfaces did not depend on the laser light polarization or wavelength. A more important factor seems to be related to the characteristics of the material and its molten phase rather than those of the laser [7].

### 2.1. Metals and Alloys

When Emmony et al. [2] investigated the damage of a germanium-made mirror by  $\text{CO}_2$  laser irradiation, they discovered a periodic pattern on the mirror surface. One of the explanations for the formation of the pattern was the scattering effect coming from dust or other particles on the mirror surface. Interference between the scattered and cavity radiations might proceed so that interference fringes could occur with a spacing corresponding to the wavelength of the laser. The most interesting feature in the surface damage was the predominantly parallel nature of the damage bars with a spacing calculated from Eq. (1), which might be explained by the interference mechanism. In the two cases of spacing, the scattered radiation has a component of velocity toward or away from the incident laser beam. If the radiation intensity falls rapidly in all directions except along the direction parallel to the surface of the laser electrodes, high radiation intensity will only occur in the interference fringes along this direction.

Isenor [5] irradiated a  $\text{CO}_2$  laser on the surface of  $\text{Ni}_x\text{P}_{1-x}$  used as a mirror material and the periodic ripple pattern was also observed on the irradiated area. In the report, the influence of the polarization and laser intensity and the atmospheric gas species on the surface pattern were investigated in detail. The ripple wave fronts were normal to the electric field and varied in spacing from a laser wavelength at normal incidence to half the laser wavelength for  $\pi$  polarization at grazing incidence. The damage was produced on the  $\text{Ni}_x\text{P}_{1-x}$  surface in a vacuum and Ar and  $\text{N}_2$  atmospheres. However, no distinct ripple pattern was observed under these conditions. In air,  $\text{O}_2$ , or  $\text{CO}_2$ , the ripple pattern was observed so that an oxygen atmosphere may be needed for the pattern formation. The following formation mechanism was also suggested. The combination of the incident, reflected, and diffracted waves could produce a complicated electric field distribution that would drive the localized plasma oscillations, which would give a locally stronger heating which would result in a greater erosion of the surface in the “valleys” of the ripple pattern.

Fuh has successfully obtained laser-induced ripple patterns on various ferric metal surfaces by using a  $Q$ -switched Nd:YAG laser [6]. Changes of the local magnetic properties associated with the rippled areas were then investigated to determine a possible reading method. All these observations are consistent with the theory of Young et al. [9] for ripple formation. Significant magnetic changes associated with a steel/chromium formation of the ripples were found on a steel substrate precoated with a layer of chromium. This technique can be used as the basis of a machine-readable laser marking system on steel surfaces, or even other surfaces that could be film coated.

For the iron with point defects, a point defect scattering center produced patterns consisting of confocal circles while a linear scatter induced fringes parallel to the linear scratches. The spacing is determined by Eq. (1). The initial surface state underwent a succession of melting and solidification by rapid quenching [7]. It could not be simply explained by the interference of light on a nonpolished iron surface and the spacing was also different. The authors take account of hydrodynamic sputtering for the formation. Non-homogeneities (asperities) were sometimes formed on the

surface of the target during the laser irradiation. It might come from an additional expansion of the asperities relative to the molten surface. Since cooling took place at the bottom of the liquid target, there was a tendency for the asperities to move away from the target. The formation of a particle (droplet) is related to the surface tension of the liquid phase. It decreased with temperature and the liquid tended to be pulled away from the hotter region to the cooler one. This process resulted in a broadening of the valleys and a narrowing of the hills. The crucial parameter for the surface patterning of iron was surface temperature and there was no simple relation to the wavelength of the incident beam. Moreover, as the beam was polarized differently for the two studied wavelengths, the theories based on beam polarization should also be neglected. The more important factors seemed to be the characteristics of the material and its molten bath rather than those of the laser. The given temperature range, higher than the melting point but lower than the ablation threshold and in which the ejection–re-deposition of the droplet occurred, was necessary for obtaining the steady state rippled surface patterning, whenever the initial state of the surface was observed.

Yu and Lu report an alternative LIPSS that was produced on Ni–P disks under low fluence near the melting threshold of Ni–P. The ripple structures induced in Ni–P disks by 248 nm excimer laser pulses are experimentally investigated by varying laser fluence (175–270 mJ/cm<sup>2</sup> for 150 pulses) and pulse number (400–1000 pulses for 118 mJ/cm<sup>2</sup>) [8]. A quantity of  $R_a/(\Lambda/2)$  was proposed to characterize as the real contact area at the head–disk interface. This quantity was defined as the ratio of roughness height  $R_a$  to half ripple period ( $\Lambda/2$ ). The maximum shear stress and the plasticity index were derived to analyze the ability of ripple structures to withstand stress and the head-ripple contact mode, respectively. Increasing fluence and pulse number may lead to an increase in ripple periodicity and, on the contrary, decreases in corresponding maximum shear stress, real contact area [ $R_a/(\Lambda/2)$ ], and plasticity index. The control of the laser parameters (fluence and pulse number) is an effective way to improve the tribology of the head–disk interface through the laser-induced ripple pattern such as periodicity and roughness height. The laser irradiation with lower fluence and fewer pulses is helpful in order to introduce required ripple structures in magnetic media. This structure could meet the requirements of elastic contacts between head and disk, and less deformation under stress, although with a slight sacrifice in contact-area reduction.

## 2.2. Semiconductors

The periodic structure was observed on the edge of the laser-annealed spots on the ion-implanted silicon [10]. The direction of the periodic fringes was always found to be perpendicular to the electric vector of the light for linearly polarized beams. No fringe pattern was observed for the circular polarization. They suggested that the observed pattern was due to heating by a standing wave resulting from the interference of the impinging wave and a radial scattered wave.

The ripple structure was observed on Si and gallium arsenide (GaAs) after picosecond laser irradiation [11]. The ripple spacing was considered to depend on Eq. (1) for the *p*-polarized waves and  $\lambda$  for the *s*-polarized waves. When the laser beam was circularly polarized, ripples could not be observed. Large and small spacings sometimes coexisted in the same region. This phenomenon seemed to disagree with the defect-scattering theory used by Emmony et al. They suggested that these surface ripples developed as the result of an exponentially growing interaction between the incident laser wave front and a scattered surface optical wave. For GaAs, the arsenic was locally evaporated and redeposited at the peaks of the ripples so that a pitlike structure was formed.

In the  $\langle 111 \rangle$  single crystalline germanium, the surface structure was a hexagonal system coming from the similar underlying symmetry of the  $\langle 111 \rangle$  surface of germanium [12]. When the incident beam irradiated the surface at an oblique incident beam, the observed high-order grating patterns became quite complex, but the observed patterns generally reflected over rectangular rather than hexagonal surface symmetry. Here, LIPSS was discussed as the formation mechanism relating to the spacing and direction of the ripple determined by the wavelength and incidence angle of the laser light. Moreover, LIPSS was discussed related to the number of laser pulses of the laser irradiation and the first pulse produced a surface roughness. That is, the spacing for the new ripples could be interpreted from the reinforcement of the initially incident weak and straggling surface disturbances caused by the interference between the incidence beam and successively scattered waves [13].

## 2.3. Polymers

Tonyali et al. examined the response of highly stressed polyimide films to excimer laser radiation (20 ns pulses at 248 nm wavelength) in a vacuum [14]. They reported changes in surface topography due to surface/near-surface damage, crack initiation, and eventually crack growth over a wide range of applied stress. The morphology of the stressed material had a significant influence on the resulting damage and suggested that the regions of highest damage were those experiencing the highest local stress.

When the laser with a wavelength of the absorption edge was irradiated on a polymer with a high glass transition temperature, a microstructure with a periodicity of about 1  $\mu\text{m}$  was formed. In this case, the XeCl laser was irradiated on polyethersulfone [15]. The optimization of the laser fluence and polarization of the laser could lead to the anisotropy and periodicity of the patterns [16]. For example, although the microstructure of the random fingerprint-like pattern was obtained by irradiation of the nonpolarized laser beam, the anisotropy of the microstructure gradually increased if the degree of polarization was increased. The grating pattern was observed for the irradiation of the plane polarized beam. Moreover, the periodicity increased as the laser intensity increased. The periodicity was 1  $\mu\text{m}$ , three times larger than the laser wavelength, and there was no effect by the interference of the incidence beams. Therefore, the thermal processes of the surface during and after the

laser radiation play a significant role in the formation of the microstructures.

Dyer and Farley reported that periodic surface structures were observed on organic polymers that were photoablated using low coherence excimer lasers [17]. Both unpolarized and linearly polarized radiation at 248 and 308 nm produced well ordered, micrometer-scale structures over dimensions greatly exceeding the coherence area of the laser at the surface. The formation of such structures was understood through effects by surface scattered wave effects.

Periodic line structures with a period of 167 nm and linewidths varying from 35 to 100 nm were produced on polyimide by direct ablation with a KrF laser using an interferometric technique [18]. Since ablation is a nonlinear process, the resolution can exceed that expected from the wavelength and numerical aperture of the system; the linewidth can be controlled by varying the laser fluence. This externally generated period of 167 nm prevents the spontaneous growth of periodic surface structures due to radiation remnants.

Bolle and Lazare contributed many papers on laser nanostructuring of polymers [19–21]. A controlled submicrometer-level rough surfaces is desired in many applications. For the first time, pure LIPSS (without any ablation or any larger structure) of submicrometer size (spacing and amplitude of 0.2  $\mu\text{m}$ ) was developed on polymer surfaces (polyethylene terephthalate, polybutylene terephthalate, polystyrene, polycarbonate, etc.) by irradiation with 1000 pulses of the polarized beam of an ArF (193 nm) and KrF (248 nm) excimer laser [19, 20]. Fluence should be below the ablation threshold of polymers and chosen in a narrow window that depends on the polymer and the wavelength. Structures were obtained also by irradiation of thin films (200 nm) coated on silicon wafers. The mechanism of ripple formation is related to the surface wave. Owing to the simplicity of this irradiation procedure large-scale surface treatments could be done. Surface properties such as friction, adhesion, and so on could be very much improved.

Periodic ripples and dot patterns with spacing smaller than 200 nm were produced on various highly absorbent polymers (polyethylene terephthalate, polybutylene terephthalate, polystyrene, polycarbonate, etc.) using a polarized beam of an ArF and KrF excimer laser [21]. The period of the structures increases with the wavelength used and with the angle of incidence of the beam, whereas the ripple direction was parallel to the polarization direction. The fluence interval in which the pattern could be produced was far below the ablation threshold of the polymer but probably allowed local melting or photolysis of the surface. For polystyrene, a strong influence of the presence of oxygen was observed, which led to the conclusion that photo-oxidative processes played a major role in the structure growing mechanisms.

Periodic structures of sub-half-micrometer size were produced on the surface of different polymers [polyethylene terephthalate, polyimide-type Kapton (DuPont), and polyimide-type XU 293 (Ciba-Geigy)] by Nd:YAG laser irradiation at 266 nm wavelength [22]. A phenomenological explanation for the ripple formation in terms of generating waveguide modes on the polymer surface was proposed.

A branched dendritic surface structure on polyethylene terephthalate (PET) could be observed after 248 nm KrF laser irradiation in a vacuum [23, 24]. These structures consisted of independent objects with lateral dimensions of several micrometers and a substructure starting at a certain center. These structures were henceforth denoted as surface dendrites. They were upheaving above the surface by about 5–30 nm and extended into the surface by about the same amount. The formation of these dendrites was most pronounced for single-pulse irradiation and fluences around the ablation threshold (for PET about 40  $\text{mJ}/\text{cm}^2$  at 248 nm). The dendrites are probably polymeric crystallites, which grew within the amorphous surface layer formed by laser irradiation of the semicrystalline polymer foil. The crystalline dendrites were formed through the process of melting and solidification. The lateral growth rate of dendrites was of the order of 100 nm/h.

Periodic surface structures generated by linearly polarized ArF excimer laser (193 nm) were studied on PET, in a narrow fluence region (3–5  $\text{mJ}/\text{cm}^2$ ) [25]. A homemade kinematic base plate ensured the reproducible positioning of the sample with respect to the atomic force microscope (AFM) and the laser beam. The main subsequent phases of the LIPSS formation were identified as laser light scattering on the originally existing granules, formation of elliptical structures around the granules, and the transformation of ellipses into ripple-shape modulation. The LIPSS generating feedback mechanism was described: the incident beam and the beams scattered on the granules and already existing LIPSS interfere causing spatially modulated melting and crystallization, which developed the structure. The dependence of the LIPSS period on the wavelength and on the angle of incidence was studied. The structure's height and surface-roughness vs the number of laser shots was measured. The experimental results were in good agreement with the theory of self-organized diffraction gratings. It was proved experimentally that the LIPSSs were formed by redistribution of the material on the surface, without significant material removal.

Some applications of polymer films required microstructuring of partly uneven substrates. This could not be achieved by conventional photolithography, casually performed with ultraviolet short-pulse lasers (excimer, fourth harmonic Nd:YAG) [26, 27]. When processing is thermally sensitive or polymers were undoped ones with low optical absorption, the precision of ablation could be improved by using femtosecond laser pulses and the heat-affected zone would be reduced. Then, a Ti:sapphire laser system was employed to perform ablation experiments on polyimide. Highly oriented ripple structures, which were related to the polarization state of the laser pulses, were observed in the cavities. The relationship between the ablation threshold fluence and the number of laser pulses shot to the same spot was described in accordance with an incubation model.

The dichroism of the laser-induced periodic microstructure on a polyimide surface was studied with polarized reflectance infrared spectroscopy. The experimental results showed that the polar C=O groups in the polyimide exhibit a greater tendency of orienting in the direction parallel to the microlines while the nonpolar C–C–C linkages between

the two benzene rings in the diamine moiety tended to orient in a direction perpendicular to the nanolines [28]. This result indicates that the polyimide molecule chains tend to orient in a direction perpendicular to the nanolines.

Surface modification on a polyimide film by pulsed ultraviolet (UV) laser irradiation with a fluence below its ablation threshold was examined [29]. It was observed that a photochemical reaction occurred and hydrophilic groups, such as -OH and -COOH, were formed on the polyimide surface after irradiation. A ripple microstructure was formed on the surface when the angle of incidence of the laser beam was 20–50°. The contact angle of the polyimide surface with water decreased and the adsorption ability of the surface to a water-soluble dye clearly increased after laser irradiation.

## 2.4. Multilayer Materials

An analytical model was proposed in order to predict the LIPSS formation on silicon dioxide/silicon and silicon dioxide/aluminum interfaces [30]. The freezing of surface waves was considered to understand the dominant mechanism for ripple formation. The model precisely predicts a linear relationship between the interface periodicity and the silicon dioxide thickness. The ripple periodicity in the substrates could hence be adjusted by varying the thickness of the SiO<sub>2</sub> overlayer. This process was expected to be useful in laser microtexturing for magnetic media of high storage density, which requires microtextures to be well controlled within a certain roughness to prevent stiction failure. The theoretical calculation had good agreement with the experimental results.

The LIPSSs by excimer laser at the interfaces of silicon dioxide/silicon have been investigated experimentally [31]. It was found that a stable, fine, and homogeneous ripple structure was preferentially generated under a comparatively larger laser beam. The ripple periodicity seemed to have no angular dependence and was enhanced with increased laser pulses for the first few pulses. The initial substrate temperature also represented an important parameter that could be used to control the interface ripple structures. The threshold pulse number for the ripple formation at different laser fluences, or at different oxide thicknesses was studied as well. This study will be helpful to understand the physics of laser-induced ripple formation and hence be useful in controlling ripple structures within the range required for the laser texturing of high density magnetic recording media.

Rapid thermal processing was reported to be capable of improving film properties [32]. In this study, the effects of rapid thermal annealing (RTA) on rapid-thermal-annealed radio-frequency-sputtered silicon oxide films and hence on LIPSS by excimer laser at the silicon dioxide/silicon interface were investigated. It was found that the RTA of the oxide film done by increasing either annealing temperature or annealing time could enhance the ripple growth but did not change the topography of the ripple structure. The ellipsometric measurements indicated that the optical constants of the film, and hence the calculated film density, increased with an increment of annealing temperature or annealing time. The increase in film density is balanced by the decrease in the corresponding film thickness. An analytical model by

Yu and Lu predicted that the increase in ripple period was a result of enhanced energy absorption caused by the decrease in equivalent reflectivity of SiO<sub>2</sub>/Si after RTA. The calculation was identified to be consistent with the experiment.

The periodicity of the ripple for a material like a multilayer film with SiO<sub>2</sub>/polysilicon/SiO<sub>2</sub>/single crystal silicon by XeCl excimer laser (wavelength: 308 nm, pulse duration: 35 ns, repetition rate: 5 Hz, pulse number: 10 pulses, fluence: 340 mJ/cm<sup>2</sup>) irradiation could not be explained using Rayleigh's diffraction condition. The ripple wave fronts were chaotic patterns rather than parallel lines [33]. The ripple wave fronts were controllable by changing the polysilicon surface topology. Moreover, since molten silicon would not be wet a SiO<sub>2</sub> surface, these ripples likely formed in order to release stress in the polysilicon film upon solidification.

## 2.5. Inorganic Materials

Ihlemann et al. reported on the ablation of fused silica using several excimer lasers (20–30 ns pulse duration at 193, 248, and 308 nm) and a short pulse laser system (500 fs at 248 nm) [34]. Ablation rates ranged from several hundred nm/pulse (193 nm or fs-laser) up to about 6 μm/pulse (308 nm). The performance of the ablation not only depended on wavelength and pulse duration but also on the existing surface condition or laser induced surface quality (e.g., roughness) of the material. Special ablation phenomena were observed there. That is, at 193 nm and moderate fluence (3 J/cm<sup>2</sup>) ablation took place at the rear side of a plate without affecting the front side, whereas at higher fluence normal ablation at the front side occurs. At 248 nm (28 ns pulse duration) the existence of two consecutive ablation phases was observed: smooth ablation at a low rate was followed by explosive ablation at high rate. The smooth shaped holes using fs-pulse lasers were formed during the first pulses, whereas high pulse numbers caused the development of a ripple structure in the ablation craters. So two different ablation mechanisms were involved. The first was based on two photon bulk absorption while the second was based on controlled surface damage in relation to (partially laser induced) singularity conditions at the surface.

When microstriae were formed by ArF excimer laser irradiation on inorganic materials such as synthetic silica glass, soda-lime glass, quartz, corundum, and calcium fluoride, the relationship between the microstriae and polarization of the laser beam was not confirmed [35, 36]. The direction of the microstriae depended on the incidence angle of laser. As the incident angle approached 90°, the directivity of the microstriae became strong and the striae line became longer. Polarization did not affect the directivity of the microstriae. The microstriae were also formed on quartz as well as on silica glass. Since soda-lime glass had the high absorption coefficient, almost all of the laser beams were absorbed and removed near the surface so that the surface became smooth. When corundum and calcium fluoride surfaces were irradiated and removed, the cleavage fracture occurred with preference to the crystal direction having a weak binding energy.

Regular structures on Al<sub>2</sub>O<sub>3</sub> surfaces were observed on the bottom of the ablation pit after Ti:sapphire laser (wavelength: 800 nm, pulse duration: 120–300 fs, repetition rate: 1 kHz) ablation by linearly polarized laser pulses [37]. These

structures did not comply with conventional ripple patterns. Instead, they more nearly resemble wickerwork and were aligned perpendicular to the laser beam polarization. They observed parallel chains, 1–2  $\mu\text{m}$  long and about 250 nm wide, both on the bottom and on the edge of the pit. Neither the general structure nor the spacing of about  $3/\lambda$  changed with the angle of incident, the pulse duration, the fluence, or the number of pulses. A similar morphology was obtained by arc discharge erosion at AgCdO electrodes, suggesting that explosive laser ablation might be characterized by high electric field effects and self-organization in the ablation craters.

Laser processing of sapphire using a Ti:sapphire laser at 790 and 395 nm and pulse widths varying between 200 fs and 5 ps was reported [38]. A clear improvement in quality was demonstrated for multishot processing with sub-ps laser pulses. For fluences between 3 and 12  $\text{J}/\text{cm}^2$  two ablation phases were observed, which was in agreement with previous work from Tam et al. using 30 ps, 266 nm laser pulses [39]. During the “gentle ablation” phase, periodic wavelike structures like ripples were observed on the  $\text{Al}_2\text{O}_3$  surface. The structures were perpendicular to the laser polarization and their spacing was almost equal to the laser wavelength, indicating metallic-like behavior of sapphire in a thin surface region due to the long lifetime of free electrons in the conduction band. The ripple modulation depth was on the order of a few tens of nm. For fluences between 1 and 2.5  $\text{J}/\text{cm}^2$ , below the single-shot surface damage threshold and at a pulse width above 200 fs, microstructures could be produced at the rear side of a 1 mm thick sapphire substrate without affecting the front surface.

## 2.6. Others

For the  $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$  (BSCCO) superconductor [40], the hexagonal microstructure, with the diagonal of each hexagon being about 0.7–0.9  $\mu\text{m}$  and 10 nm heights, was formed. However, the formation mechanism had not been clarified. According to the theory of a two-dimensional phase transition, a single crystal should melt into a so-called intermediate “hexatic” phase. The experimental results of the charged colloidal particles formed under a two-dimensional plasma system supported the idea of hexagonal structure formation during melting [75–77]. It is well known that the plasma formed during laser ablation and the surface molten layer have little interaction with the solid surface. Therefore, the theory of two-dimensional phase transition might be able to be applied to this case. These structures were formed during the solidification process of the laser induced thin liquid layer of BSCCO. Moreover, a crack of 0.1  $\mu\text{m}$  depth by 5 laser pulses ran in accordance with the *a*-axis and *b*-axis. The crack might be formed by the thermal stress induced on the surface of the target. When the number of laser irradiation pulses increased to 50, the crack became 2  $\mu\text{m}$  in depth. Furthermore, it had a pyramid-type projection of 3  $\mu\text{m}$  height by increasing the number of laser shots up to 1200 pulses. Consequently, it was based on the influence of the surface structure.

For the fullerite surface [41], the sharp regular pattern of ripples was observed on the circumference of the laser spot. In the process of ablating the surface area in the laser

spot, a wavelike morphology was created. Also, a crater in the rough surface became clearer and it became sharper as the number of laser pulses increased. The sharp ripple could be reproduced and it was observed that the ripple spacing depended on the incidence angle. The spacing by  $\lambda/\cos\theta$  was realized from the 20° incident angle. This is based on interference of the incident field with a surface scattered field. The surface field can be generated by electronic excitations or defects already present or created by the laser irradiation. If there is anything like a scratch, the spacing of a fringe from interference is given by Eq. (1). The morphology of the periodic nanostructures can be controlled by the laser conditions such as laser fluence, angle of incidence, and wavelength. On the other hand, the laser pulses of a 266 nm wavelength produced patterns similar to those observed under analogous conditions in polymers. Thermal effects were responsible for the formation of bubblelike structures and the annealing of the surfaces.

On the diamond surface [42], ripple grooves were formed perpendicular to the direction of the electric field. The spacing of the ripple was on the order of the wavelength, which was in agreement with the previous report relating to interference. However, a ripple with the small spacing of 50–100 nm was also formed besides the spacing with the wavelength order. The formation of the secondary spacing could be attributed to the out-of-phase superposition of the electromagnetic fields due to the laser pulses. It was hypothesized that the scattered wave was not only produced by the interference but also by a thin waveguide etched on the surface. When the unpolished surface was irradiated, two surface ripple trains crossed each other on the side of a crystal wall and a crosshatch pattern was created. The spacing of the ripples was not in agreement with the value calculated from Eq. (1). The consistent periodicity ( $\lambda/2$ ) observed on all the clusters nucleated along the ablation path indicated that the formation of circular corrugations on these clusters might not be due to random stacking faults, which occurred during the growth process. The periodicity of these ripples was significantly influenced by the surface roughness and morphology of the surface. On an extremely smooth surface of a single crystal and a diamond surface, an interaction was produced only between the incidence wave and the wave reflected from the surface. However, for a surface with polycrystalline grains (i.e., for pyramids with smooth facets, an unpolished diamond surface, or spherical random features on a laser-processed diamond), the interaction among the incident wave, the scattered one, and backscattered ones became more complex.

Many investigations of LIPSS have been carried out on various materials. In almost all cases, the formation of a periodic structure was taken into account from the standpoint of the laser beam characteristics. That is, the relationship between the optical characteristics of the laser beam, such as the incident wavelength and polarization, and the periodic surface ripples with spacing and direction was discussed. Some parameters characteristic of the material, the crystal structure of the material, and surface roughness were also considered to be very important since researchers think that such parameters are key factors.

### 3. CONE/COLUMN TYPE SURFACE STRUCTURING

The laser ablation method has attracted much attention with respect to the surface patterns induced by laser irradiation as mentioned in the previous session. Besides the surface patterns, microcones and microcolumns induced by laser ablation have been studied. Many target materials have been used in order to clarify this formation mechanism. They include semiconductors (Si, Ge) [45–51, 64], oxides ( $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ ,  $\text{ZrO}_2$ ,  $\text{Al}_2\text{O}_3\text{-TiC}$ ) [59–62], a nitride ( $\text{Si}_3\text{N}_4$ ) [61], a polymer (polyimide, etc.) [52–58], metals (Co, Ti, W, etc.) [63–68], and alloys [69, 70]. The lasers used were an excimer laser, a Nd:YAG laser, and a Cu vapor laser to form the microcone and column. Nowadays, even a femtosecond laser (Ti:sapphire) is used. This research field will be more actively studied from year to year.

#### 3.1. Semiconductors

The KrF (248 nm) excimer laser and a Ti:sapphire (800 nm) laser were mainly used for the Si substrate ablation. Since the column formation was related to the ambient gas species, the influence of the ambient gas species such as  $\text{SF}_6$ ,  $\text{Cl}_2$ , and air was also examined. The microcones could not be produced in an inert (Ar) gas atmosphere and did not have sharp conical spikes in a vacuum [51]. Therefore, it was concluded that their growth was driven by the chemical reaction with the chemical gases.

Sánchez et al. [43–45] reported the growth of whisker-like columnar structures on (100) silicon targets in air by ArF excimer laser (193 nm, 23 ns) irradiation. Microcolumns were not formed with preferential etching of the surrounding materials. The obtained results showed the dynamics of the hydrodynamical growth leading to the formation of the columns. These columns were typically 1–2  $\mu\text{m}$  in diameter and never below 1  $\mu\text{m}$  and presented a dispersion in height. Some of them were as high as 20–30  $\mu\text{m}$  in a 0.3- $\mu\text{m}$ -deep crater. In this case, the dependence of the evaporation was slight. The growth process of the columns was as follows. At first, small micrometer-sized depressions (Fig. 1a) on the flat surface appeared after more than 100 laser pulse shots. With more shots, the formed depressions increased in area (Fig. 1b) but did not develop so significantly in depth. Simultaneously, other depressions appeared and the result was the constriction of the nondepressed area and the formation of an elevated reticular network with a mesh size of some micrometers (Fig. 1c). The original surface was no longer identifiable and a quite flat new one appeared in the inner part of the polygons defined by the network (Fig. 1c). With additional pulses, the material of the network tended to have fewer branches and accumulated at nodes. As a consequence of this process, the branches became slim and broke, and isolated hillocks were formed (Fig. 1d). As the laser irradiation continued, the base material crawled up to the top of the hillocks along the hillock surface so that the structure became columnar (Fig. 1e). This process gradually advanced and the initial conical shape evolved into a cylindrical one after more pulses (Fig. 1f). Tall columns resulted with diameters between 1 and 2  $\mu\text{m}$ , whose height could increase as high as 15  $\mu\text{m}$  in 100 pulses. The movement of

**Figure 1.** 45° SEM views of Si microcolumns obtained after irradiation at the laser fluence of 2 J/cm<sup>2</sup> from the initial depressions (a) to the final columns (f) [note that magnification of (f) is higher]. silicon atoms in the radial direction was presumably promoted due to the thermocapillarity as a consequence of differences in temperature and then in surface tension. Liquid silicon has a higher density (2.52 g/cm<sup>3</sup>) than solid silicon (2.32 g/cm<sup>3</sup>) so that the liquid will go up as the solid–liquid interface advances during solidification (the volume of the solidified layer is greater than that of the liquid phase and the volume expansion of the solidified liquid at the top layer occurs in a short time).

Pedraza et al. [46–50] researched most actively in this field and proposed that microcolumn growth occurred through a combination of the tip melting of the columns by pulsed-laser shots and the condensation of silicon from the silicon-rich vapor produced by ablation of the foot area of the columns. This growth process is conceptually similar to the VLS method used to grow silicon whiskers so that they called it the “catalyst-free” VLS mechanism. The impurities related to any growth mechanism through surface tension effects [78] or thermal expansion of the liquid [79] might affect their morphology with the tip becoming thinner. However, the experimental results showed that the columns did not become thinner as their length became longer. Moreover, the cumulated thermal expansion model [79] is not applicable here because the microcolumn formation and growth strongly depended on the ambient atmosphere. It strongly suggests that growth advanced due to the condensation of small atom clusters and/or molecular reactions at the tips of individual columns. The fact that an oxygen atmosphere promoted column growth indicates that chemical reactions and/or oxidized species exist at the growing

tip. The column growth did not occur in an argon atmosphere or vacuum. Figure 2 shows the conical arrays of the walled silicon structure produced in 1 atm of  $\text{SF}_6$  by KrF excimer laser irradiation with 2040 pulses and the fluence of  $1.5 \text{ J/cm}^2$ . In an oxygen atmosphere, silicon microcolumns are produced as in Figure 1f. However, extremely long structures are produced in  $\text{SF}_6$ , and at first, they look like walls surrounding very deep central holes. The conical arrays formed in  $\text{SF}_6$  were more complex. They showed a kind of melted droplet-shaped morphology not only at the tips of the cones and walls but also on their sides. The axis of a column remained the same as the axis of a solid and a column grew upward along with the flow of gas, not along the liquid between columns. The top of a column was higher than the original surface. Since the tip of a microcorn is exposed to the high-density plasma generated by laser ablation, it may be etched so that the growth might be suppressed. The maximum height of a corn decreased with the increase in atmospheric pressure. From a heat balance equation, solidification of the molten silicon occurred before the melted Si moved to a tip site (time is too short) so that it deposited again with gas and made the column grow. Column formation was done with the ablation plasma induced from the pulse laser irradiation.

Her et al. produced an array of sharp conical spike microcones using a femtosecond laser [51]. The influence of the ambient gas on the shape of the spikes indicates that the chemical reaction between  $\text{SF}_6$  or  $\text{Cl}_2$  and silicon contributes to the formation of the spike shapes. The sharp spikes did

**Figure 2.** Walled Si structure produced by 2040 laser pulses at  $1.5 \text{ J/cm}^2$  in 1 atm of  $\text{SF}_6$ . Reprinted with permission from [46], A. J. Pedraza et al., *Appl. Phys. Lett.* 74, 2322 (1999). © 1999, American Institute of Physics.

not form in a vacuum,  $\text{N}_2$ , or He so that the chemical reaction was considered to be very important.

### 3.2. Polymers

Many studies of the photochemical processing of polymer films using excimer lasers have been reported. The direct etching of polyethylene terephthalate film using a XeCl laser was investigated and was shown to be consistent with a thermal model for degradation. Microstructure revealed by deep etching suggests that the UV laser might prove useful for studying polymeric materials. Polyimide and photoresist film was also directly etched [52]. Dyer et al. [53, 54] discovered polyimide cones using excimer laser ablation (Fig. 3). The cones were produced by the shielding effect of the seeding particles. Therefore, the cone density of the area was changed by the size of the seeding particles. In this case, the areal cone density and cone full angle decreased with increasing laser fluence. The microcones were also produced by the shielding effect of particulate impurities by laser ablation.

The surface of polyethylene terephthalate obtained by irradiation with the 193 nm pulsed radiation of the ArF excimer laser ( $10^7 \text{ W/cm}^2$ ) in air or the 185 nm low-intensity ( $2.5 \text{ mW/cm}^2$ ) radiation of the mercury lamp in a vacuum was studied by Lazare and Srinivasan [55]. The X-ray photoelectron spectroscopy (XPS) analysis revealed that both were depleted in oxygen, but the efficiency of the change was intensely dependent on nonlinear effects at high intensity. The pulsed radiation gave ablative photodecomposition when the energy of the pulse was  $\geq 40 \text{ mJ/cm}^2$ . The radiation area yielded a rough surface that was composed of tiplike structures of submicrometer size. The roughness increased with the accumulation of pulses and the maximum spacing of the roughness reached  $1\text{--}2 \mu\text{m}$  at 10 pulses. The roughness also showed some periodicity. Since the chemical composition of the laser-treated surface dose not vary with the accumulation of pulses, the increase in the advancing contact angle with water was interpreted as depending on roughness. Labeling reactions and XPS were used in order to probe the reactivity of the modified surface. Carboxylic acids, alcohols, and olefins were qualitatively and quantitatively probed. The laser treatment had a superior ability to create new functionalities.

The ablation of PET by ArF laser radiation was studied at different fluences for amorphous and semicrystalline samples [56]. The surface structure created on PET was interpreted as resulting mainly from a difference in the etch rate and not the ablation threshold between amorphous and semicrystalline PET. UV laser etching was proposed as a quick and easy method for observing the crystalline subsurface structure of aromatic semicrystalline polymers, as long as low fluence and a low pulse repetition rate were used. The melting of the PET surface occurred at high fluence ( $\geq 80$  to  $100 \text{ mJ/cm}^2$ ). The ablative photodecomposition process threshold was about  $20 \text{ mJ/cm}^2$ . At higher fluence of  $150 \text{ mJ/cm}^2$ , ripples were observed but looked more like “quenched drops” than those at  $120 \text{ mJ/cm}^2$ . For this structure, Novis et al. suggested that the “hills” corresponded to the more crystalline material and the “valleys” to more

**Figure 3.** XeCl laser etched polyimide (300 shots at  $70 \text{ mJ/cm}^2$ ). SEM images showing (a) unseeded spun-on film, (b) seeding with  $\sim 0.05\text{-}\mu\text{m}$ -diameter particles, and (c) seeding with  $\sim 3\text{-}\mu\text{m}$ -diameter particles. amorphous material. The droplike shape of the top of the hills was easily recognized.

Excimer-laser-induced ablation of polymers was often accompanied by a modification of the surface morphology at the irradiated regions [57]. The models by Novis et al. [56] were proposed for this effect. The origin was sought for in the different reflectivity or absorbance, or a higher energetic stability of crystalline and amorphous material. A study by Bahners and Schollmeyer on synthetic fibers irradiated by

UV laser was conducted to examine that assumption and gave evidence of a thermal contribution to laser–polymer interaction. Furthermore, a strong influence of internal or external stress fields was found. On this basis a synergetic understanding of the surface structures was proposed.

Niino et al. investigated the laser ablation of an elastomer composite with picosecond (ps) and femtosecond (fs) pulsed UV lasers (ps laser:  $\lambda = 263 \text{ nm}$ ,  $\tau = 8 \text{ ps}$ ; fs laser:  $\lambda = 248 \text{ nm}$ ,  $\tau = 500 \text{ fs}$ ) [58]. Upon laser irradiation, a unique microstructure on the surface of the elastomer composite (acrylate polymer) containing carbon black (particle size:  $18\text{--}30 \text{ nm}$ ) was observed. The laser-ablated surfaces were analyzed by scanning electron microscopy (SEM) and XPS. The formation mechanism was discussed in terms of thermal effects induced by the different pulse durations of the lasers. Intrinsic laser ablation without thermal effects was experimentally demonstrated by fs-laser ablation of the composite, where the heat-affected zone on the surface during laser irradiation was negligible. These advantages of fs lasers indicated that it is a very promising technique for various applications in precise material processing.

### 3.3. Oxides and Nitrides

For the  $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$  microcone formation, the yttrium concentration increased at the cone tip during the initial step of the microcone growth; this yttrium-rich shell seemed to suppress the laser vaporization [59, 60], which enabled us to consider an impurity shielding mechanism for the cone formation. Such phase segregation could provide the mechanism for column formation. The top of the columns must be at the level of the initial target surface or below the level.

Miyamoto and Maruo [61] explained that a  $\text{Si}_3\text{N}_4$  microcone formation mechanism was related to the debris particles (Fig. 4). (1) During the first step, debris particles produced by the laser irradiation stuck to the laser irradiated area, then (2) small protuberances were produced by an alternative ablation around the debris particles, (3) the fluences were reduced on the side of the protuberance, and (4) after these processes, the conical protuberance with a high aspect ratio was generated. Therefore, this process mainly occurs due to the etching of the base material and not to the redeposition of base material on the tip. Consequently, the top level of the microcone is below the level of the initial target surface.

For  $\text{Al}_2\text{O}_3\text{--TiC}$  [62], the mechanism comes from the shielding effect. Column growth started with the formation of small globules of solidified TiC. With subsequent laser pulses, the globules coalesced, leading to an increase in the mean globule diameter. This process continued until the surface was completely covered by the globule. At this point, a further increase in the number of pulses lead to the evolution of the globules into a columnar topography.

### 3.4. Metals and Alloys

For metals, two cone formation mechanism models were proposed. One is a kind of growth model. The nucleation of cones is considered to occur only during the stage of initial laser irradiation. Once a surface relief is created, it is accelerated to grow through the appearance of “hot” valleys,

**Figure 4.** Surface appearance of  $\text{Si}_3\text{N}_4$  irradiated by KrF excimer laser. (a)  $1 \text{ J/cm}^2$ , 100 pulses, (b)  $1 \text{ J/cm}^2$ , 1000 pulses, (c)  $3 \text{ J/cm}^2$ , 100 pulses, (d)  $3 \text{ J/cm}^2$ , 1000 pulses, (e)  $4 \text{ J/cm}^2$ , 100 pulses, and (f)  $4 \text{ J/cm}^2$ , 1000 pulses. Reprinted with permission from [61], I. Miyamoto et al., *Proc. SPIE* 1279, 66 (1990). © 1990, International Society for Optical Engineering.

where the electromagnetic energy of the light wave sustains the cone growth. As a result of this effect, the depth of the valleys increases and the cone structure becomes more and more pronounced [63]. The other was developed by Dolgaev et al. [64], who produced the microcone by combination of Si, Ge, and Ti materials and a copper vapor laser. Figure 5 shows the Ge and Ti microcones irradiated in a vacuum. The nuclei were formed by the capillary waves, which induced different reflective areas on the surface. The bottom of the wave was ablated more than the top of the wave so that the evaporation produced a metal vapor, which could deposit on the top of the wave. Cones were then produced with a height of  $20\text{--}30 \mu\text{m}$ . Both mechanisms indicate that microcones grow by the process of evaporation and deposition of metal vapor. In these papers, the densities of the cones and the irregular arrays were not mentioned.

Krebs and Bremert investigated microcones using the pulsed KrF excimer laser ablation with a laser fluence of  $7 \text{ J/cm}^2$  on thin metallic alloys of  $\text{Fe}_{50}\text{Nb}_{50}$  [70]. In the outer part with a lower energy density, microcolumnar structures evolved, which were aligned in the direction of the incident laser beam due to the recrystallization process after laser irradiation, although the laser plume emanated normal to the target surface. Most columns were narrowed in the upper part and covered on top by small droplets, but

**Figure 5.** Conical structures on the surface of a single-crystal Ge (a) and polycrystalline Ti (b). Irradiation in vacuum, laser fluence of  $1 \text{ J/cm}^2$ . Space bar denotes (a)  $20$  and (b)  $40 \mu\text{m}$ . Reprinted with permission from [64], S. I. Dolgaev et al., *Appl. Phys. A* 73, 177 (2001). © 2001, Springer-Verlag.

underneath cracks were visible. They investigated the stoichiometry transfer from the target to deposited films by pulsed laser ablation. However, they did not define the formation mechanism of the microcolumns in detail.

The authors examined the tungsten microcone using Nd:YAG laser ablation [65–68]. Figure 6 shows the SEM micrographs of tungsten microcones obtained after irradiation at the laser fluence of  $2.6 \text{ J/cm}^2$  with 1–2400 pulses. The initial few hundred pulses by the laser produced only a rough surface (Fig. 6a–d) and subsequent pulses created the microcone arrays (Fig. 6e–g). The morphology of the microcone was strongly affected by the number of laser pulses. The irradiation with more than 1200 pulses (Fig. 6f) produced microcones up to a  $20 \mu\text{m}$  height with about a  $1.5 \mu\text{m}$  diameter at the tip. This experimental result showed that the cone's height increased with the number of pulses, so that a multiplicity of pulses was required to get a cone with a

**Figure 6.** 45° SEM views of tungsten microcone obtained after irradiation at the laser fluence of 2.6 J/cm<sup>2</sup> in 4 KPa of He gas: (a) 1, (b) 30, (c) 100, (d) 300, (e) 600, (f) 1200, and (g) 2400 pulses. high aspect ratio. Figure 7 shows the relationship between the density, height of the microcones, and number of laser pulses. The microcone density decreased and height rapidly increased until about 600 pulses. They then gradually began to saturate. The cause of the decrease in the microcones was due to the absorption of the smaller microcones by the larger ones as if they were following a kind of capillary since the smaller ones were more easily melted than the larger ones during the laser irradiation. The authors also examined the effect of laser fluence on the morphology of the microcone arrays. Microcones were also formed with about a 10 μm height when the irradiation was done at the lower laser fluence of 1.5 J/cm<sup>2</sup> after 2400 pulses. Therefore, the microcone growth rate depended on the laser fluence.

For a high laser fluence, microcones were not created because the irradiated surface has been significantly melted, etched, and ablated by the very high laser fluence. The authors then observed a random pattern or a ring structure.

**Figure 7.** Relationship between the density, height of microcones, and number of laser pulses. Reprinted with permission from [65], Y. Kawakami et al., *Appl. Phys. A* 74, 59 (2002). © 2002, Springer-Verlag.

Such a different pattern growth might be due to a thermal strain wave, thermal expansion, temperature gradient, and nonuniform temperature by various spatial distributions of intensity in the laser spot. The pattern formation might be affected by the laser plasma plume because it depended on the size of the plume. These patterns were also confirmed in the laser fluence at 6.8 J/cm<sup>2</sup>. The critical laser fluence to change the morphology from microcones to the random structure was 4–5 J/cm<sup>2</sup> under these experimental conditions.

The microcone and silicon whisker growth by the VLS method [46–50] showed an analogous morphology. The growth of silicon whiskers could be attributed to the presence of various impurities. For the silicon laser ablation, chemical gases such as SF<sub>6</sub>, Cl<sub>2</sub>, and air were used to form a silicon microcolumn and microcone. However, the authors used neither an impurity nor chemical gases. The authors thought that the growth mechanism of the microcone was different from that of the silicon whisker. Their experimental results showed that the melted tungsten induced by the repetition of the pulsed laser irradiation played a significant role in the formation of the microcone. That is, the initial laser pulse produced only a rough surface like a crater structure (Fig. 8a). Successive several tens of pulse

**Figure 8.** Schematic illustrations of growth mechanism of tungsten microcones by laser irradiation. Reprinted with permission from [65], Y. Kawakami et al., *Appl. Phys. A* 74, 59 (2002). © 2002, Springer-Verlag.

irradiations could create the melted/solidification tungsten hemispheres. The decrease in the number of hemispheres was due to the *capillarity* among the random protrusions (Fig. 8b). The large hemispheres absorbed smaller ones because the surface energy could decrease. The morphology of the microcone was strongly affected by the number of laser pulses. In this process, resolidification of the slightly induced liquid tungsten took place. The protuberance and dome structures of the rough surface are easily created due to the initial melt generation. The spherical tip like a mushroom during the next several hundreds pulses (Fig. 8c) was produced by the high surface tension of tungsten (2500 mN/m) compared with Si (865 mN/m). The small mushroom structures were produced by a preferential ablation and etching around the tungsten tip. The fluence was reduced on the side of the mushroom structure. After these processes, the microcone array grew under the *shielding effect* of the tungsten tip (Fig. 8d). The top of the cones and their bottom area were easily ablated, because the top of the cones had a high efficiency of heat absorption and the bottom area had a high ablation rate compared with the side of the cones. Once the mushroom structure appears, the top of the mushroom induces the *shielding effect* on the side. Then evaporated tungsten atom and cluster from the bottom area are *deposited* on the top and side of the cones to make the cone grow. Consequently, the melting and solidification process of the tungsten tips becomes very important for producing the microcone structure.

For tungsten, the influence of various ambient gas atmospheres on the morphology of the microcone arrays was confirmed. The microcones were formed in He and air under the described experimental conditions. In  $\text{SF}_6$ , the chemical reaction between  $\text{SF}_6$  and tungsten contributed to the formation of the microcones with a blunt spike due to the etching effect, and it could not redeposit to form on the top portions of the microcones. Tungsten tips were also etched/vaporized due to a dense  $\text{SF}_6$  gas around the top sections of the microcones. Therefore, the height of the microcones was limited. In air, the vapor pressure of tungsten oxide was so highly that air acted as a highly efficient etching agent. However, the oxide vapor formation did not influence the formation of the microcones. Only oxidation of the top area occurred and left an oxide after the laser pulses stopped.

In order to investigate the influence of the laser wavelength, a KrF excimer laser (wavelength: 248 nm) was used. The laser fluence was set up with a sufficiently larger value than an ablation threshold one. The influence of the laser pulses on the formation of the tungsten microcorn by using the KrF excimer laser irradiation was investigated. The experimental result is shown in Figure 9. The large growth of microcones did not take place, although the formation of the tip was observed. The evolution of the microcorns done with different laser fluences is shown in Figure 10. The size of the tip significantly changed with different fluences, which was about  $1 \mu\text{m}$  at  $0.9 \text{ J/cm}^2$ , about  $2 \mu\text{m}$  at  $1.5 \text{ J/cm}^2$ , and further,  $3 \mu\text{m}$  at  $3 \text{ J/cm}^2$ . It was found that the density of the tips decreased with the increasing laser fluence. Furthermore, when it was  $6.3 \text{ J/cm}^2$ , it became a rocklike structure and a decrease in density took place. These results suggest that the microcorn does not grow and the tip size changes

**Figure 9.** SEM microphotograph of tungsten microcone obtained after irradiation by KrF excimer laser in air (248 nm,  $1.7 \text{ J/cm}^2$ , 20 Hz): (a) 100 pulses, (b) 600 pulses, (c) 1200 pulses.

due to the change in the temperature and quantity of the melted tungsten.

Recently, many investigations concerning the microstructuring formation of a ripple or corn under the polarization of a femtosecond laser have been carried out. For example, Baudach et al. studied the ripple orientation of a polyimide and found that it was always parallel to the electric vector of the light for linearly polarized light and that the spacing was nearly the same as the wavelength. Moreover, it had a corn structure toward the center of the cavity bottom when circularly polarized light was used [26, 27]. At the top of each cone, a small hole was observed. In order to investigate the influence of the pulse width on the nanostructuring, the

**Figure 10.** SEM micrographs of tungsten microcone obtained after irradiation at various laser peak fluences after 1200 pulses in air: (a) 0.9, (b) 1.5, (c) 2.0, (d) 3.0 J/cm<sup>2</sup>.

authors used a Ti:sapphire laser (energy: 100  $\mu$ J, damage area: 0.01 mm<sup>2</sup>, wavelength: 800 nm, pulse width: 120 fs, repetitions: 200 Hz). Figure 11 shows the influence of the polarization on tungsten nanostructuring. These morphologies were almost the same as in previous reports.

**Figure 11.** Effect of the polarized waves of tungsten surface modification obtained after irradiation by Ti:sapphire laser in air: (a) *p*-polarized waves, (b) *s*-polarized waves.

In order to form the sharper tip of the microcone, chemical etching was tried. This result is shown in Figure 12. Figure 12c and d shows very sharp tips that were etched in boiling hydrogen peroxide and distilled water. Especially, the tips etched for 90 sec shown in Figure 12d had the sharper microcone tip. The high magnification of a typical sharper tip of the microcone before and after the etching under the conditions described in Figure 12d is shown in Figure 13. It is clearly shown that facets in the crystal appear after etching. A specific crystal side was preferentially etched. Therefore, this etching technique might be able to be used to make a sharp edge that might have a significant potential for widely diversified industrial applications ranging from emission cathodes for a field emission display to microelectronic devices, since it was less than 100 nm in diameter.

Many investigations of cone- and column-type micro-nanostructuring have been carried out using laser ablation techniques. Silicon, a polymer, oxides, a nitride, and metals were used to form the microcones and microcolumns. The formation mechanisms has been proposed depending on both the target materials and laser ablation conditions such as the shielding effect of the particulate impurities and the solvent, the debris particles, capillary waves, catalyst-free VLS, and so on.

#### 4. NANOMETER-SIZED PROTUBERANCE COHERENT ARRAY

A self-assembled coherent array of tungsten protuberances was discovered around a laser-irradiated mark on a single-crystal tungsten surface [71]. The tungsten protuberances were about 150 nm in diameter and their spacing was hundreds of nm [73]. The substrates were irradiated by a *Q*-switched Nd:YAG laser at a wavelength with the fundamental (1064 nm) and the second harmonic (532 nm) at low

**Figure 12.** Modification of tip tungsten microcone by chemical etching [laser fluence: 2.6 J/cm<sup>2</sup>, pulse number: 1200 pulses, ambient gas: He (4 kPa)].

**Figure 13.** High resolution of typical tungsten microcone in the conditions of Figure 12d [ $\text{H}_2\text{O}_2$  (31%) 2 ml +  $\text{H}_2\text{O}$  100 ml, 90 sec, 83–85 °C].

pressure in an inert gas atmosphere. As it was a very interesting phenomenon, the authors investigated the influence of the laser fluence, wavelength, polarization, surface crystal structure, etc., on the arrangement and spacing of the protuberances in order to clarify the formation mechanism.

Figure 14a shows a SEM microphotograph of a laser-irradiated mark (wavelength; 1064 nm) on the orientation

**Figure 14.** (a) SEM microphotograph of a tungsten surface irradiated by the Nd:YAG laser. We can observe many cracks on the laser-irradiated mark due to the effect of crystal orientation on the tungsten surface. (b) SEM microphotograph around the laser-irradiated mark on the tungsten surface, irradiated at an angle of incidence  $\theta = 4^\circ$  with the  $p$ -polarized beam. A coherent array of ultrafine particles was observed around the laser-irradiated mark. (c) The highly magnified SEM microphotograph of the ultrafine particles arranged like a hexagonal system with about a  $1.3 \mu\text{m}$  array spacing. (d) AFM trace of the ultrafine particles arranged like a hexagonal system with about a  $1.3 \mu\text{m}$  array spacing, of which the hemisphere height was about 270 nm. of the (110) surface of a single crystal tungsten with a laser fluence at  $19.6 \text{ J/cm}^2$ . Many cracks on the laser-irradiated mark were found. They might be created by thermal shock to the single-crystal tungsten. The laser-irradiation markings observed on the three types of single-crystal tungsten surfaces such as (100), (110), and (111) were square, rectangular, and triangular, respectively [72]. These phenomena were related to the cleavage plane of tungsten. That is, when the tungsten surfaces were irradiated, the cleavage fracture occurred with preference to the crystal direction having a weak binding energy. Figure 14b shows a SEM microphotograph around the laser-irradiated mark on the tungsten surface. The rapid resolidification of a highly melted layer of tungsten was observed. Figure 14c and d shows a highly magnified SEM microphotograph and Figure 14b shows the AFM trace. The authors could observe a coherent array of protuberances of about 750 nm with the spacing at  $1.3 \mu\text{m}$  around the laser-irradiated mark. The spacings of 1.0 or  $1.1 \mu\text{m}$  were calculated from Eq. (1). The spacing values from the SEM observations were different from the calculated one. In the case of the  $17.4 \text{ J/cm}^2$  fluence, the spacing of the coherent array was also different from the calculated spacing [71]. Therefore, the surface patterns depended on the laser fluence rather than the wavelength and the angle of incidence. For another region in the same sample, it was observed that the array was like a two-dimensional cubic system based on the AFM trace of Figure 15. The array spacing was also about  $1 \mu\text{m}$ . Two types of arrays, namely, a cubic system and a hexagonal one, were finally confirmed. In the case of the angle of incidence of  $\theta = 4^\circ$  with an  $s$ -polarized beam, nearly the same results were obtained [71, 72]. This was also confirmed for the other orientations of the single-crystal surface. The array was not observed on the polycrystalline tungsten surface [73].

Figure 16a and b shows a SEM microphotograph in/around a laser-irradiated mark (wavelength; 532 nm) on the (100) surface of the single-crystal tungsten with a laser fluence of  $5.2 \text{ J/cm}^2$ . Column structures are observed in the laser-irradiated mark. This formation mechanism was explained in Section 3 of this chapter. The lower fluence might be compensated by a decrease in the reflection coefficient at 532 nm. The protuberances of about 150 nm (radius of curvature: 70–80 nm) were coherently arranged with a spacing at 640 nm. However, the array could not be observed

**Figure 15.** AFM trace of the ultrafine particles arranged like a cubic system. Reprinted with permission from [71], Y. Kawakami et al., *Appl. Phys. Lett.* 74, 3954 (1999). © 1999, American Institute of Physics.

**Figure 16.** (a) SEM microphotograph of a tungsten surface irradiated by the Nd:YAG laser irradiated at an angle of incidence  $\theta = 4^\circ$  with the *p*-polarized beam. We can observe many columns on the laser-irradiated mark due to a temperature high enough to induce melting and solidification by rapid quenching on the tungsten surface. (b) The highly magnified SEM microphotograph of the ultrafine particles arranged like a hexagonal system with about a 640 nm array spacing. (c) AFM trace of the ultrafine particles arranged like a hexagonal system with about a 640 nm array spacing, of which the hemisphere height was about 180 nm. Reprinted with permission from [73], Y. Kawakami et al., *Appl. Phys. A* 71, 453 (2000). © 2000, Springer-Verlag.

for the specimens with several tens of  $\text{J}/\text{cm}^2$  irradiation but many droplets were observed instead. For the higher laser fluence, many droplets were produced due to the increment of expansion on the inside of the tungsten. The spacing calculated from Eq. (1) was 490 or 570 nm. These values are very different from the ones observed by SEM. Figure 16c shows an AFM trace of the same area in Figure 16b. The hundreds of nm-sized protuberances were arranged like a

two-dimensional hexagonal system. Their hemisphere height was about 180 nm.

In order to investigate the influence of the laser fluence, three fluences of 2.6, 5.2, and  $10.5 \text{ J}/\text{cm}^2$  were tuned. The array structures of the protuberances at 2.6 and  $5.2 \text{ J}/\text{cm}^2$  are clearly observed. The protuberances of about 380–500 nm are coherently arranged with a spacing at 595 nm ( $2.6 \text{ J}/\text{cm}^2$ ) and 683 nm ( $5.2 \text{ J}/\text{cm}^2$ ). For the higher laser fluence of  $10.5 \text{ J}/\text{cm}^2$ , the arrays could not be found but many droplets and peeling of the surface layer induced by thermal expansion of the tungsten were observed. The spacing calculated from Eq. (1) was 453 or 644 nm. These values were very different from the ones obtained from the experimental results. For the  $17.4 \text{ J}/\text{cm}^2$  laser fluence at 1064 nm and  $5.2 \text{ J}/\text{cm}^2$  laser fluence at 532 nm, the spacing of the coherent array was also different from the calculated spacing [73]. That is, the surface patterns depended on the laser fluence rather than the wavelength of the laser.

Judging from a cross-sectional transmission electron microscope image of the protuberances, the protuberances composing the coherent array seemed to grow from the matrix surface as if they rose continuously from the base material. No grain boundary between the protuberances and the matrix surface was detected. From this experimental result, it was concluded that the formation of protuberances depended on the kind of crystal growth and that the controlling factors for the formation were the laser fluence, the crystal surface structure preferential growth direction of the crystal, cooling rate and its direction, etc. Anyway, the recrystallization of the slightly melted tungsten on the top surface induced by the repeated laser irradiation should play a vital role in the formation of the array.

In order to more fully understand this phenomenon, more studies should be necessary. The rapid solidification process of the molten tungsten induced by the laser beam should be examined more carefully especially about the rapid solidification rate, heat flow on the specimen, surface temperature, etc. The fluence also seems to be a very important factor for inducing the coherent array, since the spacing of the array was changed by the intensity of the laser fluence. The effect of the surface structure, crystal growth (dendrite), surface tension (surface energy), thermal effect, and standing wave should be carefully considered. The formation mechanism of a Coulomb crystal [75–77] formed from the Coulomb potential energy due to the charge between the protuberances might also be considered.

In summary, the authors formed different spacing coherent arrays with 150–700 nm-sized protuberances using the short-pulse Nd:YAG laser irradiation technique. The cause of the formation of the two-dimensional coherent arrays could not be explained by only the laser's characteristics such as the wavelength, incident angle, and polarization of the cones as previously mentioned. The interesting points of the coherent arrays are as follows: (1) the ultrafine tungsten protuberances of 150 nm were coherently arranged in several lattice directions, (2) two types of arrays, namely, a cubic system and a hexagonal one, were confirmed, (3) the formation of coherent patterns will not be affected by the wavelength of the laser, (4) the spacing of arrays depends on the intensity of the laser fluence, (5) coherent arrays could be observed only on the surface of single-crystal tungsten,

and (6) the recrystallized texture on the surface was confirmed for the protuberances. A much more detailed discussion should be necessary to understand this phenomenon. It is a very interesting topic for science such that a more detailed examination is expected.

## 5. RECENT TOPICS

Morphological changes during dehydration of single crystals containing lattice  $\text{H}_2\text{O}$  (hydrates) were dramatic. Surfaces became rough, polycrystalline, and laden with defects. Ionic crystal surfaces containing point defects readily desorbed energetic positive ions under UV excimer laser irradiation. Kawaguchi et al. examined the consequences of thermally pretreated single crystal brushite ( $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ ) exposed to 30 ns pulses of 248 nm laser irradiation and showed that the surface modifications strongly enhanced the emission of  $\text{Ca}^+$  and other positive ions [80]. When they were gently irradiated on the untreated brushite surface in a vacuum with 248 nm laser irradiation only, they produced "microflowers," where laser-induced heating alone activated efflorescence.

Nonerasable micrograting structures were successfully encoded in amorphous  $\text{SiO}_2$  thin film on silicon wafers by colliding a pair of focused pulses split from a single femtosecond pulse from a 10 Hz mode-locked Ti:sapphire laser with a regenerative amplifier (wavelength:  $\lambda = 800$  nm, pulse duration: 100 fs, pulse energy:  $\sim 3$  mJ/pulse). The encoded periodic spacing varied with the angle,  $\theta$ , between the two crossed pulses according to  $d = \lambda / (2 \sin(\theta/2))$ . A minimum periodic spacing of  $\sim 430$  nm was achieved for a laser wavelength of 800 nm. Volume compaction resulting from structural alterations of the silica network in amorphous  $\text{SiO}_2$  induced by intense femtosecond laser irradiation was responsible for the formation of these grating structures. Further, an array of dot structures was fabricated in amorphous  $\text{SiO}_2$  thin films by encoding two perpendicular gratings [81].

Li et al. investigated a periodic microstructure induced by a 355 nm ultraviolet polarized laser on a polyimide surface and the dependence of the structures on laser parameters. Laser-induced periodic surface structures of submicrometer size were generated on three kinds of polyimide films by a polarized Nd:YAG laser of 355 nm within a wide range of laser fluence. The formation of LIPSS was greatly influenced by the chemical structure of the polyimide, the film-making process, the number of laser pulses, and the laser fluence. The periodicity of LIPSS was decided by the wavelength, the incidence angle of the laser beam, and the apparent refractive index of the material [82].

Ripple structures by KrF excimer laser irradiation were observed on a silicon surface capped with a thin layer of patterned silicon oxide. The ripples were highly dependent on the patterns of the silicon oxide. They were centered and enhanced at the boundaries of the opened windows, forming a radial wavelike structure. The formation of the ripples was attributed to the combined effect of surface stress, surface scattered wave, and boundary effects [83].

Relatively low-energy laser illumination, specifically the second harmonic ( $\lambda = 532$  nm) of a Nd:YAG laser, was used to prepare laser-induced periodic surface structures on surfaces of polymers doped and grafted with Dispersed Red 19.

This dye strongly absorbed the laser light, and the use of 532 nm wavelength irradiation avoided the photolysis reactions on polymers that often accompanied the use of UV lasers. Li et al. found that LIPSS could be obtained on grafted polyurethane-imide film. Effects of scanning speed, laser fluence, and the angle of incidence on formation of LIPSS were examined. Nonpolarized and polarized transmission Fourier transform infrared spectroscopy was applied to characterize the orientation of azobenzene side groups, which were found to tend to align in the plane perpendicular to the direction of LIPSS [84].

Crater morphology was investigated after femtosecond laser ablation of wide bandgap insulators ( $\text{BaF}_2$  and  $\text{CaF}_2$ ) [85]. Experiments performed at a weak laser ablation rate showed a particular elastic, sound-wave-like structure, frozen on the surface, with a periodicity on the order of some micrometer and a modulation depth up to 500 nm. A superimposed and periodic fine structure (ripples) was generated, the origin of which could not be explained by the classical ripple model. Costache et al. [85] observed a periodicity ranging from 100 to 500 nm, dependent on the laser intensity rather than on the laser wavelength. Based on their recent results, demonstrating an explosive surface decomposition, they assumed self-organizing relaxation of a nonequilibrium surface to be responsible for the structures.

Pedraza and et al. reported on an interesting topic, the formation of linear arrays of nanoparticles by pulsed-laser irradiation [86, 87]. Periodic undulations,  $\sim 10$  nm high, were formed when flat Si substrates were irradiated with polarized laser light. These periodic structures had a wavelength that was a function of the light wavelength and the angle of incidence of the laser beam. At a slightly higher laser fluence,  $\sim 40$ -nm-diameter nanoparticles were formed on the surface of laser irradiated flat Si specimens. Linear arrays of Si nanoparticles with fairly uniform size were observed in a microstructured region. These nanostructures were explained within the framework of the LIPSS theory.

Laser-induced surface structuring of Si was studied using fluences close to the melting threshold and in a He gas background atmosphere. The effects of an initial surface microstructured region and of light polarization on the evolution of the surface topography were investigated. The microstructured surface topography consisted of an array of microholes surrounded by microcones of 2–3  $\mu\text{m}$  tip diameter and over 20  $\mu\text{m}$  high. Pulsed laser irradiation of laser-microstructured Si induced nanostructures. Nanocolumns having a diameter of 100 to 200 nm and a height of up to 3  $\mu\text{m}$  upon cumulative laser pulses grew on top of every microcone. The mechanisms of nanocolumn origin and growth were analyzed [86].

Sequential pulsed-laser irradiation of silicon in a  $\text{SF}_6$  atmosphere induced the formation of an ensemble of microholes and microcones. Profilometry measurements and direct imaging with an intensifying charge-coupled device camera were used to study the evolution of this microstructure and the laser-generated plume. Both the partial pressure of  $\text{SF}_6$  and the total pressure of an  $\text{SF}_6$ -inert gas mixture strongly influenced the maximum height. The height of microcones was attained over the initial surface. The cones first grew continuously with the number of pulses, reached a maximum, and then began to recede as the number of

laser pulses increased further. The growth of the cones was closely connected with the evolution of the laser-generated plume [88].

For the application of field electron emission (FEE), Karabutov et al. reported low-threshold FEE for periodic arrays of microtips produced by laser ablation of Si wafers [89]. The best samples had threshold fields as low as 4–5 V/ $\mu\text{m}$  for *n*-type Si substrates and 1–2 V/ $\mu\text{m}$  for *p*-type Si substrates, as measured with a flat-screen technique.

György et al. reported micrometer-sized crownlike structure growth on a Ti surface by multipulse Nd:YAG ( $\lambda = 1.064 \mu\text{m}$ ,  $\tau = 170 \text{ ns}$ ) laser irradiation in air at atmospheric pressure [90]. The irradiation was performed at  $8 \times 10^7 \text{ W/cm}^2$  laser-pulse intensity, below the ablation threshold. A ring-shape structure was created in the center of the irradiation spot after the action of five laser pulses. The further increase of the laser-pulse number led gradually to a crownlike structure, which had a height of 120–140  $\mu\text{m}$  for 150 pulses higher than the nonirradiated Ti surface. The forming crater's depth did not exceed the height of the grown structure. In the neighboring zone, after the action of 25 laser pulses, microcracks of the oxide surface layer developed. With the next pulses this led to the formation of a surface microrelief. Molten material movement attributed to the laser-induced plasma-recoil pressure might lead to the crownlike structure.

Polyimides were known to exhibit large ablation rates with excimer laser because of their high absorbance in the UV and low fluorescence yield [91]. Metayer et al. studied different regimes of laser ablation according to the fluence and the structures resulting from carbon product deposition. For fluences larger than the polyimide ablation threshold, but lower than the carbon one, the development of one structure was the dominant process, whereas large ablation rates led to polyimide etching above the carbon ablation threshold. The deposition of a carbon layer on the walls of ablated slits was in particular investigated using an original experimental technique. Optical microscopy and MEB showed that this carbon layer covered the main height of the ablated holes whereas a threshold (bare polyimide) for carbon condensation was evidenced at the bottom of the ablated hole. Raman spectroscopy and conductivity measurements revealed that the carbon phase was mainly graphitic. Dependence of the carbon condensation threshold on the slit width was made clear and discussed in relation to the angle of ejection of ablation debris. A procedure was developed to render the bare polyimide of the threshold region conductive. Lastly, the conductive properties of the walls of the ablated holes were exploited to perform an electrolytic metallization. Implications for the production of interconnection vertical interconnections in high density printed circuits were addressed.

This research field will evolve and generate many reports.

## GLOSSARY

**Ablation threshold** The laser fluence  $E_{th}$  [ $\text{J/cm}^2$ ] of threshold while the surface is ablated.

**Capillary wave** The wave which occurs on the liquid surface by surface tension.

**Coulomb crystal** When a coulomb interaction occurs between the charged particles and the interaction energy significantly exceeding the thermal kinetic energy of a particle, the “Coulomb crystal” is denoted by the regular arrangement between the charged particles such as the atomic arrangement in a solid crystal.

**Debris particles** Large-sized particles of hundreds of nm to several micrometers, which are contained in the laser-induced plasma plume formed by a large quantity of particles emitted from a solid by laser ablation.

**Dendrite** Many crystals, which have the shape of a branch due to the solidification texture of the melted metal.

**Field emission display (FED)** One of the various types of flat-panel displays. A field emission display has the advantages of both the CRT and liquid-crystal displays, having a high display quality while being thin and lightweight with a low power consumption.

**Laser** Light amplification by stimulated emission of radiation.

**Laser ablation** A sputtering process in which the material removal rates typically exceed one-tenth a monolayer per pulse; the surface is structurally or compositionally modified at mesoscopic length scales; and particle yields are superlinear functions of the density of excitation.

**Laser fluence** The energy density,  $E$  [ $\text{J/cm}^2$ ], of the product between the power density and pulse width of a laser.

**Laser induced periodic surface structures (LIPSS)** A very general phenomenon. It occurs from the interference of scattered light from a rough surface with the incident laser beam.

**Vapor-liquid-solid (VLS) method** The growth mechanism in which the three phases of vapor, liquid, and solid are simultaneously involved. It is used especially for the growth of a whisker.

## ACKNOWLEDGMENTS

The authors gratefully thank Dr. Shinya Sasaki of the National Institute of Advanced Industrial Science and Technology (AIST) for valuable discussions, Dr. Tomokazu Sano, Hirokazu Yamada, and Makoto Murai of Osaka University for the laser-induced tungsten microcone experiments, Dr. Yasuhisa Ando of AIST for the AFM study, and Masaru Iwashina of Vacuum Metallurgical Co., Ltd., for the chemical etching tests.

This author's work was supported by the R&D Institute for Photonics Engineering entrusted from the Advanced Photon Processing and Measurement Technologies Program of the New Energy and Industrial Technology Development Organization of Japan.

## 1. INTRODUCTION

Recent developments in nanoscience and nanotechnology have provided fresh motivation for the search of innovative nanostructured materials. As far as organic materials are concerned, two main techniques have been used to fabricate ultra-thin, nanostructured films, namely, the Langmuir–Blodgett (LB) and the layer-by-layer (LBL) techniques. The LB method was conceived several decades ago [1], following developments in surface chemistry dating from the early 20th century [2]. It was originally proposed for deposition of multilayers of amphiphilic organic compounds, but has been extended considerably to a variety of substances, including polymers [3] and other macromolecules [4]. The LBL technique is much more recent; its first form employed chemical adsorption of suitably derivatized molecules [5]. A more versatile method was proposed by Decher et al. [6], in which

physical adsorption is driven by ionic attraction. A number of review articles and book chapters have been produced recently on LB and LBL methods [7–9]. In addition to emphasizing the wide variety of materials that can be employed with these techniques, in some cases the reviews address specific issues such as the characterization techniques [7], the films formed from conducting polymers [8], the applications in opto-electronics and photonics [9], or the physical principles involved in film assembling [9]. In this article, we shall focus on the use of LBL and LB techniques for producing supramolecular structures involving inorganic compounds combined with organic materials. Particular emphasis will be placed on the special characteristics due to the nanostructured nature of the films, in comparison to the corresponding bulk or thicker film properties.

The main aim in producing hybrid inorganic/organic supramolecular structures lies in the possibility of obtaining new physical, chemical, electronic, and optical properties due to specific interactions at the molecular level and/or quantum confinement. Polymeric thin films can be used, for instance, as a matrix for inorganic particle growth in a strategy for controlling size, shape, and spatial distribution. Additionally, the build-up of structures comprising organic/inorganic layers of appropriate molecules is a well-known strategy to improve properties such as photoluminescence, catalysis, and photochromism. In electrochemical and sensing applications, in particular, nanostructured films formed from spherical particles like dendrimers or polyoxometalates were found to provide a porous architecture where specific ions can easily diffuse through. Therefore, the development of composites that can be manipulated at the supramolecular level has potential application within opto-electronic and biotechnology industries.

Before describing in detail the latest findings in LBL and LB films from inorganic/organic structures, we shall present in Sections 2 and 3 a brief description of the techniques where the focus will be in the issues directly associated with the manipulation of macromolecules and nanoparticles. Section 4 covers the extensive works carried out in the fabrication of LBL films with nanoparticles, while Section 5 is dedicated to LBL films from aluminosilicates. The use of macrocyclic compounds and dendrimers in LBL films is described in Sections 6 and 7, respectively. Because extensive literature already exists in LB films from metallic complexes, we focused on recent developments of our group exploiting ruthenium complexes. This is aimed at providing a sample of the possibilities to combine organic and inorganic compounds, particularly in the case of mixtures of ruthenium compounds with conducting polymers.

## 2. THE LANGMUIR-BLODGETT (LB) METHOD

The LB method is named after two eminent scientists that worked at General Electric (USA) in the early 20th century. Irving Langmuir was responsible for putting on a solid scientific basis the field of monolayers from amphiphilic materials spread onto aqueous subphases. Following previous work by Pockels [10] and Lord Kelvin [11], Langmuir introduced experimental, as well as theoretical procedures, to manipulate and interpret the thermodynamic properties of such monolayers, now referred to as Langmuir films or Langmuir monolayers. One such monolayer is spread from a volatile, organic solvent solution containing a small aliquot of the amphiphile onto the aqueous subphase. By employing movable barriers, the monolayer may be compressed until forming a condensed film that may be highly organized. The presence of this film is sensed by the decrease in surface tension of the subphase, which has been traditionally referred to as surface pressure. With pressure area per molecule isotherms, one can investigate the various phases formed during compression. Figure 1 shows a typical pressure-area isotherm for stearic acid, one of the most investigated amphiphiles. At large areas per molecule, the interaction between molecules is negligible and the surface pressure

**Figure 1.** Pressure-area isotherms for an Stearic acid (SA) and polyaniline monolayers.

is null. Upon compression, the monolayer suffers a phase transition to a liquid-condensed phase, denoted by an almost linear increase in pressure with the change in area. Also shown in the figure is an isotherm from a polymer film. The latter is usually nonmonomolecular in nature due to the aggregation of material at the air/water interface. Several strategies must be sought to obtain stable polymer films and therefore research into Langmuir films is a prerequisite for any further application. A review on the strategies to overcome the difficulties in processing polymers for Langmuir monolayers is given in [12].

The film in the liquid-condensed or condensed phase can be transferred onto a solid substrate by immersing and withdrawing the substrate vertically across the film. If several immersions and withdrawals are made, a multilayer film is formed. The deposited film is referred to as an LB film, even when only one layer is deposited. While transfer of stable Langmuir monolayers from amphiphilic materials is relatively straightforward, the same does not apply when more complex molecules are to be deposited. For example, polymer films at the air/water interface may be too rigid for deposition. Furthermore, films from nonamphiphilic materials such as ruthenium complexes [13] and lignins [14] tend to contain aggregates and the deposition of good-quality LB films requires optimization of experimental conditions such as the speed of immersion and withdrawal of the substrate, the surface pressure to be kept fixed during transfer, the subphase, and even the speed of compression of the Langmuir film.

## 3. THE LAYER-BY-LAYER (LBL) METHOD

Spontaneous adsorption of several monolayers onto a single substrate may be achieved by covalent bonding of derivatized groups of the monolayers with the substrate for the first layer and with the molecules of the adjacent layer for the following layers. This process leads to chemically adsorbed multilayers, also referred to as self-assembly [5] for the obvious reason that monolayers spontaneously self-assemble on each other. There are many advantages in using this strategy to build a multilayer, the main one perhaps being the high stability of the films. However, chemical adsorption requires highly specific groups to establish the covalent bonds, and this restricts the type of material that can be employed. Moreover, adsorption is easily precluded by defects on the top layer. In the more versatile version proposed by Decher et al. [6, 15], multilayer adsorption is driven by ionic attraction. Originally applied to polyelectrolytes, the method was extended to conjugated polymers [16–19] and then to a variety of materials with adsorption being driven not only by ionic interactions but also by secondary interactions such as H-bonding [20].

Because a multitude of materials are now employed, the characteristics of LBL films may vary enormously. A convenient way of classifying LBL films is based on identifying the mechanism responsible for adsorption. Oliveira et al. [9] have suggested that four main types of film may be produced.

1. Highly charged polyelectrolytes lead to molecularly thin films as originally proposed by Decher et al.

[6, 15], with adsorption via ionic attraction. This is by far the most common class of LBL films.

2. When partially charged, weak polyelectrolytes are used, much thicker layers may be obtained. Ionic attraction is still the main driving force in the process though the amount of adsorbed material may vary by one order of magnitude due to the so-called anomalous adsorption [21].
3. Secondary interactions such as H-bonding [20] can also be responsible for adsorption, either in conjunction with ionic interactions or on their own. The amount of material adsorbed depends on an even larger number of parameters, and nonself-limiting adsorption may occur [22].
4. Finally, LBL films produced with very specific interactions are also reported in the literature. In this case, multilayers may be formed with polyelectrolytes of the same charge [23].

#### 4. NANOPARTICLES IN LBL FILMS

Inorganic particles with nanometer dimensions form a new class of materials with size-dependent properties, which are unique due to the large surface area compared to their volume. These materials are relevant to diverse fields, ranging from opto-electronics which rely on quantum confinement effects in semiconductors, to magnetism, catalysis, and biotechnology. They have been studied in the form of micelles, vesicles, sol-gel glasses, zeolites, LB films, and polymers [24–29]. The immobilization of nanoparticles in supramolecular structures is an endeavor, where the main aim is to achieve confined structures that may possess properties that differ considerably from those of the same materials in other forms. Clear examples of applications of nanoparticles are the use of  $\text{Fe}_3\text{O}_4$  nanoparticles for exploiting magnetic-related phenomena, and of  $\text{TiO}_2$  and  $\text{MnO}_2$  for their catalytic and photovoltaic activity, in addition to the use in the paint, paper, and food industries as pigments, fillers, and whiteners. One of the difficulties in obtaining nanoparticles in solid films is to preserve their nanosized nature by avoiding aggregation and to achieve organization of the particles in order to maximize the potential application. This may be circumvented if the LBL technique is employed. In this context, use is made of the various extensions of the LBL technique proposed in recent years, which have extended the original paradigm of adsorption of alternated, oppositely charged polymer layers. For gold particles, for example, aggregation is avoided if the Au particles are assembled with a generation 5 dendrimer [30]. In this approach, a few atoms of Au can be located in the hollow structure of the dendrimers, avoiding aggregation. Many reports have demonstrated the use of weak and strong polyelectrolytes to prepare multilayers combining various materials including conjugated polymers, dyes, proteins, etc.

The formation of organic/inorganic nanocomposites is achieved by incorporation of nanoparticles in LBL structures, either by selective growth inside a previously built LBL organic structure which operates as a matrix for controlling particle structure, size, and distribution, or by assembling inorganic particles to replace one of the polymeric components during the film build-up process, resulting in a

layered organic/inorganic film. Since surface charge is the main requirement for film growth, in order to have an effective increase in film thickness, the inorganic spherical particles that have been used were, in most cases, modified by incorporation of a charged capping layer.

The choice of the substrates onto which nanoparticles will be assembled depends, in almost all the cases, on the application desired for the film as well as the techniques employed in film characterization. Reports have been made on the growth of LBL films onto hydrophilic, hydrophobic, or indium-tin-oxide (ITO)-coated glass, silicon wafers, polymeric-colloidal particles, etc. It should also be mentioned that identical particles may lead to films with different properties, since the polymeric counterpart in the incorporation process determines the particle distribution and interaction. Therefore, the polymer is crucial for the final film properties, which extends the capabilities of the LBL approach for nanocomposites.

In the following subsections we shall illustrate several successful attempts to obtain nanoparticles. For the sake of clarity, the description will be split into two topics: nanoparticles growing within LBL films, and layers of nanoparticles assembled in conjunction with charged species in the films.

##### 4.1. Nanoparticle Growth in a LBL Polymeric Matrix

Layer-by-layer polymer films have been employed as a matrix for growth of several crystals and nanoparticles. The strength of the polyelectrolytes is critical in determining the final characteristics of the particles and therefore their properties of interest. A matrix is comprised, for example, by poly(diallyldimethylammonium chloride) (PDDA) and sulfonated polystyrene (SPS) bilayers [31], where assembly of nickel and cobalt compounds, PbS, and manganese oxide has been obtained. The polymer base imparts the ability of sulfonate groups from SPS to act as strong binding sites for metal ions, which conversely are available for further chemical reactions. Hence, by appropriate chemistry, it is possible to convert the metallic ion into the desired oxide, hydroxide, or oxihydroxide compound. Additionally, the polymorphic crystal structure may be controlled. That is an important feature since for nickel and cobalt compounds, for instance, the less stable  $\alpha$  form presents better electrochemical properties due to larger d-space. Several reports are found in the literature employing such an approach. Fojas et al. [32] reported the nucleation of  $\text{Ni}(\text{OH})_2$  by cycling polymer-coated substrates in  $\text{Ni}^{2+}$  and NaOH solutions. Fourier transform infrared (FTIR) results indicated that the Ni particles grown are  $\alpha$ - $\text{Ni}(\text{OH})_2$ , which was corroborated by transmission electron microscopy (TEM) micrographs. Such crystals are reported in the literature [33, 34] as ribbon-like-shaped and fibrous, consistent with the microcrystals observed in [32].  $\beta$ - $\text{Ni}(\text{OH})_2$  crystals are reported [35] to be hexagonal platelet-like structures. X-ray diffraction (XRD) data showed that the d-spacing was consistent with a  $\beta$ - $\text{Ni}(\text{OH})_2$  form. The authors pointed out that  $\alpha$ - $\text{Ni}(\text{OH})_2$  may be converted to the  $\beta$ -form over time or by thermal treatment or exposure to alkali solutions.

Co and Fe compounds were studied by Stroeve et al. [31, 36, 37] for their catalytic, electric, and magnetic properties. Transition-metal layered structures can be used to enhance the electrochemical performance of nickel electrodes by modifying conductivity and chargeability. In [31], Co compounds were obtained inside a PDDA/SPS matrix previously deposited on quartz slides. UV-vis absorption data showed linear growth of the polymeric matrix as well as growth of the crystalline particles. Crystals were preferentially deposited inside the SPS layer and were not confined in a given SPS layer but rather grew within the whole film, since an increase in the number of SPS layers led to an increase in the number of crystals. Three types of crystalline structures ( $\alpha$ ,  $\beta$ , and an oxyhydroxy phase) were obtained depending on the number of cycles and environment ( $N_2$  or  $O_2$ ), again indicating that the polymorphic form can be chosen by controlling the environment and film fabrication parameters. Iron compounds were also built and the morphology and type of final crystal depended on the starting material. Lepidocrocite ( $\gamma$ -FeOOH), for example, is formed when ferric nitrate is employed and akaganéite ( $\beta$ -FeOOH) is obtained by using ferric chloride [36, 37]. The latter authors also found that the polymeric matrix restrains crystal growth in specific directions depending on the morphology of the free space (or cavities) formed by polymer chains.

Stroeve et al. nucleated PbS nanoparticles inside a LBL matrix [38]. They were particularly interested in controlling particle size and film structure, which is mandatory in exploiting quantum-confinement effects that determine size-dependent opto-electronic properties. The procedure was similar to that employed for Ni, Co, and Fe compounds: nucleation was achieved by absorption of  $Pb^{2+}$  into the polymer film followed by water rinsing and exposure to  $H_2S$  vapor. The UV-vis spectrum was redshifted and widened as the number of cycles increased, which was associated with the escalation of particle size. The crystals grow in a rhomboid form with a broad size distribution due to the constrained geometry of the void space. The XRD pattern was found to be consistent with PbS particles, and small amounts of  $PbSO_4$  impurities were possibly present.

A further step in controlling particle size and distribution into a polymeric LBL matrix was achieved by Joly et al. [39]. They observed that by using weak polyelectrolytes which allow chemistry afterwards, nanoparticles are grown selectively and controllably within specific regions of a multilayer polyelectrolyte thin film. The use of strong polyelectrolyte such as SPS tends to form layers in which all of the strong acidic anionic groups are compromised with the cationic groups of the previous layer, leaving few or no active sites available for subsequent chemistry. When weak polyacids are used, the change in pH allows control of the number of free acid groups in the final structure and the use of different bilayer combinations results in a multilayer heterostructure in which nanocluster growth is restricted to specific regions. The authors used a poly(acrylic acid) (PAA) and poly(allylamine hydrochloride) (PAH) matrix. Ag and PbS particles were obtained by immersion on a silver acetate solution or lead acetate using low salt concentrations to decrease precipitation. Oxidation was carried out in air for

silver and by exposure to  $H_2S$  for PbS. The selective deposition of the nanoparticles was confirmed by energy dispersive X-ray spectroscopy (EDXS) profiles in TEM micrographs.

## 4.2. Nanoparticles Assembled in Conjunction with Charged Species in LBL Films

### 4.2.1. LBL Nanostructures of Organic/Inorganic Composites

An alternative procedure for fabrication of LBL nanocomposites uses charged nanoparticles as a substitute for one of the polymeric materials. This was, in fact, the first approach employed and has been demonstrated for several types of particles. Usually, inorganic particles must be surface-modified by a suitable molecule that provides the necessary surface charge for LBL film growth. It seems that the kinetics of adsorption for most of the systems is similar to a polymer/polymer process. One of the earliest works in building organized organic/inorganic multilayers was reported by Kleinfelde and Ferguson [40] employing synthetic hectorite, a mica-type, layered silicate that serves as an electrical insulator, diffusional barrier, or for mediating electron transfer. The research in [40] describes a method for stepwise preparation of ordered multilayered films from ultrathin ( $\sim 1$  nm) layers of PDDA and exfoliated sheets of synthetic hectorite onto 100 single-crystal silicon wafers having a native oxide layer. Films with a thickness up to  $0.2 \mu m$  were fabricated by dripping solutions of both materials alternately onto the substrates, instead of the standard dipping procedure usually employed for polymer film build-up. Adsorption of approximately two hectorite layers per cycle occurred, indicating that some loosely bound polymer interpenetrates into the inorganic material allowing adsorption of an extra hectorite layer. This suggests that the amount of hectorite adsorbed can be varied by controlling the amount of polymer in each layer. X-ray diffraction data confirmed the structural order of the films, and the absence of reflection corresponding to the structure of the three-dimensional starting material indicated preferential orientation of the sheets parallel to the surface and the absence of the crystalline precursor within the film structure. Also, in 1994, Keller et al. [41] reported the build-up of several organic/inorganic systems, though there was no systematic study on film growth. Use was made of surface-modified particles with a loose coating layer which can be displaced by the ionic groups of the polymer in the film fabrication process, using the standard dipping procedure. Therefore, electrostatic attraction was the driving force for the film build-up. Keller et al. [41] reported the sequential layering of structurally well-defined, two-dimensional colloidal polyanions containing Zr, Al, or cytochrome compounds with a variety of polymeric cations.

Other zircon-based nanocomposites were later studied in a more detailed work [42], which was aimed at fabricating dense, polycrystalline zirconia hard coatings. Up to 150 bilayers were built onto quartz and 111 silicon wafers using a zirconia nanocluster commercial solution and SPS. The film thickness was estimated using ellipsometry to be of the

order of 2 nm. Atomic force microscopy showed a defect-free surface comprising well and densely packed structures. These films had a Vickers micro-hardness of 25 GPa, which according to the authors is higher than for zirconia coatings deposited by other methods such as sputtering, thermal spray, or laser treatment. This good performance was attributed to the high molecular packing density of the film, the ultra-small size of the zirconia nanoclusters, and the absence of voids. Heat treatments resulted in even better packing arrangements and improved structure of zirconia layers due to the burnout of the polymeric matrix layer.

#### 4.2.2. LBL Films from Magnetic Nanoparticles

The possibility of obtaining an assembly of magnetic nanoparticles/polymer with no phase segregation and the opportunity of selecting particles according to size and shape prior to deposition providing a better control over the final properties was explored by several authors [43–45]. An interesting magnetic structure comprises metallic and ferromagnetic nanoparticles encapsulated by ultra-thin graphite shells. Such structures have potential application in data storage and/or biomedicine, and metals such as Co, Cu, and Ag can be successfully cosputtered with graphite resulting in encapsulated carbon cages. Cassagneau and Fendler [43] were able to assemble Ag-GO (graphite oxide) magnetic-caged particles alternated with PDDA in an LBL-type structure. Films were found to grow linearly with the number of deposition steps and have a very flat surface, as indicated in AFM images. It was also observed that the polymer reorganizes itself around the particles.

An important issue in magnetic storage is to achieve a high signal-to-noise ratio, which can be done by partial magnetic isolation of the grains by cosputtering of chromium, carbon, and SiO<sub>2</sub> [46–48]. The nonmagnetic layer prevents cooperative switching and zigzag noises. One limitation to this approach is the poor regularity between layers and the particle size, which reduces the capability of tailoring the desired properties. Aliev et al. [44] suggested that control over spatial distribution of the particles could be achieved with the LBL approach, with the additional advantage of film fabrication under ambient conditions without the need of post-annealing. This allows the use of any type of substrate. The nanoclusters employed were superparamagnetic Fe<sub>3</sub>O<sub>4</sub> (plain and SiO<sub>2</sub>-coated) and the polyelectrolyte PDDA. Adhesion to the substrate was reported to be outstanding, since no peeling or cracks were observed after intense physical stress. Optical microscopy and atomic force microscopy (AFM) results confirmed the physical integrity of the samples after the stress experiments, and also the stability of the LBL films after 1 year of fabrication. Superparamagnetic properties were observed for films prepared from both plain and coated particles, revealing drastic reduction of the cooperative magnetization between adjacent nanoparticles with the coating layer.

Yttrium iron garnet (YIG) nanoparticles and barium ferrite were also assembled using the LBL approach and PDDA again for preventing phase segregation [45]. The authors observed that the domains might grow laterally in a two-dimensional (2D) mechanism instead of the regular vertical

fashion normal to the film growth direction observed for polymeric systems. They claim that both mechanisms cannot be differentiated by standard kinetic procedures, since lateral growth also depends on the number of layers. For high-quality films, it is important to have nanoparticle dispersion solutions, where the surface potential of the colloids must overcome attractive forces between the particles. This is achieved by the right solution parameters. Therefore, control of ionic strength and pH are crucial for determining growth kinetics. Scanning electron microscopy (SEM) results showed that YIG does not form uniform layers but rather forms domains of 0.5 to 1.5 μm. Such domains expanded laterally (and linearly) with the number of layers, regardless of the nature of the substrate.

Interesting work involving magnetic particles was developed by Mamedov and Kotov [49]. They were interested in building free-standing LBL films to act as ultra-thin membranes. The availability of mechanically resistant free-standing films may open new possibilities and applications, including nanofiltration and nanoseparation, taking advantage of the organized structure of the films. Their approach was to build up PDDA and negatively charged colloidal magnetite nanoparticles onto a cellulose acetate (CA) film that was previously placed onto a glass support. The choice of the substrate was based on its hydrophilic and solubility properties. After film deposition, CA plus LBL film was removed from the support and placed in acetone which caused dissolution of the substrate, thus leaving a free-standing ultra-thin film. Measurements indicated that the magnetic properties were preserved.

#### 4.2.3. LBL Films from Oxides

Oxide nanoparticles were largely explored using the LBL technique. Lvov et al. [50] investigated the adsorption of surface-modified nanoparticles of manganese oxide, alternated with PDDA or myoglobin (Mb) layers onto silver, quartz, and rough pyrolytic graphite substrates. Mb/MnO<sub>2</sub> structures were built to produce electroactive films. The saturation time for adsorption of the nanoparticles, measured with a quartz crystal microbalance (QCM), was similar to those typically measured for polymeric systems. The bilayer thickness for the PDDA particle system was 23 ± 2 nm where approximately 21 nm is due to the nanoparticle layer. This thickness is increased if particles are aged for 2 weeks indicating aggregation, although films were found to be stable for up to 6 months. X-ray photoelectron spectroscopy (XPS) results indicated a surface rich in carbon and oxygen with less than 7% of manganese and nitrogen. Manganese had two valences (Mn<sup>4+</sup> and Mn<sup>3+</sup>), and nitrogen appeared in two different environments suggesting the formation of contact ion pairs and long-distance charge pair formation between the Mn particles and PDDA.

Colloidal oxide particles were studied by Lvov et al. [51], using PDDA and SPS and colloidal dispersions of several SiO<sub>2</sub>-size particles (diameter of 25 ± 5, 45 ± 5, and 78 ± 5 nm), CeO<sub>2</sub>, and anionic TiO<sub>2</sub>. All systems were investigated using QCM. For SiO<sub>2</sub> layers alternated with PDDA, the thickness per layer depended on the particle concentration and the ionic strength of the solution. For 45-nm particles, for example, ca. 70% coverage was found when a

100-mg mL<sup>-1</sup> was used and there was only a sparse coverage for 0.1 mg mL<sup>-1</sup> for all particle sizes. Other assemblies were made from oxide particles (CeO<sub>2</sub> and anionic TiO<sub>2</sub>) and complex layer architectures using, in addition to polymers, glucose oxidase (GOD) (SiO<sub>2</sub>/PDDA/GOD/PDDA or SiO<sub>2</sub>-PDDA complex/SPS). A flat and smooth surface was found for these films but cross-section SEM images showed no long-range order. Atomic force microscopy measurements pointed to individual particles on the film surface. The large difference in size, morphology, and charge density between the particle and the polymer appeared to cause formation of long-distance charge pairs. Hence, the assembly was strongly dependent on ionic strength and particle concentration. Rinsing with water did not lead to desorption of the SiO<sub>2</sub> layer.

Ichinose et al. [52] described the build-up of LBL films from molybdenum oxide layers obtained via ammonium octamolybdate alternated with PAH layers. These compounds, whose generic name is polyoxometalates, have potential applications in catalysis, solid-state devices, photo and electrochromic displays, and in biochemistry and medicine. The assembly of oxide layers and PAH was found to be highly dependent on the pH of the PAH solution, which should be between 2.5 and 3.0. Saturation in the adsorption of the inorganic compound was attributed to the loss of negative charge on the molybdenum oxide layer during the adsorption, as the species in solution are not restricted to the ions—there are also protonated and condensed species. Therefore, the formation of a PAH layer at regular intervals is essential for growth control of the Mo oxide. The film thickness measured with a QCM varied with deposition time with a growth ratio of 5.7 Å/min. Scanning electron microscopy showed a very smooth surface in spite of the presence of cracks, which were attributed to the vacuum drying process for the microscopic studies.

Titanium oxides (TiO<sub>2</sub>) were employed for LBL film fabrication using PAH [53] or sulfonated polystyrene (SPS) [54] following the same approach of using modified surface particles. Cassagneau et al. [53] were able to use the TiO<sub>2</sub>/polymer structure sandwiched between ITO and gold to fabricate Schottky diodes. The presence of a capping layer did not prevent the TiO<sub>2</sub> electroactivity, which means that this approach can be extended to any oxide particle.

Nanocomposites of V<sub>2</sub>O<sub>5</sub> and polyaniline (PANI) were fabricated with the LBL technique [55], as an alternative to the previously used xerogel method [56]. It was found that obtaining nanocomposites was much easier with the LBL technique, probably due to the intimate contact between the adjacent layers of oxide and PANI, since the thickness per bilayer was only ca. 2.5 nm. Such intimate contact was reflected in the film characteristics, which differed from those of films from the separate materials or cast films from mixtures of V<sub>2</sub>O<sub>5</sub> and PANI. For example, a large shift in the V = O bands of FTIR spectra was observed, which was attributed to a more effective H-bonding between the polymer and oxide in the LBL films. Figure 2 shows the proposed structure for the PANI/V<sub>2</sub>O<sub>5</sub> LBL films, in which the architecture of the film can be controlled. Interestingly, the film properties depended on which material is the top layer [57], as demonstrated by UV-vis and Raman characterization. When the top layer was V<sub>2</sub>O<sub>5</sub>, the absorption

**Figure 2.** Schematic representation of PANI/V<sub>2</sub>O<sub>5</sub>/LBL films. Reprinted with permission from [55], M. Ferreira et al., *J. Nanosci. Nanotech.* 2, 29 (2002). © 2002, American Scientific Publishers.

spectrum peaks were at ca. 600 nm, which is characteristic of undoped PANI and/or PANI in the pernigraniline form. When the top layer was PANI, the absorption maximum shifted to ca. 800 nm, which is characteristic of doped PANI. Raman experiments were also carried out with a 20-bilayer PANI/V<sub>2</sub>O<sub>5</sub> LBL film whose last layer of PANI was partially overlaid by a 6-nm Ag film to achieve the surface enhanced phenomenon. The spectra remained similar to that obtained with no Ag coating, showing that Ag does not chemically interact with the PANI/V<sub>2</sub>O<sub>5</sub> film. The main changes were observed for the bands at 575 cm<sup>-1</sup> (benzene radical) and 1410 cm<sup>-1</sup> (C-N-C and C = N stretch), which became more intense for the Ag overlaid film. When the last layer of V<sub>2</sub>O<sub>5</sub> was also partially overlaid by a 6-nm Ag film, a more drastic change in the spectra was observed, if not in terms of new bands at least in terms of relative intensities. The spectra from the Ag overlaid film were dominated by the band at 576 cm<sup>-1</sup>. Raman scattering experiments were carried out where the LBL films with a PANI top layer were submitted to HCl vapor. The intensity of the 1336 cm<sup>-1</sup> (polaronic structures (C-N<sup>+</sup>)) band increased upon this treatment, thus indicating that PANI was in the emeraldine form, but the intensity was less than for a cast film (doped PANI). For V<sub>2</sub>O<sub>5</sub> as the top layer, the intensity of this band decreased. One possible explanation for such effects is deprotonation or overoxidation of PANI, but the latter is more plausible because V<sub>2</sub>O<sub>5</sub> is an acid semiconductor, which is unlikely to deprotonate the emeraldine salt.

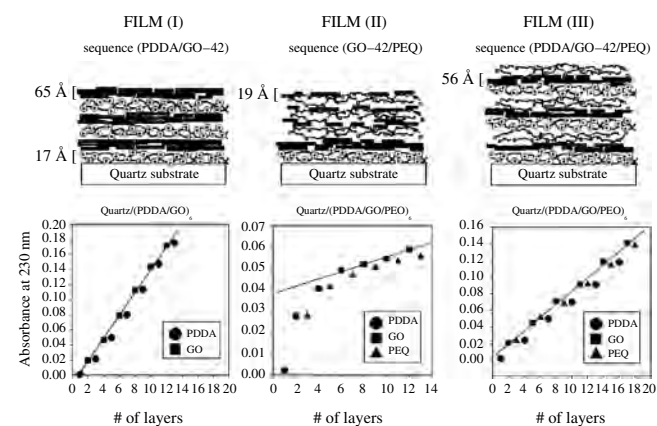

More complex oxide structures can be devised for LBL film fabrication. One example is the interest on highly dielectric thin films. Available techniques for producing structures with such characteristics, for example, magnetron sputtering, laser ablation, chemical vapor deposition (CVD), and sol-gel, require high processing temperatures, vaporization of the bulk dielectric material, or use of soluble precursors. This requirement has associated problems of

undesired elements in device fabrication. Fang et al. [58] took advantage of the LBL technique for fabrication of films from previously exfoliated perovskite-type oxides and polymeric cations that could be converted into a three-dimensional structure by means of chemical reactions. The oxides employed were  $\text{Ca}_2\text{Nb}_3\text{O}_{10}$  and  $\text{HTiNbO}_5$ , whose layers were alternated with PAH layers onto p-type Si wafers and borosilicate glass. A unilamellar colloid structure was obtained as a pure phase for  $\text{pH} \geq 8.5$ . Both oxides form dense monolayers onto PAH at  $\text{pH} 8.5\text{--}9.0$ , with only a single layer of the colloid being deposited, which suggests repulsive interactions between the sheets. X-ray diffraction data showed relatively strong Bragg peaks indicating well-ordered stacks of the oxide layers. The lamellar films could be further converted into three-dimensional (3D) structures by chemical condensation reactions, which were confirmed by thermal analysis.

Some compounds are obtained as platelets rather than particles and those are also easily assembled in a LBL structure as demonstrated by Cassagneau et al. [59], who used oxidized graphite. The adsorption process of these films is affected by the extent of oxidation of graphite that can be selectively controlled. Layer-by-layer films deposited on ITO and  $\text{SiO}_x$ -coated glass and quartz were analyzed with QCM, surface plasmon spectroscopy, UV-vis, FTIR, and AFM. The thickness of graphite-oxide (GO/PDDA) or poly(ethylene oxide) GO/(PEO) layers increased linearly with the number of bilayers, while the GO layer depended on the underlayer, as can be observed in Figure 3 that shows the schematics for three different sequential growths studied and the respective absorbance at 230 nm versus the number of layers. Poly(diallyldimethylammonium chloride) was always found to render higher coverage and thicker films compared to PEO, as expected since the first is a positively charged material and PEO is a neutral polymer.

#### 4.2.4. Metallic Nanoparticles in LBL Films

Metallic nanoparticles can be assembled in LBL films, similarly to what was described for oxide particles. The surface of the particles is modified to form a colloidal suspension.

**Figure 3.** Schematics of S-(PDDA/GO-42)<sub>6</sub>, S-PDDA/(GO-42/PEO)<sub>6</sub>, and S-(PDDA/GO-42/PEO)<sub>6</sub> films (top) and plots of absorbances versus number of layers self-assembled onto a quartz substrate (bottom). The first example of layered nanocomposite films prepared from colloidal metal particles and polyelectrolyte appears to be that of Schmitt et al. [60]. The interest in this kind of composite is in tailoring optical and electrical properties such as photo-induced charge separation for energy storage applications. The superlattices formed by gold particles and polyelectrolyte could either be layered or disordered structures, depending upon the thickness of the polymer interlayer. In [60], gold particles were prepared in a colloidal suspension with a narrow size distribution [61] and then used to produce the LBL films. Silicon wafers or glass substrates were alternately immersed into the colloidal dispersion and in a poly(ethyleneimine) (PEI) solution. For the film structure (PEI/SPS/PAH)<sub>1</sub>/(Au/PAH)<sub>4</sub> X-ray reflectivity data showed that the polymer layer was not thick enough to prevent interparticle interaction, that is, the systems were highly interpenetrated. Spacing layers were then used as control layers in film structures, such as PEI/[SPS/PAH]<sub>3</sub>/[Au/PAH]<sub>4</sub>, and X-ray reflectivity measurements showed multiple Bragg reflections indicating the well-defined layers of gold nanoparticles. The separating layers play no active role in the film. This approach to control particle interactions was extended to other polymers, with the nanoparticles being covered by different groups such as carboxylic acids or pyridine groups. The presence of gold particles was well evidenced by FTIR spectroscopy.

Control of interaction among gold nanoparticles of spherical and triangular shape in layer-by-layer (LBL) films was achieved by Malikova et al. [62]. Interaction was assessed by measuring the surface plasmon frequency, which was affected because oscillations of free electrons are largely dependent on the space available. The shape of the particles is also relevant. For example, electrons in rods can oscillate in transversal and longitudinal paths generating two well-defined surface plasmon peaks [63]. On the other hand, metallic spherical shells also display two surface plasmon bands, but these depend on the thickness and diameter of the sphere [64]. In [62], gold particles dispersed in solution were LBL processed with PDDA, with the gold particles being assembled with a flat conformation on the substrate as shown by TEM and AFM. The appearance of a new band at 650 nm attributed to interparticle interactions between adjacent monolayers occurred after four bilayers had been deposited. Particle interaction could be diminished by interposing spacing bilayers of PDDA/PAA. Such control is important for applications in catalysis, surface plasmon resonance, and to enhance nonlinear optical properties. Gold nanoparticles could also be assembled using hydrogen bonding as the driving force [65].

A direct synthesis method of 3D nanoparticle multilayers on carbon electrodes functionalized with 4-aminobenzoic acid (4-ABA) was proposed in [66]. The Pd nanoparticles were obtained from QPVP-Os (a quaternized poly(4-vinylpyridine)) complexed with [(Os(bpy)<sub>2</sub>Cl)<sup>2+</sup> and PdCl<sub>4</sub><sup>2-</sup>. After build-up, the film was electrochemically reduced to yield zero-valence 3D Pd nanoparticles. This was indeed confirmed by XPS results showing that the reduction takes place within the whole film thickness. Film growth was followed by the redox current of the Os-complex that increased linearly with the number of layers. Atomic force microscopy

images showed that before reduction, a poor surface morphology was observed. After reduction, however, Pd nanoparticles could be readily observed. The average diameter was estimated to be around 3–7 nm. The catalytic current increased with the number of layers and the particles did not show clear interfaces, which is favorable for charge transfer through the film. The nanoparticles could effectively catalyze the reduction of O<sub>2</sub> and the oxidation of hydrazine compounds.

#### 4.2.5. Quantum Dot-Type Nanoparticles

Quantum dots are nanoparticles with very well-defined emission wavelength that can be tuned by size variation associated with high fluorescence efficiency. Those characteristics put them as promising structures for electroluminescent device fabrication. Additionally, such particles can be easily assembled with several polymers rendering different LBL structures [67–72]. Gao et al. [67] took advantage of CdSe quantum dot opto-electronic properties by combining them with poly(*p*-phenylene vinylene) (PPV) electroluminescent devices. Such devices can be easily built with the LBL technique and it has been shown that the structure and material combination are determining for the emission properties [73, 74]. The large quantum efficiency of quantum dots contributes to improving external quantum efficiency of polymeric devices. Negatively charged CdSe nanoparticles, PAH, SPS, PPV (deposited as precursor and converted at 130 °C under 10<sup>-5</sup> bar vacuum for 11 hours) were used to assemble several device structures. Since emission of quantum dots depends on their size, the same device fabrication process and structure can be used for tuning different colors. The LBL technique also provides a means of controlling particle interaction using polymeric inert spacing layers, thus tailoring the final color emission. Gao et al. [67] studied several device structures, changing the composition of blocks: SPS/PPV, CdSe/PPV, CdSe/PAH, and CdSe/PAH-SPS/PPV. For CdSe/PPV, emission was found to come from CdSe rather than from PPV, which worked better as a hole injection layer. Emission from CdSe/PAH was redshifted by about 50 nm compared to CdSe/PPV, implying that there are some deep trap sites formed at the particle's surface during measurements. The two-block device was observed to be more stable. The most interesting result is that the nanoparticles were oxidized but this was prevented in the presence of PPV. X-ray reflectivity results indicated the presence of domains with an inhomogeneous distribution of CdSe particles, and with the average thickness being smaller than the particle diameter, that is, coverage was incomplete. CdSe nanoparticles were also studied by Hao and Lian [70], where assembly was made with H-bonding as the driving force.

In [42], Rosidian et al. reported on LBL films of HgTe nanocrystals. These materials display strong emission in the infrared region, therefore being relevant for the telecommunication industry. The average particle size used was 3.5 nm with size deviation of 30% as detected by TEM. Poly(diallyldimethylammonium chloride) was used as the assembling material and adsorption of the nanoparticles saturated after 80 min. The nanoparticle layer was 8-nm thick, which represents 2–3 monolayers in spite of the electrostatic repulsion. The film roughness estimated with scanning tunneling microscopy (STM) was slightly larger than

the quantum dot diameter. Layer-by-layer films showed strong emission around 1600 nm with no effect from solvent reabsorption.

Zhang et al. [72] proposed a new approach where CdTe nanoparticles are assembled with a special polymer, nitro-containing diazoresin (NDR), relying on ionic bonds. The ionic bonds are converted into covalent bonds by photoreaction of the photosensitive precursor film exposed to ultraviolet irradiation. Diazonium groups from the polycation were easily decomposed under UV irradiation forming cationic phenyl groups which could further react with the nucleophile of carboxylic acid groups and convert ionic to covalent bonds. This was achieved in 20-bilayer films, with decomposition being monitored by UV-vis and FTIR spectroscopy. The assembly of the nanoparticles was verified by XPS. The high stability of the irradiated film was checked by etching with a solvent mixture (H<sub>2</sub>O-dimethyl-formamide (DMF)-ZnCl<sub>2</sub>). For films irradiated during 30 min, only 11.9% of the particles were removed whereas 47.3% were removed for the nonirradiated film.

Finally, “coupled” nanoparticles can also be used. Those structures are anticipated to have potential applications in photocatalysis and solar energy conversion. They are large bandgap semiconductor particles with energetically low-lying conduction band. Such particles were LBL-assembled [75], using TiO<sub>2</sub>/PbS “coupled” nanoparticles and SPS. Poly(ethylene oxide) was used to modify the substrate surface and promote adhesion. The first step consisted of the preparation and characterization of the semiconducting particles. The LBL films displayed a morphology characteristic of well-packed layers.

## 5. LBL FILMS FROM ALUMINOSILICATES

The use of layered aluminosilicates in potential technological applications is limited due to their powdery nature. The conventional route to film formation is casting, spraying, or sometimes simply painting a suitable substrate with a polymer-nanoparticle mixture. However, these approaches do not allow control of film thickness, typically ranging from a few nanometers to a few micrometers, or of the particle orientation within the film. Furthermore, using these methods partial phase separation of the polymer/nanoparticle solutions may occur, leading to microheterogeneities in the film. Due to the strong negative surface charge of layered aluminosilicates, the LBL technique is suitable for the production of films in the nanometer range with vertical organization of different sandwich-like layers. In LBL films, aluminosilicate layers are alternated with positively charged polyelectrolytes, where the host lattice can have an ordered molecular arrangement. A further advantage is that the thermal and oxidative stability of organic molecules is improved when they are confined to interlamellar spaces of host lattices, owing to the reduced thermal motion and a quasi-absence of oxygen [76].

Although the mechanisms involved in the physical adsorption of clays are believed to be the same as for polyelectrolytes, significant differences have been observed in the times involved in the adsorption process. Table 1 summarizes the data for the adsorption kinetics of inorganic and

**Table 1.**

Adsorbent	Time for adsorption/saturation	Ref.
<b>Organic materials</b>		
Linear polyions	8–10 min	[78]
Anionic dye polymer	20–40 min	[79]
SPS and PAH	5 min	[80]
Anionic polythiophene derivatives	10 min	[81]
Anionic polyaniline derivatives	5 min	[81]
Ionene polymers	15 min	[82]
Proteins	10–20 min	[83]

organic materials. The inorganic species assemblies show quite large differences in saturation time, while adsorption of most of the organic materials reaches saturation within 5 to 20 min. These characteristics can be explained by plausible models shown in Figure 4. Adsorption of rigid, spherical SiO<sub>2</sub> particles appeared to be diffusion-limited (Fig. 4A). The diffusion time of SiO<sub>2</sub> from solution onto the surface is estimated to be 2 s using a diffusion coefficient of  $1.1 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ . Lvov et al. [77] demonstrated that 2 s are sufficient for SiO<sub>2</sub> assembly. If this diffusion rate is applied to the adsorption of PDDA at a concentration of  $3 \text{ mg mL}^{-1}$ , one should expect hundreds of monolayers to be adsorbed within 20 s, which was actually the minimum PDDA adsorption time required for only one SiO<sub>2</sub>-PDDA bilayer. It was concluded that the adsorption process of PDDA was not determined simply by its diffusion rate, for rearrangement of the adsorbed polymer chains may slow down the PDDA adsorption. Furthermore, the adsorption process depends on the clay nature. While adsorption of montmorillonite microplates is similar to that of organic materials (Fig. 4B) due to the flexibility of the polyions that change their conformation to achieve an efficient interaction with surface-bound opposite charges, the adsorption of molybdenum oxide is different (Fig. 4C). In the latter, protonation and condensation allow films to grow without excessive accumulation of the surface charges and the adsorption does not saturate. For montmorillonite, the adsorbed plates may reorient on the film surface to give the most stable or packed arrangement as in the case of proteins and dyes. The adsorption of montmorillonite microplates may resemble a dye assembly as most dye molecules possess rigid nonsymmetrical shapes. Their slower adsorption times (15–20 min for saturation) probably arise from rearrangement of adsorbed species to achieve stable aggregates and effective electrostatic attraction.

Several clays were demonstrated to render well-defined LBL polymeric/clay structures, among which montmorillonite is the most popular [85–90], followed by hectorite [91] and laponite [92, 93]. The polycations used are generally the

common polyelectrolytes for LBL film fabrication, but there are cases in which PPV [86] or dyes such as coumarin [94] have been employed. Montmorillonite as polyanion in LBL films was investigated by Lvov et al. [85]. Well-structured layered films or solid gels could be obtained depending on the concentration of the two components and on the preparation methods. The authors suggested that the assembly process of montmorillonite/polycation multilayers occurs with precise control of its architecture. As a result, LBL films and highly hydrated gels could be obtained, giving rise to useful functional materials. It was shown later on that the individual aluminosilicate-polyelectrolyte sheets were unexpectedly flexible and oriented in parallel to the substrate plane [89]. The LBL aluminosilicate-polyelectrolyte composites exhibited exceptionally high mechanical strength and resilience to crack proliferation [89], thus making this system promising material for gas separation and other membranes.

In a new approach, LBL films were produced under an applied electric field [90]. Positively charged PDDA was

found to bind strongly to the surface of anionic montmorillonite platelets in aqueous dispersions up to a saturation beyond which reversible physisorption occurred. The LBL films were prepared under an electric potential in a standard three-electrode electrochemical cell. Glass slides coated by Cr and Au were used as substrates. The substrate was connected to the bias source (in a potentiostat/galvanostat), immersed into a solution of PDDA (or dispersion of montmorillonite), and the desired potential was applied for 10–15 min. When the potential-assisted assembly of montmorillonite or PDDA was completed, the substrate was rinsed with ultra-pure water, dried with a stream of nitrogen, and introduced into a dispersion of montmorillonite (or solution of PDDA). In a given LBL film, only one of the components, either PDDA or montmorillonite, was assembled under a potential. The thickness of the montmorillonite layer was found to depend on the external voltage applied. The layer thickness increased when positive potentials or large negative voltages were applied but decreased slightly for films produced under a small negative potential.

Rigid platelets of Laponite with low surface charge density were obtained in LBL films where the Laponite polyanion was alternated with a cationic copolymer [93]. Film thickness increased linearly with the number of dipping cycles, as measured by ellipsometry. The characterization of these LBL films was accompanied by studies of LBL films from strong polyelectrolytes, where the influence of charge density of the polyelectrolytes on the growth of LBL multilayers from pure aqueous solutions was studied. For example, the analysis of the cationic copolymer/SPS system revealed that a critical linear charge density ( $\lambda_c$ ) of 0.036 elementary charge/Å of contour length is necessary to obtain stable multilayer growth in pure water. Above  $\lambda_c$ , the thickness per layer varies with the linear charge density of the cationic copolymers, in good agreement with current theories of polyelectrolyte solutions. Analogous results were obtained for the variation of the basal spacing of internally structured hybrid multilayers (cationic copolymer/hectorite). However, in contrast to the first system, no critical linear charge density was found for the hybrid system. This was explained by the authors due to the existence of nonelectrostatic interactions between the clay platelets and the formamide fragment.

Some applications have been suggested for alluminosilicate LBL films, including the production of inorganic hollow spheres for microencapsulation [92], humidity sensors [91], and in optoelectronics and photonics devices [86, 94]. The applicability of the LBL technique for the formation of a range of polymer-core, inorganic-shell particles and inorganic hollow spheres was demonstrated by Caruso et al. [92]. Composite particles comprising a polystyrene (PS) core and  $\text{TiO}_2$ ,  $\text{SiO}_2$ , or Laponite nanoparticle/PEI multilayers were fabricated. The influence of nanoparticle type, shape, and size on the formation of multilayer shells was examined by TEM and SEM. The LBL technique for coating polymer spheres is adaptable with small variations in the coating steps used to optimize the nanoparticle coatings of different materials. The number of polyelectrolyte multilayers separating the nanoparticle layers and the number of nanoparticle/polyelectrolyte depositions cycles may be varied to generate uniformly coated nanocomposite spheres.

The hybrid core-shell particles were subsequently calcinated to create well-defined hollow spheres with predetermined diameters.

Eckle and Decher [86] fabricated organic light emitting diodes (OLEDs) based on the PPV/Poly(methacrylic acid) (PMA) system including an insulating layer of montmorillonite. Multilayers of the cationic precursor polyelectrolyte (pre-PPV) and PMA were prepared by a cyclic immersion of PEI-coated substrates in pre-PPV and PMA solutions. Thermal conversion from pre-PPV to PPV was carried out at 270 °C for 12 h under vacuum. They demonstrated that a single clay layer affects the devices, lowering the current densities and increasing the light output in comparison with other polymer systems. Figure 5 shows the luminescence versus current density curves, whose slopes indicate the relative efficiency of the devices. Furthermore, when the distance between the clay layer and the ITO anode increases, the efficiency becomes slightly smaller. The device performance increased by a factor of at least 14 in the presence of a barrier layer. The authors also showed that the subnanometer positioning of this insulating barrier within the active medium with respect to both electrodes, which is easily controlled by the LBL technique, had an important role for the electro-optical properties of the diodes.

Nanocomposites containing a layered aluminosilicate with an expandable lattice such as hectorite and a coumarin dye were prepared using the LBL technique [94]. The aluminosilicate/coumarin dye was alternated with PDDA and deposited on hydrophilic glass substrates. The films exhibited blue fluorescence emission centered at 465 nm when excited at 386 nm and had an outstanding thermal stability. The intercalation of the dye causes the molecules to adopt

**Figure 5.** Luminescence-current density profiles showing the greatly enhanced performance of OLEDs containing a montmorillonite layer. The device without a clay layer (MLA-1, straight line) has a somewhat lower relative efficiency than those with an insulating layer. Device efficiency is further increased when the insulating inorganic layer is close to the ITO anode (MLA-2, filled circles). Reprinted, with permission from [86], M. Eckle and Decher, *Nano. Lett.* 1, 45 (2001). © 2001, American Chemical Society.

a flat conformation. The same authors observed [94] that the linear build-up of the multilayer films containing up to 20 cycles resulted in transparent films which exhibited strong blue-green fluorescence due to coumarin dye molecules adhered to the exfoliated hectorite platelets. These organic/inorganic core-shell nanoparticles may be promising building blocks for ordered ultra-thin nanocomposite films with high mechanical strength, chemical resistance, and thermal stability. Such properties are probably associated with the layered architecture and the ionic interaction with the cationic polyelectrolytes.

## 6. LBL FILMS FROM MACROCYCLIC SYSTEMS

Macrocyclic porphyrins and phthalocyanines have been widely reported as being suitable for microelectronics, photoresponsive materials, modified electrodes for catalyses, gas sensing, etc. The main characteristics exhibited by this class of materials are semiconductivity, well-defined redox activity, and high thermal stability. The fabrication of thin films of porphyrins and phthalocyanines is relevant for many fields because of the basic advantages to work with solid-state films where thickness and molecular engineering can be tailored for specific applications. The limited solubility of most metallic phthalocyanines has led researchers to employ vapor deposition techniques for film fabrication. Nevertheless, reports have been made on the preparation of ultra-thin films of substituted phthalocyanines using the LB and the LBL technique. The fabrication of LB films from phthalocyanines dates from decades ago and interesting results have been reported by a variety of groups [95–97]. Here we shall not cover such works, but rather concentrate on the more recent use of phthalocyanines in LBL films. A key for the production of LBL films has been the incorporation of sulfonated groups to metallic phthalocyanines, allowing LBL active layers of tetrasulfonated phthalocyanines to be alternated with cationic polyelectrolytes. In these films, interactions between the components may be maximized due to the nanostructured nature of the films.

The possibility of assembling sulfonated water-soluble phthalocyanines as active layers in LBL films was first reported by Lütt et al. [98]. In this seminal work, nickel tetrasulfonated phthalocyanine (NiTsPc) was assembled with PDDA. Growth of the multilayers was confirmed via UV-vis spectroscopy. Lütt et al. [98] observed significant differences between deposition of PDDA/NiTsPc onto silicon and glass substrates mainly regarding the thickness of the layers. When Si substrates were used, the thickness of the bilayers was ca. 2 nm for the few first bilayers, decreasing with the number of deposited layers to 0.8 nm after 40 bilayers had been deposited. Deposition on glass substrates did not show such dependency, with the thickness per bilayer being constant at ca. 1 nm. The latter implied that NiTsPc molecules were adsorbed in a standing up conformation onto the Si substrate (orthogonally in relation to the substrate plane) during the first layers. From X-ray reflectivity it was found that the electron density of the first deposited bilayer was not affected by the subsequent depositions [98].

In a subsequent work, Li et al. [99] presented a detailed study on film fabrication and optical properties of LBL

films made of PDDA and NiTsPc. The multilayers were grown by electrostatic attraction onto glass and silicon-charged substrates. X-ray reflectivity analysis showed that the PDDA/NiTsPc LBL films displayed a thickness of about 1.1 nm per bilayer with surface roughness of 0.2–0.7 nm (rms). Such thickness values were applied as constraints for ellipsometry measurements in order to obtain optical parameters such as refractive index,  $n$ , and extinction coefficient,  $k$ . The refractive index varied from 1.6 to 1.8. The use of LBL films from tetrasulfonated phthalocyanines in rectifying devices was evaluated by Li et al. [100]. The main scope of the work was to investigate the influence of bilayers of NiTsPc and poly(*p*-quaterphenylene-disulfonic-dicarboxylic acid) (PPP) assembled with PDDA on the potential barrier at the interface of rectifying devices made of aluminum and a *p*-type silicon semiconductor. The authors aimed at reducing the Schottky barrier across the metal/semiconductor interface. Through I-V characterization, it was found that the devices containing organic active layers did not show a Schottky behavior but rather a power-law dependence of current on voltage (at forward bias),  $J \sim V^\alpha$ , with  $\alpha = 1.4, 2.2,$  and  $2.7$  for PDDA/PPP, PDDA monolayer and PDDA/NiTsPc, respectively. This research opened up the possibility of exploiting phthalocyanines LBL films in electroluminescent devices as hole-transport layers.

L. S. Li et al. [101, 102] studied the electronic properties of conductive surfaces modified by the deposition of polyelectrolyte/NiTsPc layers. They evaluated the changes in work function of an ITO-modified glass when NiTsPc was assembled with PDDA [101] or an oligomeric viologen: oligo(hexylene 4,4'-bipyridinium dibromide) (OHBP) [102], respectively. The films were characterized by FTIR at an external grazing-angle reflection configuration and X-ray reflectivity. The work function of the films was obtained using the Kelvin probe technique. Preferential orientation for both PDDA and NiTsPc was inferred by FTIR at the grazing angle configuration [101] on drop cast films in comparison with the bulk materials. The same orientation was found in the LBL films, that is, the NiTsPc molecules seem to lie flat on the surface of the PDDA layer. Fourier transform infrared spectra also confirmed the presence of salt bridges between  $\text{SO}_3^-$  and  $\text{Me}_2\text{N}^+$  ( $1227$  and  $1200 \text{ cm}^{-1}$ ), which acted as binding forces between PDDA and NiTsPc. Kelvin probe measurements showed that the work function of the surface could be changed from 500 mV to 100 mV depending on whether the outermost layer was PDDA or NiTsPc (for any number of deposited bilayers). A possible explanation for the periodic variation on the work function of the film is that when one monolayer of PDDA is deposited atop ITO, there is an increase in the current due to the presence of dipoles from the PDDA configuration. When a NiTsPc layer is added atop the PDDA layer, a decrease in the current is observed due to the presence of another dipole layer that cancels the dipoles from PDDA.

The control of electronic properties on surfaces through molecular engineering was also demonstrated in [102], where the hole conductor behavior of NiTsPc and the electron acceptor characteristic of viologens were exploited to control the work function and photovoltaic characteristics of

LBL films made from OHBP and NiTsPc. In agreement with the results from [101], the work function of the film surface varied from 450 mV to 100 mV, depending on the terminal layer (OHBP or NiTsPc, respectively). Figure 6 shows the photovoltaic behavior of OHBP-NiTsPc on ITO evaluated by surface photovoltage spectroscopy. When one layer of OHBP is deposited on ITO (curve a), the photovoltaic response drops from 200 mV to about 105 mV at 350 nm. With the addition of one layer of NiTsPc to the film, about 30 mV of the photovoltaic response is recovered. Although this effect repeats with the deposition of additional layers of OHBP and NiTsPc, the photovoltaic effect diminishes with each addition of OHBP layer. The Kelvin probe technique and surface photovoltage spectroscopy were employed in another work by Li et al. [103] in the study of electronic and photovoltaic effects of LBL layers from PDDA and NiTsPc deposited onto conducting and semiconducting ITO and TiO<sub>2</sub> surfaces, respectively. The work aimed at investigating the charge-transfer properties between PDDA and NiTsPc. As expected, the work function of the films

**Figure 6.** Top: Surface photovoltage spectra dependence on the terminating layer of OHBP and NiPc. Bottom: Photovoltage spectra after the correction from blank ITO, that is,  $\phi_{\text{sam}} - \phi_{\text{ITO}}$ . Reprinted with permission from [102], L. S. Li and A. D. Q. Li, *J. Phys. Chem. B* 105, 10022 (2001). © 2001, American Chemical Society.

differed by approximately 300 mV depending on the top layer, whether it was from PDDA or NiTsPc. This occurred for ITO and TiO<sub>2</sub> substrates—in the dark or under illumination. Using surface photovoltage spectroscopy, it was shown [103] that the effect of the terminal layer is not significant when the PDDA/NiTsPc system is deposited on ITO. However, the presence of PDDA/NiTsPc layers seems to have a more remarkable effect for films deposited on TiO<sub>2</sub>, especially for excitation beyond the bandgap.

The electrochemical properties of LBL films comprising cobalt and iron tetrasulfonated phthalocyanines (CoTsPc and FeTsPc) were investigated by Lvov et al. [104] and Zucolotto et al. [105, 106], respectively. In these works, LBL films from phthalocyanines are used to modify electrodes for electrochemical analysis. Investigating the ion transport phenomena inside the films, Lvov et al. [104] showed that the redox process of PDDA/CoTsPc films containing one to five bilayers is controlled by charge diffusion. The diffusion coefficient for charge transport,  $D$ , was estimated as  $10^{-13}$  cm<sup>2</sup>/s for a 5-bilayer film.

In the works cited above, the assembling of tetrasulfonated phthalocyanines is expected to occur via the sulfonated group from phthalocyanine and the positively charged moiety of the polycation (e.g., PDDA, PAH). However, unusual interactions binding tetrasulfonated phthalocyanine and the polycation were observed in PAH/FeTsPc films [105]. Such specific interactions occurred between the metallic center of the phthalocyanine and the unprotonated NH<sub>2</sub> groups from PAH, as schematically illustrated in Figure 7.

Reports have been made of porphyrins in LBL films [107–111], where in addition to the study of basic concepts and film characterization, the films have been proposed for sensing [107] and to modify electrodes for electrochemical analysis [108]. The first report appears to be due to Araki et al. [107], where studies were made with two porphyrin species bearing opposite charges, viz. tetraruthenated zinc

**Figure 7.** Schematic illustration suggesting the additional interaction binding the Fe atom and unprotonated NH<sub>2</sub> groups from PAH. Reprinted with permission from [105], V. Zucolotto et al., *J. Phys. Chem. B*, in press. © —, American Chemical Society.

porphyrin ( $\text{ZnTPyPBpy}^{4+}$ ) and meso-tetra phenyl porphyrin sulfonate ( $\text{M-TPPS}^{4-}$ ). The deposition process was driven primarily by electrostatic attraction between the charged species. The multilayer structured films displayed microcrystalline morphology, with grain size of  $0.12 \mu\text{m}$ . The thickness of each bilayer was approximately  $1.27 \text{ nm}$ . The latter suggested a slip-stacked configuration with the molecules oriented coplanar with the substrate. Also worth mentioning is the work by Jiang et al. [111 and references therein] on the fabrication of LBL-patterned structures. It focuses on the assembly of several polyelectrolytes with a PPV derivative or an organometallic ruthenium electroluminescent dye (sulfonated ruthenium polybipyridyl complex): ( $\text{Ru}(\text{phen}')_3^{4+}$ ). Direct multilayer patterning of different dyes could be obtained based on the selective adsorption of polyelectrolytes onto surface templates made of carboxylic acid and oligoethylene glycol (EG) self-assembled monolayers (SAMs). By using the two dyes assembled with different polyelectrolytes it was possible to grow LBL films specifically on the COOH or on EG-modified regions of the patterned template. This new approach allows the formation of multilayer films placed in a side-by-side arrangement on the surface. The main interest in side-by-side deposition is the fabrication of patterned electrochemiluminescent devices.

## 7. DENDRIMERS IN LBL FILMS

The development of a new class of polymers, referred to as *dendrimers*, is relevant for several fields, particularly in the so-called *wet chemistry*. The interest in the fundamental understanding and application of dendrimers comes from the unique properties presented by these materials, such as monodispersity, tree-like architecture, well-defined functionalities, and the ability to self-organize into superstructures. In addition, a series of conducting or semiconducting particles can be placed into the hollow structure of the dendrimer. Dendrimers with specific properties can be successfully tailored by adjusting the functionality of the end groups. These features allow the use of dendrimers in a wide range of applications especially in the form of thin films. Nanostructured thin films made from dendrimers, in particular, may serve as active surface layers for sensing, nano-reactors, reservoirs for conductive particles, and as modified electrodes for electrochemical analysis.

The LBL technique is suitable in producing nanostructured films of dendrimers due to their water-solubility, stability, and presence of functional end groups. These groups allow the fabrication of layered structures made from dendrimers in conjunction with a number of charged species such as polyelectrolytes, biomaterials, polyoxometalates, and even with other dendrimers. The first report of LBL films from dendrimers was made by Watanabi et al. [112], where only one type of dendrimer was used. In that seminal work, polyamidoamine dendrimers (PAMAM) were assembled on themselves by functionalization of the end groups with  $\text{K}_2\text{PtCl}_4$  after each dendrimer layer had been adsorbed. This functionalization process provided sites where a further layer of dendrimer could attach. This process allowed the deposition of 8-nm thick layers at each deposition step. In a similar approach, Wang et al. [113] produced covalently bonded LBL multilayers of PAMAM G1.5 dendrimer and

nitro-containing diazoresin (NDR). The multilayered films were initially built via electrostatic attraction and then irradiated with UV light which promoted the conversion of the bonds from electrostatic to covalent.

Tsukruk et al. [114] produced LBL films with two types of dendrimers bearing opposite charges. Polyamidoamine dendrimers presenting surface amino groups for generation 4, 6, and 10 (G4, G6, and G10) and carboxylic groups for generations 3.5, 5.5, and 9.5 (G3.5, G5.5, and G9.5) were adsorbed onto each other driven by electrostatic attractions between the amino and carboxylic functional groups. An important result was that the thickness of a dendritic monolayer in the layered structure was smaller than the diameter of ideal spherical dendritic macromolecules as estimated from molecular models or from chromatography data of dendritic solutions [114 and references therein]. Such behavior can be explained by the strong interaction of the sticky groups of adjacent dendritic layers leading to the formation of a compressed, flattened structure for the dendrimers. The structural state of dendrimers on air-solid (self-assembled films) and air-water (Langmuir monolayers) interfaces was further investigated in [115].

Evidence of unexpected compressed multilayers was also found by Casson et al. [116] for LBL films assembled with a propyleneimine generation 3 dendrimer and azobenzene-containing polymer poly[1-[4-(3-carboxy-4-hydroxyphenylazo)benzenesulfonamido]-1,2-ethanediyl, sodium salt], (PAZO). When PAZO was the top layer, it adsorbed as a loosely packed layer due to electrostatic repulsion of the negative charges, resulting in a thicker layer. With a subsequent dendrimer deposition, the PAZO layer collapsed to a more compact form, as seen in Figure 8. The latter occurs due to a screening effect as the dendritic layer

**Figure 8.** Schematic diagram of the dendrimer/PAZO multilayer system showing the interpenetration of the dendrimer molecules into the PAZO polymer and the collapse of the film. (1) a terminal dendrimer layer; (2) a loosely packed layer of PAZO on a dendrimer layer; (3) a collapse of the PAZO layer when dendrimer is adsorbed onto it; (4) another layer of loosely packed PAZO on top of the dendrimer and collapsed PAZO layers; (5) a second collapse of the underlying PAZO layer when dendrimer is adsorbed. interpenetrates in the PAZO layer shielding the charges and allowing the PAZO molecules to pack close together.

The use of dendrimers as encapsulating materials or nanoreservoir materials was exploited by He et al. [30] and Khopade and Caruso [117], using multilayers built up with a PAMAM dendrimer and an anionic polyelectrolyte, SPS. Layer-by-layer films from dendrimers encapsulating gold nanoparticles were produced by He et al. [30]. The insertion of gold particles within the hollow structure of a PAMAM G5 dendrimer was carried out by mixing an aqueous solution of  $\text{AuCl}_4^-$  with an aqueous solution of the PAMAM dendrimer (at a molar ratio of 10 gold atoms per dendrimer) followed by a reduction reaction with hydrazine. Figure 9 depicts the structure of the Au-dendrimer nanocomposite. The final solution with concentration of 3.78 g/L for dendrimer and 0.58 g/L for gold was used in the fabrication of LBL films with SPS onto solid substrates modified with a monolayer of PDDA. The adsorption process was monitored by UV-vis spectroscopy showing that the growth of the Au-dendrimer/SPS multilayer nanocomposites was uniform after the sixth bilayer. The effectiveness of incorporation of Au into the dendritic structure was probed by TEM performed on Au-dendrimer/SPS layers deposited onto carbon-covered copper grids. The results showed that Au appears as nanoparticles (5–20 nm) aggregated within the Au-dendrimer structure. The nanostructure of the films was observed via AFM that showed uniform spherical gold-dendrimer nanoclusters packed on the surface.

Khopade and Caruso [117] showed that multilayers of PAMAM G4 dendrimer assembled with SPS can act as nanoreservoirs. The LBL films of PAMAM/SPS were assembled onto PS colloidal particles (925 nm). In the sequence, the SPS/PAMAM-coated PS particles were exposed to an aqueous solution containing a model fluorescent dye (4,5 Carboxyfluorescein (CF)). The presence of entrapped dye molecules in the LBL films was confirmed by photoluminescence experiments and confocal laser scanning microscopy (CLSM). In the CLSM images, the fluorescence of the entrapped dye molecules appeared as a ring on the

dendrimer/SPS-coated particles. Since CF is not expected to bind SPS, the entrapment is due to interactions of CF with amino groups of the PAMAM dendrimer. Furthermore, it was observed that ca. 80–90% of the entrapped dye molecules could be released under physiological conditions by exposing the dendrimer/SPS-coated PS particles to a stirred solution of 0.154 M NaCl at pH 6.5 (isotonic saline solution), thus suggesting the potential use of these films as drug delivery materials.

The versatility of addressing specific functional sites as end groups in dendrimers contributed to the development of a new approach concerning the mechanisms of adsorption in LBL films [23, 118]. Multilayer films fabricated with biotin-labeled polyamines and avidin were reported by Anzai et al. [23]. Despite the fact that avidin and polyamines are both positively charged, multilayer growth was possible due to the very specific interaction between avidin and biotin, since the avidin-biotin interactions are stronger than the ionic repulsion. The latter was confirmed by the fact that multilayers could not form when unmodified polyamines were used. Differences in deposition behavior and structure of the LBL films were observed depending on the geometry of the modified polyamine. Films prepared with a modified dendritic polyamine (PAMAM) provided the deposition of a monomolecular layer of avidin. Such behavior, however, was not observed when avidin was assembled with branched poly(ethyleneimine) and linear poly(allyllamine).

The nanometer-scale porous structure presented by dendrimers has become of special interest in applications where diffusion of molecules is required, such as heterogeneous catalysis and sensing. Layer-by-layer dendritic films, in particular, have been reported as modified electrodes for electrochemical catalysis [119] and bio [120, 121] or vapor sensing [122, 123]. The reason is that the porous structure of dendrimers may facilitate ion exchange throughout the film. Layer-by-layer films especially designed for electrocatalysis were prepared by Cheng and Cox [119]. The films were made up of PAMAM G4 dendrimers assembled with two different polyoxometalates (POMs), viz.  $\text{PMo}_{12}\text{O}_{40}^{3-}$  (Keggin-structure) and  $\text{P}_2\text{W}_{18}\text{O}_{62}^{6-}$  (Dawson-structure). The structure of the LBL films is shown in Figure 10. The growth of the multilayers was uniform according to UV-vis and cyclic voltammetry data. The catalytic effect of the films was confirmed via cyclic voltammetry where the electrochemical reduction of iodate and nitrite was analyzed. In addition to the catalytic effect, the stability of POM into the layered structure was improved.

The feasibility of LBL dendritic films for biosensing applications was demonstrated by Yoon et al. [120, 121]. Multilayer structured films were assembled alternating PAMAM G4 dendrimer with periodate ( $\text{IO}_4^-$ ) oxidized glucose oxidase (GOx) onto a gold electrode surface [120]. Thin films containing 1 to 5 bilayers (ca. 5.2 nm per bilayer) were used for detecting glucose via electrochemical analysis using ferrocenemethanol as an electron-transfer mediator. Glucose was detected by the increase in the anodic current plateau as a function of its concentration. Besides, the modified electrodes displayed thickness-dependent sensitivity. A linear increase of the anodic current was observed as a function of the number of bilayers in the presence of 20 mM of glucose. The sensitivity of the 5-bilayer film was

$14.7 \mu\text{A} \cdot \text{mM}^{-1} \text{glucose} \cdot \text{cm}^{-2}$ . In order to produce reagentless biosensors, modified gold electrodes were produced for glucose detection, using a PAMAM-functionalized dendrimer and GOx [121]. The primary amine end groups of a PAMAM G4 dendrimer were chemically modified with ferrocene carboxaldehyde leading to the ferrocenyl-tethered dendrimer (Fc-D). As in the case previously discussed [120], the sensitivity of the LBL modified electrodes built with Fc-D could be tuned by adjusting the number of bilayers of the films. Dendrimers exhibiting 32% of modification provided the optimum balance between conjugation with enzyme and electrocatalytic activity.

Dendrimers as building blocks for porous LBL films were exploited by Vossmeier et al. in vapor-sensing devices [122, 123]. The devices comprised gold nanoparticles assembled with different types of dendrimers onto lithographic interdigitated electrodes. High selectivity could be achieved in the devices upon appropriate choice of dendrimers with hydrophilic, amphiphilic, or hydrophobic character. Electrical conductivity was provided by the Au nanoparticles. The use of dendrimers allowed the assembly of Au nanoparticles in addition to the fact that they provided specific sites for the sorption of the analyte molecules. Three different types of dendrimers were employed, viz. polyphenylene dendrimer (PPh) (hydrophobic), poly(propyleneimine) dendrimer G4 (amphiphilic) (PPI), and poly(amidoamine)

PAMAM G3 (hydrophilic) (PAMAM). The sensor characteristics of the LBL films were evaluated by monitoring the changes in the film electrical conductivity in the presence of toluene, 1-propanol, or water vapors. Figure 11 illustrates the electrical responses of the devices in the presence of 5000 ppm of the solvents. The sensing mechanism is attributed to a swelling effect of the film in the presence of the solvent, which increases the tunneling distance between the Au particles, thus diminishing the film conductivity. Such a mechanism explains the high selectivity of the films since the swelling effect depends on the affinity between solvent and dendrimer.

## 8. LB FILMS FROM METALLIC COMPLEXES

The scientific interest in the fabrication of ultra-thin films from organometallic materials [124–127] is motivated by the possible extension of applications that today are based on inorganic compounds, especially semiconductors. The LB

**Figure 11.** Response traces measured by dosing the Au/dendrimer films with toluene, 1-propanol, and water: (a) Au/PPh; (b) Au/PPI; (c) Au/PAMAM. In each case the vapor concentration was 5000 ppm, and the temperature of the sensor cells was kept constant at  $39^\circ\text{C}$ . Lett.* 2, 551 (2002). © 2002, American Chemical Society.

technique has been exploited in this context due to the control over film thickness and architecture [128, 129], in addition to the intimate contact between distinct materials in heterostructures. Complexes of transition metals, for example, are advantageous when containing ligands with low-energy  $\pi$  electrons coupled to metal ions with various redox states [130]. In order to exploit the advantages of the LB technique, one has to optimize film fabrication conditions since most materials do not readily form stable LB films. The LB technique was conceived for amphiphilic, small molecules that are efficiently spread on an aqueous subphase and suitable rigidity to allow transfer onto a solid substrate. For macromolecules or semi-amphiphilic materials, a number of difficulties may arise. The first one comes from the poor spreadability of the material, particularly when the hydrophilic and hydrophobic parts of the molecules are not well defined. Such compounds tend to form aggregates with a consequent decrease in monolayer stability. This is an important issue as the fabrication of high-quality LB films requires stable monolayers. In the case of macromolecules, there are additional difficulties associated with the rigidity of the monolayer which hampers transfer onto a substrate. Furthermore, Langmuir films from macromolecules are most often not true monolayers, that is, they are not monomolecular layers. In any case, special strategies must be used to produce LB films. A number of such strategies have been used in the recent past, and perhaps the most frequent one is the mixture of the nonamphiphilic material with a traditional amphiphile like a fatty acid [131].

### 8.1. LB Films from Ru Complexes

Ruthenium complexes are certainly among the most used metallic complexes for the fabrication of Langmuir and LB films. Such compounds may be classified as semi-amphiphilic or nonamphiphilic—their spreading ability is generally low. As a result, stable monolayers are only formed after optimization of experimental conditions. The first attempts to produce LB films from amphiphilic ruthenium compounds, including those with long alkyl chains, were unsuccessful [132–135], mainly because the Langmuir films were unstable due to hydrolysis of the ester groups. Zhang and Bard [136, 137] and Obeng and Bard [138] investigated the electrochemical properties of LB films of  $[\text{Ru}(\text{bpy})_2(\text{bpy}-\text{R})]^{2+}$  (bpy = 2,2'-bipyridine; R is a long alkyl chain) and suggested that the monolayer of ruthenium complexes tends to aggregate on the water surface, thus leading to unstable films. In later works, it was shown, however, that stable Langmuir films could be formed. For example, while producing mixed LB films of stearic acid (SA) and the complex  $[\text{Ru}(\text{dppen})_3]^{2+}$  (dppen = 4,7-diphenyl-1,10-phenanthroline), Murakata et al. [139] showed that long alkyl chains are not required in the ruthenium complex for the formation of stable Langmuir films. Murakata et al. [139] proposed a mechanism of monolayer formation consistent with the ion-pair interaction, as depicted in Figure 12, where the metallic complex interacts with the carboxylate of SA. In the experiments by Murakata et al. [139], the incorporation of the complex alters the surface pressure isotherm of stearic acid, by introducing a phase transition between the liquid-expanded and liquid-condensed phases, which is not

**Figure 12.** Schematic diagram for the formation of the Langmuir monolayer via ion-pair interaction. Reprinted with permission from [139], T. Murakata et al., *J. Phys. Chem.* 92, 6040 (1988). © 1998, American Chemical Society.

present for the pure acid. The plateau characteristic of this phase transition was attributed to the interaction between the metallic complex and the carboxylate.

Langmuir films from other ionic Ru complexes were fabricated by DeArmond et al. [140], where the complex was dissolved in the aqueous subphase on which a fatty acid monolayer was spread. This was motivated by Palacin et al.'s work [141, 142] for cobalt(II) phthalocyanines. The area per molecule for the fatty acid condensed monolayer on a subphase containing Ru complex is 23–24 Å<sup>2</sup>, compared to 20 Å<sup>2</sup> for the monolayer on pure water. This increase was attributed to the ionic interaction between the complex and stearic acid molecules. It is known that when the subphase contains CdCl<sub>2</sub>, a stearic acid monolayer displays no liquid-expanded phase [143]. However, when Ru<sup>2+</sup> were present in the subphase, the packing of the stearic acid molecules was less efficient and the liquid-expanded phase appeared [141].

Samha and DeArmond [144] investigated Langmuir films from mixtures of stearic acid and Ru(II) ionic complexes ( $[\text{Ru}(\text{N}-\text{N})_3]^{2+}$ , where N-N = 4,4',5,5'-tetramethyl-2,2'-bipyridine, 1,10-phenanthroline, 4,7-diphenyl-1,10-phenanthroline) dissolved in the subphase solutions compared with films of stearic acid on pure water. They showed that equilibrium is reached for monolayers of these complexes within 30–60 min after spreading. Immediately after spreading, however, the collapse pressure decreased and tended to the collapse pressure of stearic acid. The area per stearic acid unit in the compressed film of stearic acid on the surface of the ruthenium complex subphase (23–24 Å<sup>2</sup>) is larger than that on the pure water subphase (20 Å<sup>2</sup>). Such behavior is due to the ion-pair interaction between the stearic acid and the metal complex ions. This was attributed to the

migration of molecules of the complex into the subphase. The collapse pressure of the film decreased with time (in the range of 30 to 60 min) becoming the same of the collapse pressure of pure stearic acid (55–65 mN/m, 120 min) [144], which indicates the migration of the complex molecules from the surface to underneath the stearic acid layer, as shown schematically in Figure 13.

The interaction of Ru complexes with fatty acids in Langmuir films has been investigated in [145]. Arachidic acid (AA) monolayers were spread on subphases containing tris(1,10-phenanthroline)ruthenium(II) chloride hexahydrate. The electrostatic interaction between Ru(II) ions and AA molecules is similar to that with  $\text{Cd}^{2+}$  ions, which caused the monolayer to be more stable. The only difference was that the Ru(II) complex kept AA molecules further apart than in the case of cadmium ions. The red shift in the UV-vis absorption spectra of the mixed LB films, in relation to the spectra of Ru(II) in acetonitrile, can probably be assigned to aggregates and a counterion effect. Interaction with fatty acid (arachidic acid) monolayers was also studied for  $[\text{Ru}(\text{L})(\text{totpy})(\text{OH}_2)](\text{ClO}_4)$  ( $\text{L} = \text{Ph}_2\text{AsCH}_2\text{CH}_2\text{AsPh}_2$ ); 4-totpy = 4'-(4-tolyl-2,2':6',2''-terpyridine) complex (2:1). The surface pressure ( $\pi$ ) versus surface area ( $A$ ) isotherms obtained for the Langmuir films showed a phase transition between the expanded and liquid-condensed states, which is not present in the  $\pi$ - $A$  curves for pure AA monolayers. In surface potential,  $\Delta V$ , versus area,  $A$ , isotherms, the critical area corresponding to the onset for the surface potential increased considerably with the incorporation of the ruthenium complex. Also, the difference between the minimum and maximum surface potential increased with the concentration of the ruthenium complex in the mixed monolayer. UV-vis, and FTIR spectroscopy of the LB films from the mixture confirmed the partial dissociation of the acid [146]. This mixed monolayer approach was also employed for

**Figure 13.** Schematic illustration of the migration of the metal complex molecules from (A) the surface of the subphase (surface film) to (B) beneath the stearic acid monolayer (subphase film). Reprinted with permission from [144], H. Samha and M. K. De Armond, *Langmuir* 10, 4157 (1994). © 1994, American Chemical Society.

other ionic ruthenium complex, for example,  $[\text{Ru}(\text{dppe})(4'\text{-totpy})(\text{H}_2\text{O})]\text{ClO}_4$ , where  $\text{dppe} = \text{PPh}_2(\text{CH}_2)_2\text{PPh}_2$  and 4'-totpy = 4'-(4-tolyl-2,2':6',2''-terpyridine) [147]. In the latter, FTIR characterization confirmed that the acid molecules were ionized and complexed with the ruthenium complex molecules.

The properties of Langmuir films from  $[\text{Ru}(\text{L}_{18})(\text{tPY-PO}_3\text{H})]\text{PF}_6$  complex, where  $\text{L}_{18} = 2,6\text{-bis}(\text{N-octadecylbenzimidazol-2-yl})\text{pyridine}$  and  $\text{tPY-PO}_3\text{H} = 2,2';6',2''\text{-terpyridine-4'-phosphonic}$  were strongly affected by the pH of the subphase and by the metal coordination [148]. The surface pressure-area isotherms displayed a smaller area per molecule at lower pHs. The *in-situ* UV-vis absorption spectra of the Ru complex at the air-water interface also depended on the pH of the subphase, because as the subphase becomes acidic, the absorption band at 363 nm from the intraligand  $\pi - \pi^*$  transitions is sharpened with a slight red shift, which reveals the formation of molecular aggregates at the air-water interface.

Uemura et al. [149] reported hybrid multilayers of natural saponite and the amphiphilic ruthenium(II) complex  $[\text{Ru}(\text{phen})_2(\text{dcCl}_2\text{bpy})]^{2+}$  ( $\text{phen} = 1,10\text{-phenanthroline}$ ,  $\text{dcCl}_2\text{bpy} = 4,4'\text{-carboxyl-2,2'-bipyridyl didodecyl ester}$ ) prepared by two methods: in method A (Fig. 14a), the hybrid monolayer was deposited by a horizontal dipping one after another; in method B (Fig. 14b) a hydrophilic surface of the transferred hybrid monolayer was dipped in an aqueous solution of an alkylammonium salt to render the surface hydrophobic with alkylammonium cations. The isotherms obtained for the films of  $[\text{Ru}(\text{phen})_2(\text{dcCl}_2\text{bpy})]^{2+}$  spread on pure water and on clay suspensions showed a dependence

**Figure 14.** Preparation methods of hybrid LB multilayers of amphiphilic ruthenium(II) complex cations and clay platelets: (a) Method A and (b) Method B. Reprinted with permission from [149], Y. Uemura et al., *J. Am. Chem. Soc.* 124, 992 (2002). © 2002, American Chemical Society.

on the clay concentration (10, 50, and 100 ppm), suggesting the formation of a hybrid monolayer of the complex and the clay at the air-suspension interface. The difference in orientation resulting from the application of the two methods was apparent in the area per cation for the multilayer. It was concluded that in method A, the multilayer was produced LBL, but the orientation of the Ru(II) complex cation in the layer was disturbed [149]. The multilayer prepared by method B was also built in a LBL fashion, but with a better defined structure with the layer oriented in one direction, that is, the hydrophobic alkyl chains of the Ru(II) complex cation would be directed to the alkylammonium salt layer, and the hydrophilic head group of the complex cation and phenanthroline ligands would face the clay layer [149].

A fullerene-ruthenium-porphyrin complex was employed in the fabrication of LB films, building upon previous experiences [150] with fulleropyrrolidines functionalized at the nitrogen with hydrophilic chains possessing the correct hydrophobic-hydrophilic balance to form stable monomolecular layers at the air-water interface [151]. The existence of a true monolayer was confirmed by means of  $\pi$ - $A$  isotherms. The  $\pi$ - $A$  isotherm for a 1:20 molar mixture of ruthenium complex and AA displayed different phases as the dyad molecules were squeezed out from the film. When  $\pi > 35 \text{ mN} \cdot \text{m}^{-1}$ , the dyad molecules were virtually on top of the hydrophobic arachidic acid layer. Photophysical studies, performed by transient absorption spectrophotometry, demonstrated that electron transfer occurs in the solid film with a lifetime of  $2.2 \mu\text{s}$ .

Another class of ligands for transition metals comprises the tertiary phosphines that may be strongly bonded to transition metal ions. Phosphines may be employed to stabilize isolated compounds or intermediates in homogeneous catalysis [152, 153], as well as in chemotherapy agents [154]. Because they possess a reasonably strong *trans* effect, phosphines lead to easily labile complexes that are essential for homogeneous catalysts [152, 155, 156]. Ru-containing catalysts with chelated biphosphine ligands for asymmetric hydrogenation have been used since the 1970's [157], and in recent years applied in classical catalytic reactions (e.g., hydrogenation, isomerization, decarbonylation, homologation of amines) [158, 159], in the activation of C-H species in the coupling of olefines [160], for oxidation [161] and incorporation of carboxylic acid in alkynes [162], hydrogenation of styrene [163], and imines [164, 165]. With regard to LB films from phosphine-containing metallic complexes, in 1993 Fu et al. [166] reported the use of a long-chain phosphine ligand,  $\text{P}(\text{C}_{18}\text{H}_{37})_3$ , coordinated to the complex  $[\text{Ru}(\text{P}(\text{C}_{18}\text{H}_{37})_3)(\text{DTBSq})]$  ( $\text{DTBSq} = 3,5$ -di-*tert*-butyl-*o*-benzosemiquinonato). These LB films were characterized using UV-vis spectroscopy, and *in-situ* cyclic voltammetry. Santos et al. [147] employed the achiral biphosphine ligand dppe with the complex  $[\text{Ru}(\text{dppe})(4'$ -totpy) $(\text{H}_2\text{O})]\text{ClO}_4$ , and the resulting LB films were assessed as electrode modifiers. Enhanced electrochemical activity was observed with the immobilization of the complex within the matrix formed by the LB film, due to the orientation conferred by the LB technique that assists the electron transport.

The molecular-level interaction between a biphosphine ruthenium complex,  $\text{mer-}[\text{RuCl}_3(\text{dppb})(4\text{-Mepy})]$

( $\text{dppb} = \text{PPh}_2(\text{CH}_2)_4\text{PPh}_2$ ; 4-Mepy = 4-methylpyridine) ( $\text{Ru-pic}$ ) [167] (Fig. 15) and stearic acid was investigated in LB films by Wohnrath et al. [168]. Langmuir-Blodgett films could also be produced from pure Ru-pic, but in this case the films that were spread on the water/air interface were not true monolayers. Transferability was considerably enhanced upon mixing Ru-pic with stearic acid. Nevertheless, the LB films from pure Ru-pic displayed higher electroactivity, partially because there was no insulating matrix of stearic acid and also because the resulting films had higher roughness. Cyclic voltammetry results also indicated that the irreversible behavior of this complex in the LB films was associated with its spatial rearrangement when Ru(III) was converted into Ru(II), which caused the electron transfer rate between film and substrate to be lower than for the compound in solution. In the latter, such restructuring induced different species. It should be stressed that cast films from Ru-pic were not electroactive, which demonstrates that this property depends on the order induced in the LB technique.

A parent biphosphine ruthenium complex,  $\text{mer-}[\text{RuCl}_3(\text{dppb})(\text{py})]$ , ( $\text{py} = \text{pyridine}$ ) ( $\text{Rupy}$ ), was also investigated for a molecular-level interaction with stearic acid in

**Figure 15.** Three-dimensional illustration and chemical structure of the complex  $\text{mer-}[\text{RuCl}_3(\text{dppb})(4\text{-Mepy})]$ . Reprinted with permission from [168], K. Wohnrath et al., *Thin Solid Films* 402, 272 (2002). © 2002, Elsevier Science.

Langmuir and Langmuir–Blodgett films [169]. The interaction was demonstrated in the Langmuir films by a non-linear increase in the area per molecule and in surface potential with the relative concentration of the ruthenium complex in the mixture. Interaction with stearic acid in the LB films occurred via complexation with the ruthenium complex, even though Rupy is not charged. It was suggested [169] that one of the chlorides was labilized to promote complexation and keep the Ru(III) oxidation state of the complex. Complexation was confirmed through FTIR spectroscopy. Another interesting feature of the LB films from Ru-pic and Rupy was the color change in comparison to cast films or solutions of the complexes in organic solvents, as illustrated in Figure 16. This color change was attributed to an order-induced effect caused by the LB fabrication process, and was enhanced due to the interaction with stearic acid.

In the previous paragraphs, we mentioned LB films from mononuclear ruthenium complexes. Langmuir–Blodgett films have also been produced from binuclear Ru species with mixed valence. The behavior of the organized monolayers of the dyad Ru(II)-Rh(III) (water soluble)

**Figure 16.** Electronic absorption spectra recorded for Rupy in various forms: in chloroform solution (a), as neat cast film (b), in neat LB films (d), or mixed LB films (c, e, f, g). and monolayers of opposite head-group charge such as dimyristoyl-phosphatidic acid (DMPA) and protonated eicosylamine (EA) has been studied [170]. The Rh(II) subunit has two 2,2'-bi-(4,4'-dicarboxy)-pyridine ligands and the bipyridine-residual of the bridging 1,2-di-(4,4-(2,2'-bi(4',4'-dimethyl)-pyridine))-ethane, which also acts as a ligand of the octahedral Ru(II) subunit with two further 1,10-dimethyl-phenanthroline ligands. The dyad has a net positive charge of  $1^+$ , if all four COOH groups in the Rh moiety are ionized. The Ru moiety has the charge  $2^+$  (Fig. 17). The surface pressure area isotherms indicated that the pure dyad is water soluble and forms no monolayer at the air-water interface. The polar heads of DMPA bind electrostatically not only to the Ru(II) center but also interact with Rh(III). The COOH groups of the Rh(III) ligands and the charge of the metal ions provide a variety of possibilities to bind the dyad to a charged monolayer and/or to incorporate a subunit into the hydrophobic moiety of the lipid monolayer. The isotherms of dyad-EA demonstrated that the dyad with a net positive charge also interacts with a positively charged monolayer: the positive head group of the EA monolayer with three deprotonated carboxyl groups of the Rh subunit while the Ru subunit was oriented towards the subphase.

The system Ru(II)-Rh(III) dyad [171] was incorporated in monolayers at the air/water interface by cospreading with a positively EA or negatively SA charged amphiphile. The morphologies of the two resulting systems after transfer onto mica were determined using two scanning probe techniques, scanning probe microscopy (SPM) and scanning force microscopy (SFM). No dyad was lost with SA upon compression and transfer of the monolayer. In contrast, much less dyad remained at the water/interface with EA as the lipid anchor.

**Figure 17.** The Ru-RH dyad: Chemical structure (left), and three-dimensional model of the dyad (right). Reprinted with permission from [170], H. Huesmann et al., *Thin Solid Films* 284–285, 62 (1996). © 1996, Elsevier Science.

## 8.2. LB Films from Metallic Complexes Other than Ru

A great deal of work has been done in organometallic materials in the form of LB monolayers and multilayers. A review of the topic was published by Nalwa and Kakuta in 1992 [172], where the electrical and nonlinear optical properties of LB films from several systems were discussed. Such systems included organoruthenium complexes, ferrocene derivatives, metal(4,5-dimercapto-1,3-dithiol-2-dithiolene)<sub>2</sub> complexes, metallophthalocyanines, metalloporphyrins, metal(dibenzotetra-aza[14]annulene)s, and siloxane polymers. Details were also given of the possible applications of these organometallic LB films in sensors, electrochromic devices, and optical switches.

Recently, LB films have also been produced from other metallic complexes as described in the review article by De Armond and Fried [124]. For instance, Zhang et al. [173] obtained a stable monolayer of the molecules Eu(TTA)<sub>3</sub>Phen and Sm(TTA)<sub>3</sub>Phen ( $\beta$ -diketone 2-thenoyltrifluoroacetone), (TTA) using a composite subphase—an aqueous solution saturated with TTA, Phen and Eu(TTA)<sub>3</sub>Phen. The reason for reproducible  $\pi$ -A isotherms and homogeneous crystalline monolayer is that the dissolution and dissociation of Eu(TTA)<sub>3</sub>Phen are effectively inhibited by the composite subphase [174]. Gao et al. [174] were the first to report the influence of different compounds introduced in organized molecular films for the fluorescence of rare earth complexes. They reported the fabrication of 10 alternate LB films: each of the two rare earth complexes was alternated with AA, trin-octyl phosphine oxide (TOPO), a long chain Schiff base (SB), 5,50,15,20-tetra-4-oxy(2-stearic acid)phenyl porphyrin (TPP(-COOH)), and a long ferrocene derivative (Fc). The results indicated that TOPO and SB enhanced while Fc and TPP(-COOH) strongly quenched the fluorescence of the rare earth complexes. The reason why TOPO and SB enhanced the fluorescence intensity of the complexes is that they can absorb energy in the ultraviolet range. The energy can be transferred to the rare earth ions either from the ligands or directly from TOPO and SB.

Monolayers of three biferrocene derivatives (BiFc) and mixed ones with AA (1:1 molar ratio) were investigated for their electrochemical properties [175]. Cyclic voltammograms on modified ITO electrodes are similar for these systems. The currents for the electrochemical reaction of  $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$  on each kind of mixed LB monolayer-modified ITO electrode were higher than those on the bare ITO electrode. The oxidation peak potential of  $\text{Fe}(\text{CN})_6^{4-}$  was more negative and the reduction peak potential of  $\text{Fe}(\text{CN})_6^{3-}$  was more positive. The electrochemical redox reaction of  $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$  could be catalyzed by ITO electrodes modified with the mixed monolayer of BiFc and AA. BiFc films were found to be more efficient for the electrochemical reaction than the LB films from ferrocene derivatives containing one redox center and long alkyl chains [176]. A variety of reports have been made on LB films from porphyrin and phthalocyanine complexes [177–187], which include proposals of applications [188–192]. For example, LB films of a porphyrin complex CoPPC<sub>18</sub>, Cobalt(II) 5,10,15-tri(*p*-octadecyloxyphenyl)-20-(*p*-hydroxyphenyl)porphyrin [192] were suitable for optical

sensing upon exposure of the films to NO<sub>2</sub>. Interaction between NO<sub>2</sub> molecules with the active layers of the LB films resulted in a change of the films refractive index. This effect was reversible and could be monitored using a Mach-Zender interferometer. Another sensor was made with LB films from a metallic porphyrin, copper(II) tetra-(*tert*-butyl)-5,10,15,20-tetraazporphyrin, [CuPaz(*t*-Bu)<sub>4</sub>] [193]. The UV-vis spectra of the 20-layer LB films were dramatically changed after being exposed to the saturated vapors of benzene, toluene, and hexane. Shifts in the Soret and Q bands were observed due to the interactions between porphyrin of the [CuPaz(*t*-Bu)<sub>4</sub>] molecules and the organic solvent molecules. The gas sensing ability for benzene and toluene was also demonstrated via QCM measurements.

## 8.3. LB Films from Mixtures of Metallic Complexes and Polymers

A large number of papers reporting the build-up of LB films from mixtures of metallic complexes and polymers have been published in recent years. The motivation for such studies arises from the potential application of these films in sensors [194], catalytic systems [191], and molecular electronic devices [195]. In order to provide a flavor of the interesting results that may be obtained, we shall concentrate mostly on recent work of our group, followed by a description of a few articles from other authors.

The interaction between ruthenium complexes and polyaniline in monolayer and LB films was studied by Ferreira et al. [196, 197]. Langmuir monolayers and LB films were produced from polyaniline and a biphosphinic ruthenium complex, referred to as Rupy. Strong, repulsive interaction between the two components led to a nonlinear change in area per molecule and surface potential with the concentration of Rupy in the mixed film. Molecular interaction was also denoted in the spectroscopic and electrochemical properties of the Y-type LB transferred films. Upon increasing the amount of Rupy in PANI, a blue shift was observed in the peak attributed to the quinoid species of the PANI UV-vis spectra [197], and the Raman spectra of mixed PANI-Rupy films also indicated the oxidation of PANI. With PANI being oxidized by Rupy, the electroactivity of the mixed films decreased with the amount of Rupy, to become undetectable when the mixed LB film was 50% mol in Rupy. In contrast, cast films from PANI and Rupy always exhibited electroactivity, because in these films the molecules are randomly oriented and interaction between the components is not strong as in the LB films [198]. The interest in combining PANI with the ruthenium complexes is to enhance the properties of the polymer films for possible applications in electronic devices and sensors. Besides, the presence of the Ru complex brings the transfer ratio close to one for the fabrication of LB films, similarly to the effect widely reported for fatty acids.

The interaction between ruthenium complexes and conducting polymers was exploited to produce sensing units [194] for artificial taste sensors—the so-called electronic tongue [199]. In this approach, nanostructured LB or LBL films are deposited onto interdigitated gold electrodes and serve as sensing units for liquid media, in which the principle of detection is impedance spectroscopy. Riul et al. [199]

showed that high sensitivity may be obtained because the films are ultra-thin and probably organized, and that sensor arrays with a combination of 4–6 sensing units can distinguish low quantities of substances corresponding to the basic tastes—salty, sour, bitter, and sweet. These tastes are represented by aqueous solutions of NaCl, HCl, quinine, and sucrose, respectively. This ability can also be employed to distinguish among samples of different liquid media, including coffee [200], coconut water [194], and to detect trace amounts of impurities in a liquid, as is the case of metals in water [199]. The electrical response of the units—that is, the impedance for various frequencies—is treated theoretically with an equivalent circuit that represents the sensor immersed in an electrolyte [200]. The figure of merit chosen is usually the capacitance associated with the nanostructured film at a given frequency, say 1 kHz, and one value is taken for each and every liquid sample tested. Obviously, the amount of data collected is enormous and statistical methods must be used to treat the data. One such method is the principal component analysis (PCA) [201], which allows one to cluster similar electrical responses among a variety of data. By way of illustration, we show a PCA plot in Figure 18, which demonstrates that beverages and solutions with different tastes and inorganic contaminants can be distinguished. In the context of applications of LB films from metallic complex, we should mention that an electronic tongue has been produced in which the sensing units were made from conducting polymers and the Rupy complex [194]. This sensor array could identify sucrose, quinine, NaCl, and HCl at the parts per billion (ppb) level, being in some cases three orders of magnitude below the human threshold. With a direct comparison with results obtained

**Figure 18.** Principal component analysis plot for sensing commercial beverages with the set of six units from LB films. Sensing units used were made from LB films of the following materials: (1) Rupy; (2) PANI; (3) PPy; (4) PPy-Rupy 30%; (5) PANI-Rupy 10%; (6) PANI-Rupy 30%; 1 = ultra-pure water; 2 = distilled water; 3 = tap water; 4 = mineral water A; 5 = mineral water B; 6 = natural coconut water; 7 = commercial coconut water A; 8 = commercial coconut water B. with cast films of the same materials, it was possible to show for the first time the superior performance of the nanostructured LB films [194].

The formation of LB films from a coordination complex involving metals ions ( $K^+$ ,  $Mg^{2+}$ , and  $Fe^{3+}$ ) and a ligand monolayer (an amphiphilic polymeric imidazole, poly(N-(2-(4-imidazolyl)ethyl)maleimide-*alt*-1-octadecene), IM-O) was reported by Jeong et al. [202] to explore the possibility of obtaining ion sensors using LB films. Surface pressure isotherms for IM-O indicated that the monolayers were not affected by changing the subphase, and that the area per molecule was slightly reduced for metal ion-containing subphases compared with that of pure water at the same surface pressure. Using XPS, they showed that the concentration of metal ions incorporated into the LB films obeyed the order  $Fe^{3+} > Mg^{2+} > K^+$ . The SEM micrographs showed that these LB films can be used in sensors or for the selective permeation of gases. Langmuir–Blodgett films that did not contain the metal ions were rarely seen over the pores. However, the metal ion-containing LB films could be placed over the pores with a few layers. This self-supporting capability of the LB films on porous substrates may therefore be exploited in the applications mentioned. Other interesting pieces of work were carried out by Miyashita et al. on the electrical and electrochemical properties of polymer Ru-based LB films [203–214]. As an example, one could mention their use of surface plasmon resonance to photoexcite the  $[Ru(bpy)_3]^{2+}$  complex in an LB film containing poly(N-dodecylacrylamide) [203] and deposited onto silver substrates. They found that the photocurrent was enhanced by a factor of 23.6 by increasing the distance between the Ru layer and the silver electrode, in a way that the quenching of silver surface states is avoided.

The redox and photoelectrochemical properties of hybrid LB films containing Prussian blue (PB) and a surfactant derivative of the ruthenium tris(bipyridine) in aqueous KCl solutions were studied in [215]. The interest in PB and  $Ru(bpy)_3$  stem from their application in various molecular devices. A large cathodic photocurrent was recorded when the LB films were irradiated with polychromatic light at a negative applied potential, indicating that both PB and the derivative of ruthenium tris(bipyridine) complex play an important role in the light-energy conversion process. This photoelectrochemical behavior resulted from the association at the molecular level of the organic and inorganic entities in the lamellar systems [215].

Hybrid, multilayered LB films were obtained by Miyashita et al. [208] with two kinds of polymer, viz. poly(N-dodecylacrylamide-co-ferrocenylmethylacrylate) (Fc copolymer) and poly(N-dodecylacrylamide-co-(4-(acryloylmethyl)-4'-methyl-2,2'-bipyridine)-bis(2,2'-bipyridine) ruthenium diperchlorate) (Ru copolymer). The cyclic voltammograms of the hetero-deposited redox polymer LB films showed current rectifying and charge storage properties. Upon light irradiation, an anodic photocurrent was observed for the films comprising a Ru copolymer LB film as an inner layer and a Fc copolymer LB film as an outer layer on the ITO (Fc/Ru/ITO) electrodes. On the other hand, cathodic currents were observed at the reverse layered structures (Ru/Fc/ITO). This is demonstration that the direction of the

photocurrent flow can be controlled by altering the architecture of the hetero-deposited LB films from redox polymers. Aoki and Miyashita [216] described a structural effect on the electrochemical behavior of hetero-deposited LB films consisting of Ru copolymer LB film (three layers) as an inner layer and Fc copolymer LB film (two layers) as an outer layer on ITO electrodes. These hetero-deposited films were prepared at different surface pressures (25 and 28 mN m<sup>-1</sup>). The results for the LB films deposited at 28 mN m<sup>-1</sup> indicated that the redox behavior of the ferrocene moiety in the outer Fc copolymer LB film was controlled by the redox condition of the ruthenium complex in the inner Ru copolymer LB film, and not directly influenced by the electrode potential. On the other hand, in the LB films prepared at a pressure less than 25 mN m<sup>-1</sup>, such behavior was not observed because the inner Ru copolymer LB films were not able to act as an insulator between the outer Fc copolymer LB films and the ITO electrode. These results indicated that the insulating property of the inner layer is improved and the electron transfer rate is decreased, when higher deposition surface pressures are employed. This is attributed to the formation of highly packed alkyl side-chains in the LB films at high surface pressures.

## GLOSSARY

**Aluminosilicate** Group of minerals with some of the Si<sup>4+</sup> ions in silicates replaced by Al<sup>3+</sup> ions. For each Si<sup>4+</sup> ion replaced by an Al<sup>3+</sup>, the charge must be balanced by having other positive ions such as Na<sup>+</sup>, K<sup>+</sup>, and Ca<sup>2+</sup> ions.

**Amphiphilic** From the Greek meaning “both” (amphi) and “lover” (philos), an amphiphile is a molecule that has a strong attraction towards both polar solvents, such as water (hydrophilic), and non-polar solvents (hydrophobic), and will be generally located at the interface between the two. When dispersed in either a polar or non-polar solvent an amphiphile has a tendency to form capsules with the ends of the molecules that are not compatible with the solvent on the inside. Stearic acid is an example with a long history.

**Composite** Multiphase material formed from a combination of materials which differ in composition or form, remains bonded together, and retains their identities and properties. Composites maintain an interface between components and act in concert to provide improved specific or synergistic characteristics not obtainable by any of the original components acting alone. Composites include: (1) fibrous (composed of fibers, and usually in a matrix), (2) laminar (layers of materials), (3) particulate (composed of particles or flakes, usually in a matrix), and (4) hybrid (combinations of any of the above).

**Electronic tongue** System for automatic analysis and recognition (classification) of liquids, including arrays of non-specific sensors, data collectors and data analysis tools. Electronic tongues may be used to identify a liquid sample and estimate its concentration and characteristic properties.

**Langmuir–Blodgett (LB)** Method used to create a molecular film of a surfactant at the air-water interface and transfer onto a solid substrate, named after the American scientists Irving Langmuir and Katherine Blodgett. (1) The surfactant is spread on the water surface with a highly

volatile solvent. After solvent evaporation of the solvent, the amphiphilic molecules start to reorganize. At this point, the molecules need place and the film is not continuous. (2) Then a barrier on the water surface pushes the molecules. A feedback (Wilhelmy plate) controls the position of the barrier and thus the pressure. Before this step, the pressure-area isotherms of the surfactant must be studied, in order to obtain information about the stability of the film, the reorientation of the molecules, the phase transitions and the conformational transformations. After this step, the deposition on a solid substrate can be performed.

**Layer-by-layer technique** Thin film fabrication technique which involves the assembly of multilayers onto a solid substrate via physical adsorption of oppositely charged layers or via secondary interactions.

**Phthalocyanine** Any of several stable, light-fast, blue or green organic pigments derived from the basic compound (C<sub>6</sub>H<sub>4</sub>C<sub>2</sub>N)<sub>4</sub>N<sub>4</sub> and used in enamels, printing inks, linoleum, and plastics.

**Polyamidoamine dendrimers (Pamam)** Dendrimers containing tertiary amines (a nitrogen (N) atom bonded to three carbon (C) atoms) as branching points and amide groups (carbon (C), oxygen (O) and nitrogen (N) atoms).

**Polyelectrolyte** An electrolyte (a solution that conducts electricity) of high molecular weight.

**Principal component analysis (PCA)** Mathematical procedure that transforms a number of (possibly) correlated variables into a (smaller) number of uncorrelated variables, referred to as principal components. The first principal component accounts for as much of the variability in the data as possible, and each succeeding component accounts for as much of the remaining variability as possible.

# Layer-by-Layer Nanoarchitectonics

Katsuhiko Ariga

ERATO Nanospace Project, Tokyo, Japan

## CONTENTS

1. Introduction
  2. Basics of Layer-by-Layer Adsorption
  3. Analyses of Layering Processes and the Layered Structures
  4. Preparation of Layered Nanostructures
  5. Applications
  6. Conclusions
- Glossary  
References

## 1. INTRODUCTION

Technologies to create precisely controlled structures have been energetically researched for many years. However, the level of structural precision is drastically changing these days; that is, microfabrication now turns into nanofabrication. This change is driven by our demands in daily life, because we realize the advantages of highly miniaturized functional systems. For example, this fact appears in the rapidly spreading use of cellular phones and mobile computers. Scientists and engineers are now requested to create and develop more and more new technologies in nanofabrication, because the development of small intelligent devices will improve our life-style with portable, easily accessible, less energy-consuming, and pollution-minimizing processes.

Although the production of three-dimensionally defined nanolevel structures is quite a difficult target to achieve, preparation of layered structures with molecular-level precision in thickness is rather easily accomplished. Construction of a controlled layer structure on a solid support sounds simple but actually involves very important techniques of surface modification and device preparation. The Langmuir-Blodgett (LB) method is well known as a technique for providing molecular layer structures of organic molecules. The LB technique provides multilayer structures of amphiphilic molecules by transferring their monolayers from water surface to solid support in a layer-by-layer manner. The procedure of the LB method usually requires formation of a well-packed monolayer on water. Amphiphilic molecules are

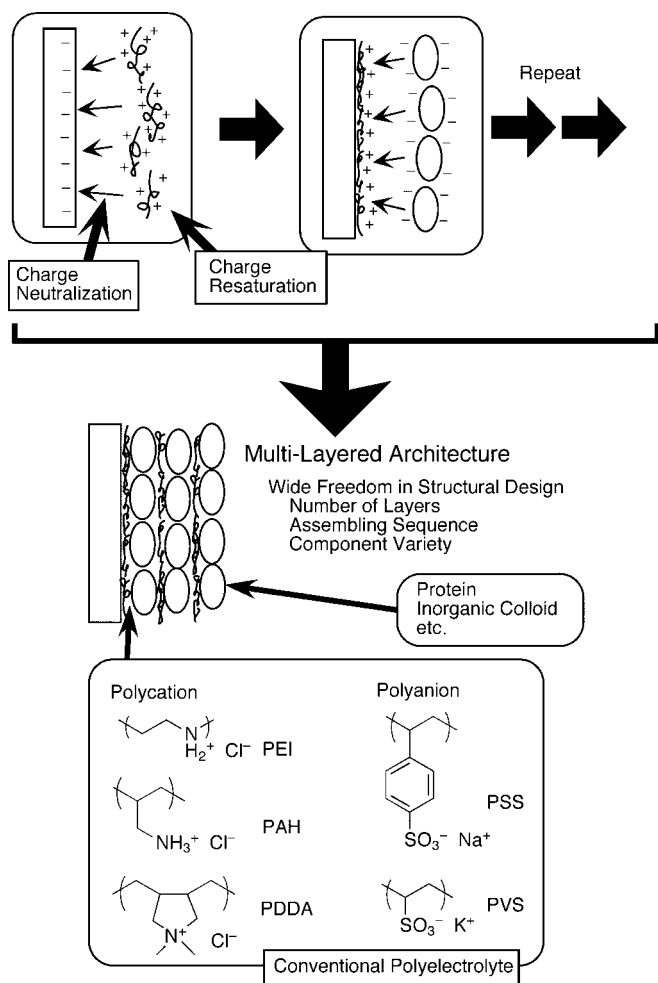

mainly used in this research, and some attractive materials such as proteins are not a suitable substance for this method. Some modified techniques allow us to prepare protein-containing LB films, but the well-packed nature of the film is sometimes disadvantageous in function exhibition because of the limited diffusion process in the film [1, 2].

Recently, alternating layer-by-layer adsorption has attracted much attention as a technique for providing nanometer-level layer-by-layer architectures by a rather simple procedure [3–10]. This technique is applicable mainly to water-soluble charged materials, including conventional and functional polyelectrolytes; biopolymers such as proteins, DNAs, virus, and sugars; colloidal particles and other inorganic materials; and dyes and molecular assemblies, including bolaamphiphile monolayers, lipid bilayers, and LB films. The films obtained are less ordered and less dense compared with the fine-structured LB films. Therefore, the alternating layer-by-layer films can compensate for the disadvantages observed in the LB films and are more useful in some kinds of applications. In this chapter, novel types of layered nanofabrication based on alternating layer-by-layer adsorption are introduced as *layer-by-layer nanoarchitectonics*.

## 2. BASICS OF LAYER-BY-LAYER ADSORPTION

In 1966, the concept of alternating layer-by-layer adsorption was first proposed for charged colloidal particles by Iler [3]. The concept was widely realized by Decher and co-workers, who demonstrated various assemblies, mainly using linear polyelectrolytes or bolaamphiphiles [4]. This method is basically conducted through electrostatic interaction, although several modified methods, such as stereo-complex assembly, charge-transfer assembly, and biospecific assembly, have recently been proposed as described later in this chapter.

The basic mechanism of the alternating layer-by-layer adsorption is illustrated in Figure 1, together with the materials used. Major driving forces in the assembly process are charge neutralization and resaturation. As illustrated in Figure 1, a cationic polyelectrolyte is adsorbed on a negatively charged surface of a solid support, and the surface charges on the two materials effectively quench each other.

**Figure 1.** The assembly mechanism and characteristics of the assembled film of alternating layer-by-layer adsorption. Formulae of polyelectrolytes frequently used in this method are also shown.

However, overadsorption usually occurs to make the surface charge reversed (positively charged in this example) at relatively high concentrations of the polyelectrolytes. The next adsorption of an anionic material again reverses the surface charge. Alternation in the surface charges allows us to fabricate the layered structure continuously. Kunitake and co-workers experimentally proved the charge reversal by a surface force measurement [11].

The simplicity of the assembly process confers a huge versatility on the applicable materials. Recent progress with alternating layer-by-layer adsorption has revealed that various materials such as polyelectrolytes and aggregated small molecules can be used in the assembly. This method is also available for various biorelated materials and inorganic substances. Atomic force microscopic (AFM) observation revealed that spontaneous saturation in adsorption results in a remarkably uniform film surface [12].

The inexpensive nature of the assembly procedure is one of the most prominent advantages of this method, because the only instruments required in this procedure are beakers and tweezers. A solid support with a charged surface is immersed in a solution containing an oppositely charged polyelectrolyte. After the solid support is rinsed in pure

water, the support is immersed in a solution of an oppositely charged material. Repeating both adsorption processes leads to alternation of the surface charge and multilayer formation of polycations and polyanions in an alternating sequence. The prepared multilayers provide wide freedom in structural design. The number of layers and the layering sequence are controlled simply by selecting the number of dipping cycles and their sequences, respectively. As easily imagined, this simple procedure can be automatically conducted. Clark and Hammond [13] and Shiratori and Yamada [14–16] separately proposed an automatic dipping machine for these procedures.

### 3. ANALYSES OF LAYERING PROCESSES AND THE LAYERED STRUCTURES

Analytical methods that are applicable to other thin films can generally be used for the evaluation of alternately assembled films. The adsorption amount can be detected by UV-vis and FT-IR spectroscopies if the adsorbed materials have specific absorption bands. The thickness of the adsorbed layers can be evaluated by X-ray reflectivity [17], surface plasmon resonance (SPR) [18], and scanning angle reflectometry (SAR) [19].

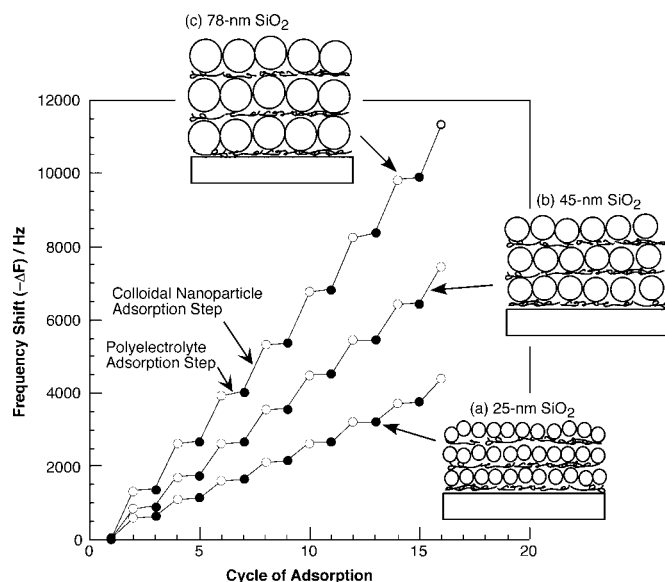

A quartz crystal microbalance (QCM) that provides the weight increase from shifts in its resonant frequency is a unique device for evaluating the assembly process [20–23]. Because all kinds of adsorbents have weight, this technique is theoretically applicable to all of the assembled materials. In addition, we can evaluate the weight of every layer with precision at the nanogram-level because of the high sensitivity of this measurement. The QCM evaluation can be conducted by assembling the films directly on the QCM plate (Fig. 2) [24]. The QCM frequency shifts in the assembly processes of three sizes of SiO<sub>2</sub> particles (25 nm, 45 nm, and 78 nm in diameter) are shown in Figure 2B as examples where larger and smaller steps correspond to the adsorption of SiO<sub>2</sub> particles and poly(diallyldimethylammonium chloride) (PDDA), respectively. A linear increase in the film mass was observed for all kinds of SiO<sub>2</sub> particles. The growth steps are 520, 910, and 1350 Hz for the 25-nm, 45-nm, and 78-nm SiO<sub>2</sub> particles, respectively, corresponding to ca. 70% coverage of the surface on the assumption of hexagonal packing of the particles.

The morphology of the films can also be analyzed by various microscopies. For example, cross-sectional observation of the protein-polyelectrolyte film can be conducted by scanning electron microscopy (SEM), revealing the constant thickness of the film. Surface roughness of the assembled films can be evaluated by atomic force microscopy (AFM). A few examples are shown later in this chapter.

## 4. PREPARATION OF LAYERED NANOSTRUCTURES

### 4.1. Polyelectrolytes

Polyelectrolytes frequently used in this method are also summarized in Figure 1. Poly(allylamine hydrochloride) (PAH), PDDA, and poly(ethyleneimine) (PEI) are used as

**Figure 2.** QCM frequency changes in the alternating layer-by-layer adsorption of SiO<sub>2</sub> and PDDA at 22 °C: SiO<sub>2</sub>, 10 mg ml<sup>-1</sup>, pH 10; PDDA, 3 mg ml<sup>-1</sup>; adsorption time, 15 min. Plots of open circles and solid circles represent SiO<sub>2</sub> adsorption and PDDA adsorption, respectively. Three different SiO<sub>2</sub> particles (a, 25-nm-diameter SiO<sub>2</sub>; b, 45-nm-diameter SiO<sub>2</sub>; c, 78-nm-diameter SiO<sub>2</sub>) were used. Reprinted with permission from [94], K. Ariga et al., *Appl. Clay Sci.* 15, 137 (1999). © 1999, Elsevier Science.

polycation components, and poly(sodium styrenesulfonate) (PSS) and poly(potassium vinylsulfonate) (PVS) are used as polyanions.

Since polyelectrolyte assembly [12–16, 25–60] is the most fundamental process, physicochemical factors that affect the assembly amount and structures of the films have been extensively researched at the initial stage of this technology. In particular, solution pH and ionic strength are quite important parameters in the assembly process, because charged state and electrostatic interaction are easily modified by these parameters. Combined analyses of AFM, SEM, and QCM have revealed that practical procedures such as washing and drying affect film thickness and roughness [25]. Experiments using PSS/PAH assemblies have demonstrated that drying the film at every step increases the thickness of adsorbed films because of the enhanced surface roughness of the film. Frequent drying during the assembly process is not profitable for preparing films of good quality. In contrast, water washing between the consecutive adsorptions was effective for successful alternating adsorption. About 10% of an adsorbed polyelectrolyte layer was removed by 5-min washing, probably because of removal of the loosely attached materials.

Alternating layer-by-layer adsorption was, of course, applied to functional polyelectrolytes. Rubner and co-workers presented several reports on layered assemblies of conjugate polymers [49, 50]. They demonstrate the fabrication of light-emitting diodes using poly(*p*-phenylenevinylene) (PPV). In this case, the cationic precursor of PPV was first assembled with polyanion, and then thermal treatment created conjugate chains of PPV. Yamada and co-workers reported nonlinear optical effects in

alternately assembled films between azobenzene-containing polycation and polyanion [51]. Second-harmonic generation intensity was sensitively influenced by the assembling cycles.

Polyelectrolytes do not have to be linear, as demonstrated by spherical dendrimer assembly with counterionic polyelectrolytes. Poly(amidoamine) dendrimers (PAMAM) have positive charges at the proper pH and can be alternatively assembled with anionic PSS [52]. A gold-dendrimer composite in which gold nanoparticles are immobilized in the compartment of the PAMAM dendrimer was also successfully assembled with PSS [53].

Assembly of UV-reactive polyelectrolytes can lead to micropatterned thin films [54]. A multilayered film of diazoresin (DAR) and poly(acrylic acid) (PAA) was assembled through the electrostatic alternating adsorption, and UV irradiation on the assembled film resulted in covalent linking between the two components through ester formation. Surfactant solution can dissolve the unirradiated film but not the irradiated film. Therefore, the UV irradiation on the assembled film through a patterned mask resulted in micrometer-scale patterns with defined thickness.

The alternating layer-by-layer adsorption can be driven by various forces other than simple electrostatic interaction. Hydrogen bonding between donor and acceptor polymers can be similarly applied in alternating layer-by-layer adsorption [49, 55]. As an interesting example, an alternating layer-by-layer adsorption based on stereocomplexation of hydrophobic poly(methyl methacrylate) (PMMA) was demonstrated by Akashi and co-workers [56, 57]. The assembly processes were conducted with acetonitrile solution of two types of PMMA. The isotactic PMMA physically adsorbed on the solid support because of its lower solubility in acetonitrile. In contrast, the syndiotactic PMMA, with a higher solubility, did not adsorb to a bare substrate, but it could be adsorbed to the isotactic-PMMA-exposed surface through stereocomplex formation. Alternating repetition of the physical adsorption and stereocomplexation led to multilayer formation between noncharged polymers.

Preparation of alternately assembled films through charge transfer interaction was reported by Ito and co-workers, who used an electron-donating polymer [poly(2-(9-carbazoyl)ethylmethacrylate)] and an electron-accepting polymer (poly(2-((3,5-dinitrobenzoyl)oxy)ethylene methacrylate)) [58–60]. The layers of their charge transfer complex are sandwiched between the donor and acceptor layers. Nonlinear optical properties of similarly assembled films were also achieved by copolymerization of a nonlinear optical dye with a donor polymer.

## 4.2. Biomaterials

Construction of multilayer structures of biological materials is an attractive focus for investigation, because such layered structures provide artificial sequences of biologically important functions [8, 17–19, 61–92]. Many highly sophisticated functions expressed in the biological world are based on controlled protein arrays. Such elegant constructions can be mimicked by this method. Typical advantages of protein immobilization by this method are summarized.

(i) *Wide Applicability of Proteins* Because most proteins, especially water-soluble proteins, have charged sites on

their surface, they are generally assembled by electrostatic layer-by-layer adsorption. QCM research using 18 proteins revealed that the assembly process with counterionic polyelectrolytes proceeded for unlimited numbers of cycles with high reproducibility in all cases [62, 63]. Except for some examples, the estimated thickness of the protein layer is approximately comparable to the protein dimensions.

(ii) *Rich Variety of Layered Structures* The film thickness and layering sequence are also easily controllable. Therefore, we can prepare protein-polyelectrolyte films with desirable thickness and layering sequences. This is an important feature for optimizing the reactor structure, as demonstrated later in this chapter.

(iii) *Minimization of Protein Denaturation* In this method, the proteins are simply adsorbed from their aqueous solution; that is, the assembly procedure is not conducted under severe physical conditions. Unnecessary disturbance of the protein structure would be minimized.

One crucial point in successful protein assembly is control of the protein solution pH; that is, the pH value should be set apart from the isoelectric point of the protein. Interestingly, control of the pH makes it possible to assemble the same protein in both a positively charged form and a negatively charged form [63]. For example, hemoglobin is positively charged at pH 4.5 and was assembled with anionic PSS, and hemoglobin in anionic form was assembled at pH 9.2 alternately with cationic PDDA. Albumin was similarly assembled with anionic heparin and cationic PDDA at pH 3.9 and 8, respectively.

Other charged biological materials can also be assembled with suitable partner polyelectrolytes. Negatively charged DNA can be assembled with various cationic materials [84–89]. Charged polysaccharides, chitosan and chondroitin sulfate, were assembled with PSS and PDDA, respectively [90]. As a remarkable example, alternating assembly between charged virus and polyelectrolyte was successfully demonstrated by Lvov et al. [17].

Some kinds of biomolecules possess specific recognition ability for specific functional groups. Such biospecific interactions are also utilized for protein assembly by alternating layer-by-layer adsorption. Concanavalin A (Con A) from *Canavalia ensiformis* (isoelectric point, ca. 5) is known to recognize specific sugar functionalities. It can be assembled with polycation PEI through electrostatic interaction and with glycogen (branched polyglucose) (Fig. 3) [91]. Similarly, a biospecific assembly was also reported for a biotin-avidin pair [92].

### 4.3. Colloidal Nanoparticles

Organic-inorganic layered nanohybrids have recently attracted attention. A convenient method for the preparation of nanohybrid films is solvent casting. Although preparations of uniformly ordered particles in two dimensions have been reported, it was not possible to create multilayers with precisely known numbers of layers. The LB method is the most powerful technique for providing defined layered structures. However, the LB technique is

**Figure 3.** Scanning electron micrographs (SEMs) of  $(\text{PDDA/PSS})_2 + \text{PDDA} + (\text{SiO}_2/\text{PDDA})_8$  film on a silver electrode of a QCM plate. (A) Cross section. (B) Top view. Assembly conditions:  $\text{SiO}_2$ , 45 nm,  $10 \text{ mg} \cdot \text{ml}^{-1}$ , 0.1 M NaCl, pH 10; PDDA,  $3 \text{ mg} \cdot \text{ml}^{-1}$ ; adsorption time, 15 min. The QCM plate with assembled films was cut and coated with 20-Å-thick Pt with the use of an ion-coater (Hitachi E-1030 ion sputter, 15 mA/10 Pa) under an argon atmosphere. The SEM images were obtained with a Hitachi S-900 instrument at an acceleration voltage of 25 kV. Reprinted with permission from [24], Y. Lvov et al., *Langmuir* 13, 6195 (1997). © 1997, American Chemical Society.

not generally applicable to inorganic materials and is rather complicated and requires specialized machines. In contrast, alternating layer-by-layer adsorption possesses both advantages, that is, simplicity in procedure and controllability in structure [9, 24, 93–114].

As previously demonstrated in Figure 2, silica colloidal particles were successfully assembled alternately with a polycation. Next, the effect of the adsorption time of  $\text{SiO}_2$  particles was investigated by successively changing the adsorption time [24]. The film growth estimated by the QCM analysis remained exactly the same when the adsorption time was changed from 20 min to 15 s. This directly demonstrates the ease of this method; that is, the adsorption process is completed within a minute. The minimum  $\text{SiO}_2$  adsorption time was separately reported to be only 2 s at a concentration of  $10 \text{ mg} \cdot \text{ml}^{-1}$  [97].

QCM frequency shifts upon the assembly of 45-nm  $\text{SiO}_2$  in alternation with polycation PDDA were monitored at various  $\text{SiO}_2$  concentrations. The frequency shifts per  $\text{SiO}_2$  step increased as the  $\text{SiO}_2$  concentration increased [24]. The effect of the copresence of NaCl in the  $\text{SiO}_2$  solution was also examined, and the magnitude of the growth step increased as the ionic strength increased. Charge shielding by increased ionic strength may explain the salt effect. The repulsive force among the effective negative charges would be suppressed by increased ionic strength, leading to a larger adsorption amount at saturation. The results obtained

suggest that film thickness and surface coverage can be optimized through adjustment of the solution composition.

Film morphology was also affected by the concentration and ionic strength of the  $\text{SiO}_2$  solution, and the best quality film with a smooth surface and constant thickness would be obtained by optimizing the concentration of  $\text{SiO}_2$  particles and the ionic strength. SEM images of the optimized  $\text{SiO}_2$ -PDDA assembled film are shown in Figure 3 [24]. The internal structure of the film can readily be seen in the cross-sectional image, where the  $\text{SiO}_2$  particles are closely packed in the layer, but long-range ordering is not found (Fig. 3A). Well-packed particles in a two-dimensional plane were also confirmed in the top image (Fig. 3B).

The surface morphology was investigated by AFM in the noncontact mode (Fig. 4) [24]. In the image of the PSS-PDDA precursor film, a height difference of only 1 nm was detected over 500 nm in the horizontal distance (Fig. 4A). In contrast, individual  $\text{SiO}_2$  particles are clearly seen in the AFM image of a  $\text{SiO}_2$ -assembled film (Fig. 4B). The observed height difference of the 10–20-nm particles reasonably agrees with the actual particle radius of 23 nm. Their relatively larger horizontal profile is probably due to the bluntness of the scanning AFM tip.

Recently, Kotov and co-workers reported detailed observation of the surface image of assembled films of yttrium iron garnet nanoparticles (YIG) with PDDA [99]. They

**Figure 4.** Noncontact mode AFM images ( $500 \text{ nm} \times 500 \text{ nm}$ ) of the surface of the assembled films. (A) Mica +  $(\text{PDDA}/\text{PSS})_4$  + PDDA film. (B) Mica +  $(\text{PDDA}/\text{PSS})_4$  +  $(\text{PDDA}/\text{SiO}_2)$  film. Assembly conditions:  $\text{SiO}_2$ , 45 nm, 10  $\text{mg ml}^{-1}$ , 0.1 M NaCl, pH 10; PDDA, 3  $\text{mg ml}^{-1}$ ; adsorption time, 15 min. Bottom figures represent height profiles along the line in the upper image. In the latter profiles, Z data represent the relative height versus the lowest point of the whole two-dimensional image. The observation was made with a TMX-2000 SPM System (TopoMetrix) in noncontact mode with a 2- $\mu\text{m}$  scanner. Measurements were carried out in the air. Silicon nitride cantilevers with spring constants of 38–66  $\text{N m}^{-1}$  were used as purchased. The resonance frequency of the cantilever was in the range of 130–150 kHz. Scanning rates were 3  $\mu\text{m s}^{-1}$ . Reprinted with permission from [24], Y. Lvov et al., *Langmuir* 13, 6195 (1997). © 1997, American Chemical Society.

noticed the two kinds of assembly modes in nanoparticle deposition, that is, layer growth and lateral growth mode. The latter mode should be avoided for preparation of a sophisticated layered structure. Grafting of the charged polymer on the nanoparticles significantly increases particle/polyelectrolyte and particle/particle interaction, resulting in the formation of a densely packed particle layer and avoidance of unfavorable lateral growth deposition.

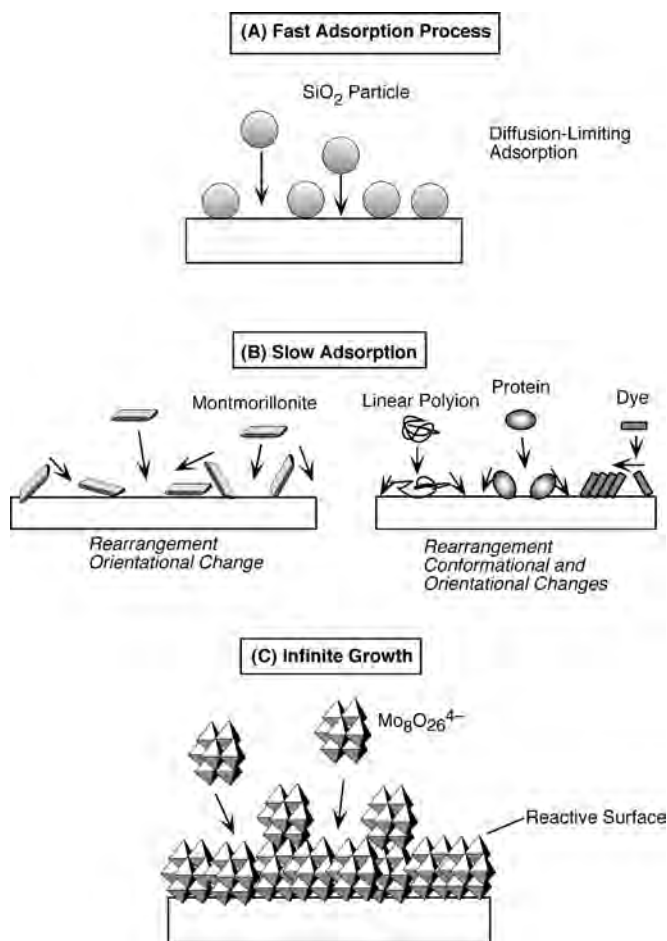

#### 4.4. Clay Microplates, Polyoxometalates, and Other Inorganic Materials

Alternating layer-by-layer adsorption is applicable to inorganic materials other than spherical particles [115–135]. As flat-textured materials, clay microplates (montmorillonite) whose average size is  $1 \times 500 \times 500 \text{ nm}$  were used [115]. Regular changes in the QCM frequency response upon the alternating assemblies between negatively charged clay microplates and polycations were confirmed. Interestingly, the frequency shifts remained unchanged regardless of the concentration of the aqueous clay dispersion from 0.03 to 1 wt%. The flat texture of the clay plates would induce efficient contact with the underlying polycations. Effective charge neutralization and resaturation suppress the effect of the remaining charges that was observed in the assembly of spherical colloidal particles. In fact, a SEM photograph of the assembled film containing the clay microplates and PEI shows the remarkable uniformity of the film thickness. An AFM observation in a lateral-force mode detected the clay sheets that lay flat one on another with a typical step of ca. 1 nm that corresponds to the single clay-plate thickness.

Assembly of a large nonspherical inorganic substance by alternating layer-by-layer adsorption was recently demonstrated by Yoon and co-workers [124]. They used micrometer-sized cationically modified zeolite crystals and PSS for the assembly of components. SEM observation revealed a beautifully stacked assembly of tablet-like crystals with even thickness. Successful assembly of two-dimensional perovskite sheets with polyelectrolytes was also reported [132].

Polyoxometalates are an interesting target as an assembly unit, because they are useful for catalysts, solid-state devices, photo- and electrochromic displays, biochemistry, and medicine. Research on alternating layer-by-layer adsorption between ammonium octamolybdate ( $(\text{NH}_4)_4[\text{Mo}_8\text{O}_{26}]$ ) and PAH was reported by Kunitake and co-workers [120]. The film growth was reproducibly constant when the adsorption time was exactly fixed. However, the adsorption amount of molybdenum oxide increased when the immersion time was elongated. Reflection-adsorption IR spectroscopy and X-ray photoelectron spectroscopy (XPS) of the prepared films suggested that polymerized octamolybdates, such as  $(\text{NH}_4)_{2n}^{2n+} \cdot [\text{Mo}_8\text{O}_{26}]_n^{2n-}$ , would be formed via protonation and condensation of  $[\text{Mo}_8\text{O}_{26}]^{4-}$  ions. The molybdenum oxide layer can grow infinitely, because the surface charge of the molybdenum oxide is kept low because of condensation.

Alternating layer-by-layer adsorption of three kinds of inorganic materials, colloidal nanoparticles, clay microplates, and polyoxometalate clusters, displayed unique characteristics in adsorption kinetics (Fig. 5) [94]. Adsorption of rigid, spherical  $\text{SiO}_2$  particles is quite fast and

**Figure 5.** Plausible adsorption mechanisms of various inorganic materials. (A) Adsorption of silica particles is based on a diffusion-limiting process, and the adsorption is completed within a short period. (B) Most of the materials require rearrangement and conformational change in their adsorption process, resulting in relatively slow adsorption. (C) Adsorbed molybdates expose the reactive surface to the solution phase, and adsorption continues indefinitely. Reprinted with permission from [94], K. Ariga et al., *Appl. Clay Sci.* 15, 137 (1999). © 1999, Elsevier Science.

appeared to be diffusion-limited. The diffusion time of SiO<sub>2</sub> from solution onto the surface was estimated to be 2 s, with the use of a diffusion coefficient of  $1.1 \times 10^{-7} \text{ cm}^2 \cdot \text{s}^{-1}$  by Lvov et al. [97]. In contrast, the adsorption behavior of montmorillonite microplates is in the range of 10–20 min, similar to those of organic materials. Relatively long adsorption times would be attributed to the rearrangement process. The planar shape of montmorillonite can produce a tight contact with an oppositely charged surface, and rearrangement of the montmorillonite microplates requires a longer time. A similar rearrangement process, such as conformational and/or orientational changes, is required for the adsorption of soft organic materials. The mode of adsorption of molybdenum oxide is a nonsaturation-type. Protonation and condensation induce infinite film growth without excessive accumulation of surface charges.

## 4.5. Organic–Inorganic Hybrids

Hierarchical assemblies are attractive targets for study because hierarchically assembled structures express high functions in biological systems. For example, lipid molecules spontaneously form a bilayer structure that constitutes a cell membrane, and the cells assemble into organisms, tissues, and our bodies. Therefore, a layer-by-layer assembly of lipid vesicles, which can be regarded as an artificial cell, would be an interesting approach to creating artificial tissues. However, exposure of the lipid vesicles to counterionic polyelectrolytes sometimes induces vesicle destruction due to strong electrostatic interaction and results in an assembly alternating between a planar bilayer and a polyelectrolyte (see below). Therefore, the development of nondestructive vesicles is indispensable for this purpose.

We have recently developed a novel class of Organic–Inorganic hybrid vesicles, cerasomes, which form cell-like lipid bilayer structures with a ceramic-like inorganic skin (Fig. 6) [136–140]. The cerasomes can be obtained from amphiphiles bearing a triethoxysilyl head and a dialkyl tail by a conventional vesicle preparation procedure. Control of solution pH is an important factor in the cerasome preparation; that is, the triethoxysilyl group was moderately hydrolyzed and polymerized into polysiloxane under weakly acidic conditions. A spherical structure with a multibilayer skin was confirmed by transmission electron microscopic observation.

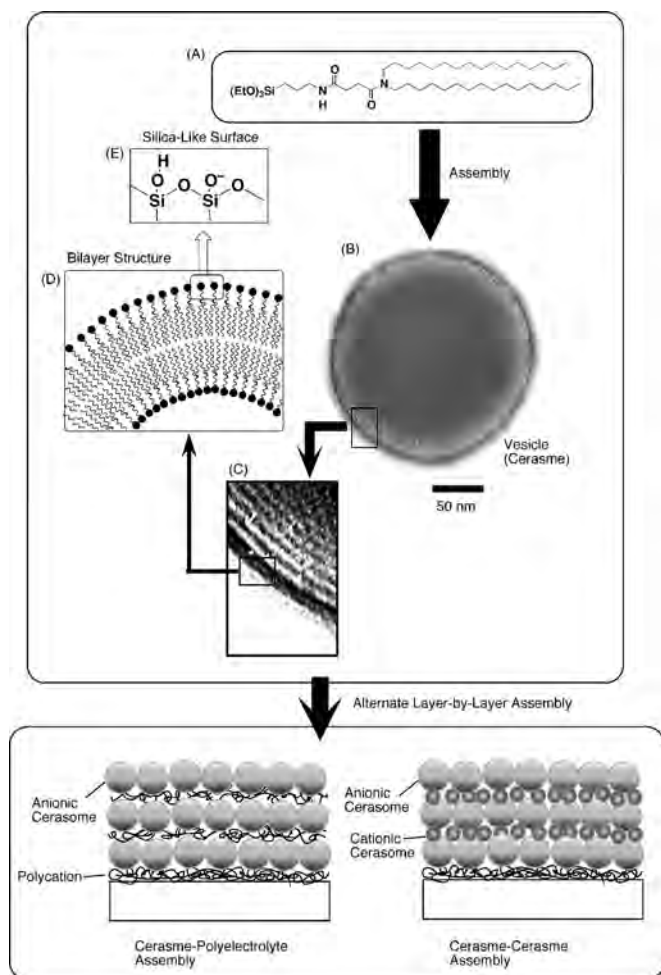

Because the prepared cerasome bears anionic charge on its surface, it can be alternately assembled with cationic components. As a first example, an anionic cerasome was alternately assembled with polycation PDDA [138]. The assembly process was monitored by QCM measurement, and regular growth in film weight was confirmed. AFM observation on the surface morphology of the assembled film revealed that the spherical structures of the cerasomes remained and were closely packed. Such a vesicular assembly was not obtained when conventional anionic vesicles from dihexadecyl phosphate were used in the assembly.

A cationic cerasome was prepared from another amphiphile with a quarternary ammonium group as well as the triethoxysilyl group and a dialkyl tail. Direct assembly between an anionic cerasome and a cationic cerasome was also demonstrated by the QCM measurement [137]. AFM observation confirmed the packing of spherical cerasome structures at both cerasome layers. The size of the cationic cerasome is smaller than that of the anionic cerasome, and thus their images can be distinguished. This is the first example of a hierarchically integrated vesicular assembly without serious destruction of the vesicle sphere. The assembly process looks like stone paving, and the structure obtained resembles biological tissues composed of living cell assemblies.

## 4.6. Dye and Lipid Assemblies

Assemblies of charged molecules form a multicharged surface, and thus they are applicable to alternating layer-by-layer adsorption. Bolaamphiphile monolayers [141–149], bilayers [71, 150], and LB films [151] can be assembled alternately with countercharged polyelectrolytes. Multicharged

**Figure 6.** Formation of an Organic-Inorganic hybrid vesicle (“cerasome”) from a dialkyl amphiphile with a triethoxysilane head. The cerasome has a bilayer structure like that of a cell membrane and silicate walls like silica particles. It is expected to form a structure like a silica particle assembly. (A) Lipid. (B, C) TEM images of cerasome. (D) Bilayer structure. (E) Siloxane linkage on the cerasome surface. Two modes of the alternating assemblies (anionic cerasome and polycation, anionic cerasome and cationic cerasome) are also depicted.

dye molecules were also assembled with polyelectrolytes by stacking of the dye molecules [152–163].

In particular, hybrid assemblies between proteins and lipid bilayers are interesting because biomimetic structures composed of these components would be constructed by a procedure much easier than the LB technique. The QCM frequency shifts for the films from cationic lipid bilayer and anionic enzyme lactate dehydrogenase (LDH) are plotted in Figure 7, where successful assemblies between the bilayer and the enzyme are clearly demonstrated [71]. A similar assembly method was successfully applied to alcohol dehydrogenase (ADH). Calculation based on a ball-packing model indicates that these proteins form a monolayer or a bilayer structure in a single adsorption process.

The adsorption behavior of dye aggregates on a polyelectrolyte surface provides insight into alternating layer-by-layer adsorption [152]. QCM analyses of assembly processes of various dyes and counterionic polyelectrolytes allow us to

**Figure 7.** Frequency shift upon alternating layer-by-layer adsorption between LDH (●) ( $0.2 \text{ mg ml}^{-1}$ ) and lipid bilayer (○) (lipid concentration,  $1 \text{ mM}$ ) and LDH; [HEPES buffer],  $10 \text{ mM}$  (pH 7.0); room temperature.

guess the orientation of the adsorbed dye. The experimentally estimated thickness of Congo Red on PDDA is  $12 \text{ \AA}$ , which is smaller than the long axis of the molecule ( $19 \text{ \AA}$ ) but is significantly larger than the short axis ( $5 \text{ \AA}$ ). Congo Red molecules probably adsorbed on PDDA in edge-on orientation with a tilted orientation, which was also supported by red-shifted UV characteristics. In contrast, side-on orientation was suggested for Acid Red 26 and Ponceau S. Data on various dye adsorbents revealed a set of general rules on adsorption orientation. The dye exposes its charged side to the polyelectrolyte surface by maintaining at least one charged site in contact with the outer solution phase. This adsorption mode satisfies charge neutralization on polyelectrolyte surfaces and avoids unfavorable contact of the hydrophobic side of dye molecules with water.

#### 4.7. Hybrid Layering

As previously described, alternating layer-by-layer adsorption offers freedom in film construction. This characteristic allows us to design and prepare various kinds of hybrid layering structures. Silica colloidal particles with different sizes were assembled in the same film in two kinds of structural designs for demonstration [24]. The consecutive assembly of two kinds of layers was done in a separated layer mode; that is, the first four layers were made from  $45\text{-nm SiO}_2$  and the following six layers were assembled with  $25\text{-nm SiO}_2$ . QCM responses on growth steps for the two sizes of  $\text{SiO}_2$  particles are highly constant. Another example was demonstrated in a neighboring layer mode; that is, a four-unit layer ( $45\text{-nm SiO}_2/\text{PDDA}/25\text{-nm SiO}_2/\text{PDDA}$ ) was repeatedly assembled. Interestingly, individual growth steps in this film were identical to the corresponding adsorption steps in the former assembly. Therefore, it is concluded that individual adsorption steps are not affected by the previous adsorption sequences.

Hybrid assemblies were also demonstrated with the use of biological materials and inorganic material. Glucose oxidase (GOD) was assembled with clay microplates with the help of polycationic PEI [63]. Figure 8 shows the QCM responses upon the assembly of four-unit layers (GOD/PEI/clay/PEI) on clay/PEI underlayer films. The observed QCM changes showed strange profiles. The frequency shift showed the adsorption of a thicker GOD layer, and negative growth in the next PEI adsorption steps, implying peeling out of some GOD molecules during immersion of the film in the PEI solution. Somehow, excess adsorption occurs in the first GOD adsorption step, but the extra GOD in the excess layer is self-excluded during the cationic PEI adsorption step. The clay sheets stably adsorbed on the resulting surface in the third step, and the formation of a superlattice unit was completed by the final PEI adsorption. Assemblies between rigid components such as clay microplates and enzymes were usually reported to be unsuccessful. PEI can bridge two negatively charged rigid substances as a flexible glue. Similar heterogeneous assemblies were achieved between  $\text{SiO}_2$  particles and GOD, with PDDA as the glue.

#### 4.8. 3D Assembly

The fundamentals of alternating layer-by-layer adsorption have been established, and several modification methods for producing more elaborate assemblies have recently been proposed. Intercalation of dye molecules into inorganic platelets makes it possible to prepare three-component inorganic/dye/polyelectrolyte assemblies [119]. Alternating

**Figure 8.** QCM frequency changes in three-component alternating layer-by-layer adsorption between PEI, clay microplate, and glucose oxidase at 22 °C: clay microplate, 0.3 mg ml<sup>-1</sup> at pH 6.5; PEI, 1.5 mg ml<sup>-1</sup>; glucose oxidase, 2 mg ml<sup>-1</sup>; adsorption time, 20 min. Open circles, solid circles, and open squares represent montmorillonite, PEI, and glucose oxidase adsorption processes, respectively. Reprinted with permission from [63], Y. Lvov et al., *J. Am. Chem. Soc.* 117, 6117 (1995). © 1995, American Chemical Society.

assembly of CdTe nanocrystals with PDDA was controlled by electrical fields, and patterned assemblies were deposited on a multielectrode support [121]. A patterned structure of assembled films of nanoparticles and polyelectrolyte was also achieved by a lithographic approach [112]. Alignment of chromophores in an assembled film of azobenzene polymer with PDDA was controlled by polarized light irradiation [29].

Among various modifications, the most pronounced improvement in alternating layer-by-layer adsorption is three-dimensional assembly on an invisible colloidal support. So far, solid supports in a visible size such as a quartz plate have mainly been used for this method. However, the assembly mechanism of this technique does not require the use of these solid supports; that is, microscopic materials can be used for this method. Three-dimensional (3D) assembly on colloidal particles has recently been reported by several groups [164–171].

The first example is a 3D assembly for biological substances. Precursor layers of polyelectrolytes were first assembled on colloidal particles. Charge alteration upon polyelectrolyte adsorption can be monitored by surface potential measurement. On the precursor layer, proteins were sequentially assembled in a manner similar to that of conventional assemblies on a plate surface. This strategy would be more fruitful than a reactor prepared on a macroscopic support, because the particle system has an inherently high surface area. Preparation of a multienzyme film on polystyrene particles and their coupling reaction were demonstrated by Caruso and Schüller [165]. A more interesting assembly design was proposed that combined an enzyme and magnetic particles ( $\text{Fe}_3\text{O}_4$ ). Prior to enzyme layer assembly, magnetic particles were assembled on a polystyrene particle, resulting in the production of particles with both enzymatic and magnetic properties. These particles can be collected by an external magnet. Therefore, they can be regarded as a reusable biocatalyst.

The 3D assembly can be similarly applied to inorganic materials [167]. As illustrated in Figure 9, multilayer assemblies between  $\text{SiO}_2$  nanoparticles and polyelectrolyte were first prepared on support particles. Destruction of the center particles provides hollow spheres. Dissolution of the center particles upon exposure of the particles to appropriate

**Figure 9.** Three-dimensional alternating layer-by-layer adsorption on a colloidal template provides multilayer-coated particles, hollow inorganic spheres, and hollow hybrid spheres. Reprinted with permission from [167], F. Caruso et al., *Science* 282, 1111 (1998). © 1998, American Association for the Advancement of Science.

solvents results in hollow organic–inorganic hybrid spheres. Hollow inorganic spheres without an organic component were similarly prepared by calcination.

Hollow spheres prepared by 3D assembly can be used for encapsulation of guest substances, because permeability through the sphere skin would be controllable by several perturbations [172–177]. Polycation PAH and polyanion PSS were alternately assembled on a melamine formaldehyde core that can be decomposed at low pH. The permeability of the polyelectrolyte capsule obtained was controlled by changing the dielectric environment of the surrounding solvent system. Usually, a polyelectrolyte shell cannot be penetrated by macromolecules such as proteins. However, the capsules became permeable even by proteins when the capsules were exposed to a water/ethanol mixture. Resuspension of the capsules in water closed the opened pores, resulting in encapsulation of the enzymes. The polyelectrolyte skin is permeable by small materials such as substrates for enzymatic reaction; therefore, the enzyme-entrapped polyelectrolyte capsule can be used as a biocatalytic reactor.

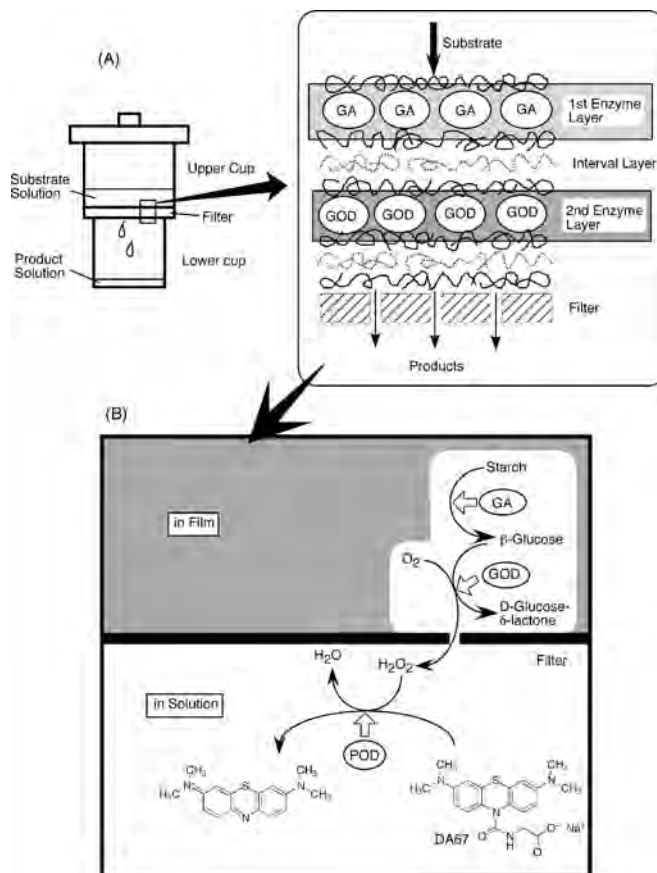

## 5. APPLICATIONS

### 5.1. Nanobioreactor

Alternating layer-by-layer adsorption has led to the imagination of functional applications, because highly functionalized materials such as protein and microparticles can easily be assembled in controlled layer structures. As one of the straightforward applications, preparation of multienzyme reactors was demonstrated [61, 67, 68]. The reaction scheme used for the reactor function is depicted in Figure 10. Two enzymes, glucoamylase (GA) and GOD, were assembled in the film, and another enzyme, peroxidase (POD), was used in solution phase for a coloring assay reaction. The substrate is starch that is hydrolyzed into glucose through hydrolysis of the glycoside bond in starch by GA. The glucose produced is converted to gluconolactone by GOD with  $\text{H}_2\text{O}_2$  as a coproduct. POD in solution oxidizes DA67 (indicator) with  $\text{H}_2\text{O}_2$  as an oxidant. The reaction can easily be followed by monitoring the strong absorbance of the oxidized DA67 at 665 nm.

A multienzyme reactor composed of GOD and GA was examined with the experimental setup depicted in Figure 10. The enzyme film was assembled on an ultrafilter (limiting molecular weight 5000). The substrate, water-soluble starch, in 0.1 M 1,4-piperazinediethanesulfonic acid (PIPES) buffer (pH 7.0), was placed on enzyme-immobilized ultrafilters in the upper cup. The starch solution was passed through the enzyme film by pressure from a syringe. The filtrate obtained was assayed by POD and DA67 to quantify the resulting  $\text{H}_2\text{O}_2$ . The concentration of unreacted starch was assayed by the iodostarch reaction, but the unreacted starch was not detected in the filtrate at all.

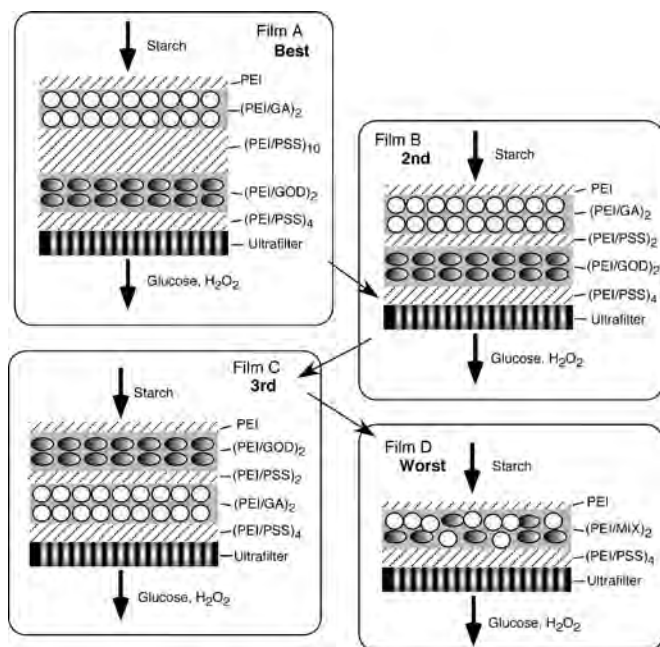

Free design of multienzyme films allows us to examine the effect of the film construction on reactor performance. In order to investigate the influence of layer order and layer separation, the reactor performance of four kinds of films was examined. The film structure and the order of reactor performance (yield of the product  $\text{H}_2\text{O}_2$ ) are schematically

**Figure 10.** (A) Structure of a multienzyme reactor composed of GA and GOD. (B) Sequential reaction catalyzed by the multienzyme reactor. To evaluate the reaction, DA67 oxidation by POD in the filtrate is coupled with the sequential reaction in the film.

summarized in Figure 11. All of the films have a precursor layer [(PEI/PSS)<sub>4</sub>] on the filter. Inner enzyme layers and outer enzyme layers are separated by a (PEI/PSS)<sub>n</sub> interval layer, and the outermost surface was covered by a single layer of PEI.

Film A and film B have inner layers of GOD and GA outer layers and showed the best and the second best performances, respectively. Matching in the direction of reactant flow and the sequence of the enzyme layers resulted in a higher yield of the product. The difference between these films is the separation between the two kinds of enzyme layers. Inhibition of GA by gluconolactone, which is the product of the glucose oxidation, may be more effectively suppressed in film A, having a larger spacer layer between GOD and GA. Film C has a reversed ordering of the enzyme layers and provides less efficient reactor performance. In this film, glucose has to diffuse against the solution flow, and that process is apparently disadvantageous. Film D has two mixed layers of GA and GOD and showed the worst yield. The coexistence of GA and GOD might result in the lowest activity because of the inhibition of GA by gluconolactone [178, 179]. The above-mentioned results strongly support the superiority of controlled layering than random immobilization.

**Figure 11.** Reaction efficiency of various films. (A) Film composed of GA outer layers and GOD inner layers with thick spacer layers (the highest efficiency). (B) Film composed of GA outer layers and GOD inner layers with thin spacer layers (the second highest efficiency). (C) Film composed of GOD outer layers and GA inner layers with thin spacer layers (the second lowest efficiency). (D) Film composed of GA and GOD mixed layers (the lowest efficiency).

Here the advantages of the multienzyme reactors prepared by the alternating layer-by-layer adsorption between proteins and polyelectrolytes are briefly summarized. The most pronounced advantage is freedom of film construction. Various film structures are easily prepared through changes in the dipping number and sequence, and thus optimization of the reactor structures can be achieved rather easily. Simplicity of the procedure excludes usage of specialized equipment, making the method inexpensive, which is an important feature for practical purposes. An increase in thermal and duration stabilities of the enzyme immobilized in the assembled film was also demonstrated [64]. Alternating layer-by-layer adsorption does not have special requirements for a solid support. The support just has to bear some degree of charge, and charge introduction treatment is widely established.

## 5.2. Electrochemical Application and Sensors

The layer-by-layer adsorption method is easily applied to many kinds of solid surfaces. Therefore, modification of an electrode by this method would be useful for molecular device development. Here, some recent applications of alternating layer-by-layer adsorption to electrochemical usages are introduced.

An enzyme-coated electrode provides the basis of a biocatalytic device including an enzymatic bioreactor. When an electron is directly exchanged between the electrode and

an enzyme, a chemical mediator is omitted and the system is simplified. Rusling et al. reported redox behavior and chemical conversion at an electrode modified by the alternating layer-by-layer adsorption technique [77]. Epoxidation of styrene by myoglobin-containing, alternately assembled films was demonstrated. Myoglobin is directly reduced at the electrode and oxygen is converted to hydrogen peroxide. Metmyoglobin ( $\text{MbFe}^{\text{III}}$ ) is converted to an active oxidant form, ferrylmyoglobin ( $\text{MbFe}^{\text{IV}}=\text{O}$ ), upon conversion of the hydrogen peroxide to water, and the latter form may oxidize styrene. Similar catalytic activity was achieved with cytochrome P450-containing film.

Electrically wired enzymes have attracted attention because of their potential application in biosensors and molecular devices. Layer-by-layer structures composed of alternating layers of charged enzymes and countercharged redox polyelectrolytes would easily make electrochemical contact with an electrode. Calvo et al. demonstrated that glucose oxidase, lactate oxidase, and soybean peroxidase were electrically wired to an underlying electrode through poly(allylamine) with a covalently attached osmium complex [73]. Lactate oxidation by the corresponding enzyme was driven indirectly by an electrode. A bienzyme system with glucose oxidase and peroxidase was also proposed.

Thin-film characteristics are favorable for a quick sensing system, and thus alternating films on appropriate device surfaces are quite suitable for sensor preparation. As easily imagined from the above-mentioned examples, enzyme multilayers immobilized on an electrode surface provide wide variety in sensor preparation. For example, a cholesterol sensor was recently proposed that included an alternating film containing cholesterol oxidase [83]. Much simpler polyelectrolyte assemblies are also useful for sensor devices. Alternating assembled films of PEI and poly(maleic acid-co-ethylenimine) was used for the detection of copper and nickel ions [48]. Uptake of these ions to the films is monitored by SPR. As a unique application, a smoke sensor was proposed that would include films of PAH and PAA alternately assembled on a QCM device [16]. Exposure of the film to smoke from tobacco induced an incredible shift of the resonance frequency. The frequency response upon smoke adsorption was recovered by heat treatment.

## 5.3. Electronics and Photonics

For the construction of molecular photoelectrical devices, immobilization of bacteriorhodopsin is an attractive research target. Its long-term resistance to thermal, chemical, and photochemical degradation makes bacteriorhodopsin one of the most promising biological candidates for biophotonics. Tripathy et al. reported that layer-by-layer assemblies using cationic PDDA and the anionic bacteriorhodopsin were successfully constructed by the alternating layer-by-layer adsorption technique. Generation of photocurrent from the assemblies confirmed the biological activity of bacteriorhodopsin after the assembly process [74, 75].

Many applications of alternately assembled film of non-biological materials have also been extensively researched. In particular, assemblies of inorganic materials and conductive polymers were used for various electronic and photonic

devices, such as a rectifying junction device and light-emitting diodes.

Alternating assembled film can incorporate metallic components as a coordination complex. Rubner et al. reported light-emitting devices based on alternating layer-by-layer adsorption of Ru(bpy)<sub>3</sub> complex polyelectrolyte and poly(acrylic acid) (PAA) [33]. The Ru(bpy)<sub>3</sub> complex is known to emit light in an electrogenerated chemiluminescence process. When a thin insulating layer (PAH/PAA layer) existed at an anodic electrode, the luminescence level of these devices was significantly diminished. Therefore, luminescence intensity was observed to be controlled by the film construction and bias types. Great freedom of film construction in alternating layer-by-layer adsorption makes it possible to design vectorially functioning devices.

The importance of layering sequences was also pointed out in these functions. For example, Eckle and Decher fabricated organic light-emitting diodes based on poly(*p*-phenylenevinylene) and poly(methacrylic acid) that included an isolating layer of clay microplates [116]. Introduction of the clay layer lowered the current density and increased the luminescence intensity in comparison with a pure polymer assembly, and these characteristics were easily modified by the deposition sequences of these components. The most important advantage in alternating layer-by-layer adsorption, freedom in layering construction, can lead to easy device optimization.

Diode nanowire devices were prepared by combining template synthesis and the layer-by-layer adsorption. Kovtyukhova and co-workers assembled nanoparticles (TiO<sub>2</sub> and ZnO) and PSS between metals in a matrix of porous alumina membrane [125]. Removal of the matrix resulted in free-standing nanowire with the nanoparticle assembly film sandwiched by the metals. The prepared nanowire showed current-rectifying behavior.

## 6. CONCLUSIONS

Preparation of well-controlled structures in nanometer-level precision is an indispensable research target for the current development of nanoscience and nanotechnology. In particular, the formation of layered nanostructures is more easily accomplished than the total construction of three-dimensional structures. We need a simple and inexpensive methodology that can be generally applied to various materials. Alternating layer-by-layer adsorption satisfies these requirements. Recent developments in this method have expanded the application area from the visible range (2D assembly on visible support) to a microscopic scale (3D assembly on invisible particles). The potential and recent progress of this method could lead to various practical applications, from electronic devices to medical uses.

## GLOSSARY

**Alternating layer-by-layer adsorption** Method to produce thin film through alternating adsorption of materials. Electrostatic interaction between cationic and anion polyelectrolytes is mainly used as an adsorption force.

**Atomic force microscopy (AFM)** Microscopy for observation of surface morphology with molecular-level resolution produced by controlling atomic force between sample surface and monitoring tip.

**Cerasome** Lipid vesicle with a ceramic-like surface.

**Langmuir–Blodgett (LB) film** Thin film prepared by layer-by-layer transfer of monolayers from water surface to solid support.

**Quartz crystal microbalance (QCM)** Device to monitor mass change with nanogram precision through the resonance frequency shift of quartz crystal based on its piezoelectric property.

## 1. INTRODUCTION

Lead sulfide nanoparticles are subject of increasing research interest. On the one hand, this research is motivated by the opportunity to study quantum confinement effects inside zero-dimensional structures [1]. On the other hand, the optical properties of semiconductor nanoparticle-doped materials can be precisely engineered by choosing their composition, size, and the host matrix. Moreover, some interesting properties, such as the optical nonlinearity, are significantly enhanced with respect to the corresponding bulk materials [2]. Thus, the realization of improved or new optical devices becomes possible.

Historically, semiconductors other than lead sulfide were much more intensively studied. Most of the work was done in Cd(S,Se)-doped glasses, partly because they are commercially available as sharp cut-off optical filters. For example, the strong optical nonlinearity of semiconductor nanoparticles was first observed in Cd(S,Se)-doped glasses [3]. Other semiconductors, such as CuS or HgS, are seldom studied. The interest in lead sulfide is, however, strongly increasing over the last few years. In the 1980's and 1990's, many groups studied the linear and nonlinear optical properties of semiconductor-doped glasses and observed original features such as the blue shift of the absorption edge

or the high optical nonlinearity. The theoretical work that accompanied the experimental work provided explanations for most of these observations by the quantum confinement of free carriers inside the nanoparticle.

Bulk PbS was primarily studied for near-infrared detector applications. PbS is a narrow bandgap semiconductor with its absorption band in the near infrared around 3  $\mu\text{m}$ . In nanoparticles, the absorption resonance can be shifted to the visible wavelength region by choosing an appropriate particle size. Thus the 1–2  $\mu\text{m}$  wavelength region can be easily covered. This spectral region is of paramount interest for telecommunication devices or sensors. A further specific feature of PbS is its very large exciton Bohr radius. Hence, strong quantum confinement is obtained relatively easy. This is an important fact, as theoretical considerations predict that for this case the most interesting quantum confinement features can be observed.

During the last 20 years, many different techniques have been developed for semiconductor nanocrystal synthesis. For both fundamental research studies and applications, it is necessary to control the average size of the particles, in order to obtain a very narrow size distribution of particle sizes, control the electronic surface states, and also to control the shape and organization of the particles. Most of the developed synthesis methods aim to overcome these problems, and to obtain semiconductor nanocrystals inside a specific host material as for many application, it is often necessary to embed the nanocrystals in a solid matrix.

This entry is considered a concise introduction to lead sulfide quantum dots only. Great care was taken to consider all important aspects of the field and to include all available recent results. For more detailed information, the reader should consult the cited references or the more general introductions to the exciting field of semiconductor quantum dots that can be found in [4–7].

The organization of this article is as follows: the theoretical investigations of lead sulfide nanoparticles are described in Section 2. Section 3 gives an overview on the extensive particle elaboration techniques, followed by the results of the particle characterization illustrated in Section 4.

Some important optical features of lead sulfide nanoparticles are discussed in more details in Section 5. The last section deals with the application of PbS nanoparticles. Tables 1–4 provide an overview on research done on the theoretical considerations, the material elaboration, its characterization, and its nonlinear optical properties, respectively.

## 2. THEORETICAL INVESTIGATIONS

### 2.1. Quantum Confinement

The optical properties of lead sulfide nanoparticles are fundamentally changed with respect to the bulk material. This modification is caused by the confinement of the free carriers

into the volume of the nanoparticle. Thus, the available electron and hole states are modified, which, in turn, affects the particle-light interactions. As this characteristic feature can only be explained in the framework of quantum theory, it was named quantum confinement and, consequently, the semiconductor nanoparticles are often denoted as quantum dots. The quantum confinement influences the absorption and the emission as well as the carrier dynamics of the semiconductor.

One of the most striking quantum confinement effects is the blue shift of the linear optical absorption offset. This effect can be understood in a very straightforward way. In a bulk semiconductor, the conduction electrons and holes are free to move around. However, in a confined geometry,

**Table 1.** Theoretical considerations concerning PbS nanoparticles.

Studied property	Theoretical model	Specific features	Ref.

Raman scattering spectra selection rules for Raman scattering photoluminescence spectra	Kubo	nonadiabatic approach (Jahn–Teller effects) multiphonon transitions	[38]

the carriers feel confined. Thus, in a first approximation, their wavefunctions have to be zero at the surface of the particle. This problem corresponds to the well-known particle-in-a-box problem, resulting in discrete energy levels and an increase of the ground state energy.

The first theoretical description of quantum confinement in semiconductor nanoparticles was published in 1981 [8]. In this joint effective mass and particle in a sphere approach, the electron wavefunctions are forced to zero at the particle surface. The nature of the confinement is governed by the relationship between three lengths:  $a$ ,  $a_e$ , and  $a_h$  ( $a$  is the crystal radius,  $a_{e,h}$  the electron/hole Bohr radii:  $a_{e,h} = \hbar^2 \kappa / m_{e,h} e^2$ ,  $\kappa$  the semiconductor static permittivity, and  $e$  the electron charge). In lead sulfide, the electron and hole radii are both in the order of  $a_{e,h} \approx 9$  nm [9], that is, bigger than the nanoparticle size of most elaborated particles ( $\approx 2$ –5 nm). Consequently, lead sulfide nanoparticles can be described in the so-called strong confinement limit which is defined by  $a \ll a_{h,e}$  [8]. In this case, the confinement energy separation between electron/hole energy levels is dominant over the Coulomb interaction energy. Therefore, in a first-order approximation, the electrons and holes can be considered as two independent particles confined inside a spherically symmetrical energy wall with infinitely high potential wells. The effective bandgap of the nanoparticle can be calculated by

$$E_g = E_g^{\text{bulk}} + \frac{\hbar^2 \pi^2}{2\mu a^2} - 1.786 \frac{e^2}{\varepsilon a} - 0.248 E_{\text{Ry}}^* \quad (1)$$

where  $E_g^{\text{bulk}}$  is the bulk energy gap,  $\mu = m_e m_h / (m_e + m_h)$  the reduced mass,  $\varepsilon$  is the semiconductor dielectric constant, and  $E_{\text{Ry}}^* \equiv \mu e^4 / (2\kappa^2 \hbar^2)$  the exciton effective Rydberg energy. The second and most important term scales with the inverse of the square of the sphere radius and the inverse of the reduced mass. The two further terms are small corrections, which describe the electron-hole Coulomb interaction (third term) and the remnant of the exciton effect, that is, the spatial correlation between the two particles (fourth term) [10]. One can notice that because of the small effective electron/hole mass in PbS, the actual value of  $E_g$  is very sensitive to small changes in the particle size.

This basic model provides an understanding of the confinement effect and its dependence on the particle size. However, especial for very small particles, some of its assumptions, such as the parabolic band structure or the infinite confinement potential, are not realistic. For example, the potential barrier between nanoparticles and the matrix in PbS-doped Langmuir–Blodgett (LB) films was experimentally evaluated to 4.5 eV [11]. Moreover, the band nonparabolicity has been described by a two-band model, using a basis set of  $sp^3$  pseudo wavefunctions centered at the Pb and S atoms [12]. Actually, this improved model was successfully applied to explain the blue shift of PbS particles with sizes as low as 2.5 nm. Further modified models were published (see Table 1), including a nonparabolic band structure [13, 14] or an infinite confinement potential at the semiconductor glass interface [15, 16].

A different approach to explain the electronic properties of semiconductor nanoparticles is given by the tight-binding method. It starts from one atom and its electronic

orbit structure. The semiconductor nanoparticle is then constructed by adding more and more atoms and calculating the electronic energy structure of the resulting particle [17–20]. This appropriate approach is feasible because of the rather small number of atoms in one particle. For example, a 3.5-nm diameter PbS nanoparticle contains only 912 atoms. Kane et al. applied this approach to describe the size effects on the absorption spectra of PbS nanoparticles and observed good agreement with experimental results [19]. This model was also used to study the influence of the particle shape on the absorption spectra. This is a very important feature as very small crystals are rarely of perfect spherical shape. Calculations for CdSe nanoparticles show that the first transition energy is only dependent on the smallest particle dimension, whereas higher transitions are affected by the particle anisotropy [20]. This shape dependence of the optical absorption spectra was experimentally verified in PbS nanoparticles of different shape [21].

The calculation of the lowest optical absorption can be extended to the calculation of the entire electronic energy structure. Some important differences between the band structure of bulk PbS [22, 23] and PbS nanoparticles [24–26] were found. Exact theoretical analysis of the energy spectra in the framework of a four-band  $kp$  method with a full account of anisotropy effects results in pronounced optical transitions, which are forbidden in an isotropic approximation. The band anisotropy effects are more pronounced for excited states and increase with the confinement.

The application of most of these theoretical models are limited by the fact that they include specific material parameters (such as  $\varepsilon$  or  $n$ ) which are only known with precision for the bulk material. These parameters can change drastically for nanoparticles. For example, the size dependence of the refractive index was experimentally investigated [27]. For particles with average diameters below 25 nm, the refractive index decreases with decreasing particle size from the bulk value of  $n_{\text{bulk}} = 4$  to  $n = 2.1$  for 3-nm sized particles.

## 2.2. Phonon Coupling

Similar to the confinement of electrons or holes to the nanoparticle volume, size quantization also effects the phonons. The effects of confinement on the vibrational modes of PbS nanoparticles are dramatic, owing to the dispersive phonons and unusual dielectric properties of the bulk material. In a basic model, the phonon wavefunction is confined to the nanoparticle while the bulk dispersion relations are retained. More appropriate treatments use a classical dielectric model, which couples the phonon amplitude to the electrostatic potential, but still neglect phonon dispersion [28, 29]. The application of spherical boundary conditions results in confined longitudinal and surface modes.

The modified electronic structure of PbS nanoparticles affects the exciton-phonon coupling efficiency. In bulk PbS coupling of electrons and holes to polar phonons is strong because of their high ionicity. In nanoparticles, this coupling is expected to be much smaller. In fact, in the strong confinement limit, the size quantized electron and hole states ideally have identical wave functions and can be thought of as lying on top of each other, thus cancelling each other's coupling to the lattice. Therefore, the coupling to polar phonons

should vanish. Coupling to acoustic phonons occurs through deformation potential and piezoelectric interactions. The sodium chloride crystal structure of lead sulfide is centrosymmetric and thus not piezoelectric, so the deformation potential coupling is isolated. PbS nanoparticles are thus well-suited to test theoretical predictions of the vibronic nature of the excited states and the homogeneous line shape.

Once the electronic wave functions and vibrational modes are known, they can be used to calculate the coupling of excitons to optical modes. Measurements of the exciton photon coupling showed that the actual coupling to optical phonons is very small due to the net charge neutrality and is at least 10 times smaller than values obtained for nanoparticles in other material systems [30]. Moreover, the coupling to acoustic modes is larger than the coupling to optical modes. These conclusions are consistent with the original theoretical predictions for nanoparticles in the strong quantum confinement limit [31].

For a more accurate treatment of materials with dispersive phonons, it is essential to satisfy the appropriate mechanical as well as electromagnetic boundary conditions. It was shown that correct boundary conditions demand the coupling of longitudinal and transverse modes [32]. In the special case where the vibrational amplitude is completely confined to the nanoparticle, the modes can be classified as coupled spheroidal and uncoupled torsional modes. The uncoupled modes are purely transverse, have no associated electrostatic potential, and hence are not expected to be optically active. The coupled solutions have a mixed longitudinal and transverse character involving the mechanical amplitude and the electrostatic potential. Since they involve the electrostatic potential, the coupled modes should be optically active, which was experimentally confirmed [33].

These calculations can be extended in order to determine the Raman cross-section of the phonon modes [34]. However, when measured by time-integrated Raman scattering, the electron-phonon coupling was found to be about four times more important than expected [35]. This discrepancy was explained by trapped charges built up on the nanoparticle surface during steady-state Raman measurement. The resulting local field enhances the coupling of excitons to polar phonons by at least an order of magnitude. The use of short excitation pulses should resolve this problem.

Devreese et al. developed a theory of phonon-assisted optical transitions in semiconductor nanoparticles, which takes into account the nonadiabaticity of the exciton-phonon system [36–38]. The role of the nonadiabaticity was shown to be of paramount importance in spherical particles, where the lowest one-exciton state can be degenerated or quasi-degenerated. In nanoparticles of lower symmetry, the effects of nonadiabaticity reveal themselves mainly due to the phonon-induced mixing of states which belong to different energy levels.

### 2.3. Nonlinear Optical Properties

The overall polarizability  $\chi = \varepsilon - 1$  of a medium is defined in its scalar form as  $\chi^{(3)}E = P/\varepsilon_0 = \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \dots$  [4]. The first term describes the linear response; the second term corresponds to frequency doubling, summation,

and subtraction; and the third term describes four-wave mixing and other processes. It can be shown that in centrosymmetric media, such as most semiconductor nanoparticles, the even order terms must be zero [39]. In the case of PbS nanoparticles, the most important term is  $\chi^{(3)}$  corresponding to the third order or Kerr-type nonlinearity. This effect can also be interpreted as a nonlinear dephasing and one introduces the complex nonlinear refractive index  $n_2$  by  $n = n_0 + n_2 \cdot I$ , where  $n_0$  is the complex linear refractive index and  $I$  the light intensity.

The nonlinear optical properties of bulk semiconductors are mostly of electronic nature. Near the electronic bandgap, absorption saturation leads to a strong negative optical nonlinearity. The response time of the nonlinearity is, however, relatively long, as its mechanism is based on real electronic transitions with quite slow decay rates ( $\approx 10$  ns<sup>-1</sup>). It was shown that the spectral region near half the bandgap is more favorable for nonlinear optical applications [40]. In this case, the nonlinearity is somewhat smaller, but its response time is much faster and the linear absorption is significantly lower.

Similar to the linear optical properties of semiconductor quantum dots, the effects of the quantum confinement on the nonlinear optical properties depend on the size of the particle in respect to the different Bohr radii. Different theoretical models for the nonlinear optical properties of semiconductor nanoparticles in the strong confinement limit were published [2, 31]. The separation between the discrete energy levels inside the valence and conduction bands, is large. Thus, in a first approximation, electronic intraband transitions can be neglected with respect to state filling of the lowest interband transition. Hence, the nonlinear response of quantum dots can be described in the framework of a saturated two level system [31]. Using a nonlinear Kramers–Kronig relation [41], the real part of the nonlinear refractive index  $n_2$  can be calculated from the absorption changes induced by the saturation of the absorption. In this theory, the nonlinearity will saturate as  $n_2 = n_2'(1 + I/I_S)$ . The main improvement of nanoparticles, with respect to bulk material, is that the absolute absorption change and, consequently, the nonlinear refractive index change can be much larger before the transition saturates. This is particularly important for nonlinear devices, where in the case of bulk semiconductors, the transition already saturates before sufficient index change, that is, dephasing occurs. The larger saturation intensity in quantum dots is partially caused by their much faster recombination. However, the theory predicts that relatively complete saturation of absorption should be possible in quantum dots, because there are no competing mechanisms such as bandgap renormalization that inhibit strong absorption saturation in bulk.

At present, only a limited number of articles dealing with the nonlinear properties of PbS nanoparticles are published. Thus, the reading of some articles not directly dealing with lead sulfide can be useful for the understanding of the nonlinear properties of PbS nanoparticles [7, 42–44].

## 3. SYNTHESIS

Table 2 summarizes the main synthesis methods of PbS nanoparticles reported up to the present. The different synthesis methods will be reviewed with particular consideration

**Table 2.** Main PbS nanoparticles synthesis method. The synthesis have been divided into to main groups: PbS not embedded in a matrix and embedded in a host material. In the dimension row it is reported the mean diameter for spherical particles and the width x length for road or wire shaped particles. The presence or not of structured absorption spectra is reported in the abs row. Particles shape is abbreviated as follow: s = spherical; c = cubic; r = road; tp = triangular pyramid; w = wire. (n.r = not reported).

Not embedded in a matrix

to particle's average size and size distribution, particle's surface states, and particles shape. The different approaches for nanoparticles fabrication have been divided into two main groups considering particles not embedded in a host matrix and materials doped with PbS nanocrystals.

### 3.1. Particles Not Embedded in a Host Matrix

One of the most used chemical routes to PbS nanoparticles dispersed in solvents is colloidal chemistry [21, 45–57]. This method consists in the reaction of the lead precursor (typically a lead salt: lead acetate, nitrate, or perchlorate) and the sulfur precursor (very often H<sub>2</sub>S or Na<sub>2</sub>S) in suitable solvents, while the nucleation and growth process are controlled through suitable stabilizer (also called capping agent) and/or controlling the environment conditions (pH, temperature, solvents). Using this approach, PbS nanoparticles can be prepared both in polar and nonpolar solvents with the surface covered by many different capping agents. The obtained particle size is normally in the nanometer range, with a size distribution ranging from 5% up to 25% (standard deviation). The capping agent plays a very important role also in controlling the surface states and hence the optical properties of the PbS quantum dots. For example, PbS colloids stabilized with PVA [21, 48, 49, 56] or hydroxypropyl cellulose (HPC) [54] showed structured absorption spectra, while the use of other stabilizers very often did not cause structured absorption spectra. The shape of the particle is also strongly dependent on the used surface capping agent. For example Patel et al. [21] have found that the shape of particles stabilized with PVA is spherical, while particles stabilized with PVP or gelatin have a mixture

of needle, cubic, and spherical shapes. It is worth noting that both the size and shape of the particles are influenced not only by the used stabilizer, but also by pH, temperature, concentration, and solvents.

Colloidal core-shell CdS-PbS [50] nanoparticles were synthesized by Pb<sup>2+</sup> ions displacing Cd in Cd-S bonds on the surface of CdS colloids. TiO<sub>2</sub>/PbS coupled semiconductors were also obtained by colloidal chemistry [52]. PbS nanoparticles are formed in a water solution containing TiO<sub>2</sub> colloids, by reacting lead nitrate and sodium sulfide in the presence of mercapto acetic acid, which is used for linking the TiO<sub>2</sub> and PbS nanoparticles. It was found that TiO<sub>2</sub> acts as a stabilizer in the PbS growth. TiO<sub>2</sub>/PbS nanocomposite films were also obtained by depositing the colloidal solution on a substrate whose surface is appropriately activated.

Colloidal PbS nanoparticles have also been prepared without using any stabilizer [46]. In this case, the growth processes are slowed down by carrying out at low temperature just above the solvent freezing point.

PbS nanoparticles have also been synthesized using a micelles-mediated colloids method [56, 58, 59]: Lin and Xicheng [56] prepared a microemulsion in the system water/surfactant/apolar solvent, allowing the reaction between the lead and sulfur precursors inside the micelles. Size and size distribution of the particles depends on size and size distribution of the micelles, which in turn, depends on the nature and concentration of used surfactants. The surface of the nanoparticles is covered by the surfactant molecules used for the preparation of the microemulsion. As in microemulsion, micelles are generally spherical; PbS particles also maintain the same shape. Yang et al. [58] used a bicontinuous cubic phase in which monodispersed lead sulfide nanoparticles with 4–14 nm in diameters have been grown. They used a sodium dioctyl

sulfosuccinate (AOT)/water/ $\text{Na}_2\text{S}$  system in which sodium dioctyl sulfosuccinate (AOT) forms a mesoporous phase with long-range, three-dimensional periodicity called bicontinuous cubic phase, where the aqueous pores are interconnected through small channels. Lead sulfide nanoparticles have been grown inside the pores and then transferred into a chloroform solution by functionalizing the surface by *n*-dodecanethiol. Schneider et al. [59] used the micellar organization of a block copolymer, polystyrene-*b*-poly(4-vinylpyridine) (PS-P4VP), composed of blocks with different solubility properties. Toluene is used as a selective solvent for the PS block. By adjusting the lead-to-polymer ratio, temperature and pH, PbS particles of different sizes (2–20 nm) and morphology (sphere, cubes, or needles) have been obtained.

Sonochemistry [60] was used for synthesizing round-shaped PbS nanoparticles starting with lead acetate and sulfur. In fact, when ultrasound is applied to a solution, bubbles are formed in the liquid. During the implosive collapse of the bubbles, a localized hotspot is generated and a temperature up to 4700 °C and pressures up to 180 MPa can be reached. In these extreme conditions, elemental sulfur and lead ions can react to provide PbS nanocrystals. Also in this case, the growth of the nanoparticles can be controlled by using stabilizers.

Formation of PbS spherical nanoparticles in ethanol was obtained using a supercritical fluid process [61]. A supercritical ammonia/ $\text{Pb}(\text{NO}_3)_2$  solution at 160 °C and 24 MPa is rapidly expanded in a  $\text{Na}_2\text{S}$ -ethanol solution containing polyvinyl pyrrolidone (PVP) as a stabilizer, to produce PbS nanoparticles with a size distribution of about 12–15%.

Synthesis methods, using just a single source precursor for PbS, were also investigated. Trindade et al. [62] injected a solution of lead(II) dithiocarbamate complexes dissolved in toluene into tri-*n*-octylphosphine oxide (TOPO) at 150–250 °C, obtaining spherical nanoparticles with a size distribution of about 20%. More recently, Boudjouk et al. [63] used metal bis(benzylthiolates) for the synthesis of pure PbS and PbS-CdS solid solution nanoparticles. Both the size and shape of the nanoparticles depends on the pyrolysis temperature, which can be carried out in the presence or not of solvents.

Formation of PbS nanoparticles was also obtained through gas phase synthesis [64]. Lead sulfide aerosol is formed at normal pressure by sublimating PbS powders in a tube furnace blowing  $\text{N}_2$  and charged by a radioactive  $\beta$ -source ( $\text{Kr}^{85}$ ). In a differential mobility analyzer, the charged particles are size-selected on the basis of their electric mobility, which is a function of their charge level, mass, and shape, and then subjected to a second heating step. Spherical particles ranging from 5 to 20 nm can be obtained. For bigger particles, the standard deviation is about 5%, while for smaller particles it is approximately 20–30%.

Solid state reaction leading to 40-nm diameter PbS particles was reported by Ye et al. [65]. PbS nanocrystals were prepared at room temperature through self-propagating, solid-state reactions of  $\text{Pb}(\text{OH})_2$  and  $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ .

PbS nanocrystals were also epitaxially grown on an arachidic acid (AA) monolayer [66] or on an InP(110) substrate [67]. In the first case, AA monolayers are formed at the water-air interface of a water solution containing lead nitrate. Equilateral triangular pyramidal nanocrystals have

been *in-situ* generated by exposing the AA monolayer to  $\text{H}_2\text{S}$ . In the second case, the formation of self-assembled PbS nanodots was obtained through molecular beam epitaxy in an ultra-high vacuum chamber onto a *in-situ* cleaved InP(100) surface. Triangular pyramidal PbS dots were also obtained in this case.

### 3.2. Particles Embedded in a Host Matrix

PbS nanoparticles have been embedded in many different kinds of host materials, both as film and as bulk. Films will be discussed first and then bulk materials (both monoliths and powders) will be considered.

#### 3.2.1. Thin Films

Polymers are one of the most used matrices to embed PbS nanoparticles. Several types of ion-containing polymers have been used for the preparation of polymer films doped with PbS quantum dots. Ionomers, defined as ion-containing copolymers, are frequently used because microphase separation of the ionic polymer part results in the formation of ionic aggregates within a matrix of the nonionic polymer component. This micro- or nano-ionic aggregate can react with lead ions and then can be exposed to  $\text{H}_2\text{S}$  to form the PbS nanoparticles [12, 19, 68, 69]. In a different approach, lead complexes are directly attached to one block of the copolymer, leading to the direct formation of lead ions containing microdomains, and then exposed to  $\text{H}_2\text{S}$  [70–72].

Control of particle size, size distribution, and shape, can be achieved controlling the ionomer aggregate sizes. In fact, it was demonstrated that these aggregates serve as micron/nano reactors for the synthesis of PbS quantum dots [19, 69, 71]. In general, spherical nanoparticles a few nanometers in diameter have been obtained.

Nanoreactors have also been obtained in multi-layer thin films of polyelectrolytes. Such multilayer films are constructed using a layer-by-layer process scheme involving the alternate absorption of oppositely charged polymers onto a substrate. By choosing suitable polyelectrolytes and adjusting the pH of the deposition solution, it is possible to control the ionic aggregate, which will react with the forming nanoparticles. Spherical PbS nanoparticles with a 2.5 nm diameter have been obtained in polyallylaminehydrochloride/polyacrylic acid (PAH/PAA) multilayer films by immersing it first in a lead acetate, aqueous solution and then exposing it to  $\text{H}_2\text{S}$  [73].

Incorporation of PbS in polymer films was also obtained in poly(ethylene oxide) (PEO) or gelatin by the coprecipitation method [74]. In this case,  $\text{H}_2\text{S}$  is added to a water solution of PEO-lead acetate or gelatin-lead acetate. The final solution is deposited on a suitable substrate and then dried.

Gaponik and Sviridov [75] deposited polyaniline films doped with PbS quantum dots on an indium tin oxide (ITO) glass slide. In this case,  $\text{Pb}^{2+}$  ions were trapped in the polymer matrix by electrodeposition of a solution of aniline,  $\text{HNO}_3$ , and  $\text{Pb}(\text{NO}_3)_2$ . PbS nanoparticles are formed after the immersion of the film in  $\text{Na}_2\text{S}$  solution.

Poly-*p*-xylylene-PbS nanocomposite films were synthesized by cryochemical solid-state synthesis [76]. It is based on the low-temperature, co-condensation of metal sulfide

and monomer vapors followed by the low-temperature solid state polymerization of the obtained condensates. With this method, polymerization proceeds at temperatures below the glass transition temperature of the forming polymer matrix. Thus, it is possible to obtain very fine particles (around 4 nm) dispersed in an hydrophobic polymer matrix with very low particles/matrix interaction.

PbS nanoparticles in polymer films or membranes have also been obtained through template-mediated crystallization. The templates create a micro/nano reactor in which nucleation and growth of PbS takes place. Moreover, they control size, size distribution, morphology, and organization of nanoclusters.

Wang and Yang [77] used lead bis(2-ethylhexyl) sulfosuccinate ( $\text{Pb}(\text{AOT})_2$ ) as a surfactant, which can self-assemble into an ordered structure in solution also containing poly(vinyl butyral) (PVB). Films can be obtained by depositing the solution on suitable substrates. Rod-shaped PbS nanoparticles are formed inside the template upon exposure to  $\text{H}_2\text{S}$  of the  $\text{Pb}(\text{AOT})_2$ -loaded PVB films. Dutta et al. [78] used a layer-by-layer deposition technique for building supramolecular multilayers on solid substrates by alternating layers of polydiallyldimethylammonium chloride (PDDA) and polystyrenesulfonate sodium salt (PSS). *In-situ* nucleation of PbS particles was achieved by immersing the PDDA-PSS multilayer film into a aqueous solution of  $\text{Pb}(\text{NO}_3)_2$  and subsequent exposure to  $\text{H}_2\text{S}$ . Spherical and cubic nano- and micro-particles can be obtained with a very broad size distribution. *In-situ* generation of confined lead sulfide has also been obtained in bilayer lipid membranes (BLM) [79] and in Langmuir–Blodgett (LB) films [80–83]. Langmuir–Blodgett and bilayer films are organized, molecularly assembled, multilayer films characterized by alternating stacking of hydrophilic and hydrophobic layers. The formation of metal semiconductor particles can take place if the hydrophilic head group of the constructing molecules has a metal-ion binding ability. The amount and spatial arrangement of the precursor metal ions are controlled by the self-assembled head groups. Upon exposure to  $\text{H}_2\text{S}$ , these metal ions react with the sulfur ions forming the confined metal sulfide nanostructure. In general, PbS wires have been obtained in LB films [80–83].

PbS nanoparticles in PVA films were also obtained by a gas aerosol method [84]. An aerosol of microdroplets can be used to create a microreactor in which nanoparticles can nucleate and grow. With this method, microdroplets of a solution of PVA and lead nitrate are electrostatically generated applying a very high voltage to a stainless capillary inside a reaction chamber where a substrate is placed at a ground potential. PbS nanoparticles are formed in the solution microdroplets by reaction with  $\text{H}_2\text{S}$ , generated inside the reaction chamber, by the reaction of sodium sulfide and diluted hydrochloric acid. Spherical particles of a 4.4-nm diameter can be obtained in PVA films with a size distribution better than 15%.

Glass or ceramic films doped with PbS quantum dots have been obtained by sol–gel. Three different approaches have been used for obtaining sol–gel films doped with lead sulfide quantum dots. One approach consists of the independent preparation of semiconductor nanoclusters and the matrix sol and their successive mixing. Following this

method Martucci et al. [85, 86] prepared PbS-doped  $\text{SiO}_2$ - $\text{TiO}_2$  and  $\text{ZrO}_2$ -organic modified silicate (ORMOSIL) planar waveguides by doping a matrix solution containing the matrix precursor with a colloidal solution of PbS stabilized with 3-mercaptopropyltrimethoxysilane. With this procedure, spherical PbS nanoparticles with a size distribution of about 10% have been obtained. A different approach consists in the preparation of a porous matrix containing lead oxide or lead ions, followed by exposure to  $\text{H}_2\text{S}$ . del Monte et al. [87] used this approach for preparing PbS nanoparticles in  $\text{SiO}_2$ -ORMOSIL films. Homogeneous lead salt distribution at the solution stage was obtained through the use of glycidoxypropyltrimethoxysilane (GPTMS), which can coordinate the lead acetate through the epoxy group, while 3-mercaptopropyltrimethoxysilane was used for controlling the aggregation process. Homogeneously dispersed PbS nanoparticles with size distribution as low as 5% were obtained. PbS nanoclusters were also adsorbed on the internal surface of  $\text{TiO}_2$  by dipping  $\text{TiO}_2$ -porous, sol–gel films into a concentrated solution of coated lead ions followed by impregnation in  $\text{Na}_2\text{S}$  solution [88, 89]. With this process, particles of about 3 nm have been obtained, while larger particles are obtained when the coating process is repeated several times. The last approach consists in the preparation of a deposition solution containing all the precursors both for the matrix and the lead sulfide. Lead sulfide nanoparticles precipitate in the matrix after heat treatments. Using this approach,  $\text{ZrO}_2$  films doped with PbS quantum dots have been fabricated [90, 91].

$\text{SiO}_2$  glass films doped with PbS spherical nanoparticles were also obtained by RF-sputtering [92]. The used target was a  $\text{SiO}_2$  glass plate over which several different PbS polycrystalline pellets were placed. The size of the particles depends on the relative surface area of PbS pellets in the composite target.

PbS nanoparticles have been embedded in  $\text{SiO}_2$  glass film by a co-evaporation method [93]. The two evaporation sources ( $\text{SiO}_2$  and PbS) were placed in a vacuum chamber and well separated from each other by mechanical shields. The substrates were placed onto a rotating sample holder for alternating exposure to the two evaporation sources. By adjusting the evaporation rate of the sources and the post-deposition heat treatments, it is possible to control the size and volume fraction of the PbS nanocrystals.

### 3.2.2. Bulk Materials

Polymers are one of the most used matrices also in the case of bulk materials doped with PbS nanocrystals. The synthesis procedures are very often the same as for the polymer films; so with the same method both bulk and films can be prepared.

Bulk polymeric matrices doped with spherical PbS nanoparticles have been prepared using ionomers [72, 94] and a co-precipitation method [27], whose methodology has already been described for films.

Leontidis et al. [95, 96] used the template-mediated, crystallization method to control the shape of lead sulfide nanoparticles in bulk polymers. Micelles were formed using an ionic surfactant (sodium dodecyl sulfate (SDS)) and water soluble nonionic polymer (polyethyleneoxide (PEO)).

By adding lead and sulfur ions to the PEO/SDS solution, lead sulfide nanocrystals are formed on the polymer-bound micelles. The shape of the nanoparticles is controlled by the shape of the micelles, which are strongly affected by the pH of the solution. PbS nanoparticles encapsulated in polymethylmethacrylate (PMMA) nanocages have been synthesized by Qiao et al. [97] using PMMA as a template to control the growth of PbS nanocrystals. Spherical particles of 30 nm with a size distribution of about 6% have been obtained.

PbS nanoparticles have been embedded in a polymer matrix using a  $\gamma$ -irradiation process [98] for promoting both the polymerization and the reaction between sulfur and lead precursors.

The sol-gel technique was used widely for preparing bulk glass or ceramic materials doped with PbS QD. As for the films, three different approaches have been used. Xerogels (*i.e.*, dried gel) doped with PbS have been obtained by independent preparation of PbS nanoclusters (by colloidal chemistry) and matrix sol and their successive mixing [99, 100]. Gacoin et al. [99] prepared colloids stabilized with 3-mercaptopropyltrimethoxysilane while Pellegrini et al. used reverse micelles [100].

Monolith SiO<sub>2</sub> glass [101], SiO<sub>2</sub> xerogel [102], and PZT (PbO-ZrO<sub>2</sub>-TiO<sub>2</sub>) glass ceramics [103] doped with spherical PbS nanoparticles have been obtained through the preparation of a porous matrix containing lead oxide or lead ions, followed by exposure to H<sub>2</sub>S. Moreover, PbS nanocrystals have been precipitated in SiO<sub>2</sub>-ORMOSIL [104] and TiO<sub>2</sub> xerogel [105] from a one-pot solution containing all the precursors—both for the matrix and the lead sulfide.

The sol-gel method was also used for the preparation of mesoporous silica powders doped with PbS nanowires [106]. The mesophase was synthesized by using a pluronic P123 as a template and tetraethyl ortosilicate as a silica precursor. After calcination, the surface channels of the mesopores were functionalized with thiol groups (SH), then impregnated with lead ions, and finally PbS nanowires were grown inside the channels by heat treatments in N<sub>2</sub> at high temperatures. The obtained nanowires are a several hundred nanometers in length and 6 nm in diameter.

Glasses doped with PbS nanoparticles have also been obtained by a traditional glass-melting technique. Borelli and Smith [9] and Lipovskii et al. [107] melted the raw materials (including sulfur) at a temperature higher than 1000 °C, then promoted the nucleation and growth of the nanocrystals annealing the samples just over the glass transition temperature in reducing atmosphere. Mukherjee et al. [108] prepared a lead silicate glass and precipitated the lead sulfide nanocrystals annealing the glass in a H<sub>2</sub>S atmosphere. The size and size distribution is strictly related to the heat treatment schedule.

Ion implantation was used to synthesize PbS nanoparticles in SiO<sub>2</sub> glass and Al<sub>2</sub>O<sub>3</sub> single crystal ceramic [109]. Lead and sulfur ions beams are impinging onto the substrate and then annealed in reducing atmosphere. The size and size distribution of the particles mainly depend on the ion dose and energy and on the annealing conditions. Generally, very broad size distributions are obtained.

PbS nanostructures have also been grown inside the pores of zeolite [110, 111]. Zeolites are sodium (or potassium)

alumino silicate ceramics with an interconnected porous structure. Sodium ions can be exchanged with lead ions, and semiconductor nanocrystals can be grown inside the pores after H<sub>2</sub>S exposure. The particle size and size distribution depends not only on the zeolite structure but also on the ion exchange conditions.

PbS quantum dots with 3–5 nm diameters were grown in the interlamellar region of layered zirconium phosphonate powders [112]. Zirconium phosphonate crystals have a layered structure in which semiconductor nanoparticles can be grown. First, the phosphonate crystals are immersed in a NaOH solution in order to adsorb sodium ions, then lead cations are exchanged into the interlamellar region and finally exposed to H<sub>2</sub>S.

## 4. CHARACTERIZATION

### 4.1. Morphology

As already pointed out in the previous sections, most of the properties of PbS nanoparticles depend on their size, size distribution, and shape. The transmission electron microscopy (TEM) is the most frequently used investigation technique for evaluating the morphology of nanocrystals (see Table 3). This technique is used in almost all the references reported in the synthesis section. It enables one to resolve particles with a diameter lower than 1 nm, and using high resolution electron microscopy (HRTEM), it is also possible to resolve the lattice planes and measure the distance between them (see, *e.g.*, Figure 1). For quantum dots (QD) dispersed in a solvent, a few drops are deposited on copper grids covered with a carbon membrane and allow the solvent evaporate. For particles embedded in a solid matrix (bulk or film), fragments of materials are deposited (sometimes first dispersing it in a solvent) on copper grids covered with a carbon membrane (sometimes a holey carbon membrane). A more complex sample preparation is necessary for cross-sectional TEM [109].

The morphology of PbS nanoparticles has also been investigated by atomic force microscopy (AFM) [66, 67, 113, 114]. Particles have been grown on different substrates (InP(110) [67], or LB film [66]) and size and shape of particulate films have been studied with AFM. Atomic force microscopy images of triangular pyramidal PbS dots with an average lateral size as low as 15 nm are reported [67]. Atomic force microscopy images of PbS QD prepared by a colloidal [113] or gas condensation method [114] and then deposited on a suitable substrate have also been taken, but with a lower resolution.

### 4.2. X-Ray Diffraction

The crystal structure of nanoparticles can be studied by X-ray diffraction (XRD); moreover, from the line broadening of the diffraction peaks it is also possible to evaluate the mean particle diameters through the Scherrer formula [115]. An XRD spectra of PbS nanoparticles has been reported by many authors, both embedded in a matrix [9, 12, 27, 68, 71, 72, 76–78, 83, 85–87, 90, 92, 93, 96, 99, 101, 102, 104–107, 112, 116, 117] and not embedded in a matrix [21, 48, 55, 58, 60, 61, 63]. The PbS nanoparticles showed a cubic rock-salt

Phys.* 86, 79 (1999). © 1999, American Institute of Physics.

structure (galena) corresponding to JCPDS #5-592. A typical XRD spectra of PbS nanocrystals embedded in a glass matrix is reported in Figure 2. From the image, it is evident the effect on the line broadening of the particle mean diameter as the particle diameter increases the full width at half maximum of diffraction peaks decreases. In general, PbS nanocrystals with an average diameter as low as 2–3 nm can be evaluated using the line broadening of diffraction peaks but the size evaluated by XRD is not always in good agreement with the size evaluated by TEM measurements. Differences can be originated by a very broad size distribution, variation in shape, and also when PbS nanoparticles are partially amorphous. Wang and Heron [118] examined the validity of the Scherrer's equation by using a direct simulation of Bragg diffraction from PbS nanoparticles, and they obtained an empirical relationship relating the Scherrer's cluster diameter  $d_s$  (in Å) to the real cluster diameter  $d$ :  $d = 0.45 + 1.14d_s$ .

Information on the size distribution can also be obtained by the Fourier analysis of the profile of isolated reflections [76], but this method is not often used and TEM measurements are preferred.

**Figure 2.** X-ray diffraction patterns of glasses containing 4.5 wt.% PbO reacted with  $H_2S$  gas at (a) 25, (b) 200, (c) 250, and (d) 400 °C. From the XRD spectra, it is also possible to evaluate the lattice constant of PbS nanocrystals [101, 102], it is reported that the lattice constant of PbS nanoparticles in glass is constant for particle diameters larger than 4.5 nm, while it decreases for smaller particles [101].

Preferred lattice plane orientation of PbS rods in PVB film has been observed from XRD patterns [77]. In fact, when preferred orientation of the PbS nanocrystal structure is present, the intensity distribution of the observed diffraction peaks deviates from those reported in the JCPDS cards for bulk PbS.

### 4.3. Vibrational Spectroscopy

Raman and infrared spectroscopy are well-established techniques in studying the structure of crystalline and amorphous materials by evaluating the lattice vibrations. Many studies demonstrated that the vibrational modes of PbS nanocrystals are not the phonons of the bulk crystals [33, 35, 38, 119–121].

In bulk semiconductors, the observed Raman shifts usually correspond to the longitudinal optical phonons (LO), while other modes such as the transverse optic (TO) and the surface phonon (SP) modes, in general, are not observable because of the symmetry restriction and low intensities, respectively. As the surface-to-volume ratio is large in nanoparticles, it is possible to observe SP modes; moreover, multiphonon processes are also detected.

A Raman spectra of 2-nm diameter PbS nanocrystals stabilized with PVA [33] showed the presence of an intense band at  $217\text{ cm}^{-1}$  due to the first-order LO mode, while a shoulder around  $190\text{ cm}^{-1}$  was attributed to SP mode. A very sharp peak centered at  $68\text{ cm}^{-1}$  was attributed to TO modes and a small peak around  $275\text{ cm}^{-1}$  was assigned to

two phonon processes. Similar results were also obtained for nanocrystals prepared by an electrochemical technique [120] and a frequency shift of the main band at  $217\text{ cm}^{-1}$  towards the lower side with increasing crystalline size is observed.

Both Machol et al. [119] and Krauss et al. [33] reported far infrared spectrum of small (2 and 4.3 nm, respectively) PbS colloids stabilized with PVA, which showed a broad and intense peak centered at  $90\text{ cm}^{-1}$  due to coupled modes (they have a mixed longitudinal and transverse character), while a smaller and even more broader peak centered around  $275\text{ cm}^{-1}$  is assigned to two phonon processes. The spectra were essentially temperature-independent within the range 15–300 K.

Infrared (IR) vibration bands centered at 1175, 1160, 1110, 990, and  $835\text{ cm}^{-1}$  were attributed to Pb-S bonds by Parvathy et al. [102] in PbS/SiO<sub>2</sub> sol-gel nanocomposite, accordingly to the IR vibrations of bulk PbS.

### 4.4. Optical Absorption Spectroscopy

The optical absorption spectroscopy is the most widespread characterization technique applied to lead sulfide nanoparticles [1, 9, 11, 12, 16, 21, 24, 27, 46–52, 54, 56–61, 68, 71, 72, 74, 76–78, 84–93, 95, 96, 99–102, 104–107, 110, 113, 116, 119, 122–173].

Absorption spectroscopy is available to most research groups and it enables a fast and straightforward proof for the existence of nanoparticles. The quantum confinement of the carriers into the nanoparticles causes a strong blue shift of the bulk optical absorption band to visible or near-infrared wavelengths. By using adequate theoretical models, it is even possible to deduce the nanoparticle size from the position of the absorption offset or the first excitonic transition. The experimental results can be divided into featureless absorption spectra and spectra resolving the signature of room temperature excitonic transitions.

Most research groups, especially those dealing with thin film samples, record a broad, featureless absorption band [12, 21, 48, 68, 76, 85–87, 89, 90, 93, 95, 96, 100–102, 104, 105, 122, 123, 125, 130, 140–142, 144, 146, 148, 150, 156–159, 161]. The absorption offset position varies in general between  $\lambda_{ab} = 500$  and 1100 nm, as a function of the particle size. These wavelengths correspond to band energies of  $E_g = 1.1$  to 2.5 eV. The absorption curves of silica-titania thin films with different PbS-doping ratios is displayed in Figure 3. The arrows indicate the expected position of the first excitonic peak. In general, the lack of the excitonic shoulder can be explained by the poor precision of thin film absorption measurements. Further problems are due to inhomogeneous broadening due to the finite size distribution of the PbS nanoparticles. Moreover, the exciton can be quenched due to the large dielectric constant, the small effective mass, and the relatively large Bohr radius of the electrons and holes in lead sulfide. These features also explain the very broad absorption band that are observed.

In some cases it was, however, possible to resolve one [9, 48, 57, 61, 78, 99, 113, 132, 137, 139, 142, 143, 147, 149, 151, 163] or even more [21, 54, 72, 77, 119, 122, 142, 145, 155, 167, 173] excitonic peaks in the optical absorption spectra. Most of these results are obtained in powders or colloidal

**Figure 3.** Absorption spectra of  $\text{SiO}_2\text{-TiO}_2$  films doped with 5, 10, and 25 mol% of PbS, and one undoped film (ST). The arrows indicate the expected position of the first excitonic peak for particles with the mean diameters obtained from XRD measurements. Reprinted with permission from [85], A. Martucci et al., *J. Appl. Phys.* 86, 79 (1999). © 1999, American Institute of Physics.

solutions, which are known to show the smallest size distribution. Moreover, colloidal solutions allow very efficient surface passivation which further increases the optical quality of the nanoparticles. Figure 4 displays the absorption spectra of PbS-doped glass. The first two excitonic transitions are clearly resolved and the particle size dependence of their position is evident. The position of the first excitonic transition ( $1S_c-1S_h$ ) is situated in the same wavelength region as the absorption offset in the case of featureless spectra. In the case of multiple excitonic peaks, the second and third peaks are in general in the 350–400 nm and 280–300 nm region, respectively.

#### 4.5. Photoluminescence

Photoluminescence (PL) [38, 48, 49, 54, 57, 68, 91, 93, 105, 106, 119, 125, 130, 131, 139, 140, 145, 147, 151, 153, 158–161, 164] and photoluminescence excitation (PLE) [57, 93,

**Figure 4.** Room temperature absorption spectra of glasses with PbS quantum dots. Diameters are: 6.6 (solid line), 7.5 (dashed line), and 9.3 (dotted line). Reprinted with permission from [132], P. T. Guerreiro et al., *Appl. Phys. Lett.* 71, 1595 (1997). © 1997, American Institute of Physics.

125, 130] spectroscopy is used less frequently than optical absorption. Photoluminescence measurements allow the resolution of well-defined emission peaks on thin films, which displays only broad absorption features in the absorption spectra. Most of the published results contain only one emission peak which can be attributed to the lead sulfide nanoparticles. Typical PL and PLE spectra of small PbS nanoparticles are shown on Figure 5. In general, the PL position varies in-between 450 and 1100 nm as a function of the PbS particle size. Lu et al. observed two [54], Lifshitz et al. [125] three, and Nanda and Sahu [147] even four emission peaks. The observed PL excitation peak is situated at 260–475 nm, about 100–130 nm below the corresponding emission peaks. Only Chen et al. found two excitation maxima at 610 and 665 nm conjointly with one single emission band at 804 nm [57].

#### 4.6. Optical Pump-Probe Measurements

Pump probe measurements or transient absorption spectroscopy allow the characterization of the time evolution of the optical absorption and thus the electron dynamics inside lead sulfide nanoparticles. In this experiment, a strong pump beam causes absorption bleaching or induced absorption which is then probed by a time-delayed probe beam. Patel et al. used a pump probe scheme with a regeneratively amplified mode-locked femtosecond Ti-sapphire laser system to measure the transient absorption of PbS nanoparticles stabilized with PVA [21]. They found that the absorption decay is governed by two processes with decay times of 1.2 and 45 ps, which are independent from pump power, probe wavelength, particle size and shape, and surface capping (see Fig. 6). The fast decay is possibly due to trapping, while the slower decay can be attributed to electron-hole recombination mediated by a high density of trap states.

Guo et al. measured transient-induced absorption peaks in surface-capped lead sulfide particles [142]. The decay time

**Figure 5.** Photoluminescence excitation (PLE) and photoluminescence (PL) spectra of two doped  $\text{SiO}_2$  films with PbS volume fractions of 0.03 and 0.08. The excitation wavelength was 311 nm. Reprinted with permission from [93], R. Thielsch et al., *Nano Struc. Mater.* 10, 131 (1998). © 1998, Acta Metallica Inc.

**Figure 6.** Transient absorption decay profiles of photoinduced electrons in PbS nanoparticles stabilized with PVA (circles). The short (top) and intermediate (bottom) scans are fit simultaneously to a double-exponential function deconvolved with a Gaussian of 400 fs FWHM representing the instrument response (solid lines). Time constants of 1.2 and 45 ps for the two decay components are generated from the fitting. Reprinted with permission from [21], A. A. Patel et al., *J. Phys. Chem. B* 104, 11598 (2000). © 2000, American Chemical Society.

was in the order of 150 to 160 fs. It was suggested that this feature arises from the trapped carrier-induced Stark effect.

Machol et al. studied the dynamics of the excitons strongly confined in lead sulfide nanoparticles by using 90 fs laser pulses generated by a mode locked dye laser [119]. The relatively small damping of the exciton transition allowed the observation of the ground state biexcitons as well as an ultra-fast sinusoidal relaxation. This oscillatory response was attributed to quantum beats involving confined TO phonons in the nanoparticles.

#### 4.7. Optical Nonlinear Characterization

The nonlinear properties of lead sulfide nanoparticles have been studied using different experimental techniques: nonlinear M-line spectroscopy [85, 86, 123, 174], degenerated four-wave mixing (DFWM) [85, 123, 174], Z-scan [90, 124, 131]; third harmonic generation (THG) [126], or pump probe spectroscopy [56, 122, 128]. A detailed summary of these techniques can be found in [6]. The use of different techniques is necessary to characterize different types of samples (bulk, thin films, or colloidal solutions) and to obtain complementary information (see Table 4). However, great care has to be taken when comparing results from different nonlinear experiments. In fact, the experimental conditions are rarely comparable. Moreover, it is important to know which element of the nonlinear susceptibility tensor is actually probed. Nevertheless, good agreement was observed, for example, for results from M-line and DFWM measurements made under equivalent experimental conditions [123].

**Table 4.** Nonlinear optical properties of PbS nanoparticles.

State	Method	Pulse duration, rep. rate	$\lambda$ [nm]	$\chi^{(3)}$ [esu]	$n_2$ [cm <sup>2</sup> /W]	Time constant	Ref.

PbS nanoparticles show high negative nonlinear response for resonant and nonresonant wavelengths. The nonlinearity is several orders of magnitude higher than for bulk lead sulfide. The nonlinear refractive index of PbS-doped silica titania thin films at 1.064  $\mu\text{m}$  wavelength is in the order of  $n_2 = -10^{-10}$  to  $-10^{-11}$   $\text{cm}^2/\text{W}$  for nanosecond excitation and  $-10^{-12}$  to  $-10^{-13}$   $\text{cm}^2/\text{W}$  for picosecond excitation [85, 123, 174]. These measurements were done on films elaborated by the sol-gel technique. In this case, the main particle size was  $\sim 3$  nm and the doping concentration was 5–25 mol%. At 532 nm wavelength, the measured  $n_2$  was about 10 times higher than at 1.064  $\mu\text{m}$ , and the difference between the nanosecond and picosecond experiments was comparable.

Similar results were observed in PbS-doped zirconia-ORMOSIL thin films [86]. For a 2.9- $\mu\text{m}$  thick film doped with 10 mol% PbS, the  $n_2$  was measured to  $-6 \cdot 10^{-11}$   $\text{cm}^2/\text{W}$  at 1.064  $\mu\text{m}$  with nanosecond excitation. This value is about twice as high as for corresponding silica-titania films. Looking at the absorption spectra, it can be seen that the blue shift of the absorption offset is less important in the case of the ORMOSIL film. This feature is confirmed by HRTEM measurements, which show that in this case the PbS nanoparticles are about twice as large (4.8 nm instead of 2.3 nm). Consequently, the excitation is nearly resonant, explaining the higher  $n_2$  values.

Using picosecond excitation, the nonlinear refractive index of PbS nanoparticles dissolved in polyvinyl alcohol (PVA) is  $-2 \cdot 10^{-10}$  and  $-2 \cdot 10^{-11}$   $\text{cm}^2/\text{W}$  at 532 nm and 1.064  $\mu\text{m}$ , respectively [131]. In the case of surface-modified PbS nanoparticles in microemulsion (PbS concentration of  $2 \cdot 10^{-3}$  mol/l),  $n_2$  was measured at 780 nm to  $-5 \cdot 10^{-12}$   $\text{cm}^2/\text{W}$  (femtosecond excitation) [124]. Third harmonic generation measurements were used for PbS nanoparticles embedded in L-B films. By pumping at 1.064  $\mu\text{m}$ ,  $\chi^{(3)}$  values of the order of  $10^{-20}$  V/m (corresponding to  $n_2 \approx 10^{-14}$   $\text{cm}^2/\text{W}$ ) could be observed [126]. The highest published nonlinearity was measured in PbS-doped  $\text{ZrO}_2$  films [90]. Using Z-scan with nanosecond excitation at 1.064  $\mu\text{m}$ ,  $n_2$  was measured to  $-10^{-8}$  to  $-10^{-9}$   $\text{cm}^2/\text{W}$ .

The difference between the values measured for nanosecond and picosecond excitation is coherent with the fact that the nonlinear response can be explained by a saturated two-level system. In fact, the important parameter is not the pulse duration, but the light intensity. The peak intensity is typically in the order of 10–100  $\text{MW}/\text{cm}^2$  and 1–10  $\text{GW}/\text{cm}^2$  for nanosecond and picosecond excitation, respectively. The typical saturation intensity for PbS nanoparticles is in the order of 100–900  $\text{MW}/\text{cm}^2$ , just in-between the intensities applied in the two cases. This interpretation could be confirmed experimentally by measuring  $n_2$  for different light intensity in-between 10 and 4000  $\text{MW}/\text{cm}^2$ . The experimental curve fits very well to the corresponding theory (see Fig. 7). For a 25 mol% PbS-doped silica-titania film at 1.064  $\mu\text{m}$ ,  $I_s = 840$   $\text{MW}/\text{cm}^2$ , and  $n' = 1.2 \cdot 10^{-11}$   $\text{cm}^2/\text{W}$  could be deduced [123]. The saturated two-level system is, however, only applicable for wavelengths below or near the absorption threshold of the semiconductor. For longer wavelengths, two-photon absorption is supposed to be responsible for the nonlinear response [131].

**Figure 7.** Absolute refractive index change as a function of the guided intensity for a 25 mol% PbS-doped  $\text{SiO}_2$ - $\text{TiO}_2$  thin film.

In most experiments, the response time of the nonlinearity was observed to be in the order or below the laser pulse duration [85], even for femtosecond excitation [56, 122]. This is a considerable improvement comparing to bulk semiconductors, where the nonlinear response time is typically in the order of  $\geq 10$  ns.

The nonlinear response of the PbS nanoparticles is dominant in respect to the contributions of the matrix or solvent. Moreover, the module of  $n_2$  is, in general, linearly proportional to the PbS concentration [85, 124], suggesting that for doping concentrations below 25 mol%, one can neglect interactions between the single particles.

The important role of the nanoparticle surface was investigated by studying different surface-capping agents. With this purpose, different kinds of PbS nanoparticles were produced and characterized under the same conditions [56, 122]: (i) PbS modified with polymers, (ii) cetyl-trimethyl-ammonium-bromide capped PbS (CTAB), and (iii) PVA stabilized and sodium-dodecyl-benzene-sulphonate (DBS) capped PbS. The transient nonlinear optical properties were measured using femtosecond, time-resolved optical Kerr effect spectroscopy. For the three samples, similar  $n_2$  values were measured:  $3.8 \cdot 10^{-14}$ ,  $5.9 \cdot 10^{-15}$ , and  $6.3 \cdot 10^{-15}$   $\text{cm}^2/\text{W}$  for i, ii, and iii, respectively. This large nonlinearity of the PbS nanoparticles is attributed to the reduction of surface trapped electrons and the corresponding surface-induced charge separation due to the static electrical field effect. The main difference between the two capped samples consist in lower surface losses for the CTAB-modified particles ( $\chi^{(3)}/\alpha = 3.6 \cdot 10^{-21}$  for (ii) and  $1.1 \cdot 10^{-21}$   $\text{cm}^2/\text{V}$  for (iii)). The higher nonlinearity of the polymer-modified sample (i) can be explained by the local concentration effect due to cross-linking of the nanoparticles by the polymer chains through -Pb-COO- groups.

#### 4.7. Electric Measurements

Hoyer and Könenkamp studied the photoconduction in heterogeneous thin films consisting of a porous titania matrix and PbS nanoparticles adsorbed in the pores of the  $\text{TiO}_2$  matrix [89]. They found that titania serves as the interconnecting matrix to isolated PbS particles. Particles smaller than 2.5 nm act as efficient sensitizers in the visible wavelength region. Upon illumination, photogenerated electrons are injected from the PbS into the insulating titania and give rise to photoconductance with typical values of  $10^{-10}$  ( $\Omega\text{cm}$ ) $^{-1}$  at illumination levels around 10  $\mu\text{W}/\text{cm}^2$ .

The photoelectrical properties of poly-*p*-xylylene PbS nanocomposite films were investigated by Nikolaeva et al. [76]. The dark conductivity was found to be characterized by a linear current-voltage dependence. Ultra-violet irradiation leads to a reversible increase of the conductivity. This phenomena was observed even under irradiation at wavelengths over 630 nm corresponding to an energy below 2 eV.

Yang et al. prepared photoelectrochemical electrodes by chemical deposition of PbS nanoparticles on titania nanocrystalline films and followed by the modification with thiols [136]. These electrodes generated photocurrents as high as 542  $\mu\text{A}/\text{cm}^2$  under irradiation with 400 nm light. However, they underwent photodegradation. The modification with thiols increased the photostability, although it decreases the photocurrent due to the resistance brought about by the carbon chains of thiols.

Using intensity-modulated photocurrent spectroscopy (IMPS), Bakkers et al. studied the electronic structure and decay dynamics of a long-lived photoexcited state in lead sulfide nanoparticles absorbed as a monolayer on a gold surface [173]. By scanning the Fermi level of the gold, they found that the excited state consists of an electron in a deep trap and a hole in the highest occupied molecular orbital (HOMO). It was found that the trapped charge carrier has a lower tunneling probability than the free carrier, indicating that distance is the determining parameter for electron tunneling.

Ogawa et al. measured the photoelectrochemical properties of lead sulfide nanoparticles incorporated in self-assembled monolayers (SAMS) on gold [148]. They found either cathodic or anodic photocurrents, depending on the nature of the solution mediator (hole or electron scavenger) and the applied potential.

Kundu et al. measured the piezoelectric coefficients of lead zirconate titanate doped with lead sulfide nanoparticles [103]. The samples were poled in a bath of silicone oil at a temperature of 353 K for 10 min at an applied electrical field of 25 kV/cm. The measured values of saturation polarization, remnant polarization, and coercive fields increased with increasing PbS particle size. Moreover, an improvement of the piezoelectric and pyroelectric behavior was noticed for the composites as compared to the base glass ceramics.

In order to study the electrical properties of PbS nanoparticle-doped, zirconia films, Sashchiuk et al. deposited them on ITO/glass substrates, followed by their coverage with gold contacts [91, 153]. The current-voltage characteristics depended on the PbS particle size and exhibited nonlinear, nearly symmetric curves, associated with the space-charge limited current or the tunneling of carriers through the nanocrystalline film.

Nanda and Sahu fabricated a self-assembled heterojunction by means of an electrochemical deposition of PbS nanoparticles on indium tin oxide substrate [175]. A large current and large capacitance were observed in the case of a device from particles of a smaller size, which was believed to be due to the large surface area contact. The rectifying behavior of the heterojunction was found to be weak as compared to the usual *p-n* junctions.

## 5. DISCUSSION OF OPTICAL PROPERTIES

### 5.1. Excitons-Absorption Spectra

In semiconductor nanoparticles, the bulk model of conduction and valence bands has to be replaced by discrete electron and hole energy levels. In this case, the effective bandgap energy can be defined as the minimal energy that is required for creating one electron-hole pair or exciton. This quasi-particle corresponds to the hydrogen-like bound state of an electron-hole pair which interacts via the Coulomb potential. The excitonic states usually lie slightly below the bottom of the conduction band. In bulk semiconductors, the exciton binding energy is low (few tens of meV) and excitons are often thermally dissipated. Thus, low temperature spectroscopy is necessary to study bulk excitons. In nanoparticles, the two charged carriers of the exciton are confined to the same volume. Thermal dissipation requires much higher temperatures and the exciton structure becomes visible even at room temperature. The observation of an exciton absorption feature in PbS nanoparticles is, however, difficult. PbS is a narrow bandgap semiconductor with weak exciton binding energy due to strong Coulomb screening. Moreover, the enhanced sensibility to particle size dispersion widens the exciton peaks.

The excitonic absorption line of nanoparticles saturates much faster than the absorption band of the corresponding bulk semiconductor. In addition, this saturation is accompanied by induced absorption near resonance. This feature is due to the formation of biexcitons via absorption of a second phonon. Thus, the ground state biexciton (two electron-hole pair states) is visible as an induced absorption line on the low energy side of the exciton resonance. Its experimental observation is dependent on weak dumping of the exciton transition. This condition is fulfilled for PbS nanoparticles. Thus, the biexciton ground state could be observed in a pump-probe experiment [119]. By using time-resolved pump-probe experiments, it was even shown that bleaching and induced absorption has a similar time evolution [128]. Fast ( $\sim 10$  ps) and slow ( $\sim$  ns) decay components are clearly distinguished with the same time-constant. The fast component is attributed to the recombination of free carriers or carriers trapped in shallow traps, whereas the slow one is assigned to trapped carriers.

The excitonic absorption of PbS nanoparticles is also influenced by external carriers. It was shown that the injection of electrons into PbS colloids in aqueous solution leads to a blue shift of the absorption edge [49]. This effect was explained by trapping of the excess carriers into surface states of the particles. In fact, colloidal semiconductors are usually synthesized with a very high density of surface defects. The appearance of the shift actually depends critically on the method of colloid preparation. PbS colloids prepared at  $\text{pH} < 6$  have long-living bleaching of the initial absorption, which disappears several seconds after the injection of the electrons. After the addition of hydroxide ions to the colloids solution ( $\text{pH} > 8$ ), the absorption bleaching disappears. In fact, the hydroxide ions saturate the surface defects on which the electrons are trapped. However, the absorption spectrum is only very weakly influenced by the pH change.

The quantum confinement has also an influence on the temperature-dependence of the bandgap. In bulk semiconductors, this temperature-dependence is linked to lattice thermal expansion and to electron-phonon coupling. In PbS nanoparticles the position of the exciton absorption should be nearly temperature-independent. First, the influence of thermal lattice expansion diminishes with decreasing particle size as the energy levels become determined by the particle size instead of the lattice constants. Second, the electron-phonon coupling intensity decreases with decreasing particle size due to increasing energy separation of the discrete phonon and electron energy levels. This feature was experimentally confirmed by studying the temperature-dependence of the absorption spectra of PbS nanoparticles embedded in a glass matrix [127]. For larger particles with diameters above 8.5 nm, bulk-like temperature-dependence was observed. With decreasing size, the temperature coefficient decreases by more than one order of magnitude from the bulk value. The exciton energy of 4.5-nm sized particles was found to be almost independent of temperature as for isolated atoms.

## 5.2. Carrier Dynamics–PL

Time-resolved PL measurements show that decay mechanisms are complex, consisting of multi-exponential processes. After excitation, the first step of relaxation is the electronic relaxation inside the conduction band and the hole relaxation inside the valence band. This is mainly due to electron-phonon interactions and is expected to be on the timescale of 100 fs or less. Once the electron is relaxed to the bottom of the conduction band and the hole to the top of the valence band, they can recombine radiatively or non-radiatively. If there are few or no bandgap states, the recombination should be primarily radiative, that is, strong band edge luminescence is observed. The corresponding lifetime is in the order of nanoseconds or longer. In a more precise description of semiconductor nanoparticles, the bands have to be replaced by excitonic states. Thus, the absorption of a photon will create an exciton in an excited state. The electron and hole of the exciton will recombine after relaxation to the exciton ground state.

When electron states are present within the bandgap due to surface or internal defects, they act to trap the charge carriers on time-scales faster than radiative recombination, typically a few picoseconds to tens of picoseconds. Further trapping from shallow trap states to deep trap states can take place on the tens of ps to hundreds of ps timescales. The trapped charge carriers can recombine nonradiatively or radiatively, producing trap state emission that is red shifted with respect to bandedge emission. The trap state varies significantly in their energy levels or trap depth, which in turn determines how fast the trapping occurs and how long the trap states live. The trap states have lifetimes on the timescale from tens of picoseconds to nanoseconds, microseconds, or even longer.

Consequently, two emission lines are observed from semiconductor nanoparticles: excitonic and trapped-electron luminescence [68, 130]. The excitonic emission is sharp and is located near the absorption edge of the material, whereas the trap emission is broad and stokes-shifted towards longer

wavelengths. For most applications, the sharp excitonic luminescence is preferable. Thus, great care has to be taken in order to limit the number of electronic trap states at the surface of the nanoparticles.

Low temperature PL measurements show even three emission features [125]. UV-excitation at 340 nm of PbS nanoparticles embedded in a polymer film reveals an excitonic emission in the blue (450–490 nm) and two additional nonexcitonic bands in the green ( $\approx 550$  nm) and red ( $\approx 633$  nm). The blue emission was assigned to exciton emission. Thus, its position depends on the particle size. The red and green bands correspond to trap states, deep inside the bandgap, and therefore, they are independent of the particle size. In addition, the intensity of the red band is enhanced for the smallest particles. The red emission can, therefore, be associated with surface defects, as for small samples the surface-to-volume ratio is maximal. The green band may be associated with trapped electron-hole recombination at a stoichiometric defect site, located at the interior part of the nanoparticles, as its intensity is decreasing for decreasing sample size.

The temperature-dependence of the PL spectra reveals information on the relaxation processes and the mutual interaction among states. The continuous decrease of the luminescence intensity of the blue band with an increase in temperature suggests a coupling to lattice phonon that enables a transfer of carriers into nonradiative states. The increase in luminescence intensity of the green and red emission band up to 65 K, suggests that the corresponding states are thermally populated by carrier transfer from exciton states. Above 65 K, thermal activation competes with quenching of nonradiative transitions, and thus, the intensity of the green and red bands decreases with a further increase in temperature. This thermal activation model was also suggested for other semiconductors.

The great influence of the surface properties on the PL could be shown by studying PbS nanoparticles in solutions with different pH values [49]. Poly vinyl alcohol stabilized PbS colloids, prepared at pH 5, have a weak broad emission from 600 to 800 nm with a low quantum yield, indicating that radiationless carrier recombination is the dominant relaxation process. Addition of hydroxide ions to adjust the pH to 10 increases the excitonic bandedge luminescence by about a factor of four. At the same time, the long-wavelength luminescence, which is assigned to surface-trap relaxation, only increases very slightly. This result confirms the fact that hydroxide is very efficient for saturating surface traps.

The influence of the nanoparticle shape on the carrier dynamics was found to be insignificant. The shape of PbS nanoparticles can be monitored from mostly spherical to needle or cubic shape by changing the surface capping polymer. While the absorption spectrum depends on the shape of the nanoparticle, the electronic relaxation dynamics remains about the same for the apparently different-shaped particles [21]. The electric relaxation was found to feature a double exponential decay with time constants of 1.2 and 45 ps, independent of probe wavelength and excitation density. The shape independence can be attributed to the dominant influence of the surface properties on the electronic relaxation. While shapes are different, the different samples should have similar surface properties. Therefore, if the

dynamics are dominated by the surface, changes in shape may not affect the electronic relaxation dynamics substantially. The extremely short lifetime of trapped electrons in PbS nanoparticles is most likely due to the high density of trap states.

## 6. APPLICATIONS

The great research effort made with PbS nanoparticles results in improved elaboration processes as well as in an increasing understanding of their physics. In the continuation of this research, the implementation of PbS nanoparticles in some applications was proposed and realized. It could be shown that their specific properties may be very beneficial for the device operating.

### 6.1. Optical Amplification

Due to their strong light-emission, semiconductor nanoparticle-doped materials are good candidates for infrared emitting materials with high quantum efficiency. Potential applications are wideband optical amplifiers or laser sources for telecommunication purposes [176]. The emission wavelength can be easily chosen by monitoring the mean size of the particles, and the emission width is defined by the size dispersion. Moreover, in comparison with epitaxially grown semiconductor structures presently used for infrared lasers, semiconductor-doped glasses are inexpensive as well as robust materials. Despite the presence of highly efficient intrinsic Auger recombination, room temperature optical gain could be obtained in different semiconductor quantum dot materials [177–180], including PbS-doped glass [129]. When pumping into the first-excited exciton transition, optical gain was observed in the vicinity of the ground-state exciton resonance. The spectral position of the emission peak could be changed from 1317 to 1352 nm by tuning the pump wavelength between 900 and 980 nm. This tunability relies on the strong carrier confinement and the inhomogeneous broadening in the sample due to the particle-size distribution. The actual spectral width and position of the gain was limited by the pump pulse.

### 6.2. Passive Q-Switching

The fast absorption bleaching of PbS-doped glass was successfully used for passive Q-switching of Cr:forsterite [132] and erbium-doped glass lasers [133, 134]. Compared to active Q-switching, passive Q-switching with a saturable absorber is simpler, more compact, more robust, and does not require auxiliary electronics. These points are of paramount interest for erbium-doped, eye-safe lasers used in telemetry and ranging. Most of currently used absorbers for Er-doped lasers have relatively high saturation intensities in the order of 40–200 MW/cm<sup>2</sup>, whereas the low saturation intensity of PbS-doped glass in the 60–180 kW/cm<sup>2</sup> range allows complete bleaching with intensities achievable with standard micro-lasers. Laser pulses of 110 ns duration and 0.2 mJ energy were obtained with 6 nm PbS nanoparticle-doped glass inside an Er<sup>3+</sup>:glass laser cavity [134]. 1 μJ, 30–50 ns long pulses at 1–2 kHz repetition rate were observed in a different experiment [133]. In the case of the Cr:forsterite laser, nearly

transformed limited, 4.6 ps long laser pulses at 110 MHz repetition rate and a tunability range from 1.207 to 1.307 μm were reported [132]. In that case, the absorption saturation intensity of the PbS-doped glass containing 6.6-nm sized nanoparticles was estimated to be 200 kW/cm<sup>2</sup>. It was shown that the nonlinearity in the glass host limits the maximum intracavity power, which can be saturated by nanoparticle absorption [135]. Above a fluence of around 10 mJ/cm<sup>2</sup>, bright third-harmonic generation is detected and the PbS-doped glass no longer operates as a saturable absorber.

### 6.3. Refractive Index Modification

Bulk PbS has a refractive index of  $n_b = 4$ , which decreases for nanoparticles. It has been shown that nanocomposites of polymers and semiconductors may exhibit optical properties that cannot be obtained with pure polymers alone. The introduction of PbS nanoparticles into a polymer matrix increases its refractive index to values of up to  $n_{nc} = 3.0$  [27, 74]. This value has to be compared with the maximum refractive index of pure organic polymers of about 1.7. Thus, the composite material becomes suitable for some optical applications, such as the manufacture of improved efficiency solar cells. The refractive index was found to be nearly constant in the 1000 to 2500 nm wavelength region. Moreover, the engineering of the refractive index is straightforward as it scales quasi-linearly with the PbS concentrations.

In the case of these polymer films, light scattering losses at the high index nanoparticles could be reasonably limited by choosing particles with average diameters below 50–100 nm. However, the very low waveguiding losses required for integrated optic devices may be a problem. The scattering losses depend on the refractive index difference between particles and matrix, the size, and the form of the particles. The scattering losses for a slab waveguide of homogeneously PbS nanoparticle-doped glass can be evaluated by using a simplified Mie scattering algorithm [123]. For spherical particles (size: 3 nm; PbS concentration: 5 vol%) in a silica glass host ( $n = 1.51$ ), the calculated scattering losses are about 0.047 dB/cm at 1.064 μm and 0.021 dB/cm at 1.3 μm. Hence, the contribution of the scattering losses to the overall waveguide losses can be neglected. However, for larger particles (>10 nm) scattering losses represent a serious limitation. By using high index host materials, such as chalcogenide glasses, the scattering losses can be considerably reduced and the presence of large particles becomes feasible.

### 6.4. Light-Converting Devices

A further application field of lead sulfide is the fabrication of light-converting electrodes which can be obtained by sensitizing porous titania with PbS nanoparticles [88, 89, 136]. In this device, visible light is absorbed by the semiconductor particles, followed by electron transfer into the porous TiO<sub>2</sub> films. The use of PbS nanoparticles implies several advantages as compared to organic dyes: the bandgap and, thereby, the absorption range are easily adjustable by the size of the particle, and the bandedge type of absorption behavior is most favorable for effective light harvesting. Internal photocurrent quantum yield of more than 80% and open circuit photovoltages of 300 mV were realized.

## 7. CONCLUSION

Over the last few years, lead sulfide nanoparticles were the subject of vigorous research activities. This work enabled a better understanding of their physical properties which, in turn, allowed the enhancement of the particle fabrication techniques. Important improvements of the characterization techniques are accompanying this process. Particle size dispersion and problems with the particle surface quality have been the most important limitations of PbS nanoparticles. However, the improved elaboration techniques, including surface passivation, can resolve these problems.

It seems that the most interesting properties of lead sulfide nanoparticles are their saturable absorption, their strong emission, and their capacity to sensitize dielectric matrices for photoelectric devices. Some early devices were already demonstrated in the laboratory and commercial devices can be expected in the near future. In parallel, the increasing quality of lead sulfide nanoparticles will enable us to continue the exciting investigation of strong quantum confinement effects.

## GLOSSARY

**Blue shift** Shift of the optical absorption edge due to the quantum confinement of electrons and holes inside semiconductor quantum wells or nanoparticles.

**Exciton** Quasi particle inside semiconductors similar to an hydrogen atom and consisting of an electron and hole linked by the Coloumb interaction. In contrast to bulk semiconductors, in quantum dots excitons are observable at room temperature.

**Quantum confinement** Confinement of electrons and holes inside semiconductor nanoparticles. The quantum confinement changes radically the optical properties of the semiconductor. It enhances especially its nonlinear optical properties.

**Sol-gel** Recently developed chemical processing route for the fabrication of glasses and ceramics as thin film or bulk materials. Sol-gel allows to elaborate high purity materials, does in general not require high temperature processing, and requires only low investment.

**Surface passivation** Saturation of electronic trap states at the surface of semiconductor nanoparticles. Surface passivation enhances significantly the linear and nonlinear optical properties of the nanoparticles.

## CONTENTS

1. Introduction
  2. Mechanistic Aspects of Energy Transfer
  3. Light-Harvesting in Natural Photosynthesis
  4. Artificial Light-Harvesting Nanostructures
  5. Conclusions: Artificial Photosynthesis—Perspectives and Future Goals
- Glossary  
References

## 1. INTRODUCTION

Higher life on Earth depends on photosynthesis. The ability to convert sunlight into biochemical energy has helped proliferate not only photosynthetic organisms but also those with heterotrophic metabolisms which thus indirectly depend upon efficient light-harvesting, the first step of a very complex orchestration of photophysical, biochemical, and biological processes. Recent breakthroughs in structural biology have permitted insight into the architecture, at molecular level, of the apparatus involved. Functionality is in all cases obtained by engineering into supramolecular assemblies different molecular components with tailored properties. The result is not just the summation of the parts' properties, but fully new ensemble characteristics emerge which are essential for its function. Because the dimensions of these discrete functional units are well within the 2 to 100 nm range the term *nanostructure*<sup>1</sup> seems appropriate. Nature has learned through evolution that it is easier to fabricate copies of such discrete functional nanostructures than to synthesize directly larger microstructures. This results in a considerable information and atom economy both at the

<sup>1</sup> To our knowledge, the first to use the term *nanostructure* was the French paleontologist A. M. Mangin in 1975 who described *nanostructures* of silicified limestones in *C. R. Hebd. Acad. Sc. Ser. D*, 281, 973 and 1079. Presently "nanostruct" appears either as title or keyword in more than 6000 publications each year.

genetic as well as at the molecular level. In this chapter we shall focus on nanostructures which perform the function of light-harvesting. At first we will describe the natural light-harvesting systems, or photosynthetic antennae; then we will review efforts in mimicking this process with fully synthetic molecules. Finally some implications useful for designing efficient artificial photosynthetic systems will be addressed.

One of the first membrane proteins to be crystallized was the bacterial photosynthetic reaction center of the bacterium *Rhodospseudomonas viridis* and its structural elucidation by means of X-ray crystallography in 1985 [1] was a feat which only three years later was honored by awarding the Chemistry Nobel Prize to R. Huber, H. Michel, and J. Deisenhofer. The high resolution structure (initially at 3 Å resolution) has allowed unprecedented insight into the architecture of this molecular machinery which after excitation by light leads to charge separation and after a cascade of electron transfer steps charge recombination is prohibited. The so-formed exciton reaches a final state where the electron and the hole (positive charge) are on opposite sides of the photosynthetic membrane. The thus created potential energy is used to pump protons across the membrane. The protons in turn serve for driving the adenosine triphosphate (ATP) synthase. This rotary nanomachine (for whose study P. D. Boyer and J. E. Walker shared the 1997 Chemistry Nobel Prize) converts adenosine diphosphate to ATP which, having an energy rich phosphate bond, is used by all living cells as energy currency and thus to drive uphill biochemical endergonic reactions. Solving crystal structures of reaction centers from other bacteria (*Rhodobacter sphaeroides*) at improved resolutions, such as 2.65 Å [2], or of light and dark adapted reactions centers [3] has led to further understanding of the rather intricate phenomenological events which occur post-light-harvesting. Studies of bacterial mutants, where by targeted point mutations amino acid residues in the protein matrix have been interchanged, have revealed the role of the proteinaceous scaffold in accelerating or retarding the electron transfer rates between the various cofactors. Ample excellent reviews and books [4, 5] have been dedicated to bacterial reaction centers. This research effort, which has included structural biologists, biochemists,

and especially photophysicists, has triggered, for more than a decade, synthetic efforts by chemists to assemble manmade (nano)devices mimicking the elementary processes in reaction centers. This field has also been amply reviewed [6–9]. This chapter describes the energy transfer events related to light-harvesting which precede the electron transfer cascades in the reaction centers.

One interesting evolutionary observation is that different photosynthetic organisms have developed widely different light-harvesting systems. These match the illumination conditions of the habitat so it is not surprising that bacteria which live at 10 m under the water surface have different antennae and other pigments which collect light at other wavelengths than the bacteria or algae living at water surface, which in turn have different light-harvesting complexes than the plants. Thus, there are many ways in which capture of light has been optimized under the pressure of evolution. However, this is in stark contrast with the photosynthetic reaction centers which all have the same genetic ancestor. Only recently, by solving the crystal structures of photosystem II (PSII) at 3.8 Å resolution [10] and that of photosystem I (PSI) and 2.5 Å resolution [11], a remarkable feat of the Berlin research groups around Horst-Tobias Witt and Wolfram Saenger, was it possible to show the great similarity of these reaction centers to the bacterial reaction center. Apparently, once archaeobacteria have learned how to effect photoinduced charge separation and to convert this into useful energy by avoiding the charge recombination, this was carefully conserved during evolution. In other words, photosynthetic species with a different mechanistic cascade have not survived and are presently not known.

Figure 1 represents schematically the essence of a photosynthetic apparatus, either natural or artificial. A light-harvesting nanostructure, or antenna, is coupled to the reaction center by means of an energetic trap. Within the antenna rapid energy transfer steps occur which eventually funnel the energy within the trap. From the trap the reaction center is excited and here successive electron transfer reactions take place. Of course, one can trigger the electron transfer cascade by exciting directly the primary

**Figure 1.** Photosynthetic antenna and reaction center. Adapted with permission from [12], R. E. Blankenship, in “Research Opportunities in Photochemical Sciences” (A. D. Nozik, Ed.), NREL/CP-450-21097, DE96007867, 1996.

electron donor, an excitonically coupled pair of (bacterio)chlorophylls, the so-called “special pair.” The presence of the antenna is, however, beneficial for three reasons: (i) a much larger cross section is achieved so that the probability of capturing a photon is greatly increased, (ii) a broader range of wavelengths can be used so that not only the rather narrow absorption of special pairs from the solar spectrum is filtered out, and (iii) the reaction center can be cycled much more rapidly, in some species even about 8000 times per second.

An analogy of the rapid cycling of the reaction centers coupled to antennas is the following: When a photographer uses a flash to capture the image of a fashion model, the strong photoexcitation causes the model to close the eyes. Several seconds may pass before (s)he can reopen the eyes and be composed for the next flash and picture. This is why photoshooting sessions are usually done in daylight, sometimes at dusk or dawn, and many pictures are taken successively, with modern cameras, several times per second. This improves the yield in obtaining usable pictures and shortens the duration of sometimes costly photosessions. Similarly, by using an antenna, diffuse and even dim light may be used by reaction centers which are closed only for a few tens of nanoseconds which is sufficient for the electron transfer to be completed successfully.

## 2. MECHANISTIC ASPECTS OF ENERGY TRANSFER

Two different mechanisms exist for excitation energy transfer (EET), one which operates between weakly coupled molecules, the so-called dipolar mechanism as initially proposed by Förster [13, 14], and one which occurs between closely spaced molecules which interact strongly due to orbital overlap and here an electron exchange mechanism may function, as proposed by Dexter [15].

In both cases a donor molecule  $D^*$  in its singlet excited state transfers its energy to an acceptor molecule  $A$ , initially in its ground state.

In Figure 2 the Förster mechanism is represented in the upper part. While the electron from the donor lowest unoccupied molecular orbital (LUMO) flips to the highest occupied molecular orbital (HOMO), at the same time an electron from the acceptor is promoted into the excited state. Note that this is not an optical phenomenon (i.e., the photon which is emitted by the donor upon returning to the ground state is not the same photon as the one absorbed by the acceptor). In the Dexter mechanism the orbitals of the donor and acceptor have to overlap to allow an electron exchange as indicated by the arrows (lower part of Fig. 2). The rate of the Förster energy transfer  $k_{\text{EET}}$  is given by the equation

$$k_{\text{EET}} = \frac{9\kappa^2(\ln 10)c^4}{128\pi^5 n^4 N \tau_R^D R_{DA}^6} \int_0^\infty f_D(\nu) \epsilon_A(\nu) \frac{d\nu}{\nu^4}$$

where  $\kappa^2$  is an orientation factor due to the scalar product between the transition dipole moments of the donor ( $\mu_D$ ), respectively acceptor ( $\mu_A$ ), and the distance vector  $R_{DA}$ :

$$\kappa^2 = [\vec{\mu}_D \cdot \vec{\mu}_A - 3(\vec{\mu}_D \cdot \vec{R}_{DA})(\vec{\mu}_A \cdot \vec{R}_{DA})]$$

**Figure 2.** Schematic representation of the two possible energy transfer mechanisms from an excited singlet state donor ( $D^*$ ) to an acceptor molecule (A).

After the standard definition of the unit vectors, if  $\alpha$  is the angle between the transition moments of the donor and acceptor,  $\beta_1$  is the angle between  $\mu_D$  and the distance vector  $R_{DA}$  connecting the donor and the acceptor and  $\beta_2$  is the angle between  $\mu_A$  and  $R_{DA}$  one may write

$$\kappa^2 = \cos \alpha - 3 \cos \beta_1 \cos \beta_2$$

It is clear that  $\kappa^2$  may vary between 0 and 4 accounting for accelerating or slowing down the excitation energy transfer for certain orientations.

An other important factor in determining  $k_{\text{EET}}$  is the integral which describes the spectral overlap between the fluorescence of the donor  $f_D(\nu)$  and the absorbance of the acceptor,  $\varepsilon_A(\nu)$ , being the molar decadic extinction coefficient. Other constants are the speed of light  $c$  (in  $\text{m s}^{-1}$ ), the refraction index of the medium  $n$ , and the number of molecules per millimole  $N$  (Avogadro's number  $\times 10^{-3}$ ). Furthermore,  $\tau_R^D$  is the radiative fluorescence lifetime (measured in s) of the donor which also depends on the fluorescence quantum yield  $\tau_R^D = \tau^D/\Phi_D$ , where  $\tau^D$  is the lifetime of the first excited singlet state of the donor in the absence of any energy and/or electron transfer processes.

A more convenient way of rewriting this Förster equation is to compress the constants and the overlap between the donor fluorescence with intensity normalized to unity, and the acceptor absorbance into the so-called Förster radius  $R_0$ . If the integration is done in the wavenumber scale ( $\text{cm}^{-1}$ ) then the following expression is obtained [22]:

$$R_0^6 = \frac{8.785 \times 10^{17}}{n^4} \int f_D(\nu) \varepsilon_A(\nu) \frac{d\nu}{\nu^4} \quad (\text{in nm}^6 \text{ units})$$

Accordingly, the Förster equation becomes

$$k_{\text{EET}} = \frac{\kappa^2}{\tau_R^D} \left( \frac{R_0}{R_{DA}} \right)^6$$

Distances between donor and acceptor of over 5 nm may be encountered where this mechanism still operates. Typical rates encountered in nanostructures are of the order  $10^{10}$  to  $\sim 10^{12} \text{ s}^{-1}$  which translate in hopping times of ps to a few hundred fs between adjacent pigments.

The Dexter mechanism which can only function at close range is similar to an electron transfer which allows a mutual exchange of the electrons. For an efficient transfer the requirement is that the excited state of the donor  $D^*$  exceeds energetically that of the acceptor A. In the usual electron transfer beside the energy of the excited state also the redox potentials of the donor and acceptor dictate the rate of the process. In contrast to the Förster mechanism, not only does energy transfer between the singlet states of the chromophores occur but also triplet-triplet exchanges may take place. Using the classical formalism adopted for nonadiabatic electron transfer [16–19] one may calculate  $k_{\text{EET}}$  by the equations

$$k_{\text{EET}} = \nu_{\text{EET}} e^{-\frac{\Delta G^\ddagger}{RT}}$$

$$\nu_{\text{EET}} = \frac{2H^2}{h} \sqrt{\frac{\pi^3}{\lambda RT}}$$

$$\Delta G^\ddagger = \frac{\lambda}{4} \left( 1 + \frac{\Delta G^0}{\lambda} \right)^2$$

where  $H$  is the intercomponent electronic interaction (or matrix element describing the electronic coupling),  $\Delta G^0$  is the Gibbs free energy change of the process, and  $\lambda$  is the reorganizational energy. In the case of an energy transfer process  $\lambda$  is mainly due to the reorientation of bond angles and adjustment of bond lengths upon excitation from the ground to the excited state. The original formulas due to Dexter [15] are usually written as

$$k_{\text{EET}} = \frac{4\pi^2 H^2}{h} e^{-\beta_{\text{EET}}(R_{DA}-R_C)} J_D$$

where  $J_D$  is the following overlap integral:

$$J_D = \frac{\int f_D(\nu) \varepsilon_A(\nu) d\nu}{\int f_D(\nu) d\nu \int \varepsilon_A(\nu) d\nu}$$

As in electron transfer phenomena  $\beta_{\text{EET}}$ , is an attenuation factor (also termed damping factor, i.e., a constant) which depends on the nature of the bridge connecting the donor D and acceptor A separated by  $R_{DA}$  and which have a contact distance  $R_C$ .

An important aspect is that both mechanisms may sometimes operate in one and the same particular case.

### 3. LIGHT-HARVESTING IN NATURAL PHOTOSYNTHESIS

In order to absorb daylight, molecules need to have an extended conjugated  $\pi$ -system, the so-called chromophore or color bearing group. An increase of the conjugation leads to a narrowing of the HOMO–LUMO gap and electronic transitions are allowed at increasing wavelengths. With different pigments, the solar spectrum filtered by the atmosphere can be spanned. Scheme 1 summarizes the chemical formulae of some chromophores encountered in natural light-harvesting nanostructures. Two main classes of pigments have evolved, namely carotenoids (Car) which are rather rigid, rodlike, conjugated polyenic molecules with absorption in the ultraviolet (UV) and high energy side of the visible spectrum, and tetrapyrrolic chromophores which have two strong absorptions at both ends of the visible spectrum. Among the tetrapyrroles one distinguishes the chlorophylls (Chl) of plants and bacteriochlorophylls (BChl) from photosynthetic bacteria, both which are cyclic tetrapyrroles. The parent, fully unsaturated system is the  $22\pi$  electron system of porphyrins (Por). According to Hückel's  $4n + 2$  rule, this system, with  $n = 5$ , has aromatic character and thus high stability, and diatropic ring current. Due to their high thermal stability porphyrins are frequently encountered in oil (petro- and geoporphyris) and serve as a geological clock for tracing the transformations within sediments. While heme, the blood pigment in vertebrates, is a typical porphyrin, porphyrins are less used in photosynthesis. This is because of the high symmetry of the conjugated  $\pi$ -system. The redshifted transitions (so-called Q bands) are of low extinction coefficient and thus inefficient for light harvesting. The degeneracy of these transitions is lifted

**Scheme 1.** Main cyclic tetrapyrrolic chromophores with their atom numbering. Note that Chl *a* and Chl *a'* are epimers differing only by the configuration at carbon  $13^2$ .

by reducing one or two of the conjugated double bonds. A  $20 \pi$ -electron system thus forms chlorins while an  $18 \pi$ -electron system forms bacteriochlorins. In both these systems, the Q bands are due to electronic transitions which are now strongly allowed and thus have at least an order of magnitude higher extinction coefficients than porphyrins and are thus perfectly suited for light harvesting. Heme and chlorophylls are also known as the *pigments of life*, the first being used in respiration which represents the reversed energetic process of photosynthesis, the latter being based mainly on chlorophylls. Confusion sometimes arises due to the nonsystematic nomenclature of these tetrapyrroles. Thus, while all chlorophylls are chlorins having a fused five-membered ring, there are bacteriochlorophylls which are also chlorins and not bacteriochlorins (see Scheme 1). Open chain tetrapyrroles or bilins such as phycocyanobilin from cyanobacteria and biliverdin are cousins of porphyrins and chlorophylls which share their metabolic pathway up to a point and/or are degradation products. Photosynthetic organisms have evolved differently by fine-tuning the main absorption characteristics, namely wavelength range and extinction coefficient of their antenna systems. This has led to a wide variety of light-harvesting nanostructures.

#### 3.1. Structural Features of Natural Antenna Systems

Our present understanding of natural photosynthesis is based upon the notion of the photosynthetic unit (PU) introduced in 1936 by Emerson and Arnold [20]. By experimenting with light flashes they could convincingly show that for one  $\text{CO}_2$  molecule, which plants reduce to " $\text{CH}_2\text{O}$ " or " $\text{C}\cdot\text{H}_2\text{O}$ ", the empirical formula of carbohydrates, several hundreds of Chl molecules must be involved. Thus only relatively few Chls actively take part in transforming light energy into chemical energy. These special chlorophylls which are involved in electron transfer were assigned to the reaction center (RC), another fundamental notion introduced by Hans Gaffron [21]. Most of the other chlorophylls in the photosynthetic unit have more a spectator role: each one of them can be hit by a photon whereby the excitation energy is rapidly and efficiently transferred toward the RC. Due to the large number of these antenna Chls, the probability or cross section for harvesting photons is greatly increased. Energetically the process runs "downhill" and has often been compared to a funnel. The most redshifted antenna pigments trap eventually the whole energy and from there it is transferred to the RC which absorbs light at still longer wavelengths (are further redshifted). This directionality of energy transfer ensures the high quantum yield due to the fact that back energy transfer is inhibited. Figure 3 presents schematically these events. An excellent review by van Grondelle et al. on energy trapping in antenna systems discusses in detail these processes bringing not only photophysical evidence but also the mathematical interpretation of the data [22]. More recent studies on the major light-harvesting complex of plants are summarized in [23].

### 3.1.1. Self-Assembling Light-Harvesting Nanostructures of Green Photosynthetic Bacteria

Early during evolution, when synthetic and genetic economy was stringent for photosynthetic organisms, in order that these could build large and efficient antenna systems, which could harvest sunlight even under water as deep as 100 m, self-assembly of chromophores was used. This very simple architectural principle, which is frequently encountered in nature, for instance in viruses, is based on the fact that it is much easier to fabricate several copies of the same building block (or tecton, i.e., molecular brick) and then induce self-assembly to a desired nanostructure than to build on the basis of a complicated blueprint large functional components for which a multitude of genes and molecules are needed. The self-assembly algorithm, once it is allowed to proceed correctly, ensures that due to a fine balance between entropy and enthalpy, in the end, only the desired structure is obtained. The final architecture is encoded within the structure of the tectons and the supramolecular interactions for which they have been programmed [24]. Figure 4 illustrates such a self-assembly process where from monomers, under appropriate conditions, one can form dimers, oligomers, and finally large nanostructures.

Misplaced components, for instance the tecton in the upper left which kinetically might be stable, are allowed to disassemble so that actually a repair mechanism operates. It is essential that the final nanostructure serves a function which the components alone could not have fulfilled. In our case the desired function is efficient light harvesting. This can be ensured by amplifying the cross section for capturing photons by a relatively large number of chromophoric tectons but which all must transfer their excitation energy to collectors (i.e. energetic traps) within the photosynthetic units.

Green photosynthetic bacteria (*Chlorobiineae*) have evolved for this purpose an unique organelle—the chlorosome, or green sac. Both the *Chlorobiaceae* (such as *Chlorobium tepidum*) and the *Chloroflexaceae* (e.g., *Chloroflexus*

**Figure 4.** Illustration of a typical self-assembly process.

*aurantiacus*) which are, however, phylogenetically quite distant, have well-developed chlorosomes. Chlorosomes are typically oblong ellipsoids resembling a flattened nanocigar with dimensions of approximately  $10 \times 25 \times 100$  nm which is attached via a baseplate to the inner side of the cytoplasmic membrane. The sizes and number of chlorosomes are dependent not only on the species but also on illumination conditions showing that light harvesting is strongly genetically regulated. Early electron microscopy images employing freeze-fractured membranes have shown that within the interior of the chlorosome, long cylindrical rods are encountered and these are separated from the cytosol by a monolayer lipid membrane [25, 26]. Figure 5 presents an artist’s view of this intriguing organelle which has been the object of intense study and debate. It is now generally accepted that the chlorosomal rods are constituted of self-assembled bacteriochlorophyll molecules [27, 28], and that proteins do not have a structural role in the organization of the chromophores.

Very recently, by sequencing the entire genome of the photosynthetic bacterium *Chlorobium tepidum* [30], genetic evidence has been brought forth that the 10 chlorosomal proteins (CsmA, CsmB, . . . CsmH, CsmI, CsmJ, and CsmX) are embedded in the membrane and that various mutants where the genes of these proteins have been knocked out are still forming fully functional chlorosomes [31, 32]. This has shattered the dogma that only proteins can function as scaffolds for light-harvesting pigments. For an excellent biochemical review see [33].

Another interesting aspect of the chlorosome, studied in depth by Frigaard et al., is related to the redox active components and the role of quinones which act as quenchers for the fluorescence of BChl *c* aggregates if exogenously added [34–37]. Also studied was the role of oxygen which triggers in *Chlorobium tepidum* an uncoupling of the chlorosome antenna under aerobic conditions in order to prevent degradation by formation of toxic singlet oxygen species and radicals [38]. In contrast to this, chlorosomes of *Chloroflexus aurantiacus* were not affected by oxygen.

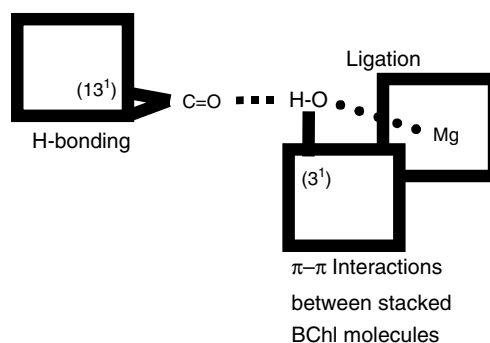

We have been involved relatively early in investigating the structural details of how BChl molecules self-assemble.

**Figure 5.** The chlorosome organelle. Graphic courtesy of Nils-Ulrik Frigaard (Pennsylvania State University). Arrows denoting the energy transfer are gray and pointing downward while arrows denoting the electron transfer pathway are black and pointing mostly upward. **1** Monolayer lipid membrane. **2** Chlorosomal proteins which are part of the chlorosome envelope [29]. **3** Chlorosomal rod element containing self-assembled BChl *c*. **4** Detail of how BChl *c* self-assembles into circular aggregates—note that the long chain alcohol chains esterifying the 17-propionic acid residue are all pointing either to the exterior of the rod ensuring hydrophobic inter-rod interactions and with the monolayer lipids, or all toward the inside [49]. **5** Chlorosomal baseplate. **6** Fenna–Matthews–Olson protein trimers which act as an energy trap. **7** Cytochrome *c*. **8** Reaction center—note that the energy transfer cascade ends at the special pair of chlorophylls where charge separation occurs and the electron reaches the iron sulfur centers which are shown as cubes. **9** Rieske’s protein involved in electron transfer from the menaquinone (MK). **10** Ferredoxin.

Various spectroscopic techniques such as resonance Raman [39, 40], UV-visible absorption [41], Fourier transform infrared (FT-IR) [42], circular dichroism (CD) [43] and solid state nuclear magnetic resonance (NMR) with  $^{13}\text{C}$ -labelled [44, 45] BChls have ascertained the primary binding scheme indicated in Figure 6 and that the BChls are assembled into stacks.

On the basis of our experimental evidence, a crude model of the chlorosomal rods was proposed as early as 1994 by Holzwarth and Schaffner employing a heuristic molecular modeling approach [46]. For the first time this model explained satisfactorily most of the accumulated structural evidence and described how the cylindrical rods are formed by self-assembled BChls. Thus, stacks of BChl molecules formed by the relatively strong ligation of the central magnesium atom by hydroxy groups of the 3-(1-hydroxyethyl) group which can have either *R* or *S* chirality are joined together by multiple cooperative hydrogen bonds having the same hydroxyl group as donor and the  $^{13}\text{C}$ -carbonyl groups as acceptors. Cooperative interactions imply that for instance a hydrogen bond operating

**Figure 6.** Schematic supramolecular interactions between bacteriochlorophyll molecules in a nonpolar environment. Essentially, the magnesium atom of one BChl is ligated by a hydroxy group in a second BChl and due to its strong polarization the same hydroxy group acts as donor in a hydrogen bond to an acceptor carbonyl group in a third BChl. Between the off-setted, helical stacks of BChl molecules,  $\pi$ - $\pi$  interactions are encountered.

simultaneously with metal ligation is stronger than if these occurred independently or that multiple hydrogen bonds (e.g.,  $n$ ) reinforce each other and are stronger than  $n$  times one hydrogen bond between similar groups. This cooperative bonding was evident from sigmoidal curves describing the kinetics of the self-assembly process [47] which shows a pronounced dependency on the concentration, temperature, and medium polarity. These hydrogen bonds stitch together adjacent stacks leading to a curvature with a helical arrangement of the BChl molecules. This helicity is independent of the *R/S* configuration of the 3-(1-hydroxyethyl) group [43] and shows a counterclockwise arrangement of the transition dipole moments of the chromophores (i.e., negative chirality according to the exciton chirality theory) [48]. Figure 6 presents a view perpendicular to the stacks in such a crude model employing BChl *d*. Due to the curvature angle given by the hydrogen bonding between the stacks, 18 or more stacks may form a tubular structure. Convincingly, the diameter of the modeled helical tubes corresponded well with those observed for the chlorosomal rods in different bacterial species. Thus the increase in diameter from ca. 5 nm in *Chloroflexus* rods to over 6 nm in *Chlorobium* rods could be explained on the basis of different peripheral substituent sizes.

Remarkable is the fact that this cylindrical arrangement of chromophores was proposed before the first X-ray crystallographic structure of the LH2 system of purple photosynthetic bacteria was solved (see Section 3.1.2) heralding the importance of a closed ring structure in the delocalization of excitons and ensuring rapid energy transfer. Other models have been proposed which differ mainly in the parallel versus antiparallel orientation of the BChl molecules and these have been reviewed [27, 28]. More recently, van Rossum et al. have proposed a refined model, where in the interior of the cylinder in Figure 7, a second more curved aggregate of BChls is positioned [49]. This newer model was based on multidimensional solid state NMR studies conducted both on isolated chlorosomes and on purified BChl *c* uniformly labelled with  $^{13}\text{C}$  which was induced to self-assemble [44, 50].

**Figure 7.** Holzwarth–Schaffner initial model for chlorosomal self-assembled BChl *d* with the long chain alcohol esterifying the 17-propionyl ester residue shortened to a methyl group. Carbon atoms are represented as cyan, nitrogens as blue, oxygen as red, and magnesiums as white spheres. 18 Stacks are viewed from above the helical cylinder.

Credit is here due to the pioneering works of several chemists who have brought forth evidence for the self-assembly of (B)Chls in spite of rebuke from their more biological oriented colleagues. Thus Krasnovskii and co-workers were the first to observe that BChl *c* self-assembles *in vitro* [51, 52], while Smith et al., in a seminal paper, have shown that the redshifted absorption spectra of the natural system can be fully reproduced with self-assembled BChls [53]. Worcester and co-workers, using small angle neutron scattering, have subsequently shown that hydrated Chl *a* forms micellelike assemblies [54, 55]. Olson and co-workers have performed several early spectroscopic studies on BChl *c* in nonpolar solvents [56–60] or aqueous solutions [61, 62] and have discovered the so-called “hexanol effect” [63]. This curious effect deserves a brief description. It consists initially of disruption of the self-assembled BChls within the chlorosomes which is associated with a blueshift and sharpening of the absorption maximum. This is common also in smaller alcohols, amines, or pyridine which all compete for the ligation of the magnesium atoms and disrupt any hydrogen bonding. This transformation is usually irreversible, but in the case of hexanol, when water is used to partially remove it, a reassembly of BChls occurs with almost entire recovery of the redshifted absorption spectrum and CD signals [64]. The excitation energy transfer to the BChl *a* protein complex which acts as an energetic trap (see Fig. 5 and discussion) within the baseplate is perturbed [65] and also the transmission electron microscopy images show that swelling is the main morphological change [66] of such hexanol and then water treated chlorosomes. Both in nonpolar solvents as in aqueous medium, the self-assembled BChls have rather close contacts which lead to strong excitonic interactions with

broad and redshifted absorption maxima and intense CD signals. These assemblies have, however, different molecular structures. In an aqueous medium, the hydrophobic interactions between the long alcohol tails force the relatively large macrocycles into close  $\pi$ – $\pi$  interactions. Additionally, due to the aqua–magnesium complexes which being polar are well solvated, this ensures a micellelike segregation similar to the one encountered in surfactants. Hexanol apparently has the right hydrophilic/hydrophobic ratio to allow the transformation from one nanostructure into the other one.

Another interesting effect associated with the BChl *c*, *d*, and *e* nanostructures as well as with chlorosomal preparations is the variability of CD signals. It is now again accepted that this is mainly due to size variations and the related contributions of Rayleigh light scattering and the linear dichroism to the CD signal. In DNA-based nanostructures this effect has been studied and termed “giant CD” or “polymer and salt induced CD” [67–69]. Thus if the size of the nanostructures is larger than about a tenth of the wavelength at which a Cotton effect is observed, then enhancements and distortions of the signal are possible. With supramolecular associations of chromophores which absorb light at, for example, 500 nm, if these nanostructures are larger than about 50 nm, due to this effect, the stereochemical interpretations must be done with caution.

A lot of effort has been invested in characterizing the energy transfer processes in chlorosomes and BChl assemblies and these have been sufficiently reviewed. Ultrafast spectroscopies [70, 71] have shown that the energy transfer rates within the chlorosomal rods are very similar to those of the BChl self-assemblies. Both exhibit a very fast component of about 10 fs stemming from the initial coherent oscillations, and similar kinetics in their isotropic and anisotropic absorption difference spectra together with a 1–2 ps component which does not represent single step energy transfer between neighboring BChl *c* pigments but long range energy transfers which span many pigments within one rod. A second relatively fast component may represent inter-rod transfer which is in the range of 7–10 ps. Slight differences exist between the chlorosomes of *Chlorobium* and *Chloroflexus*, due to the different BChl *c* substitution patterns, as well as between the isolated BChl *c* aggregates, which reflect small differences in the transition moment organization and a somewhat more disordered structure in the aggregates. The component which is completely absent in the self-assembled BChl *c* aggregates and is important in the intact chlorosomes is the energy transfer from the BChl *c* rods to the BChl *a* protein complex (also known as the Fenna–Matthews–Olson or FMO complex) in the 30–40 ps range. In other species containing also BChl *d* and *e* this energy trapping by the more red shifted BChl *a* FMO complex (which absorbs light at about 800 nm) spans a 30–160 ps range [72, 73]. Thus the energy funnelling principle illustrated in Figure 1 is realized by efficient light capture by the self-assembled BChl rods (with a relatively broad absorption at 730–760 nm), very rapid energy transfer steps by incoherent excitation hopping, and final trapping within the BChl *a* protein complex. From there the special pair in the reaction center is photoexcited for triggering the electron transfer cascade. If the energy trap is absent, as in the case of self-assembled BChl aggregates, trapping occurs by diffusing the excitation to

randomly positioned redox active defect sites which act as quenchers. This was proved by adding sodium dithionite as reducing agent which greatly increases the BChl *c* fluorescence yield [74]. If, however, a covalently linked semisynthetic BChl *a* trap is included in the BChl *c* aggregate, efficient trapping occurs as demonstrated by Tamiaki et al. in the first supramolecular artificial light-harvesting device to be assembled [75]. Incorporation of BChl *a* into vesicles or liposomes containing BChl *c* aggregates [76, 77] is also effective. Very recently fluorescence from single chlorosomes as well as atomic force microscopy images were recorded by Tamiaki and his colleagues [78].

### 3.1.2. Pigment–Protein Complexes

A different organizational principle of chromophores is encountered in the pigment–protein complexes. These function either as light-harvesting systems, intermediate energy traps, or reaction centers. Here the carefully engineered protein matrix ensures the exact orientation of the pigments which allows a fine tuning of the direction of transition dipole moments and thus of the energy transfer rates and efficiencies according to the Förster mechanism (Section 2). In the reaction centers the electron transfer rates are also finely tuned by the protein. Furthermore, by positioning close to the chromophores special amino acids either as charged residues (Arg, Glu, etc.), hydrogen bonding (Ser, Tyr, etc.), or aromatic ones (Trp, Phe, Tyr, etc.) capable of  $\pi$ -stacking, the absorption properties can be influenced quite dramatically. Evolution, of course, has optimized these complex nanostructured machineries. Histidines are by far the preferred ligand for magnesium atoms of (B)Chls while carotenoids are usually bound only by weak hydrophobic interactions without a specific ligand. Several examples of such pigment–protein complexes will be briefly discussed.

**PSI Antenna of *Synechococcus elongatus*** In plants two photosystems I and II (PSI and PSII) are present and act in conjunction. Their individual isolation and purification are difficult from the plant thylakoid membranes. However, in the much simpler photosynthetic bacteria, either PSI or PSII can be expressed and these have very high sequence homology to the photosystems encountered in different plants. Berlin researchers have achieved the crystallization and structural elucidation of both PSI [5] and of PSII from *Synechococcus elongatus*, a thermophilic cyanobacterium [4]. While PSI is trimeric, resembling a clover leaf, PSII is a homodimer. Figure 8 describes schematically the main differences between the two photosystems. Thus while PSII has relatively isolated light-harvesting nanostructures, in PSI one can distinguish an inner core antenna system engulfing the reaction center and a peripheral antenna. Both PSI and PSII reaction centers are in overall architecture remarkable similar to the earlier known bacterial reaction centers [1, 2] emphasizing that there is only one common ancestor for achieving light induced charge separation. The electrochemical potentials are, however, different and this is probably due to the fact that the special pair of chlorophylls in PSI (P700) is actually a heterodimer composed of a Chl *a* and the epimeric Chl *a'* (see Scheme 1) and the ligation of their Mg atoms by methionine residues. Other slight differences

**Figure 8.** Schematic differences between PSI and PSII. Abbreviations: A = Antenna, RC = reaction center, P\* = excited special pair: P670 for PSII and P700 for PSI, Phe = pheophytin, Q = quinones, FeS<sub>x</sub> = iron sulfur clusters. are that in PSII, like in the bacterial reaction center, the primary electron acceptor is a chlorophyll which has lost its magnesium atom, namely a pheophytin, and that the final electron acceptors are a quinone for PSII and iron sulfur centers for PSI. The lower resolution of the PSII crystal structure does not yet allow one to discern fine stereochemical features allowing assignment of the direction of transition moments in antenna Chls or to exactly elucidate the ligands of the tetramanganese cluster involved in water splitting. For this reason we will not discuss the PSII chlorophyll–protein complexes here.

The much higher resolution of PSI has allowed us very recently to elucidate an important structural feature of its core complex which is instrumental for the energy funnelling from the peripheral antenna toward the reaction center [79]. (B)Chls have two nonidentical sides from which the magnesium atom can bound be a fifth ligand giving rise to two diastereoisomeric complexes. Figure 9 shows the crystal structure of PSI with the magnesium atoms highlighted as spheres. In total there are 96 chlorophyll molecules.

We have denoted as *anti*-ligated (B)Chls the diastereoisomer where the magnesium ligand is on the opposite side

**Figure 9.** PSI viewed in the membrane plane luminal side up, stromal side down. Spheres represent magnesium atoms of chlorophylls.

of the 17-propionic acid residue which is esterified with a long chain alcohol such as phytol in plants [43]. The other diastereomer is denoted as *syn*. Figure 10 shows two Chls from the PSI crystal structure both coordinated by histidine residues one being in a typical *anti* configuration and the other one being *syn*.

A simple counting of the *syn* Chls revealed that these are only 14 out the total 96 which translates by a crude Boltzmann distribution into an energetic difference of 1.1 kcal/mol. The *syn* Chls are not only less stable than the *anti* ones but if coordinated by a histidine, their absorption spectrum, according to semiempirical ZINDO calculations, is slightly shifted by about 4 nm. Astonishingly, however, is the very controlled position of these *syn* Chls carefully engulfing the reaction center [79]. The Chl ligands have been strictly conserved during evolution, as could be seen from the sequence alignment in different plant and bacterial species, a fact which implies that the incorporation of Chls in the protein matrix is a nonrandom process. Probably a highly stereoselective self-assembly process occurs which allows binding of the magnesium atom only from the desired side. An enzymatic process requiring two different enzymes for chaperoning *syn*- or *anti*-ligation appears less probable. Figure 11 shows the disposition of the *syn* Chls which are exclusively in the core antenna system.

Recently Byrdin et al., also on the basis of the PSI crystal structure, have interpreted the energy transfer kinetics using a detailed modeling of the system by applying excitonic coupling theory [80]. The *syn* Chls are interconnected into clusters characterized by medium to rapid energy transfer rates in the 3 to 11 ps<sup>-1</sup> range. They appear not to be strongly redshifted having assigned “colors” between 670 and 680 nm. Far more redshifted are, however, two dimers of *syn-syn* Chls which are situated some 2.5 nm from P700, the special pair of PSI. It thus appears probable that the energy funnelling occurs also in this case cascadelike, from the peripheral antenna, to the inner core rich in *syn* Chls which are not redshifted to dimeric Chls which are redshifted and finally to the P700 heterodimer, which absorbs

**Figure 10.** The two different diastereomeric configurations of histidine coordinated Chls. At left a typical *anti*-ligated Chl. Note the sharp curling of the phytol chain on the opposite side of the histidine ligand. At right a *syn*-ligated Chl. Note that in this case the propionic acid residue is on the same side as the histidine ligand while the esterifying phytol curls back to the other side. The role of the phytol chain is to ensure a hydrophobic environment thus steering the coordination of magnesium from the other side which is more hydrophilic.

**Figure 11.** Disposition of the *syn* chlorophylls (colored in red) around the electron transfer chain chlorophylls (colored in blue) of the reaction center. Green chlorophylls are all *anti* coordinated. Note that for the upper right chlorophyll the ligand is uncertain. Reprinted with permission from [79], T. S Balaban et al., *Biochim. Biophys. Acta* 1556, 1 (2002). © 2002, Elsevier.

light at 700 nm (as its name implies) where charge separation occurs. Carotenoid–Chl interactions are also different for the *syn* and *anti* configurations affecting most importantly the Soret band.

**The Fenna–Matthews–Olson Complex** John Olson was historically the first to be able to isolate a (bacterio)-chlorophyll–protein complex from the green bacterium *Prosthecochloris aestuarii* (previously named *Chlorobium limicola*) and to crystallize it. Apparently serendipity played here a role but it was the prepared mind who realized the importance of this discovery [81]. The crystal structure was solved at an astonishingly high resolution for that time (2.8 Å) by Fenna and Matthews [82] and since then this complex has been the workhorse for spectroscopic investigations and for testing various theoretical models of energy transfer and trapping [83, 84]. The FMO complex is a trimer and energy trapping occurs from the chlorosomal antenna in one unit and is transferred to the other two units before excitation of the reaction center. Only seven BChl *a* per monomer are present, two of which are *syn*-ligated, confirming the higher stability and thus propensity of the *anti* Chls. Blankenship and co-workers have shown by crystallizing and solving the structure of the FMO complex from *Chlorobium tepidum* that it has a similar architecture which enables it to function as the energy sink of the antenna, although some differences are encountered for the BChl *a* molecules [85]. Figure 12 shows the BChl *a* molecules from a monomer in the latter structure together with their ligands in their original orientations and without the protein matrix. Also in this case the *syn* Chls appear to be “special” and are most probably the energetic trap as they are closely situated, having a Mg–Mg distance of 12.5 Å forming thus a redshifted *syn-syn* dimer ligated on two consecutive histidines (red in Fig. 12). The central *syn* BChl *a* (#7 in the original numbering [82]) of this dimer has been recognized before as the energetic trap having the largest intersubunit

**Figure 12.** The seven Chls of an FMO monomer. *Anti* chls are green; *syn* Chls which are on two consecutive histidines are red.

interactions within the trimer. For evidence that BChl #6 is the reddest pigment see [86].

As BChl *a* absorbs at longer wavelengths than the antenna BChls (which are actually chlorins; see Scheme 1) a downhill energy transfer is operating. The reaction center absorbs light at still longer wavelengths and must be supplied from the energetic trap. If the *syn* Chls are involved either in the intertrimer energy transfers or act as the traps remains to be ascertained. We have written a thought-provoking article discussing this feature [87].

Recently Oba and Tamiaki have also counted *anti*-ligated Chls (which they denote as back-face ligated) and *syn* Chls (denoted as front-face ligated) in all known chlorophyll protein complexes and have also concluded that *anti*-ligation is energetically more favorable [88, 89].

**The LH2 of Purple Bacteria (*Rhodospseudomonas acidophila* and *Rhodospirillum molischianum*)** Purple bacteria have a fascinating peripheral light-harvesting complex, the LH2, which is an integral membrane complex consisting of two rings of BChl *a* molecules embedded in an aggregate of polypeptide matrices. The first X-ray crystallographic structure to be solved was from *Rhodospseudomonas acidophila*, strain 10050, which has involved almost a decade of research and crystallization trials by Cogdell and co-workers [90, 91]. Crystals with heavy atom derivatives could be prepared in order to solve the phase problem. Based on these coordinates, the crystal structure of a second LH2 complex from *Rhodospirillum molischianum* could be solved soon thereafter in a collaborative effort between the research groups of Klaus Schulten and Hartmut Michel [92]. Both nanostructures have the same overall architecture, the main difference being the oligomerization state and thus their symmetry: while the *acidophila* LH2 is a nonamer, the *molischianum* LH2 has eightfold symmetry. This implies that the function of light harvesting and energy transfer is actually independent of the symmetry and almost the same optical properties are encountered. These are determined by the disposition of the pigments and the orientation of the transition dipole moments. One ring of *anti*-ligated BChl *a* molecules, which are loosely coupled, absorbs light at about 800 nm and has been denoted as B800

(B stands for bulk Chl). The second ring, denoted as B850, is formed of dimers which are closely spaced and are red-shifted absorbing light at about 850 nm. Interestingly all the B850 BChls are *syn*-ligated. Figure 13 shows a view of the BChls in the *acidophila* LH2 from above the ring of the 18 B850 BChls *a* as well as a view in the plane of the membrane. One *syn-syn* BChl dimer and one B800 BChl are precisely oriented (almost perpendicular to each other) by two polypeptides which are  $\alpha$ -helical and span the membrane. Furthermore, a carotenoid molecule is also present having close contact with both the dimer and the B800 monomer. The two polypeptides which are termed  $\alpha$  and  $\beta$  together with the associated pigments form a so-called protomer [93]. Interprotomer interactions lead to self-assembly of the circular structure. Nine protomers come together in the *acidophila* LH2 leading to a disposition of the  $\beta$ -polypeptides on a outer circle having a diameter of 6.8 nm while the  $\alpha$ -polypeptides form an inner circle with 3.6 nm diameter. While the Mg to Mg distance in opposite BChls from the B800 ring is 6 nm, the corresponding distance in the B850

**Figure 13.** The BChl *a* molecules in *acidophila* LH2 with their ligands. The B800 BChls are green (ligated *anti* by an *N*-formylmethionine residue) while the B850 BChls are red (ligated *syn* by histidines). Note the different orientation of the BChl planes in the two rings. The BChl *c* ligands have carbon atoms colored cyan, nitrogen blue, oxygen red, and sulfur yellow. The figure was produced with HyperChem® using the PDB coordinates.

ring is ca. 5 nm. Only eight protomers self-assemble in the *molischianum* LH2 leading to a similar architecture.

The B800 BChls are situated nearer to the cytosolic side of the membrane. Their role is to function as antenna and to transfer the singlet excitation energy to the B850 ring via a Förster mechanism (see Section 2). Detailed investigations of the energy transfer kinetics in the LH2 of the purple bacteria *Rhodobacter sphaeroides* and *Rhodospseudomonas palustris* using femtosecond pump-probe techniques have been performed [94].

These studies could distinguish between intra- and inter-ring energy transfer processes. Within the B800 BChls which have a Mg-Mg distance of 2.1 nm a very fast energy transfer occurs with a time constant of 400 fs. The B800 to B850 inter-ring energy transfer occurs slower within 700 fs although the average separation between the Mg atoms is smaller, namely 1.8 nm. Both these processes involve the Förster mechanism, which as discussed in detail in Section 2, beside the distance dependence involves a spectral overlap between the fluorescence of the donor and the absorption of the acceptor as well as an orientation factor of the transition dipole moments. The latter two factors are more favourable for the intra-ring energy transfer, although the distance is larger. Once the excitation has been transferred to the B850 ring, because of the extensive  $\pi$ - $\pi$  overlap of these BChls, a different mechanism operates. A delocalized exciton coupling mechanism of Dexter type which involves orbital overlap occurs in this case. The B850 BChls have Mg-Mg distances of under 1 nm (9.6 Å within a protomer and 8.9 Å between adjacent protomers) being ideally suited to delocalize and to store the energy within this ring until it can be transferred further to the LH1 complex. This process occurs within 3 to 5 ps and is followed by a slower 35 ps energy transfer process to the reaction center [95]. The overall efficiency for the excitation transfer from the LH2 to the LH1 and from there to the RC is extremely high (about 95%) due to the optimal orientation of pigments within the complexes.

The carotenoids (rhodopin glucoside in the *Rps. acidophila* LH2 and lycopene in the *Rs. molischianum* LH2) are also involved in light harvesting but at lower wavelengths (about 500 nm) than the BChls. Due to their low fluorescence yield they transfer sluggishly the excitation energy via the Förster mechanism but having close contacts with both the B800 and B850 again the Dexter mechanism can operate. Energy can in principle be transferred directly from the carotenoid  $S_2$  state or after the fast (100 fs) radiationless decay from the  $S_2$  to the  $S_1$  state, from the latter (see Fig. 14). Due to the unfavourable orientation of the  $S_1$  transition dipole which is oriented along the long molecular axis and thus being almost perpendicular to the  $Q_x$  and  $Q_y$  transitions of the B800 BChls, excitation transfer from this carotenoid to B800 is rather limited. In contrast, due to its proximity to the  $\alpha$ -B850 BChl *a* (5.4 Å to the central Mg atom) and to the  $\beta$ -B850 BChl *a* (8 Å to the central Mg atom) and to the parallel alignment to the  $Q_x$  transition a favourable  $S_2$ - $S_2$  transfer occurs. Beside this dipolar or Coulombic, Förster-type singlet-singlet energy transfer, a Dexter type mechanism involving electron exchange can occur also between the triplet states which has been shown much earlier to involve only the B850 BChls [96]. A second carotenoid molecule per protomer which in the initial

**Figure 14.** Schematic energy diagram with the energy transfer pathways and time constants from the carotenoid  $S_2$  state to the B800 and B850 BChls. The dotted line indicates that only a small amount (5%) is transferred from the internal conversion state  $S_1$  to the BChls. There is no back transfer from BChl to the Car due to energy funneling. structure [90] was not seen in the electron density map, probably due to local disorder, has later been put into evidence [93]. It is certain that beside their light harvesting role, carotenoids play an important structural role in holding chlorophyll-protein complexes together. Being rather stiff and nonpolar they interact with hydrophobic amino acids ensuring rigidity to the nanostructure. Carotenoidless mutants assemble much more labile complexes. The third role of carotenoids involves efficient quenching of the BChl triplet states, again through electron exchange mechanism. This prevents generation of the reactive species singlet oxygen [ $O_2(^1\Delta_g)$ ] which may generate subsequently radicals and thus could lead to cell damage. The protective role of carotenoids has made them wide spread in natural photosynthesis being the second most abundant pigment class, after chlorophylls.

Several studies related to the *Rs. molischianum* LH2 complex have also been performed and these have been reviewed [97–99]. Molecular modeling of the LH2 complexes surrounding the LH1 complex (which is discussed below) and which engulfs the reaction center have been reported [100, 101]. The exact number of LH2's surrounding the larger LH1 may vary between different purple bacterial species as well as with illumination conditions. Under dim light the ratio LH2/LH1 increases.

**The LH3 of *Rhodospseudomonas acidophila*** The crystal structure of the smaller LH3 light-harvesting complex which is also present in some purple bacteria such as *Rhodospseudomonas acidophila* and which absorbs light at higher energies having B800 and B820 absorbing BChls was recently disclosed by Cogdell and co-workers [103]. Surprisingly, the overall structure resembles closely that of the LH2 complex consisting of a ring of 9 loosely coupled *anti* BChls *a* responsible for the 800 nm absorption band and a tightly coupled ring of 18 *syn*-ligated BChls *a* which absorb at 820 nm. It is very interesting to understand the structural

difference which leads to the blueshift of the B850 ring in LH2 to B820 in LH3 (see Fig. 14). Apparently it is not the coupling energy which is different, as the distances and the orientations between the BChls are almost identical. Rather it is the site energy which is different. That is, due to slight variations in the geometry of the individual BChls, the absorption is blueshifted. Most notably, the 3-acetyl group which has its carbonyl group coplanar with bacteriochlorin plane in the B850 LH2 ring, due to the more extended conjugation, leads to the redshifted absorption. In the LH3 BChls this acetyl group, due to subtle interactions with the protein matrix, has its carbonyl group twisted out of the plane and is thus not in conjugation, a fact which explains nicely the 30 nm blueshift. Figure 15 presents the very similar arrangement of three consecutive *syn* BChls while Figure 16 shows the different orientation of the 3-acetyl groups.

Another reason for the blueshift lies in the more ruffled conformation of the bacteriochlorin ring in the LH3 complex, whereas in the LH2 complex a more domed conformation is encountered. Extensive theoretical calculations by John Shelnutt and Craig Medforth coupled with experimental data supplied by Kevin Smith and Jack Fajer have convincingly shown that conformationally perturbed cyclic tetrapyrroles have not only very different absorption characteristics but also different fluorescence and excited states lifetimes [104–108]. This shows that the protein can very finely tune the spectroscopic properties of the bound pigments.

To a similar conclusion, namely that the difference in the absorption wavelengths between the LH3 and the LH2 complexes is due to the difference in site energies and not from the coupling energy, comes a recent study by optical single-molecule fluorescence spectroscopy of Aartsma and co-workers [109].

**The LH1 of Purple Bacteria** Electron microscopy images of two-dimensional crystals of the LH1 complex from *Rhodospirillum rubrum* obtained by Gosh and co-workers have shown also a circular structure but with a 16-fold symmetry [110]. Again  $\alpha\beta$  heterodimeric polypeptides with  $\alpha$ -helices spanning the membrane are used for positioning the pigments. Absorption occurs at about 875 nm, more redshifted than the B850 ring of the LH2. Furthermore, within the membrane plane the positioning of the LH1 hexadecagon formed by the BChls coincides with the depth at which the B850 ring is embedded.

The reaction center complex fits well within the ring of LH1, although it sits deeper within the membrane. From

**Figure 15.** Similarities in the chromophore arrangement in the LH2 and LH3 complexes.

**Figure 16.** The arrows indicate the OC–CC torsion angle of the carbonyl group which is more conjugated in the LH2 complex.

some species the isolation of LH1 cannot be performed without the RC. The energetic cascade is realized by initial light harvesting of the B800 ring of the LH2, transfer to the neighboring B850 ring then to the LH1, and from there to the reaction center. Here the special pair is photoexcited. Hu and Schulten have argued that the long debated role of the accessory BChls could actually be that they trap the energy from LH1 and transfer it then efficiently to the special pair [98]. Thus they appear to be involved in an initial energy transfer while their role in electron transfer, once the special pair has been excited and the electron is ejected, has been the subject of debate. Whether this electron actually resides on one of these accessory BChls or whether the latter has just a spectator role as the electron is passed directly onto the magnesium-free pheophytin has different mechanistic implications. For an excellent discussion with stimulating concepts and synthetic models for studying the superexchange mechanism see the book chapters by Paddon-Row (Chapter 1, Vol. 3 in [19] and/or [111]).

**The Peridinin Complex** The high resolution structure of this light-harvesting complex from *amphidinium carterae* has shown that the carotenoid peridinin is the main pigment and eight carotenoids are being associated closely with two Chl *a* molecules [112]. The complex is a trimer and having reversed the usual stoichiometry between pigments absorbs light predominantly at shorter wavelengths. Figure 17 shows a monomeric unit highlighting the close contacts between the carotenoid and Chls.

**Figure 17.** Stereoview of the monomeric unit in the peridinin light-harvesting complex. Carotenoids are light (yellow) and the Chls are dark (green).

**The LHCII of Plants** This light-harvesting complex of photosystem II of plants is the largest and outermost antenna complex which due to its abundance accounts for about half of the pigments in plant photosynthesis. Its structure has been determined by Kühlbrandt et al. using electron diffraction of two-dimensional crystals to a resolution of 3.4 Å [113]. Three membrane-spanning  $\alpha$ -helices bind 12 Chl *a* and Chl *b* molecules together with 3 carotenoids. In the initial structure the assignment of the Chl *a* or Chl *b* as well as their orientations was uncertain due to the low resolution. Furthermore, only two of the carotenoids, namely two central lutein molecules, were visible. A lot of effort has been invested into assigning the Chl *a* and *b* binding sites as well as the position of the third carotenoid molecule, neoxanthin. These have included mutagenesis studies where mutant apoproteins were expressed in *Escherichia coli* and after isolation were reconstituted in the presence of chlorophyll and carotenoid cofactors. By replacing the Mg binding residues with noncoordinating amino acids the spectral characteristics of each chlorophyll molecule could be assessed [114]. A similar procedure was used for determining the binding site and orientation of the elusive neoxanthin molecule [115, 116]. Interestingly, while occupation of the binding sites with at least one lutein is essential for correct protein folding, the neoxanthin occupancy does not influence the folding process.

A recent detailed femtosecond transient absorption study has unravelled the carotenoid to chlorophyll energy transfer processes by using recombinant LHCII reconstituted with different carotenoid contents [117]. The data analysis has shown that most of the energy transfer occurs directly from the initially excited state  $S_2$  of the carotenoids to Chls with time constants under 100 fs. Only a relatively small part of the energy transfer (under 20%) occurs after relaxation from  $S_2$  to the  $S_1$  carotenoid state. The two luteins have transfer times of about 50 and 75 fs while the neoxanthin has about 90 fs and it transfers its energy almost exclusively to Chl *b*. Three different Chl *b* molecules could be distinguished which receive energy directly from the carotenoids. As there are five Chl *b* and seven Chl *a* there is less energy transferred directly to Chl *b* as estimated in a previous study in the LHCII of *Arabidopsis thaliana* [118]. Figure 18 shows the energy levels and the proposed energy transfer pathways.

**Figure 18.** Qualitative kinetic scheme for the energy transfer from carotenoids to chlorophylls in LHCII. Adapted with permission from [118], J. P. Connelly et al., *Biochemistry* 36, 281 (1997). © 1997,

While the energy transfer from carotenoids to Chl *b* involves both the  $B_x$  and  $Q_x$  state, the transfer to Chl *a* occurs only via the  $Q_x$  Chl state.

Investigations on the smaller chlorophyll-protein (CP) complexes from plants which have a high degree of homology to LHCII such as CP29 have also been performed [119]. The inner-antenna subunits CP43 and CP47 flank the PSII reaction center and contain 12 and respectively 14 Chl molecules and their role is to transfer the excitation energy from the outer LHCII antenna to the reaction center, in an energetic cascade similar to that encountered in bacterial photosynthesis.

Worth mentioning here are also Paulsen's reconstitution studies of LHCII with artificial dyes such as terrylene which acts as an energy trap [120]. A single cysteine residue has been inserted near the *N*-terminus and the dye benzoylterrylene-3,4-dicarboximide (BTI) could be covalently coupled via a maleimido linker. The site specificity was verified by the fact that maleimido-BTI was not bound by a mutant apoprotein containing no cysteine at all. Reconstitution of this apoprotein containing the artificial energy trap was effected with the natural pigments in the usual way [121, 122]. Quenching of the donor (Chl *a*) fluorescence allowed an estimation of the energy transfer efficiency to BTI to be 70% at 297 K and 85% at 77 K. Elegant proof of this high efficiency was provided by digestion with trypsin which cleaves only the *N*-terminal part leaving intact the pigment binding domains. The fluorescence in the trypsin digested LHCII labeled with BTI rose to the level of the nonlabeled complex. Thus in this biomimetic study, for the first time a self-assembled recombinant light-harvesting complex from higher plants has been shown to mimic perfectly the efficient light harvesting and subsequent energy transfer to an artificial trap. However, in this case no charge separation occurs, as in the fully functional natural system.

Shown is maleimido-BTI attached to the Lhcb1 recombinant apoprotein via a cysteine residue near the *N*-terminus (R is a *tert*-butylphenol group).

Very recently, single molecule spectroscopy of oriented LHCIIb as trimers has been performed in collaboration between the groups of Paulsen and Wrachtrup [123]. Photobleaching in one step was observed for most complexes a fact which indicates energy transfer between the subunits. An excellent feature article on the energy transfer in LHCII was published recently by van Amerongen and van Grondelle [23].

## 4. ARTIFICIAL LIGHT-HARVESTING NANOSTRUCTURES

In this section we review recent synthetic efforts to construct artificial nanostructures mimicking the natural light-harvesting apparatus described. Two different approaches have been followed: (i) covalent assembly of large molecular structures having nanometer dimensions and (ii) a supramolecular approach where noncovalent interactions are engineered between chromophoric molecules.

### 4.1. Covalent Arrays

The evolution of synthetic chemistry has allowed the construction of impressive architectures which are covalently linked. This tedious bond-by-bond construction mode makes use of well optimized synthetic procedures, such as palladium catalyzed cross-coupling reactions, acetylene scaffolding, esterifications, or amide bond linkages where from small molecular building blocks nanostructures can be accessed. A precise control of the architecture is possible so that geometry and device performance can be finely tuned. The major disadvantage of this procedure resides in the limited amount of material which one obtains in the end of such a multistep synthetic sequence which then is available for photophysical studies.

An early investigation of a rigid rodlike nanostructure encompassing ruthenium and/or osmium trisbipyridyl complexes was a collaborative effort between German and Swiss synthetic chemists and Italian photophysicists in Bologna [124]. This was the first example where two metal chelating units were separated by a rigid bridging ligand with linear geometry which restricted the electronic communication between the metal centers due to a [2,2,2]-bicyclooctane insulating spacer. Model compounds served the monometallic complexes of the same ligand as well as ruthenium and osmium trisbipyridine complexes.

The bisacetylenic-[2,2,2]-bicyclooctane spacer, as could be inferred from its X-ray structure, is 1 nm long and assures a separation of 1.7 nm between two metal centers chelated by the bispyridine (bpy) ligands. The absorption and luminescence spectra of the mixed [Ru–Os]<sup>4+</sup> complex is exactly the sum of the mononuclear complexes showing that there is no electronic communication between the metal centers. Eloquently, the absorption spectra of the three complexes [Ru–Ru]<sup>4+</sup>, [Ru–Os]<sup>4+</sup>, and [Os–Os]<sup>4+</sup> show two isosbestic points (at 416 and 466 nm) where each metal complex unit absorbs 50% of the incident light. Also the electrochemical measurements show constant values for the halfwave potentials versus the standard calomel electrode ( $E_{1/2}$  vs SCE) of ca. 1.26 V for a [Ru]<sup>2+</sup> complex and 0.84 V for a [Os]<sup>2+</sup> complex having the same coordinating ligands. As the [Os]<sup>2+</sup> unit has a more bathochromically shifted absorption and the lower  $E_{1/2}$  value than the [Ru]<sup>2+</sup> unit, a unidirectional energy transfer can occur from the donor [Ru]<sup>2+</sup> metal center to the [Os]<sup>2+</sup> metal center which acts as acceptor.

Upon irradiation at the isosbestic points, the fluorescence of the Ru-based luminescence in the [Ru–Os]<sup>4+</sup> complex, after correction for 50% absorption of the Os-based unit, shows a pronounced quenching (about 10 times smaller quantum yield) than the model compounds [Ru–Ru]<sup>4+</sup> or the monometallic complex [Ru]<sup>2+</sup>. At the same time there is no quenching of the Os-based luminescence, the quantum yield being about the same as in the [Os–Os]<sup>4+</sup> or [Os]<sup>2+</sup> model complexes. Furthermore, the excited state lifetime of the Ru-based unit is drastically decreased from 231 ns in the [Ru–Ru]<sup>4+</sup> complex to 22 ns in the mixed [Ru–Os]<sup>4+</sup> complex and concomitantly, with practically the same lifetime (21 ns) there is a rise in the luminescence of the Os-based unit. This is direct evidence that energy is transferred *intramolecularly* from the Ru-based center to the Os-based center. The rate for this energy transfer can be calculated from the experimentally determined lifetimes  $\tau$  of the [Ru–Os]<sup>4+</sup> complex and  $\tau^0$  of the [Ru–Ru]<sup>4+</sup> complex, that is, in the presence and respectively absence of the energy transfer with the equation.

$$k_{\text{EET}} = \frac{1}{\tau} - \frac{1}{\tau^0} = 4.1 \times 10^7 \text{ s}^{-1}$$

The theoretical rate calculated by a Förster dipole–dipole mechanism gives a value for  $k_{\text{EET}}$  of the same order of magnitude, albeit a little smaller, namely  $2.4 \times 10^7 \text{ s}^{-1}$ . For this calculation, in the Förster formula (see Section 2) the value of the overlap integral was calculated as  $4.7 \times 10^{-14} \text{ M}^{-1} \text{ cm}^{-3}$ ,  $R_{DA}$  was taken as 1.7 nm,  $\tau_R^D = \tau^D / \Phi_D$ , where  $\tau^D$ , the radiative lifetime of the Ru-based donor in the absence of energy transfer, was 231 ns and the fluorescence quantum yield of the Ru-based donor  $\Phi_D$  was 0.015.

If exclusively a Dexter exchange mechanism is considered, in order to explain the observed energy transfer rate, a value of  $0.4 \text{ cm}^{-1}$  is obtained for the through-bond electronic interaction energy  $H$  between the two metal centers. The reorganization energy  $\lambda$  could be estimated as ca. 0.2 eV from the Stokes shift, while the free energy  $\Delta G^0$  could be calculated to be  $-0.33 \text{ eV}$  from the difference between the spectroscopic energies of the Ru-based donor and the Os-based acceptor measured from their luminescence maxima at 77 K. If the Dexter mechanism would

operate only 50% to the observed energy transfer, then the corresponding value for  $H$  would have been  $0.3 \text{ cm}^{-1}$ . Clearly in this case there is a contribution from both mechanisms to the energy transfer process as the Förster mechanism alone cannot explain the observed energy transfer rate unless the real orientation factor  $\kappa$  is different than the one assumed.

#### 4.1.1. Multiporphyrinic Nanostructures

Porphyrins have been the most used pigments in artificial light-harvesting nanostructures as they are available synthetically by various procedures, are thermally quite robust, and show interesting photophysics. Several excellent reviews have appeared describing mainly covalent assemblies of porphyrins [125, 126]. While the former review focuses on the structure, several examples of crystal structures obtained by the group of K. M. Smith being described, the second review describes synthetic routes to such multiporphyrin arrays. Neither theme will be treated here and the interested reader is referred to these fairly recent sources.

Among the first series of molecules to be constructed with the aim of studying the energy transfer among different chromophores was the following series with  $n = 3, 4,$  and  $6$  [127]:

Harriman and co-workers together with the late Lord Porter have studied both by stationary and time-resolved fluorescence the zinc metallated tetraphenylporphyrin covalently linked via different dialkoxy chains to a tetratolyl free base porphyrin. In the case for  $n = 2$  and the ethyleneglycol unit links both *ortho* positions of the phenyl rings, a strong ground state interaction by exciton coupling was encountered between the porphyrin rings. In all cases, upon excitation of the zinc porphyrin energy is transferred to the free base acceptor porphyrin. The efficiency of the energy transfer ( $\Phi_{\text{EET}}$ ) could be estimated from the fluorescence quenching at  $605 \text{ nm}$ , where only the zinc donor emits. For the  $n = 2$  case, with *ortho*-linkage the  $\Phi_{\text{EET}}$  was almost quantitative (94%) and occurred with a rate constant of  $8$  to  $9 \times 10^9 \text{ s}^{-1}$  depending whether measured in benzene or the more polar dimethylformamide as solvent. As the linker length is increased,  $\Phi_{\text{EET}}$  drops to 75% for  $n = 3$ , and only 35% for  $n = 4$ , while the rates decrease to  $5$  and  $4 \times 10^9 \text{ s}^{-1}$  respectively. Interestingly as the chain length is further increased to  $n = 6$ ,  $\Phi_{\text{EET}}$  becomes 48% indicating that a flexible conformation with more closely spaced donor and acceptor can now be populated. If Förster-type calculations are performed, the measured rates indicate separations between the donor and acceptor smaller than estimated from molecular models in a fully extended conformation. Furthermore, a random orientation of the transition dipole moments has to be considered in this case which leads to an averaging of the

factor  $\kappa^2$ . From the time-resolved measurements it was concluded that a slow equilibration exists between an open conformation with increased separation between the Zn donor and the free base porphyrin and a more closed conformation. Triplet-triplet energy transfer processes, which in principle can occur only via a Dexter mechanism, were found to be negligible.

Also an early and very thorough study of energy transfer coupled with electron transfer which deserves mention is due to Gust and co-workers at the Center for the Study of Early Events in Photosynthesis, Arizona State University, in collaboration with De Schryver in Leuven, Belgium and Bensasson and Rougée in Paris [128]. This work was based on previous studies of various dyad, triad, tetrad, and pentad molecules which were specially constructed to generate long-lived charge-separated states upon photoexcitation and multistep electron transfer reactions mimicking thus natural reaction centers (for earlier reviews see [6, 7, 129]). Various porphyrinic dyads of type  $P_{\text{Zn}}-P$  and triads of type  $C-P_{\text{Zn}}-P$  (where  $C$  is a carotenoid moiety) were synthesized and their photophysics was investigated. The novelty consisted of a fine tuning of the redox properties and thus of the excited state energies by introducing electron withdrawing groups, such as pentafluorophenyl, for stabilizing the radical anions formed upon electron transfer.

The absorption spectra of dyads **A** and **B** are essentially a superposition of the spectra corresponding to the monosubstituted porphyrins (denoted as  $P_{\text{Zn}}$  and  $P$ ) which thus act as independent chromophores. Due to the amide linkage, which has partial double bond character, a folded conformation where the porphyrin rings could  $\pi$ -stack is excluded and this was supported by the solution NMR studies where no aberrant shielding effects were seen for the protons and no close interporphyrin contacts could be put into evidence by nOe studies. Time resolved studies by single photon timing showed that in a dyad of type **A** where both porphyrins are free bases, there is no quenching of the porphyrin singlet excited states by any electron or energy transfer process. Thus upon excitation at  $590 \text{ nm}$  a decay of the fluorescence was observed which could be fitted by a single exponential with a lifetime of  $7.8 \text{ ns}$  which is comparable to that of the separated free base porphyrins with the same substituents ( $7.9$  and  $8.3 \text{ ns}$ ). The energetic diagram shown in

Figure 19 could be inferred by estimating the energies of the first excited singlet states of the porphyrins from the difference in energies (or frequencies) between the longest wavelength absorption maxima and the shortest wavelength emission maxima. Furthermore, the energy of the state after electron transfer,  $P_A^{\bullet+}-P_B^{\bullet-}$ , could be estimated from the first oxidation potentials of the isolated donor porphyrin  $P_A$  and the first reduction potential of the acceptor porphyrin  $P_B$  measured by cyclic voltammetry in the model compounds having the same substitution patterns.

As the state  $P_A^{\bullet+}-P_B^{\bullet-}$  lies about 0.2 eV above the first excited singlet states of the two electronically similar porphyrins, it is expected that it would be populated only very slowly. Accordingly the  $^1P$  states can relax only by intersystem crossing to the triplet state, by internal conversion, or by fluorescence with a normal lifetime.

The situation is different for dyad **A** when the left porphyrin is metalated with zinc ( $P_{Zn}-P$ ). Although again the absorption spectrum is a linear combination of the constituent chromophores, in emission the fluorescence of the zinc porphyrin is almost entirely quenched so that only fluorescence from the free base can be detected by stationary methods. This could be due to either an energy or an electron transfer process. A nice confirmation that only an energy transfer process occurs could be obtained by time-resolved fluorescence measurements by exciting at 590 nm and recording at different wavelengths the decays which were then analyzed by the global technique method developed by Wendler and Holzwarth [130]. Good fits were obtained for three components with lifetimes of 42 ps, 1.5 ns, and 7.9 ns over the whole spectral range between 630 and 730 nm of the Q bands. By scaling the relative amplitudes of the three components, at each wavelength where the decays were measured, to the corrected steady-state fluorescence spectrum, the so-called decay associated spectrum was obtained. While the 1.5 ns component had a negligible amplitude at all wavelengths and could be ignored, the slow 7.9 ns component reflected the emission spectrum of the free base porphyrin having a *meso*-methylbenzoate group.

**Figure 19.** Energy diagram for the model dyad P-P. Adapted with permission from [128], D. Gust et al., *J. Am. Chem. Soc.* 113, 3638 (1991). © 1991, American Chemical Society.

This value is also comparable to the lifetime which was measured in the model monoporphyrinic compounds. The fast component is typical for an energy transfer process as it shows a positive amplitude at ca. 635 nm [i.e., only where the decay of the zinc-metallated porphyrin occurs and a negative amplitude, i.e., a rise (or growth in fluorescence) at 710 nm where only the free base porphyrin can fluoresce]. This proves unambiguously that energy is being transferred from  $P_{Zn}$  to P. The energy diagram is presented in Figure 20.

In this case due to the higher energy of the first excited singlet state of the  $^1P_{Zn}-P$  (estimated at 2.08 eV) than that of the corresponding free base ( $P_{Zn}-P^1$  estimated at 1.90 eV), energy transfer from the zinc donor to the free base can occur while the reverse case must be very slow. Again the rate of the excitation energy transfer can be calculated from the measured lifetimes with the formula

$$k_{EET} = \frac{1}{\tau} - \frac{1}{\tau^0} = 2.3 \times 10^{10} \text{ s}^{-1}$$

where  $\tau$  is the measured lifetime of the zinc porphyrin first excited singlet state in the dyad (42 ps) and  $\tau^0$  is the lifetime in the absence of energy transfer, taken as 1.6 ns in a model zinc porphyrin substituted with a *meso*-acetamidobenzoate group. The efficiency of the energy transfer  $\Phi_{EET}$  can be calculated as a quantum yield from the product of the lifetime and rate constant ( $\Phi_{EET} = \tau \times k_{EET} = 0.97$ ) which means that the energy transfer is not only very fast but also almost quantitative. The much slower rate constant of the reverse process ( $k_{-1}$ ) can be estimated from the free energy difference  $\Delta G^0$  which in this case measures  $-0.18$  eV assuming an equilibrium constant  $K = k_{EET}/k_{-1}$  and that  $\Delta G^0 = -RT \ln K$ . At 298 K,  $k_{-1}$  equals  $2.1 \times 10^7 \text{ s}^{-1}$  and is thus three orders of magnitude slower. Also negligible is the formation of the  $P_{Zn}^{\bullet+}-P^{\bullet-}$  state as the rate of the singlet-singlet excitation energy transfer process is much faster than that of an electron transfer process with a driving force  $\Delta G^0 = -0.19$  eV.

The situation changes in case of dyad **B** which consists of a *meso* tris-*p*-tolyl-zinc porphyrin linked to a *meso* tris-pentafluorophenyl free base porphyrin ( $P_{Zn}-P_F$ ). Due to the

**Figure 20.** Energy diagram for the model dyad  $P_{Zn}-P$ . Adapted with permission from [128], D. Gust et al., *J. Am. Chem. Soc.* 113, 3638 (1991). © 1991, American Chemical Society.

electron-withdrawing pentafluorophenyl groups an anionic charge on the free base is in this case stabilized increasing the driving force so there is a competing electron transfer pathway to the  $P_{Zn}^{\bullet+}-P_F^{\bullet-}$  state. Figure 21 presents the energetics and interconversion pathways between the various states.

Similarly to the dyad discussed before, upon excitation at 550 nm, almost the entire fluorescence of the zinc porphyrin at 600 nm is being quenched. By time-resolved studies and global analysis of the decays at several wavelengths in the 640–725 nm region, two components were found with lifetimes of 82 ps and 2.7 ns. Again the faster component showed a decay at 650 nm, where the zinc porphyrin emits and a rise at 710 nm where only the free base is emitting. Accordingly, the fast component is due to the singlet-singlet energy transfer and the lifetime of the  $^1P_{Zn}-P$  state is 82 ps. In this case, however, a second quenching process may occur, as indicated in Figure 21 by an electron transfer process to the  $P_{Zn}^{\bullet+}-P_F^{\bullet-}$  state in an exergonic process by nearly 0.5 eV. This process could be put into evidence by recording the steady state fluorescence excitation spectra at the free base emission at 720 nm. The corrected excitation spectrum is significantly lower than the absorption spectrum of the dyad, especially for the bands due to the zinc moiety at 550 and 590 nm. Thus the energy transfer is incomplete and its quantum yield could be estimated from these spectra at about 0.77. The rate of the energy transfer process  $k_{EET}$  could be calculated from the equation  $\Phi_{EET} = \tau k_{EET}$  where  $\tau$  is the measured 82 ps lifetime. Thus  $k_{EET}$  is  $9.4 \times 10^9 \text{ s}^{-1}$ . From the energy difference between the  $^1P_{Zn}-P$  and  $P_{Zn}^{-1}P$  states of 0.16 eV, the equilibrium constant at 298 K is calculated to be 510 which makes the rate for the reverse process to the energy transfer  $1.8 \times 10^7 \text{ s}^{-1}$ . As this much slower rate can be neglected, only the three rate constants contribute to the observed lifetime of the  $^1P_{Zn}-P$  state,

$$\frac{1}{\tau} = k_{EET} + k_0 + k_{eT}$$

where  $k_0$  is the rate in the absence of any energy and electron transfer process and can be estimated as  $6.3 \times 10^8 \text{ s}^{-1}$

**Figure 21.** Energy diagram for the model dyad  $P_{Zn}-P_F$ . Adapted with permission from [128], D. Gust et al., *J. Am. Chem. Soc.* 113, 3638 (1991). © 1991, American Chemical Society.

from the fluorescence lifetime of 1.6 ns encountered in a similarly substituted zinc porphyrin without the free base acceptor. From this equation, the electron transfer rate  $k_{eT}$  can now be calculated as  $2.2 \times 10^9 \text{ s}^{-1}$  and the quantum yield  $\Phi_{eT}$  for the direct transformation of  $^1P_{Zn}-P$  into the  $P_{Zn}^{\bullet+}-P_F^{\bullet-}$  state is  $\Phi_{eT} = 82 \times 10^{-12} \times 2.2 \times 10^9 = 0.18$ .

The longer lived component of 2.7 ns which can be attributed to the decay of the free base of the  $P_{Zn}^{-1}P$  state has an appreciably shorter lifetime than the one encountered a model free base porphyrin substituted with three *meso*-pentafluorophenyl groups (8.5 ns). This lifetime shortening must be due to another quenching process, namely the electron transfer process from the  $P_{Zn}^{-1}P$  into the  $P_{Zn}^{\bullet+}-P_F^{\bullet-}$  state which according to the Figure 21 is exergonic by ca. 0.32 eV. The rate of this process,  $k'_{eT}$ , can be evaluated from the two lifetimes  $\tau$  and  $\tau_0$ ,

$$k'_{eT} = \frac{1}{\tau} - \frac{1}{\tau_0} = 2.5 \times 10^8 \text{ s}^{-1}$$

where  $\tau$  is the 2.7 ns lifetime and  $\tau_0$  is the fluorescence lifetime in the absence of electron transfer (i.e., the 8.5 ns obtained for the same model free base porphyrin). The quantum yield for this electron transfer process is  $\Phi'_{eT} = \tau k'_{eT} = 0.68$ . This example has shown how the two very related process, namely energy and electron transfer, can be distinguished by a combination of stationary and time-resolved fluorescence techniques.

Finally we turn to the analysis for the carotenodiporphyrin triad  $C-P_{Zn}-P_F$ . Also in this case the absorption spectra are a linear combination of the separate chromophoric systems indicating no electronic interactions among the different parts of the triad. The fluorescence spectra upon excitation of the Soret band at 425 nm show almost complete quenching of the zinc porphyrin fluorescence and only bands from the free base porphyrin at ca. 640 and 710 nm. Again a combination of energy and electron transfer processes could be the cause of this quenching effect. The energetic diagram and the states involved are summarized Figure 22.

From time-resolved single fluorescence by single photon timing again after global analysis of the decays, two exponential components were found having lifetimes of 62 ps and 2.9 ns. The fast component showing a decay at 650 nm and a

**Figure 22.** Energy diagram for the triad  $C-P_{Zn}-P_F$ . Adapted with permission from [128], D. Gust et al., *J. Am. Chem. Soc.* 113, 3638 (1991). © 1991, American Chemical Society.

rise where only the free base fluoresces (at ca. 710 nm) can be ascribed to the singlet–singlet energy transfer from the  $C^{-1}P_{Zn}-P_F$  state to the  $C-P_{Zn}^{-1}P_F$  state. The fluorescence decay of a model compound consisting of a carotenoid-zinc-porphyrin dyad, where no energy transfer can occur, showed a lifetime of 0.31 ns which is much shorter than the lifetime of a zinc porphyrin lacking the carotenoid. This shortening is indicative of a quenching process probably due to the formation by photoinduced electron transfer of the species  $C-P_{Zn}^{*+}-P_F^{-}$ . Following a similar reasoning as in the case of dyad **B**, the rate for the energy transfer process  $k_{EET}$  could be estimated as  $9.4 \times 10^9 \text{ s}^{-1}$  and the  $\Phi_{EET} = \tau k_{EET} = 0.58$  while the rate for the competing electron transfer process  $k_{eT}$  was found to be  $2.3 \times 10^8 \text{ s}^{-1}$  and the corresponding quantum yield for formation of the  $C-P_{Zn}^{*+}-P_F^{-}$  state by way of  $C-P_{Zn}^{-1}P_F$  was calculated to be 0.67. The same state can, however, also be accessed directly from the  $C^{-1}P_{Zn}-P_F$  and the overall quantum yield may vary with the excitation wavelength. Based on the total light absorbed at 590 nm, the quantum yield of the  $C-P_{Zn}^{*+}-P_F^{-}$  state by all paths was determined to be 0.64. From this species, by a secondary electron transfer step the long-lived charge separated state  $C^{*+}-P_{Zn}-P_F^{-}$  is formed as put into evidence by transient absorption spectroscopy where the radical cation of the carotenoid absorption could be measured at about 960 nm and having a monoexponential decay of 240 ns. The quantum yield based upon the total light absorbed at the excitation wavelength of 590 nm for this state was calculated to be 0.32. This means that 50% of the  $C-P_{Zn}^{*+}-P_F^{-}$  state indeed undergoes the secondary electron transfer to the desired long-lived charge separated state.

Calculation of the energy transfer rates by means of the Förster formula taking into account the orientation factor  $\kappa^2$ , which due to the amide linkage with variable orientations can have limiting values between 0.25 and 2.25, shows a large discrepancy to the experimentally measured rates in both dyads **A** and **B**. The measured rates are a factor of 14 faster for dyad **A** and a factor of 80 faster for dyad **B** than those predicted by the Förster mechanism for an orientation factor with random conformation. This discrepancy was attributed to the existence of another mechanism involving stronger electronic coupling, of Dexter type. That this was indeed the case could be proved by the simultaneous occurrence of photoinduced electron transfer which must proceed via electron exchange interactions. All the measured rates for the zinc porphyrin-free base systems are in the “normal” and not in the “inverted” Marcus region [16, 131]. Charge recombination occurs probably by direct electron transfer from the fluorinated porphyrin to the carotenoid and due to the large spatial separation between the charges this explains why the charge-separated state is long-lived. For applications in photovoltaic devices it is a stringent requirement that the energy rich charge-separated state produced upon photoexcitation has a long lifetime and that the unproductive charge recombination is inhibited allowing the energy to be used in further steps.

More recent work has involved elegant synthesis of covalently assembled multichromophoric arrays in the group of

Lindsey [132–137] which has also been recently reviewed [138]. Much of the synthetic effort has been possible only after extensive optimization of reaction conditions involving porphyrin syntheses [139–144], functional group manipulations, and devising of special protective groups adapted for porphyrin chemistry [145]. The photophysical studies and nanostructure design and synthesis have run in parallel to optimize light-harvesting or optoelectronic properties. Complex architectures have been rationally designed comprising Zn (or Mg) metalated porphyrins as energy donors and free base porphyrins (**Fb**) as energy acceptors. The preferred linkage between the porphyrin macrocycles was a diarylethylene group which, besides the advantage of being readily assembled, induces only a weak electronic coupling between the units. The thus assembled nanostructures have absorption and redox properties which are essentially the sum of the corresponding units, allowing a modular, bottom-up approach to the construction of complicated architectures with desired functions. The weak electronic coupling is due to the limited orbital overlap between the diarylethylene bridge with the extended porphyrin orbitals which are thus almost orthogonal. A further advantage of this linker group is its rigidity which leads to architectures with well defined geometries. Apart from slight rotation, the overall geometry remains constant allowing Förster-type calculations to be performed.

A further increase of the steric hindrance of the linker by adding *ortho*-methyl groups restricts the torsional mobility leading to slower energy transfer rates from the Zn to the FB moieties. Thus while in the unhindered dimer (**ZnFbU**)  $k_{Zn \rightarrow Fb} = 24 \text{ ps}^{-1}$ , introduction of the xyl group either in distal position to the Zn porphyrin (**ZnFbD**) or in proximal position (**ZnFbP**) leads to a slowing down by a factor of two of the  $k_{EET}$  to 45 and 48  $\text{ps}^{-1}$ , respectively. A bis-hindered linker (as in **ZnFbB**) leads to further slowing down to 88  $\text{ps}^{-1}$ . These structures are shown in Figure 23.

In the tetrameric array depicted in Figure 24, the measured energy transfer rate (26  $\text{ps}^{-1}$ ) is essentially the same as in the unhindered dimer **ZnFbU**, a fact which indicates that the same electronic communication among the porphyrin units exists. The observed rates are by a factor of up to 25 times more rapid than those predicted by the Förster equation for a pure through-space energy-transfer process. Accordingly an important through-bond contribution of electron exchange must operate in these systems. Understanding the factors controlling these rates have allowed the design of very efficient artificial light-harvesting units.

Strong influence on the frontier orbitals and thus upon  $k_{EET}$  can be achieved by either modifying the position of the linker from the *meso*- to a  $\beta$ -pyrrolic position on the porphyrin macrocycle, or by replacing the mesityl group by the electron-withdrawing group pentafluorophenyl (Fig. 25).

The pentafluorophenyl enhances the electronic communication in the  $\beta$ -position by a factor of more than 2 and at the same time causes a 10-fold attenuation in the *meso*-position. This fact was nicely explained by the switching of ordering of the  $a_{1u}/a_{2u}$  frontier orbitals and electron density distribution which changes with the position of linker attachment. Also important are whether the *meso*- or  $\beta$ -pyrrolic positions are unsubstituted. Thus, if one

**Figure 23.** Dimeric structures for studying the effects of the torsional mobility of the diarylethylene linker on the  $k_{\text{EET}}$  rates.

compares the rate  $k_{\text{Zn} \rightarrow \text{Fb}}$  of  $24 \text{ ps}^{-1}$  in **ZnFbU** with the much slower rate encountered in a similarly linked dimer but with another substitution pattern of the porphyrin, which was prepared earlier by Osuka and co-workers [146], one can see how subtle substitution differences in these compounds drastically alter their behavior.

This compound has shown a rate  $k_{\text{Zn} \rightarrow \text{Fb}}$  of  $417 \text{ ps}^{-1}$  and an lower energy transfer efficiency  $\Phi_{\text{EET}}$  of 78% although

**Figure 24.** Tetrameric array with  $k_{\text{Zn} \rightarrow \text{Fb}} = 26 \text{ ps}^{-1}$ .

**Figure 25.** Influence of the free base (**Fb**) linkage in the *meso* or  $\beta$ -pyrrolic positions on the energy transfer rate constants.

the same diphenylethyne linker is present. Due to the four flanking methyl groups in the  $\beta$ -pyrrolic positions in this case electronic communication is almost completely hindered.

The following light-harvesting array has four antenna Zn porphyrins linked to a central free base energy acceptor (Ar = 2,6-dimethoxyphenyl group). Architecturally similar to the earlier Harriman system, this second generation antenna is more efficient due to the rigidity of the linkers and of the through-bond operating Dexter mechanism.

A hexameric wheel of porphyrins consisting of alternating zinc metalated and free base porphyrins has also been prepared [136]. Due to the *meta*-phenylene linkages a somewhat slower energy transfer process is observed,  $k_{\text{Zn} \rightarrow \text{Fb}}$  of  $34 \text{ ps}^{-1}$ , than in the case of the dimeric assembly **ZnFbU** ( $k_{\text{Zn} \rightarrow \text{Fb}}$  of  $24 \text{ ps}^{-1}$ ) although the center-to-center distance is smaller. Within the completely Zn-metalated hexameric cavity, a spindle consisting of a dipyridil-substituted free base porphyrin could be complexed [147]. This host-guest complex combines the covalent approach for construction of the preorganized wheel-like guest cavity and of the spoke with a supramolecular approach using self-assembly for forming the complex.

M = 2H or Zn

In the case of *p*-phenylene linkers, due to the shorter distance, larger electronic couplings are encountered which lead to increased rates. Only  $3.5 \text{ ps}^{-1}$  are needed for the transfer rate from a trimesityl substituted zinc porphyrin to the free base linked by a *p*-phenylene bridge. If instead of the mesityl group a pentafluorophenyl group is inserted, again a slowing down to  $10 \text{ ps}^{-1}$  was encountered.

The central metal atom also affects the energy transfer rates. Within a series of diphenylethyne linked dimers the energy transfer rates decrease from **CdFbU** ( $15 \text{ ps}^{-1}$ ), to **ZnFbU** ( $24 \text{ ps}^{-1}$ ) to **MgFbU** ( $31 \text{ ps}^{-1}$ ). For the Cd derivative, the energy transfer efficiency  $\Phi_{\text{EET}}$  also drops from nearly quantitative ( $>99\%$ ) to 87% mainly due to the very short inherent lifetime ( $\sim 100 \text{ ps}$ ) of the photoexcited Cd porphyrin. Energy transfer may be effected also between a Zn porphyrin as donor and a Mg porphyrin as acceptor; in this case a  $k_{\text{Zn} \rightarrow \text{Mg}}$  of only  $9 \text{ ps}^{-1}$  was measured.

In trimeric assemblies a branching energy transfer can occur as the energy of the lowest excited singlet state of porphyrins decreases in the order  $\text{Zn} > \text{Mg} \gg \text{Fb}$ . Thus excitation of the zinc porphyrin, if it is in a central position, can lead to branched transfer both to the  $\text{Mg}^*$  or  $\text{Fb}^*$ . A second transfer step may then occur directly from  $\text{Mg}^*$  to Fb:

This modulation of the transfer rates closely mimics the one encountered in natural systems where stepwise transfers occur between different pigment pools. This versatile covalent building block bottom-up construction principle has also been used by Lindsey and co-workers to construct mixed arrays incorporating accessory pigments besides porphyrins such as boron-dipyrin [135, 148], perylene [149], and/or phthalocyanines [150]. The latter will be presented in Section 4.1.2.

In this molecule eight highly fluorescent boron-dipyrin (BDPY) antenna molecules transfer their energy to the central free base porphyrin. The blue-green BDPY absorption cumulated over eight molecules is comparable in intensity to the porphyrinic Soret band. Dual fluorescence with exponential decays with time constants of  $\sim 2$  and  $\sim 20 \text{ ps}$  were encountered and explained by the existence of two excited state conformers, which differ in the orientation of the 5-phenylethynyl ring of the BDPY units.

Gossauer and co-workers have elaborated aesthetically very pleasing architectures, such as the niphaphyrins, and have demonstrated fast and very efficient ( $>98\%$ ) intramolecular energy transfer [151–153] in the niphaphyrin **b** depicted from the Zn porphyrins to the free bases. Here again the Dexter mechanism was invoked to explain the encountered fast rates for energy transfer:

Among the covalent architectures investigated are also ones having threefold symmetry due to a 1,3,5-triethynylbenzene as the central radialene unit or even tetraedric symmetry imposed by a central tetraphenylmethane unit. By varying the number of rigid phenylethynyl units, the porphyrin units become increasingly separated. In the smaller arrays with center-to-center distances of 2.3 nm, through a careful analysis which included time resolved fluorescence studies and the anisotropy decay, it could be established that the energy transfer occurs through both Förster and Dexter mechanisms at a ratio of about 1:3 respectively. At a larger distance of ca. 3.5 nm, the Förster mechanism is less present, the ratio being 1:10. This is because of the very good through-bond communication enabled by the spacers. At still larger distances 4.7 nm as in the array to be shown, there is a drop in the Dexter mechanism and the Förster mechanism dominates, their ratio being in this case ca. 2.1:1.

Two such nanometric covalent arrays having threefold symmetry due to Gossauer are shown:

Note that introduction of the pyridine rings allows further elaboration by supramolecular interactions, as will be shown in Section 4.2.

A  $\beta_{\text{EET}}$  value of  $0.15 \text{ \AA}^{-1}$  for the attenuation factor was found by a linear regression of the logarithmic rate constants for EET versus the distance  $R_{DA}$  in several such arrays where the Dexter mechanism prevails and which shows an exponential distance dependence. As mentioned before a power  $-6$  distance dependence is encountered for the Förster mechanism. This small attenuation constant again indicates that the phenylethynyl spacers induce good through-bond communication. A much higher value for  $\beta_{\text{EET}}$  of  $1.7 \text{ \AA}^{-1}$  was reported earlier for triplet-triplet energy transfer between a donor and an acceptor separated by saturated cyclohexanediyl spacers [154]. According to Marcus and Sutin [16] the attenuation factor in the distance dependence

of electron transfer is  $\beta_{eT}$  and because actually the Dexter energy transfer process is a double electron transfer, the following relationship holds:  $\beta_{\text{EET}} \approx 2\beta_{eT}$ .

As electron transfer mediated by a variety of covalent linkers has been much more extensively studied than the energy transfer, this represents a very useful approximation to just double the  $\beta_{eT}$  values known for certain linkers and thus obtain the  $\beta_{\text{EET}}$  values. For an excellent recent review on the comparison between electron and energy transfer see [111] by Paddon-Row.

Important for the efficiency of the excitation energy transfer is also the excited state lifetime of the chromophores. Transfer between two Zn-metallated porphyrins is faster by a factor of 4 than between two free base tetraarylporphyrins. However, the efficiency is higher in the latter case due to the longer lifetime of the free base porphyrins. Ni-metallated porphyrins are not to be used in efficient antennas due to their short excited lifetime and the high energy of the singlet state which makes energy transfer both to the free base or Zn-metallated porphyrins an endergonic process by more than 0.7 eV.

Notable in the previous nanostructure is the insertion of a thiomethyl group which should allow selective attachment to gold nanoelectrodes and direct measurements of current versus voltage curves. Such studies have not been reported yet on these superb molecules, although electron conduction through thiol derivatized porphyrins synthesized by either the Lindsey or Tour group has been amply reported by Reed and co-workers [155, 156].

A very interesting orientation dependence of the energy transfer efficiency from anthracene donors to a porphyrin acceptor was recently reported by Indian chemists [157]. In the following tin-metallated porphyrin which accepts two axial oxo ligands, either hydroxy groups or the depicted 9-oxymethylene-anthracenes, energy transfer occurs only from

the anthracene group in the *meso*-position:

Thus, while the *meso*-tetratolyl-bis-anthryl compound on the left shows very low energy transfer efficiencies (<10%), due to an unfavorable Förster orientation factor  $\kappa$ , the compound on the right shows efficient fluorescence quenching of the *meso*-situated anthracene group by the porphyrin moiety. This was nicely demonstrated also by a model compound where the same anthracene-substituted porphyrin has the central tin atom ligated by only two hydroxy groups which shows almost complete (>90%) fluorescence quenching of the anthracene upon 250 nm irradiation. Further proof was that the fluorescence excitation spectra, with emissions collected at the porphyrin emission maxima, matched well the absorption spectra of the model with axial dihydroxy ligands and the compound on the right, but not the one on the left. This represented a clear demonstration that the directionality of energy transfer is critically dependent on the geometry of the system.

Japanese chemists have designed the most extended covalent porphyrinic architectures to date. Osuka and co-workers, after developing an efficient synthetic method for oxidative *meso-meso* coupling of porphyrins using  $\text{Ag}^{\text{I}}$  ions [158], could prepare orthogonal windmill-like porphyrin arrays. The metalated multiporphyrinic arms harvest energy and transmit it to an energy sink represented by the central *meso*-linked dimer which gives a characteristic split Soret band [159]. In this formula R is a *n*-hexyl solubility inducing group,  $n = 1, 2$  or 3, and  $\text{M} = \text{Ni}$  or  $\text{Zn}$ :

Similar reaction conditions were developed which allowed oligomerization of porphyrins having two free *meso* positions [160]. Using this synthetic methodology in a controlled and repetitive manner, the longest manmade nonpolymeric molecule was constructed by Osuka et al. comprising 128 consecutive *meso*-linked porphyrin units [161]. Here the nanostructures merge into the microstructure world having dimensions of over 0.1  $\mu\text{m}$ . The calculated length amounts to 106 nm (for  $n = 62$  in the formula below) if one estimates that one porphyrin unit is 0.835 nm long.

The photophysical properties of such rigid, extremely long rodlike molecules are very interesting and have been studied in detail [162, 163]. Additionally, resonance Raman studies have been undertaken when, by irradiating the sample at certain wavelengths corresponding to electronic transitions, the vibrational Raman spectrum is accumulated [164]. Rapid energy transfer due to the well defined geometry and the lack of any energy sink which could disrupt the energy flow along equivalent porphyrins make such light-harvesting arrays ideal candidates for molecular photonic wires. Due to the orthogonal orientation of the porphyrin rings, the electronic communication is largely inhibited so that each unit retains its individual character. However, exciton coupling occurs which leads to splitting of the Soret bands. The absorption spectra change systematically as the number of porphyrins increases. While the high energy Soret band remains constant (at ca. 413 nm), the low energy band of this couplet shifts batho- and hyperchromically upon increasing the number of porphyrin units indicating a progressive increase of the splitting energy. This is in agreement with the simple point dipole approximation of the exciton coupling theory developed by Kasha et al. [165, 166] although multipole interactions might give a better description. For an excellent earlier review on chlorophyll singlet excitons see [167].

In a monomeric porphyrin the two transitions  $B_x$  and  $B_y$  are degenerate but even in the simplest case of a dimer **Z2**, due to exciton coupling, the  $B_x$  transitions oriented along the long molecular axis become split with the energy  $\Delta E$  (also known as Davydov splitting [168]), while the  $B_y$  and the equivalent  $B_z$  transitions, being perpendicular, remain unperturbed as shown in Figure 26. Accordingly the Soret band becomes split having a redshifted  $B_x$  component while the  $B_y$  and  $B_z$  remain as in the monomer.  $\Delta E$  for a dimer can be calculated with the formula

$$\Delta E = \frac{\mu^2}{2\pi \epsilon_0 R^3}$$

**Figure 26.** Transitions in a monomer and *meso-meso* coupled dimeric porphyrin. Adapted with permission from [163], Y. H. Kim et al., *J. Am. Chem. Soc.* 123, 76 (2001). © 2001, American Chemical Society.

where  $\mu$  represents the transition dipole moment and  $R$  is the center-to-center distance between the chromophores.

For  $N$  interacting chromophores the following relation is valid:

$$\Delta E = E_0 \cos[\pi/(N + 1)]$$

$\Delta E$  is thus twice the energy difference between the red-shifted  $B_x$  band and the unperturbed  $B_{yz}$  peaks and can be read directly from the absorption spectra. A linear relationship was obtained for  $\Delta E$  with increasing number of porphyrins  $N$  when plotted as a function of  $\cos[\pi/(N + 1)]$  having a slope  $E_0$  of  $4250 \text{ cm}^{-1}$ . Importantly, as the length of the array increases, the absorptivity is greatly enhanced and for **Z64** extinction coefficients as high as  $10^6 \text{ M}^{-1}\text{cm}^{-1}$  were measured. The Q bands are hardly affected as the length of the array increases. As the whole visible region of the spectrum is covered these nanostructures are very efficient light harvesters.

In the arrays longer than **Z8**, exciton-exciton annihilation processes become operative as seen from the appearance of

fast decay components in time resolved fluorescence measurements by single photon timing. From the cooperative spontaneous emission, also termed as superradiance, the coherence length could be estimated. The superradiance coherent length is defined as the ratio of the radiative decay rate of the porphyrin array to that of the monomeric porphyrin **Z1** (which has a lifetime of 2.64 ns). This length reflects the degree of excitonic intermolecular coherence and for the B850 ring of LH2 (and LH1) it has been estimated to be comprise about four BChl *a* units. In the previous porphyrin arrays, 6 to 8 units were estimated to be the radiative coherence length. This increased length is probably due to the direct covalent linkage of the porphyrins which keeps a center-to-center distance of only 0.84 nm which is somewhat shorter than the separation between the magnesium atoms of the BChl *a* ligated by the LH2 polypeptides.

In an extension of this work, Tsuda and Osuka, devising a novel oxidative coupling using in conjunction scandium trifluoromethanesulfonate and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, have prepared from the above *meso-meso*-linked porphyrin oligomers, fully conjugated porphyrin tapes [169]. The dimer **Z2** cyclized in 86% yield while the tetramer below was obtained from the corresponding **Z4** tetramer in 78% yield. In contrast to the noninteracting *meso-meso*-linked porphyrins the fused porphyrin rings are fully conjugated having one of the strongest electronic interactions encountered so far which manifests itself by shifting the visible absorption maxima into the infrared region of the spectrum.

These fully conjugated porphyrin oligomers may be of use as molecular wires. Other linkages which have been shown to facilitate electronic communication between porphyrin rings were simultaneously and independently pioneered by Therien et al. [170–173] and Anderson et al. [174–179] and since then have been reviewed [180] and further developed. These include the *meso*-butadiyne-bridged porphyrin arrays which besides showing molecular wire behavior have extremely high second order polarizabilities being of use in the fabrication of nonlinear optical materials. A *meta*-phenylene linkage in a porphyrin dimer with a butadiyne bridge is, however, fully insulating but can give rise to *cis*-oid and *trans*-oid conformations which could be imaged by Sanders and co-workers using scanning tunneling microscopy (STM) [181].

A very different behavior was encountered in porphyrin oligomers with increasing lengths having 1,4-butadiynylene and 1,4-phenylene bridges between the porphyrin rings [178]. By flash-photolysis time-resolved microwave conductivity measurements it could be shown that the 1,4-phenylene type bridges lead to a singlet state  $S_1$  with a very small excess polarizability ( $<20 \text{ \AA}^3$ ) which is characteristic of a tightly bound Frenkel-type exciton. In contrast, the butadiynylene linked oligomers have very large excess polarizabilities for their  $S_1$  states which increases up to  $960 \text{ \AA}^3$ , with increasing oligomer length, a characteristic for loosely bound, Wannier–Mott type excitons. The optical absorption and fluorescence spectra also indicate strong electronic interactions in this case. However, the triplet excited state of the latter oligomers is much more localized having an excess polarizability of  $50 \text{ \AA}^3$ . In a preliminary previous study it was shown that in a similar oligomeric butadiyne-linked porphyrins with ca. 10 units, the photoinduced charge separation is long-lived having a half life of ca. 100 ns [182].

Because energy transfer and electron transfer are very related phenomena, as can be seen from the two mechanisms described earlier (see Section 2) which often operate in conjunction, and because conduction is a higher form of electron transfer some explanatory remarks may be in order here. It is interesting how mathematicians, physicists, and chemists evolve for the same phenomena completely different terminology which sometimes also hampers interdisciplinary synergistic collaborations. Chemists due to chemical formulae and systematic nomenclature have evolved a very precise archiving system of their research and thanks to modern databases can retrieve within seconds complete information on a certain molecule such as if it has been prepared before or its properties such as toxicity, melting point, color, odor, etc. Physicists, working on different problems, may come across the same phenomena and as their literature searches are done primarily by keywords, which are arbitrary, thus nonsystematic, and also nonexhaustive. Systematization of information in mathematics is even worse, and here often knowledge of related problems and solutions can be retrieved only by consulting experts in the field.<sup>2</sup>

<sup>2</sup> Henry Poincaré was known as the last universal expert in mathematics. Currently “experts” exist only in limited branches of the field. An anecdotal case of a researcher trying to solve analytically a very complicated triple integral which he could not solve numerically or find either tabulated or in the literature is by the method of Fock: He writes the problem to be solved clearly on a piece of paper and knocks at the door of Academician Fock. The next day he had the solution.

Solid-state physics has long ago elaborated the description of phenomena encountered upon photoexcitation of molecular crystals composed of chromophores. In such a multichromophoric assembly, *excitons* are formed which are neutral, electron–hole pairs. These may differ in properties, and by the way these are described (or derived), from the excited state of an individual chromophore. This is also the point where chemists and physicists sometimes start diverging in terminology due to their different backgrounds. Once charge separation has occurred, a combination of electrostatic and electron-exchange interactions with other nonspectator molecules in the vicinity may take place. If electron exchange is inhibited, due to large distances and/or noninteracting orbitals, then the interchromophoric interactions are mainly electrostatic and the exciton resides exclusively on a single molecule and thus is called tightly bound or Frenkel type [183]. Excitation energy transfer among adjacent chromophores occurs in this case by the Förster mechanism by way of collapse of the exciton on one chromophore and transfer mediated by a virtual photon to the adjacent chromophore which becomes thus a “new” exciton. For long, one-dimensional, Osuka-type **Z** oligomers or the *p*-phenylene-linked oligomers, this leads to a “photonic wire” behavior. On the contrary, for the Osuka tapes, or the butadiynylene oligomers, due to the strong electronic interaction either by direct orbital overlap or by mixing with the bridge orbitals, electron exchange occurs (i.e., a Dexter mechanism operates). In this case the electron and hole forming the exciton may become distonic and thus reside on different chromophores within the time frame of the observation. One speaks in this is the case of weakly bound electron–hole pairs or of Wannier–Mott type excitons [184, 185].

In the *p*-phenylene bridged oligomers the porphyrin units are isolated from each other, just as in the Osuka-type **Z** oligomers. Beginning with the dimer also here the Soret band shows a Davydov splitting while the Q bands are hardly affected. Upon excitation, as a negligible increase of polarizability is observed, only localized Frenkel-type excitons are formed. In contrast to the *p*-phenylene bridge, a 1,4-butadiynylene bridge mediates strongly electronic communication between the porphyrin rings. The strong orbital delocalization mediated by the bridge is seen in increased batho- and hyperchromic shifts of the Q bands as the number of porphyrin units within one oligomer increases. The singlet excited state is neutral but highly polarizable, which speaks for the formation of a loosely bound Wannier–Mott-type exciton, the correlation length being estimated as 3 to 4 porphyrin units. Within a such polymeric nanostructure with more than 10 porphyrinic units, dissociation of the exciton is expected into separate mobile charges. However, the triplet state  $T_1$  is localized on only one porphyrin unit, irrespective of the nature of the bridge linking the porphyrin units. These observations can be nicely accounted for by a relatively large contribution of a planar singlet excited state where the 1,4-butadiynylene bridge adopts a cumulenic limiting structure (Fig. 27). Such a planar limiting structure is not possible with a 1,4-phenylene bridge due to severe steric hindrance between the  $\beta$ -pyrrolic hydrogens and the *ortho*-hydrogens within a *para*-quinoid structure. According to molecular models, these hydrogen atoms

**Figure 27.** Photoinduced formation of a cumulenenic structure of the butadiynylene bridge with the + and – charges being localized on other porphyrinic rings. Solubility inducing substituents have been omitted for clarity.

would approach less than 0.5 Å in a fully planar structure which is thus energetically unacceptable. The uniqueness of the 1,4-butadiynylene bridge resides in the absence of hydrogens which would prevent planarization and thus fully delocalized molecular orbitals. We expect that a 1,4-bis-ethynylphenyl linker would also mediate efficiently electronic communication between porphyrin units attached in the *meso*-positions. Due, however, to the increased linker length and separation of the chromophores, a smaller super-radiance coherent length is in this case to be predicted. In a crystal structure of a dimer ( $n = 1$ ) the porphyrin planes are actually coplanar [176]. In solution and in more extended oligomers deviation from planarity can occur as the rotation barrier around the porphyrin-ethynyl single bonds is expected to be lower than 1 kcal/mol. For comparison, the rotation barrier in 1,2-diphenylethyne is 2.4 kJ/mol in the ground state but rises to ca. 20 kJ/mol in the singlet excited state [186].

An important aspect, often neglected, is that high solubility has to be ascertained in order to allow purification and full characterization of such nanoarrays by decorating the porphyrins with certain groups. A special such group is the 3,5-di-*tert*-butylphenyl group introduced to porphyrin chemistry initially by Crossley and Burn [187, 188] also for making extended porphyrin wires having conjugated benzo and polyazabenzofused groups. The molecular electronic properties of such fused rigid oligoporphyrin wires have also been subsequently investigated [189]. These wires have dimensions of up to 5.6 nm and thus are able to span a membrane. Due to the excellent solubility induced by the 3,5-di-*tert*-butylphenyl group this length could be doubled in only one synthetic step accessing thus molecular wires suitable for contacting with microelectrodes. We propose to name the 3,5-di-*tert*-butylphenyl group as “Crossley’s crutch” because it helps porphyrin chemists not only to solubilize extremely well complicated architectures but also to visualize these either by scanning probe microscopy techniques [190, 191] or X-ray diffraction techniques as these voluminous groups pack well into crystal structures [192]. Furthermore, selective electrophilic chemistry may be performed on the porphyrin ring leaving intact the *meso*-aryl groups due to the steric hindrance of the *t*-butyl groups

[193, 194]. Even better solubilizing groups such as the 3,5-bis(octyloxy)phenyl or 3,5-bis(isoamyloxy)phenyl have since been devised but extrapolation of the photophysical properties from one substituted porphyrin to another should be done with care. This is mainly because the rotational diffusion times become slower and also affected are the fluorescence lifetimes [163]. No crystal structures have yet been reported with such groups. The longest alkyl chains which could be appended onto a porphyrin and from which crystals suitable for X-ray analysis could be grown were two *meso*-undecyl sidechains [195]. There is a trade-off between solubility, molecular complexity, and ability to crystallize which has to be taken into account when devising porphyrinic architectures with desired properties. Apparently the *n*-hexyl sidechains, as has been systematically explored by Sanders, are a good compromise which confer enough solubility but still yield crystals which are the best way to obtain structural information on the assembly of such nanostructures.

Sakata and co-workers have not only prepared the first *meso*-tetrakis-3,5-di-*tert*-butylphenyl copper porphyrine which could be successfully imaged [190], dawning thus the era of “photogenic molecules” [196], but could also prepare a unique “Mandala-type” porphyrin array [197] having 21 porphyrin units with an impressive molecular formula of  $C_{1244}H_{1350}N_{84}Ni_{20}O_{88}$  with a molecular mass of over 20 kDa as evidenced by matrix-assisted laser ionization, time-of-flight (MALDI-TOF) and dimensions of roughly 6.5 nm which were successfully imaged by STM on a Cu(111) surface as distinct squares having a fine structure. Although photophysical studies were not performed, this would be a very interesting study if different metalated and free base porphyrins could be inserted into desired positions. This architecture can be actually considered as a dendrimer made only out of porphyrin units. Dendrimers are considered in Section 4.1.3.

Another interesting covalent nanostructure synthesized more recently in the laboratories of the same Japanese

chemists is the following tetramer with butadiyn linkages. Astonishingly, the copper mediated Glaser–Hay coupling employed in the synthesis does not lead to higher oligomers [198]. In this case in their design the authors combined the Therien–Anderson 1,3-butadiyn linkage which facilitates electronic communication with the overall geometry of the Lindsey-type tetramer having *meso*-aryl linkages:

The photophysical studies of this nice porphyrin square, which shows absorption spectra similar to the corresponding Anderson linear tetramers [176], although announced as being under investigation, have not yet been reported.

A thorough investigation of the intramolecular energy transfer in bisporphyrins has shown a sixfold increase in the transfer rate in the case of a *cis*-phenantroline bridge (which leads to 1.3 nm center-to-center distance) compared to an  $\alpha$ - $\alpha$ -bipyridine bridge (2.3 nm) [199]:

For the bipyridine linker, also a folded *syn*-conformer is present to about 30% due to the unrestricted rotation around the 2,2'-bipyridyl single bond. In this conformer as well as in the phenantroline case a pure Förster mechanism cannot account for the observed energy transfer rates and this is explained by the large size of the porphyrins which have comparable dimensions to their center-to-center separation, and thus considerable exchange (Dexter-type) interactions may occur. Very interesting in these or similar systems would be to be able to switch between conformers and thus between the energy transfer mechanisms by using, for example, weakly complexing metal ions to the bipyridine.

In conclusion of this section describing covalent nanostructures encompassing porphyrins devised for studying energy transfer, the study of Vollmer et al. deserves mention [200]. In this study, a molecular photonic wire having a porphyrin core and four pentathiophene arms terminated by anthryl groups has been synthesized in a multistep sequence. Different chromophores have thus been linked by the pentathiophene bridge which mediates efficiently electronic communication. Singlet–singlet energy transfer occurs upon selective excitation of the four anthracene donors within less than 10 ps, the resolution time of the experimental setup. However, no clear-cut mechanistic conclusions could be drawn in this particular case, due probably to a mixing of Dexter and Förster contributions to the energy transfer rate. Replacement by saturated spacer molecules, which interrupt the conjugation of the oligothiophene bridges, but keep the same overall geometry, could shed light upon this problem.

#### 4.1.2. Phthalocyanine-Based Nanostructures

Phthalocyanines (Pc's) are extremely robust chromophores having applications as industrial dyes and pigments. Their stability and high absorption coefficients in the visible region make them better candidates for light-harvesting purposes than porphyrins. However much fewer studies have been performed with Pc's due to two main synthetical difficulties which have to be circumvented. The first difficulty is related

to a much lower solubility in organic solvents which is associated with the need for tailored substituents in order to allow chemical reactions and chromatographic purifications to be performed for accessing nanostructures. The second obstacle is due to the complex isomeric mixtures which are usually obtained for substituted Pc's. For example, a tetrasubstituted phthalocyanine can have the following four isomers if only one substituent is present in each benzoannulated pyrrole ring, as is the case when a metal templated reaction is used for Pc formation:

The percentages show the statistical expectation with which the isomers, indicated by their symmetry group, should be formed assuming thermodynamic control of the reaction and similar energies. Significant deviations from the expected ratio have been observed depending also on the templating metal atom or the precursor used for the tetracondensation. This is usually a phthalodinitrile or synthetic equivalent such as the diamide, anhydride, or diiminoisoindoline. In many cases further elaboration of functional nanostructures has been performed without isomer separation, a fact which leads also to inhomogeneous photophysical properties. Sometimes very different physical and chemical behaviors are encountered between these regioisomers. Recently, we could show that for tetrasulfonated Pc's ( $R = SO_3^-$ ) isomer specific rates are encountered for the loss of an electron from the tetra-anions in the gas phase [201]. Also the self-assembly properties of these isomers differ. The alternative to working with inhomogeneous preparations, thus exhibiting properties which are hard to quantify, is of course to symmetrize the Pc's with identical disubstituted benzoannulated pyrrole rings.

The first covalently linked nanostructures with several Pc's were synthesized by Leznoff and co-workers, of which two examples, a tetranuclear [202] and a pentanuclear array [203–205], are presented here:

In these cases, due to the nonconjugated linkers, no electronic communication occurs between the Pc macrocycles.

Several light-harvesting pentads having a phthalocyanine core and porphyrins as antennas were prepared by Lindsey and co-workers and the photophysical properties were investigated by Bocian and Holten [150]:

Various metals, such as Mg or Zn, or the free bases could be selectively inserted in the pentads which were actually mixtures of the four isomers described. Rapid energy transfer occurs from the porphyrins to the Pc. Excitation of the free base porphyrins at 515 nm leads to emission exclusively from the phthalocyanine with high quantum yields. The energy transfer is very fast (time constant of ca. 1 ps) and quantitative for the free base and zinc metallated pentads. In the case of the magnesium pentads, due to the matching energy levels, some competing electron transfer occurs from the excited porphyrins. Furthermore absorption over a very wide wavelength range (from 400 to 750 nm) together with good electronic communication mediated by the phenylethynyl groups makes these star-shaped arrays excellent light-harvesting nanostructures. The complex kinetic behavior observed might also be due to slightly different behavior among the isomers.

An even more impressive covalent nanostructure having eight porphyrin units tightly coupled to a central

phthalocyanine was synthesized by Li and Lindsey [206]:

This nonamer also absorbs light across the solar spectrum and exhibits rapid and efficient energy transfer from the porphyrins to the Pc.

In an extension of these two studies, a strongly coupled linear array comprising a perylene unit a bis-porphyrin and a Pc light trap has been synthesized and investigated for rapid energy funneling [207]:

By selective excitation of the perylene unit (at 490 nm) exclusively fluorescence from the Pc is observed, with a high quantum yield ( $\Phi_f = 0.78$ ). A rapid energy cascade occurs from the perylene via the two porphyrins and finally to the Pc whose excited state is formed with time constants of 2 (90% of the amplitude) and 13 ps (10%). This energy transfer “wire” is superior to the ones based exclusively on porphyrins, being 5 to 10 times faster than the single step energy transfer from a zinc porphyrin to a free base porphyrin covalently linked in the *meso*-positions by a bis-(*p*-phenylene)ethyne linker.

Different linkers which mediate electronic communication between Pc's, synthesized also with push-pull substituents in view of applications for nonlinear optical materials, have been elaborated by Maya et al. [208–209]:

Somewhat weaker electronic communication than in these cases with ethynyl ( $n = 1$ ) and buta-1,3-diyndiyl-bridge ( $n = 2$ ) are encountered with these mono and bis-(*E*)-1,2-diethynylethene-(*E*)-hex-3-ene-1,5-diyne-bridges:

The increase in conjugation does not lead to significant changes in the ground state absorption spectra. This might be due either to reaching the limit of the conjugation length or to slight deviations from planarity of the sterically encumbered tetrasubstituted *E*-double bonds.

An excellent review on the ground and excited state optical properties of Pc's linked to porphyrins and porphyrazines was written by Tran-Thi [210].

#### 4.1.3. Dendrimers

Dendrimers are an elegant approach for obtaining covalent nanostructures using repetitively the same reaction sequences enabling transformation from one generation ( $G_n$ ) to the next ( $G_{n+1}$ ).

Porphyrinic dendrimers have been synthesized in several groups. Thus Norsten and Branda have obtained in relatively good yield (48% after purification by column chromatography) the following first generation ( $G_1$ ) dendrimer [211]:

The synthetic strategy involved conversion of the 4-carbomethoxyphenyl groups first by  $\text{LiAlH}_4$  reduction into the benzylic alcohol, then into the corresponding chloromethyl derivative which was afterwards used to append four other porphyrins by ether linkages. The resulting pentaporphyrin has now 12 carbomethoxy groups which can be similarly elaborated to a second generation porphyrinic dendron, as the ether linkages should be stable to all reaction conditions involved. Apparently, the absorption spectrum indicates no ground state interaction between the porphyrin rings, being the sum of the individual components. Remarkable is also the relatively high solubility in solvents such as dichloromethane and chloroform of the free base derivative and in tetrahydrofuran of the pentazinc metalated dendrimer.

A different, more convergent approach was followed in the Sanders group for preparing a nonmetalated zinc porphyrinic dendron with folding arms. Pd-mediated coupling of phenylacetylenic groups appended into the *meso*-position of porphyrins allowed construction of the sidearms as well as coupling of the central porphyrin to a 5-iodoisophthalic acid moiety. Esterification under mild Mitsunobu conditions provides a wedge having four porphyrin units linked upon the iodobenzene derivative which in the final step connects two wedges via the central porphyrin. The yields of the sequence are remarkably high (about 78% per coupling step) and involve no protection/deprotection steps. By MALDI-TOF mass spectrometry the correct molecular ion for  $\text{C}_{660}\text{H}_{804}\text{N}_{36}\text{O}_{16}\text{Zn}_9$  nanostructure was encountered at 10,087 Da. The folding arms were used to bind DABCO molecules, a fact which could be followed by visible absorption changes in the Soret band which becomes redshifted, and an exciton coupling between two DABCO linked porphyrins becomes visible. It is thus possible to modulate the physical and photophysical properties such as viscosity, solubility, or excited state lifetimes through complexation with a bidentate ligand which affects profoundly the conformation of this dendrimer.

Earlier studies by Fréchet and co-workers have shown that indeed the absorption and emission are profoundly affected by encapsulation within third or fourth generation poly(benzylether) dendrimers [212]. Using a *p*-nitroaniline core as solvatochromic probe, when nonpolar solvents such

as carbon tetrachloride or toluene are used, a strong bathochromic shift occurs in the higher generation dendrimers when solvent access at the core is prevented. The core's local polarity corresponds to that of highly polar solvents such as dimethylformamide. Similar abrupt shifts in the fluorescence emission were found in phenylacetylene dendrimers synthesized by Moore and co-workers upon passing from the fourth to the fifth generation [213]. An energy gradient can be formed due to a special arrangement of the linear phenylacetylenic chains [214, 215]. More recently Melinger et al. have studied the photophysics of such phenylacetylene dendrons with unsymmetrical branching having a perylene trap [216].

Symmetrical branched dendrimer.

Symmetrical branched dendrimer with extended phenylacetylenic arms [349].

### Unsymmetrical branched dendrimer.

Without the perylene trap the higher generation dendrons have large molar extinction coefficients ( $>10^5 \text{ M}^{-1}\text{cm}^{-1}$ ) and exhibit high fluorescence quantum yields (65–81%). With the perylene trap rapid energy transfer occurs with over 90% efficiency. While the symmetrical branched dendrons depicted have *meta*-phenylene linkages which do not allow extended conjugation, the *ortho*- and *para*-phenylene linkages permit the delocalization of electrons through the contribution of *ortho*- and respectively *para*-quinoid limiting structures. This is manifested by a large bathochromic shift (ca. 50 nm) of the absorption maxima of the perylene trap as well as of the phenylacetylenic backbone.

Dendritic architectures having an anthracene core, phenylacetylene scaffolding, and triphenylamine as terminating antenna groups, which are also effective hole transporters, have been assembled into an electroluminescent device [217] of organic light emitting diode type. Although the phenylacetylenic backbone was efficient in mediating the energy transfer, the device performance was limited by self-quenching effects due to aggregation on the solid support. Better performances were achieved in modular devices with dendrimers having a coumarin or pentatiophene cores which also allow color tuning [218, 219].

Jiang and Aida have prepared a poly(benzylether) dendrimer attached to a porphyrin core [220]. Only a limited amount of overlap occurred between the fluorescence of the dendritic arms and the Soret absorption of the porphyrin core allowing some energy transfer to be observed upon excitation in the UV region (280 nm). The transfer efficiency was quite high ( $\sim 80\%$ ) only in the tetrasubstituted fourth and fifth generation dendrimers ( $G_4$  and  $G_5$ ). If, instead of a *meso*-tetraakis-substituted porphyrin only three, two, or one dendritic arms were present, due to the increased mobility and conformational freedom,  $\Phi_{\text{EET}}$  dropped to 32, 20, and 10% respectively.

If instead of the poly(benzyl ether) dendrons triphenylene-type dendrimers are attached to the porphyrin core, due to the better spectral overlap, higher efficiencies were encountered even in lower generations of dendrimers [221]. One problem associated with the dendrimer architecture is that energy collected at the periphery is transferred to the interior and thus it is not available for further use such as charge separation, as in natural light-harvesting nanostructures. However, a spectacular application was shown earlier by Jiang and Aida where instead of the porphyrinic core, an azobenzene core was used which could be isomerized from *cis* to *trans* upon irradiation [222]. An unusual rate acceleration by two orders of magnitude was observed only in the high generation poly(benzyl ether) dendrimers upon irradiation with low flux infrared (IR) frequencies matching the vibration mode of the aromatic rings ( $\sim 1600 \text{ cm}^{-1}$ ). This result was interpreted that the dendritic shell insulates the azobenzene core from collisional deactivation and that at the same time it acts as a IR photon antenna.

A similar *meso*-tetraarylporphyrinic core was very recently incorporated into a glycodendrimer by Stoddart and co-workers [223]. Either peracetylated, perbenzoylated, or hydrolyzed sugar units were used. As expected the glycodendrons do not show any electronic interaction with the porphyrin core. When exciting at 230 nm in the case of benzoate substituted dendrimer, complete quenching of the porphyrin emission was observed. This was explained by the absence of an energy transfer from the benzoate groups to the porphyrin core and by either a very fast radiationless deactivation or by an electron transfer process which quenches the luminescence. Also in this case dual fluorescence behavior was observed with two lifetimes, one shorter than the usual porphyrin decay which was attributed to the existence of multiple conformations in solution due to the bulky  $\beta$ -D-glycopyranoside units.

Suslik and co-workers have prepared several polyphenyl ester dendrimers with a *meso*-tetraarylporphyrin core and have studied the binding of various nitrogen ligands to the central zinc atom [224]. A certain shape selectivity of the binding constants was observed but no photophysical measurements were performed in that study.

Diederich and collaborators were among the first to have synthesized water soluble dendrimers having a porphyrin core and have studied their spectroelectrochemistry [225].

Very recently, by STM investigations, single physisorbed dendrimers having a porphyrinic core could be imaged [226].

Several phthalocyanine dendrimers were also synthesized. As shown in the previous section, the existence of multiple isomers must be considered in cases where the macrocycle periphery is functionalized by different groups. Only one example is given here where the usual phthalocyanine aggregation by  $\pi$ - $\pi$  stacking was prevented by encapsulation within an ether-amide dendrimer [227]. The phthalocyanine dendrimers have been much less employed in energy transfer studies, although the favorable optical properties

and the high stability of phthalocyanines should make these excellent candidates for applications.

Fréchet and co-workers have synthesized a large number of dendrimers encapsulating different chromophores and have studied the energy transfer processes encountered therein [228]. Some of this work has also been reviewed [229, 230].

Laser dyes based on 7-aminocoumarin were appended into Fréchet-type [poly(arylether)] dendrimers. The julolidine coumarin C<sub>343</sub> was inserted at the dendritic core by esterifying the 3 carboxy group while the periphery at each successive generation was functionalized with the 7-aminoethylcoumarin C<sub>2</sub> by alkylation of the NH group with benzylic halides. The formula presents the third generation G<sub>3</sub> dendrimer. Energy transfer from the C<sub>2</sub> donors absorbing at 310–380 nm and the C<sub>343</sub> acceptor absorbing between 400 and 480 nm is almost quantitative in the lower generations G<sub>1</sub>–G<sub>3</sub> and decreases slightly for the fourth generation to 93%. No ground state interactions were observed in the dendrons, the absorption spectra being the sum of the individual chromophores, and the poly(aryl ether) backbone is transparent in the 300–500 nm region. Due to a perfect overlap between the emission of the donor C<sub>2</sub> and the absorption of the C<sub>343</sub> the Förster mechanism was expected to operate. Calculations of the average distances between donor and acceptor, based on multiple conformations, gave 1.4 nm for the G<sub>3</sub> and 1.8 nm for the G<sub>4</sub>

dendrons. The observed energy transfer rates  $k_{\text{EET}}$  were  $2.0 \times 10^{10} \text{ s}^{-1}$  for  $G_4$ , somewhat slower than the theoretically expected Förster rate ( $5.3 \times 10^{10} \text{ s}^{-1}$ ). For  $G_3$ , the theoretical rate was  $19.9 \times 10^{10} \text{ s}^{-1}$  reflecting the power six distance dependence. The measured rate for the smaller dendrimers  $G_1$ – $G_3$  was faster than the instrument response so only a lower value could be given. An important aspect is that “energy hopping” from one donor  $C_2$  molecule to another apparently does not occur in this case due to the large Stokes shift which makes the donor–donor overlap integral two orders of magnitude smaller than the donor–acceptor one.

Films cast from these dendrimers have just been investigated by photoluminescence scanning near-field optical microscopy (PL SNOM) and formation of redshifted excimers could be put into evidence for the  $G_1$ – $G_3$  dendrimers [231]. The spatially resolved PL SNOM images of the red edge emission show pronounced nanoscopic domains in  $G_1$ , which due to site isolation of the luminescent core chromophore  $C_{343}$  become more homogeneous in  $G_2$  and  $G_3$ . In  $G_4$  the site isolation in this light-harvesting dendrimer film is fully accomplished.

Design principles learned from these studies were recently put to use in preparing a UV to near-IR frequency converter based on fluorescence resonance energy transfer [232]. In this study a first generation dendrimer with four  $C_2$  coumarine dyes was prepared with a perylene core in 31% yield based on the commercial starting material 3,4,9,10-perylenetetracarboxylic acid dianhydride.

Upon excitation of the donor  $C_2$  coumarine at 345 nm, the donor emission was completely quenched indicating over 99% energy transfer to the perylene core. Simultaneously an increase of emission from the core in the 720–800 nm NIR region was observed in comparison to the model perylene compound lacking  $C_2$  donors. This amplification has sometimes been termed the “antenna effect,” a fact which may cause confusion. Rather, due to the increased number of chromophores at the periphery of the dendrimer, the photon capture cross section is correspondingly increased. Due to the efficient energy transfer, emission from the

core is enhanced in comparison with the case when direct excitation of the core is performed. Similarly, in the natural systems, where several energy transfer steps occur, a funnelling of the energy to the reaction center takes place (see Section 1).

Moving toward applications, Fréchet and co-workers have prepared dendrimers having coumarine chromophores as antennas and groups suitable for formation of self-assembled monolayers on silicon wafers [233].

Mixed monolayers encompassing coumarine  $C_2$  as donors and the julolidine derived coumarine  $C_{343}$  as energy acceptors were prepared which showed photophysical properties dependent on the molar ratio of donors and acceptors as well as on the nature of the dendritic architecture.

Campagna et al. have extended the elegant studies of electron and energy transfer in metal complexes also to the nanoscale size by investigating various dendrimeric nanostructures. If in a ruthenium tris-bipyridine complex one of the pyridine rings is replaced by a 1,4-pyrazine, this can function as a ligand to two ruthenium centers and thus acts as branching point in a dendrimer which can be constructed in a controlled manner, either in a “complexes-as-metals” or “complexes-as-ligands” fashion [234]. The luminescence originates from the MLCT (metal-to-ligand-charge-transfer) band which is the excited state with the lowest energy. An important feature is that the energy gradient is in this case reversed; the innermost chromophores are higher in energy and act as antennas for the peripheral complexes which are lower in energy.

In collaboration with Vögtle, the Bologna photophysics school of Balzani has studied various other dendrimers [235, 236]. In dendrimers having poly(ether-amide) or poly(benzylether) linkers and a tris(bipyridine) ruthenium core, when full encapsulation is achieved in the higher dendrimer generations, the fluorescence quantum yields as well as the excited-state lifetimes are considerably increased in aerated solutions. This was explained by the low diffusion rates and solubility of oxygen molecules which quench the triplet states. The longer lifetime and bathochromically shifted emission (by 30 nm) in the poly(ether-amide) dendrimers compared to the poly(benzylether) ones is due to the better stabilization of the MLCT excited state by the more polar former dendrimers. In a very recent and important study,

a cascade of energy transfer steps was engineered in the dendritic architecture shown [237].

Three different chromophores were hierarchically mounted on a polyamine core: (i) 8 dansyl (5-dimethylamino-1-naphthalenesulfonyl) units, (ii) 24 3,5-dimethoxybenzene units, and (iii) 32 naphthalene units at the periphery. The chromophores do not interact electronically with each other as judged by their unshifted absorption spectra in comparison with the isolated chromophores. Upon excitation of the naphthalenes, enhanced fluorescence from the dansyl units is detected. Interestingly this fluorescence can be effectively quenched upon addition of a fourth chromophore, which is still further redshifted, namely eosin, together with [18]crown-6 used for solubilizing this anionic dye in dichloromethane, the solvent used for the photophysical measurements. This effect could be explained by encapsulation of eosin as guest molecules (presumably in their monoprotonated forms) within the dendritic polyamine host. Thus eosin can be extracted from an aqueous phase by a dichloromethane solution of the depicted dendrimer. After extraction, the dansyl fluorescence is quenched which indicates that eosin is efficiently encapsulated within the dendrimer. It is likely that it is positioned within the polyamine core by an acid–base type of interaction, as poly(benzylether) dendrimers containing naphthalene units do not bind eosin. Proof that the fluorescence quenching is indeed due to energy transfer was provided by recording the excitation spectrum (at the wavelength corresponding to the eosin maximum) which closely matched the absorption spectrum of the host

dendrimer indicating that all three chromophores (i)–(iii) contribute to supplying light energy to the eosin trap. As the fluorescence lifetime of the dansyl groups is 16 ns, the rate constant for its quenching by eosin must be over  $1.2 \times 10^9 \text{ s}^{-1}$  which is in very good agreement with the value obtained by calculation of a Förster-type energy transfer with a reasonable separation of 1 nm between donors and the eosin acceptors. Because two exponential decays of the eosin fluorescence were observed, even at very low eosin concentration, it was concluded that this trap molecule can occupy two “substantially different” sites within the dendrimer.

A very thorough investigation of light-harvesting dendrimers synthesized by Müllen and co-workers has been made [238, 239] by single molecule fluorescence spectroscopy. The following second generation pentaphenyl derived dendrimer having eight perylenedicarboximide (PMI) chromophores either in the positions indicated by R or by (R) has been studied:

Collective on/off jumps of the fluorescence intensity were observed for single dendrimer molecules, a fact which was also encountered during the observation of single natural light-harvesting antenna systems LH2 [240, 241]. Thus, although the system contains eight chromophores it behaves like a single emitting quantum system. Due to folding of the branches, two chromophores can become closely spaced giving rise to a dimerlike entity. This has different optical properties, such as emission wavelength and lifetime, than an isolated monomeric dye at the dendron’s periphery.

More recently, a tour de force regarding the synthesis of a more elaborate polyphenylene architecture encompassing three different chromophores which enable a vectorial energy transfer has been realized by Müllen and co-workers [242]. The dendritic nanostructure (shown in Fig. 28) has at its core a single terrylene tetracarboxydiimide (TDI) chromophore which absorbs at ca. 650 nm and emits at ca. 700 nm. An inner shell is composed of four perylenedicarboximide (PMI) with two absorption maxima at ca. 490 and 520 nm. Its emission peaks at 550 nm but has a

**Figure 28.** Shape persistent vectorial energy transfer dendrimer of Weil et al. [242]. The central TDI chromophore is presented in green, the four intermediate PMI chromophores are red, and the eight outer antenna NMI pigments are yellow, while the pentaphenyl linkers, which confer rigidity and prevent a collapse of the dendritic arms, are presented in black.

redshifted tail which overlaps with a blueshifted shoulder of the TDI absorption band. Finally, an outer shell amounting to eight naphthalene dicarboxmonoimide (NMI) consists of the main light-harvesting unit absorbing below 400 nm and which emits at about 400 nm. Again the tail of this emission band overlaps with the blue wing of the PMI absorption, making this system one of the best optimized so far.

The PMI chromophore can be viewed as a pericondensed naphthaleno homolog of NMI. Similarly, extension of the chromophoric system by one perinaphthaleno unit and another dicarboxmonoimide transforms the PMI into the central energy trap TDI. An important aspect is that the Förster energy transfer, for which a radius  $R_0 = 6$  nm has been calculated from the overlap of the PMI fluorescence and TDI absorption, occurs sequentially (i.e., stepwise from NMI to PMI and only afterwards to the energy trap TDI) just as in the natural systems. No transfer can occur directly from the outer antenna NMI to the trap due to the zero spectral overlap. By exciting the NMI periphery, a strong fluorescence from the TDI trap is detected which is about threefold more intense than if irradiating directly in the TDI absorption. Similarly, by exciting the intermediate PMI chromophores, only a slightly reduced fluorescence intensity is emitted from the TDI trap as compared to the case when the outer NMI antenna is irradiated at its absorption maximum. Our interpretation of these results is that there is no “amplification effect” of fluorescence intensity. Rather, the increased number of antenna chromophores have a larger cross section for capturing photons than only one central TDI trap. Through the four intermediate PMI chromophores, the excitation is efficiently

transferred to the trap from any excited NMI molecule which leads to about the threefold increase in fluorescence observed from the trap compared to the case when exciting directly the trap. The pentaphenyl linkers are instrumental in maintaining the separation between the pigments so that no aggregation, excimer formation, and self-quenching effects occur. These findings allow an optimization of multichromophoric assemblies for photonic devices. Their high thermal and temporal stability make them suitable candidates for solar-cell applications. However, we are skeptical that it would be easily feasible to trigger artificial reaction centers in the inner core of a dendritic architecture. To be able to use the thus created chemical potential, access of reactant species should be possible; otherwise, charge recombination and thermal deactivation are the most likely processes to occur. Very recently nanotubes were synthesized by an elegant cross-linking of dendrimeric porphyrins [350].

## 4.2. Supramolecular Assemblies

The alternative way of constructing multichromophoric arrays with light-harvesting properties is to use noncovalent interactions by applying the principles of supramolecular chemistry [24]. The major advantage is that instead of constructing the nanostructures in a bond-by-bond manner, employing only weak interactions one can access large functional architectures in a tecton-by-tecton manner. The disadvantage is that a strict control of the assembly process has to be assured in order not to have large dispersions in size (i.e., nonunique nanostructures). Besides ligation of metal ions, which is also the strongest supramolecular interaction, hydrogen bonding,  $\pi$ - $\pi$  interactions, as well as hydrophobic or dispersive forces may be used for constructing supramolecular assemblies. Some excellent reviews by Lawrence et al. [243] and Stoddart and co-workers are available [244–247]. A visionary survey of this field is to be found in [248]. A shorter but useful review dealing with electron and energy transfer in supramolecular systems is due to Ward [249]. Special emphasis on the photophysics for driving molecular machines is to be found in [250, 251].

An early photophysical study on the effects of complexation of cations such as  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cu}^{2+}$ ,  $\text{Ni}^{2+}$ , and  $\text{Eu}^{3+}$  into the voids of benzocrown ethers attached to the *meso*-position of metalated terta-arylporphyrins (the central metal being Zn, Mn, or Sn) has shown a pronounced luminescence dependency on the nature of the cation [252]. When  $\text{Eu}^{3+}$  was complexed, an intramolecular electron transfer takes place from the excited triplet state of the porphyrin. The reverse electron transfer was found to be diffusion controlled and a bimolecular process. An interesting zinc porphyrin host molecule, comprising two [18]- $\text{N}_2\text{O}_4$  macrocycles preorganized by a biphenylene strap, underwent intense fluorescence quenching upon addition of silver triflate [253]. As potassium triflate had no effect on the fluorescence of the host, and low concentrations of silver triflate also do not quench the fluorescence of a normal zinc porphyrin such as zinc-octaethylporphyrin, it could be unambiguously proved that the observed effect is due to an intramolecular electron transfer process involving the

complexed  $\text{Ag}^+$  ions by the crown macrocycles:

From titration experiments it was concluded that an average of about 2.6 silver ions were bound per molecule. Upon irradiation of the silver complex, the singlet excited state has a main deactivation pathway, which explains the observed quenching of the fluorescence, by forming a charge separate state which was long-lived. The charge recombination is retarded probably by the displacement or even dissociation of the  $\text{Ag}^+$  ions and it involves thus a large reorganization energy.

These two examples show that one of the simplest supramolecular interactions, such as metal ion chelation, can lead to drastic changes in luminescence behavior. Using these interactions in the assembly of functional light-harvesting nanostructures has to be done with caution as the energy transfer processes may become secondary. Additionally, if heavy metal atoms which also have rich coordination chemistry are employed, fluorescence quantum yields may drop by orders of magnitude due to the heavy-atom effect [254].

A pioneering series of synthetic, physical, and photochemical studies involving cyclodextrins chemically modified by attaching covalently on their periphery several chromophore molecules and which can additionally form within their hydrophobic cavity inclusion complexes with different dye molecules, which can thus act as energy traps, have been performed by the research groups of Jean-Marie Lehn and Bernard Valeur [255–259]. In view of the circular nature of the arrangement of the “antenna” chromophores imposed by the  $\beta$ -cyclodextrin scaffold composed of seven D-(+)-glucopyranose units, there is an obvious resemblance to the natural LH1, LH2, and LH3 purple bacterial complexes. It is worth mentioning that these circular, smaller, synthetic nanostructures have been studied well before the first structural data became available on the natural complexes and both the energy hopping and trapping mechanisms appear to be very similar.

At left, is depicted the formula of the  $\beta$ -cyclodextrin to which seven naphthyl chromophores have been covalently linked. At right is presented the laser dye molecule DCM-OH, a 2-sytryl-derivative of a 4-(dicyanomethylene)-4H-pyran which can be tightly bound within the cone shaped cavity formed by the seven glucose units. The definition introduced in these studies, “an enhancement of light sensitivity due to an increase of the overall cross section for light absorption is called the ‘antenna effect’,” is the one which has been generally adopted. By “light sensitivity” it is meant that the reaction center traps more efficiently and rapidly photons as in the case when it is itself directly excited. With 7 or 14 naphthyl (or the more polar naphthoate) chromophores fast energy hopping occurs which is directed toward the “red,” lower energy chromophores. As the geometry is not fixed, various orientations of the naphthyl residues and accidental  $\pi$ -stacking which may lead to the formation of red-shifted dimers (or excimers) can occur. In the case when a guest molecule is present, good spectral overlap between the naphthoate emission and the DCM-OH absorption lead to an efficient energy transfer, as confirmed by the fluorescence quenching of the naphthyl emission upon titrating increasing amounts of the dye to the cyclodextrin host in buffered aqueous solution at pH 10 containing 5% (v/v) ethanol. Simultaneously increased fluorescence is emitted from the dye molecule at about 610 nm. A Job plot, at two different excitation wavelengths, confirmed efficient complexation with a 1:1 stoichiometry of the dye guest molecule. By carefully correcting the amount of light directly absorbed by the dye, the authors could conclude that the quantum yield of complexed DCM-OH molecules is much higher than that of buffered solvated molecules and that the efficiency of the energy transfer must be very close to 1 (i.e., nearly quantitative). By time resolved experiments, it could be shown that energy transfer must be fast, well under 45 ps, the time resolution of the apparatus. Further thermodynamic characterization of the complex has demonstrated that the association constant is one of the largest ever measured for a  $\beta$ -cyclodextrin derivative ( $\log K = 5.1$ ) and that there is a large entropic contribution (ca. 70%) to the free energy of

complexation. Only a small part of the dye molecules is laterally complexed as concluded by comparison with unsubstituted  $\beta$ -cyclodextrin which should laterally complex equally well. Complexation by inclusion within the heptanaphthoate cyclodextrin is much more favorable due to  $\pi$ - $\pi$  interactions with the naphthyl groups. Assuming a random orientation of the naphthyl chromophores and thus an average orientation factor  $\kappa$  of 0.67, rates of  $1.8 \times 10^{12}$  to  $2.8 \times 10^{10} \text{ s}^{-1}$  could be calculated with the Förster formula for the energy transfer. These are well within the measured order of magnitudes, especially if one takes into account the formation of excimers which have broader and more redshifted spectra with increased overlap with the DCM absorption which thus account for faster energy transfer than from isolated monomers. Another important aspect of these studies was that apparently once a naphthoate chromophore is excited, it transfers the excitation energy directly to the entrapped dye molecule. Because of the Stokes shift, the energy hopping between adjacent equivalent chromophores, which could be put into evidence in the absence of guest molecules, is much less favorable than the energy trapping. In the words of the authors "heterotransfer" of energy is faster than the "homotransfer." The same phenomenon is encountered in the natural antenna systems coupled to reaction centers.

#### 4.2.1. Multiporphyrinic Arrays

Various research groups have been involved in building supramolecular architectures with porphyrinic tectons. Again the advantages of the well combed porphyrin chemistry [260] such as versatile synthetic methods and attractive photophysical properties have been put to use. These nanostructures can be classified by the type of the strongest supramolecular interaction which is used to self-assemble the tectons. We will differentiate between metal complexes and exclusively hydrogen-bonded assemblies. Only short reviews have appeared on this topic, describing mainly some of the work carried out in the groups of the respective authors [261].

##### Assembly of Porphyrinic Nanostructures Using Metal Ligation

The rich coordination chemistry of metal ions has made possible the tailored construction, by means of self-assembly, of various aesthetically pleasing multiporphyrinic architectures. However, as mentioned, for artificial light-harvesting purposes only special metal atoms which do not quench the assembly's fluorescence can be used. Only a few selected examples can be presented here.

Some early nanostructures where palladium atoms were used to stitch together *meso*-4-pyridyl substituted porphyrins are due to Drain and Lehn [262]. By using the ability of 4-pyridyl groups to form linear complexes using *trans*-dichloropalladium(II) but kinked complexes when using *cis*-dichloroplatinum(II) discrete assemblies can be formed. Dimers and the following tetramers (or "squares" as the authors name them), either as porphyrin free bases or as zinc complexes, could be prepared. Heating to 50 °C for 48 hr leads to preferential formation of the squares while other oligomeric species are disassembled.

The control of the architecture is assured by the *cis* or *trans* heavy metal bis(benzonitrile) dichloride square planar

precursor and by having either adjacent or "vicinal" *meso*-4-pyridyl groups (i.e., in positions 5,10) or what we call "distal" positions (i.e., 5,15) of the porphyrin macrocycle. In the jargon of porphyrin chemists these disubstituted *meso* positions are sometimes incorrectly referred as *cis* and *trans*, respectively. Notable is the fact that although the overall size and architecture of the porphyrin squares depicted are similar, in the first case the "heavy" Pd atoms which stitch the porphyrins are situated on the square edges while the Pt atoms act as corners. Photophysical measurements have shown that the Soret absorption bands are broadened in the dimers and even more in the tetramers while the heavy atom effect was responsible for the observed fluorescence quenching, in comparison to the monomeric porphyrins. Formation of polymeric species was observed by mixing in a 1:1 ratio the distal and the vicinal bis-*meso*-4-pyridyl porphyrins isomers with *trans*-Pd(NCPh)<sub>2</sub>Cl<sub>2</sub>. The excitation spectra of this species was completely depolarized, in contrast to that of the corresponding dimers or tetramers. It would be interesting to investigate whether modern microscopy techniques can distinguish between the two photogenic squares shown.

In later independent studies Drain et al. extended this concept to access in a controlled manner various architectures. The self-assembly process is dictated by the stoichiometry of the tectons and thus an oligomeric nanostructure is obtained by controlling the amount of different porphyrins and either palladium or platinum metal ions. Linear tapes or nonamers could be obtained by design [263].

Here R is either a methyl or a *tert*-butyl group which induces better solubility to these “tapes.” By mixing two equivalents of the mono-pyridyl porphyrin to two equivalents of the distal disubstituted one and two equivalents of the labile benzonitrile palladium complex a mixture of dimer, trimer, and tetramer is formed in a 3:8:2 ratio. Only the trimer is shown. Similarly, by mixing the vicinal disubstituted pyridyl porphyrin (termed by the authors an “L-shaped porphyrin”) with equimolar amounts of the tetra-4-pyridylporphyrin (X-shaped) and the corresponding platinum precursor (3 equivalents) after 4–5 days at 50 °C, a mixture of the trimer, tetramer, and pentamer in a ratio 2:4:1 is obtained as determined by electrospray mass spectrometry. Only the tetramer LXXL is shown. Instrumental in these cases is the reversibility of the metal–pyridyl coordination which assures that the thermodynamically stable product is favored in the end. This coordination is more stable for platinum than the palladium complex.

Spectacular in what can be achieved by using this stoichiometry control is the preferential formation of the nonamer depicted as follows in over 90% yield. The reaction is completed within 30 minutes of mixing of the following reactants: 12 equivalent Pd precursor benzonitrile complexes, 1 “X”-shaped central tetrapyrrolyl substituted porphyrin, 4 “L”-shaped vicinal dipyrrolyl porphyrins for the corners, and 4 “T”-shaped tripyridyl porphyrins for the edges. R is the *tert*-butyl group. Evidently by using differently metalated porphyrins assembly of polymetal complexes with controlled architecture and thus interesting material properties can be achieved.

The nonamers are extremely stable and by  $\pi$ – $\pi$  interactions tend to stack strongly with a stacking energy which has been estimated at ca. 5 kcal/mol per porphyrin face. Formation of columns was observed by atomic force microscopy (AFM) which, after deconvolution of the tip profile, indicated dimensions of approximately 5 × 5 × 5 nm. Interesting photonic applications are envisageable with these polymetalated porphyrinic nanostructures.

Similar architectures have been more recently constructed in the group of Nolte where the R group has been replaced by a long chain alcohol group and the self-assembly at the air–water interface has been investigated [264]. Also other multiporphyrinic assemblies such as the ruthenium complex depicted were investigated:

The scope of this study was to prepare stable chromophoric monolayers which could be transferred by Langmuir–Blodgett technique to a glass surface with good transfer ratios. Compression of the films leads to well ordered layers with tetraporphyrin metal squares which are orthogonal to the surface. The fatty hexadecyloxy chains (cetyl) are responsible for adopting the perpendicular orientation to the water surface while  $\pi$ – $\pi$  stacking of the multiporphyrin planar nanostructures induce the high stability of the monolayers toward collapse.

A mixed layer-by-layer deposition onto a hydrophobic glass substrate mediated by  $\text{PdCl}_4^{2-}$  ions was performed by alternatively transferring monolayers of *meso*-tetrakis-(4-pyridyl)porphyrin and *meso*-tetrakis-(4-carboxymethoxyphenyl) free base porphyrins [265]. Here the ionic (or electrostatic) pairing between the carboxy and pyridyl groups is expected to be important at the air–water interface, in addition to the palladium coordination as proposed by the authors.

An assembly in which it would have been interesting to study the energy transfer was synthesized by Burrell et al. The crystal structure could be solved by X-ray diffraction [261]. The perpendicular arrangement of two antenna zinc porphyrins to the central free base energy trap ( $M = 2\text{H}$ ) should have an unfavorable Förster orientation factor  $\kappa$  for the energy transfer but a through-bond mechanism involving the two distal pyridine ligands could operate in this case:

Other interesting nanostructures assembled by the coordination of the central metal atom within porphyrins were reported recently by several groups. Sanders and co-workers, in an extensive study which included the syntheses and X-ray structural characterization of several porphyrinic coordination arrays, described the formation of the undecamer depicted as follows [266]. Here the axial ligation of the central tin porphyrin is engineered using benzoic carboxyl groups of two *meso*-substituted porphyrins, while the four peripheral rhodium(III) substituted porphyrins are ligated by 4-pyridyl substituents. An iodine atom completes the Rh coordination sphere.

The R group is *n*-hexyl, the ideal substituent when solubility is desired but also for obtaining suitable crystals for envisaged X-ray diffraction studies. If instead of Rh and Ni porphyrins, which have low fluorescence quantum yields, other lighter metals could have been employed for building this nanostructure, it would have been very interesting to study the energy transfer. A perpendicular orientation of the porphyrin rings as imposed by axial ligation should also lead to an unfavorable orientation factor  $\kappa$  by the Förster mechanism. However, in this case, also the Dexter mechanism would not be very efficient due to the reduced orbital overlap due to the *meta*-phenylene linkage of the phenylacetylene bridges.

The following mixed metal complex incorporating also a ruthenium center and resembling the Drain–Lehn dimers was assembled in a modular stepwise manner [267]. First the octahedral ruthenium bis-“L”-shaped (following Drain’s nomenclature) porphyrin complex was formed after which the square planar “diphos” corner was closed. The authors name their assemblies “heterobimetallic molecular squares of porphyrins.” As only two porphyrins are involved, the term “square of porphyrins” which implies a pseudo- $D_{4h}$  symmetry is maybe misleading, as well as “molecular” which is actually supramolecular. Furthermore, in the case of zinc metallated porphyrins, the complexes are actually “heterotrimetallic.” Although photophysical studies were in this study not undertaken, both synthetic and photochemical extensions of this work are envisageables.

A more thorough study by other Italian chemists and photophysicists was undertaken on the following ruthenated porphyrin dimers and pentamers with a side-to-face coordination staged also through pyridyl ligands [268]:

The axial 4- or 3-pyridyl-Ru ligation is more stable than a pyridyl-Zn bond ensuring preferential formation instead of oligomers of the previous species which are stable toward dissociation even in dilute toluene solutions which were used for detailed photophysical studies. The ruthenium porphyrin units are higher in energy, both as singlet and triplet states, than the corresponding free bases or zinc metalated porphyrins. The supramolecular assemblies differ markedly in their photochemical behavior from the corresponding monomers. The Ru monomer undergoes from the singlet level efficient (100%) intersystem crossing (ISC) to the longer lived triplet state. However, in the case when it is axially coordinated by either a 3- or 4-pyridyl-*meso*-porphyrin strong fluorescence quenching of the free base or zinc porphyrins was observed due to the heavy atom effect of the nearby situated ruthenium center. This causes an enhanced ISC in the free base or Zn porphyrins to the triplet states from where efficient triplet-triplet energy transfer takes place. The driving force  $\Delta G$  is large in the case of the free base so that the transfer from the ruthenium moiety to the free base triplet is irreversible and has rate constants between  $10^8$  and  $10^9$  s<sup>-1</sup>. In the case of the Zn-porphyrin assemblies,  $\Delta G$  is small so that an equilibrium is established between the states prior to deactivation.

Wilson and Anderson have linked one porphyrinic molecular wire into a supramolecular nanostructure by ligating the zinc atoms with distal bis-4-pyridyl substituted free base porphyrins [269].

It would be interesting to study the energy transfer mechanisms between the two antenna zinc dimers and the central free base dimer which can act as the energy trap. Due to the butadiyne linkages the overlap integral would be different from all systems studied so far.

Gossauer and co-workers have synthesized the pyridyl derivatized porphyrinic tripods mentioned before or star-shaped hexaethynylbenzene (niphaphyrins) and studied the complexation with their macrocyclic covalent assemblies of porphyrins [270]. Only one example is shown having a longer linker of the central tripod guest molecule:

The binding constants are extremely high, between  $1.4 \times 10^9$  and  $1.1 \times 10^{10}$  M<sup>-1</sup>, which explains the high stability of such complexes which can survive even the ionization during mass spectrometric investigations by

MALDI-TOF. Peaks corresponding to the 1:1 complex were found in the positive mode which were greatly increased in intensity by using the aprotic matrix DCTB (2-[(2*E*)-3-(4-*tert*-butylphenyl)-2-methylprop-2-enylidene]malononitrile) dissolved in chloroform [271] instead of the common MALDI matrix 1,8,9-anthracenetriol, which being protic and in large excess, can compete for complexation of the zinc atoms and displace the polypyridyl ligand.

Hunter and Hyde have also constructed several elaborate supramolecular assemblies which make use of pyridyl groups to ligate porphyrins (Fig. 29).

In Figure 29, the meso-aryl substituents having either alkyl or alkoxy long chains have been omitted for clarity. Energy and photoinduced electron transfer were studied in these systems [272]. While the terephthaloyl diamide spacer in the first formula is inert, the naphthalenediimide spacer acts as an electron acceptor. A stability constant of  $3 \pm 1 \times 10^8 \text{ M}^{-1}$  was determined for these complexes which dissociate in very dilute solutions ( $>10^{-8} \text{ M}$ ). In the case of the terephthaloyl linker, the fluorescence of the zinc porphyrins is significantly reduced at concentrations where complexation occurs, compared to dilute solutions having

uncomplexed units. This effect is due to *intracomplex* excitation energy transfer from the zinc porphyrins to the free base. In case of the naphthalenediimide spacer, the free base fluorescence at ca. 650 nm is quenched to an extent of 70% and this is attributed to an *intracomplex* electron transfer process from the singlet state of the free base porphyrin to the naphthalene diimide electron acceptor. While a through-bond electron transfer mechanism would involve 24 bonds (i.e., ca 3.5 nm) the through-space separation is only about 1 nm. Probably the high rate of the observed electron transfer is due to a through-space or a solvent mediated mechanism involving the solvent molecules within the void between the chromophores in the complex. The bis zinc-porphyrin unit linked by the naphthalenediimide spacer shows only weak fluorescence which upon complexation is not altered. This fact speaks that also here *intramolecular* electron transfer occurs from the excited zinc porphyrins to the naphthalenediimide electron sink. This relatively early study has shown the potential of a supramolecular approach which allows one through choice of concentration to switch on and off electron and energy transfer processes within carefully engineered assemblies.

In a later study [273] Hunter and co-workers assembled a 2:1 complex between a Zn metalated bis-porphyrin and a *meso*-tetrakis-aryl free base porphyrin having 4-formamidopyridyl groups in such a way that all four zinc atoms of the energy donors can be ligated by the four pyridyl groups in the energy trap. The binding constant for a one zinc-pyridine coordination has been estimated at ca.  $10^3 \text{ M}^{-1}$  [272, 274, 275]. In this case the 2:1 complex shows cooperativity between two identical binding sites with association constants of  $(2.0 \pm 0.5) \times 10^6 \text{ M}^{-1}$  per binding event. Vapor pressure osmometry confirmed the formation of the 2:1 complex whereas mass spectrometric techniques failed to put into evidence associated species indicating that upon ionization the complex dissociates. The rate of the energy transfer which occurred with high efficiency was estimated at  $10^9 \text{ s}^{-1}$ .

**Figure 29.** Excitation energy transfer and electron transfer events shown schematically in supramolecular porphyrin assemblies formed by pyridine-Zn ligations.

In this formula the coordination of the bisporphyrin clip is depicted as being from the vicinal (5,10) *meso* position of the central free base porphyrin which acts as the energy trap. However, a distal (5,15) coordination also appears to be possible. Molecular modeling calculations which might shed light on the stabilities of the two nonequivalent structures or other structural evidence were not yet presented for this interesting complex.

More recently, by using different 4-formamidopyridyl groups and cobalt atoms which form six-coordinated porphyrin complexes, complex oligomeric arrays could be prepared [276]. For a dodecamer the following cyclic geometry was proposed where the arrows stand for the respective substituted 4-pyridyl ligands.

Stang and co-workers, elaborating on their concept of preparing macrocyclic arrays using biphosphine-coordinated transition metals as building blocks, have also made use of pyridyl groups. However, the pyridyl nitrogen is used here to coordinate the heavier metal atoms and not the central zinc inside the porphyrin [277].

Several other porphyrinic cyclic arrays were prepared, some of them displaying interesting chirality imposed by (*R*) or (*S*) BINAP-phosphines which lead to mirror imaged and very intense excitonic couplets of the Soret band in the CD spectra. As mentioned due to the heavy atoms these arrays have low fluorescence quantum yields and very short lifetimes and thus would be of little use as light-harvesting nanostructures.

A hexakis pyridyl-functionalized porphyrinato-benzene was recently synthesized and the ability of the pyridyl ligands to form platinum complexes was put into evidence [278]. Of course instead of the platinum complex substituted with long dodecyl chains which confer an amphiphilic character to the sixfold charged cation (the counterion being trifluoromethanesulfonate), zinc porphyrins could have been used to construct hierarchically a light-harvesting nanostructure by coordination. Interestingly, due to steric hindrance only 6 of the 18 pyridyl nitrogens bind platinum atoms. The assembly was further characterized both in solution, using resonance light scattering, a very useful technique to study chromophore aggregation perfected by Pasternack [279–282], and on solid supports by transmission electron microscopy. While in solution, little or no aggregation was observed; from chloroform solutions by aggregation on carbon-coated copper grids, very large, micrometer-size rings were formed. These “porphyrin wheels,” as previous studies by Nolte and other Dutch and Belgian researchers have termed such assemblies [283, 284], are formed mainly by  $\pi$ - $\pi$  interactions which in this case appear not to be disturbed by the presence of multiple charges. Deposition upon solid supports of such self-assembling microstructures might have important applications in solar cell technology.

In this formula, both the implied orientation of the 5-(benzyloxy)-porphyrinato groups around the central benzene ring as well as the positioning of the platinum atoms only on the 15-(4-pyridyl) groups, although probable, may actually not be true. Upon complexation of 2–4 equivalents of the platinum diimine ligands the porphyrin fluorescence was completely quenched due to the heavy atom effect.

Several other pyridyl substituted porphyrins and phenylene-bridged zinc-bis-porphyrins (with or without additional electron acceptor groups such as quinones or pyrromellitimide) were synthesized by Shulga and the photophysics of the supramolecular assemblies, formed upon complexation of the zinc metalated porphyrins by the pyridyl groups, were performed by Zenkevich and von Borzyskowski [285–288]. The following formulae show typical such assemblies where other nonpyridinic peripheral porphyrin substituents have been omitted for clarity.

Again in these studies, by using pentafluorophenyl groups, the potentials are shifted so that vectorial photoinduced electron transfer to the electron sinks is made possible. However, a detailed structural characterization of the supramolecular assemblies (such as by high-field NMR or X-ray analysis) which would clearly differentiate between the 2:1 complexes shown and complexes (or oligomers) with other stoichiometries is lacking. This is also maybe why, in some cases, a clear distinction between the energy and electron transfer rates, from the time-resolved fluorescence and absorbance studies, was not possible. The interested reader can consult a recent review of this work [289].

As a final example of a porphyrin self-assembly mediated by pyridyl groups, a very nice structure presented by Fujita et al. deserves mention [290]. A porphyrin triangular prism comprised of three porphyrins ligated by six  $[\text{Pd}^{\text{II}}(\text{en})]^{2+}$  building blocks (where *en* stands for ethylenediamine) was obtained and its crystal structure could be solved. The palladium atoms hinge together two 3-pyridyl groups situated in the *meso*-positions of adjacent porphyrins. All coordination

sites are thus equally satisfied. This example illustrates the preferential formation of discrete nanoarchitectures by self-assembly. Upon complexation of a pyrene molecule within the prism, the  $D_{3h}$  conformation was desymmetrized to a  $C_2$  complex as inferred from 800 MHz  $^1\text{H-NMR}$  studies. Strong  $\pi$ - $\pi$  interactions between the pyrene guest and the porphyrin walls of the host must occur in order explain the observed redshift of the porphyrin Q bands upon complexation. Interesting photophysical properties are expected from such a nanoprism.

As an alternative to pyridyl groups as the ligand of central metal atoms in porphyrins, Ogawa and Kobuke have prepared an imidazolyl substituted porphyrin dimer that self-coordinates showing an oligomeric distribution which peaks at about 150 porphyrin units. According to molecular modeling, if a linear geometry presumed, the array should have a length of about 110 nm [291]. Due to the R-substituents, which in this case was *n*-heptyl, these coordination nanostructures are still remarkably soluble in organic solvents such as chloroform. This is also an indication that due to the nearly perpendicular geometry of the *meso*-linked unit extended  $\pi$ - $\pi$  interactions between oligomeric strands are not possible. This is in contrast to the large planar coordination arrays presented previously.

The monomeric 5-(1-methylimidazol-2-yl)-porphyrinc building block with a free *meso*-position dimerizes in solution by coordination of the zinc atom by the 3-imidazolyl nitrogen. Upon oxidative Osuka coupling of this monomer and formation of the *meso*-linked dimer, in the absence of polar solvents, extensive oligomerization occurs. Very recently it was shown that these oligomers have extremely large third-order optical nonlinearities and, as expected from the Osuka-type *meso*-linkage of the dimers, the Soret band is split [292].

Another similar interesting polymeric assembly of porphyrins mediated by metal ion ligations but using crown ethers as the ligands was very recently presented by Shinmori et al. [293]. A detailed complexation study of alkaline ions was shown to induce dimerization of a distal bis-substituted benzo-15-crown-5-porphyrin which is especially favorable for potassium ions. Additional *face-to-face* stabilization leads to an increased stability constant (ca.  $10^{18} \text{ M}^{-3}$ ) for a 2:2 complex. When different metals are introduced within the porphyrin additional ligands may be coordinated. The dimer formation was not only inhibited but also dissociation occurred in the case of a cobalt porphyrin in presence of dimethylaminopyridine (DMAP). Thus the bis-cobalt ligation by DMAP is stronger than the *face-to-face* aggregation assisted by metal ion complexation. By silver ion promoted oxidation the *meso-meso* linked Osuka-type dimer shown at right could be obtained in 13% yield. Due to the perpendicular orientation of the two porphyrin rings, dimer formation upon complexation within

the benzo-crown ethers of  $K^+$  is in this case not possible. Instead an extended oligomer was formed which had a molecular weight of ca. 100 kDa which corresponds to an aggregate with a distribution peaking at ca. 50 bis-porphyrin units. From simple molecular modeling (Fig. 30), if a linear geometry is inferred, an approximate length of over 100 nm is to be expected. However, multiple conformations of the crown ethers may exist so that a linear geometry may not be maintained for the longer oligomers.

Potassium ions do not quench the fluorescence of the aggregate and thus such large antenna systems would be suitable for artificial light-harvesting.

In the previous structure, if instead of potassium, silver ions would be used (similar to the example presented in the beginning of this section [253]), although for light-harvesting purposes this would not be a useful construct, maybe molecular electronics applications could be envisageable. Electron transport, mediated by metalated porphyrins between the silver atoms, could be possible on the decinometer scale. Additionally, such a wire composed of discrete silver atoms would appear to be insulated due to the crown ether ligands and the perpendicular bisporphyrins, so that interstrand electron jumps would be much less probable. A linear silver(I)-mediated network of *meso*-tetrakis(4-pyridylporphyrin) could be characterized by X-ray diffraction of single crystals [294]. Within the voids of the  $\pi$ -stacked network, solvent molecules and the hexafluorophosphate counterions were clathrated. This silver network showed interesting redox behavior and the fluorescence was apparently not quenched in the solid state. Very recently, the self-assembly of this same tetrapyrrolyl porphyrin was studied on gold [Au(111)] electrodes using STM showing that it

**Figure 30.** An extended metal ligated oligomer from the Shinmori et al. bis-porphyrins decorated with benzo-15-crown-5 ethers. Metal ions are shown as disks.

is possible to tune surface interaction and to modulate the surface mobility by the electrode potential [295].

**Assembly of Porphyrinic Nanostructures Using Hydrogen Bonding** The first to synthesize hydrogen bonded supramolecular species and to show by detailed photophysical measurements that energy transfer can occur efficiently in such assemblies were Harriman, Magda and Sessler [296, 297]. Several nucleic acid bases were covalently attached onto porphyrins. In solution, due to multiple hydrogen bonding base-pairing was induced as depicted in this formula for cytosine derivatives:

Alternatively, the stronger guanine–cytosine (G–C) base pair was used to enhance the association constant:

The photophysical properties of the assemblies were compared to those of model compounds such as the free base octaethylporphyrin (OEP) and the zinc-metallated counterpart (ZnOEP). Even at high concentrations (in the molar range), equimolar mixtures of OEP and ZnOEP behave exactly as the separated noninteracting molecules. In the porphyrin conjugates where the hydrogen bonding group has been connected by an amine linkage there is a decrease both in the fluorescence quantum yields and in the lifetimes in comparison to the corresponding OEP models. This was attributed to an intramolecular electron transfer process from the tertiary amino group in the linker. There is little or no energy transfer from the Zn donor to the free base acceptor in this case. At higher concentrations, depending on the strength of the association constant, additional fluorescence quenching of the zinc donor occurs which indicates that energy transfer is occurring. This was confirmed by time-resolved measurements from which also the respective rate constants could be differentiated into those occurring for a singlet–singlet excitation energy transfer process in the  $(2-9) \times 10^{-8} \text{ s}^{-1}$  range and those for a triplet–triplet process occurring in the  $(5-100) \times 10^{-5} \text{ s}^{-1}$  range. The association constants between the different conjugates varied by one order of magnitude between ca. 24 and 225  $\text{M}^{-1}$ , the weakest being for guanine–guanine self-association and

the strongest for the cytosine–guanine base pairs. An important aspect is that the rate of the energy transfer, once an assembly is formed by hydrogen bonding, is practically independent of the nature of the connecting zipper bases (termed also “recognition groups”) and increases strongly upon increasing the number of zinc-porphyrin donors. This is in accord with the Förster mechanism due to the increased probability of matching an excited donor moiety with an acceptor moiety at a preferred orientation and smaller separation. Additionally, due to the flexible linkers, a Dexter mechanism may occur at small separations when the orbitals of a donor and an acceptor overlap.

Drain while in the group of Lehn [298, 299] and later independently [300] has also engineered self-assembly of porphyrins exclusively by hydrogen bonding. By using different complementary recognition groups, discrete multiporphyrin arrays could thus be built in a controlled manner. The following “bisporphyrin supramolecular cage” was formed by stitching with a alkyltriaminopyrimidine (TAP) “wedge” two bis *meso*-uracyl OEP molecules, either as free bases, zinc, or chloroferric complexes [298]:

Alternatively, a “rosette” is formed by appending two porphyrins on a 1,3,5-triazine and stitching each donor–acceptor–donor face by a complementary acceptor–donor–acceptor barbituric acid wedge [299]:

By using the complementary 2,6-diacetamidopyridine and uracyl recognition groups introduced by Lehn and

co-workers [301], Shi et al. recently showed by NMR, electrospray ionisation mass spectrometry (ESI-MS) and vapor phase osmometry (VPO) that preferentially a tetrameric assembly is formed from vicinal *meso*-disubstituted porphyrins in chloroform solutions [300]:

In the same study [300], a nice crystal structure could be solved for the free base 5,10-bis-(2,6-diacetamido-4-pyridyl)porphyrin, where water molecules mediate hydrogen bonding in the crystal lattice.

In an attempt to mimic the self-assembly of natural bacteriochlorophylls (BChls) encountered in chlorosomes (see Section 3.1.1) Balaban et al. have synthesized various zinc metallated porphyrins where a hydroxy group and a carbonyl group were appended onto *p*-phenylene spacers situated in vicinal or distal *meso* positions of porphyrins having also two other long chain solubilizing groups [195]. A hydrogen bonding network acting cooperatively with  $\pi$ – $\pi$  interactions was put into evidence in the crystal structure of such a free base porphyrin. Here the inner pyrrolic nitrogens devoid of hydrogen atoms, which could be localized in the electron density map, act as hydrogen bond acceptors while the hydroxy group is the hydrogen bond donor as shown in Figure 31.

In Figure 31 the central porphyrin is a hydrogen bond acceptor from two neighboring porphyrins, one from above and one from below. At the same time it is a hydrogen bond donor through the hydroxymethylene groups to two other porphyrins not shown in the figure. Note the different orientation of the porphyrin planes and the very regular extension of the otherwise flexible undecyl sidechain which has a kink allowing it to deviate above and below the porphyrin plane. Due to the deviation of the *meso-p*-phenylene groups from the porphyrin plane (dihedral angle of 65°), ligation of a zinc metallated porphyrin by a 4-hydroxymethylenephyl group is energetically disfavored in a  $\pi$ -stacked arrangement. Thus, although all the functional groups encountered

Figure 31. Hydrogen-bonding network in the crystal.

in BChls are presented, the self-assembly algorithm cannot operate in the same manner. For better tailored systems see the following.

Similar hydrogen bonding to the inner pyrrolic nitrogens was more recently put into evidence in other crystal structures of 5,15-diarylporphyrins synthesized by the group of Sanders [266, 302].

In another earlier interesting crystallographic study by Barkigia et al. which was related to models for the antenna complexes of green photosynthetic bacteria, it was shown that a zinc porphyrin analog of BChl *d* forms stacked dimers of the type shown schematically [303]:

Surprisingly, the 3-hydroxyethyl group (in which the 3<sup>1</sup> carbon atom had *R* configuration) does not bind as expected

the central zinc atom and prefers to hydrogen bond the carbonyl group of an antiparallel stacked porphyrin. There is a slightly shorter interplane distance within such a doubly hydrogen bonded dimer than between the dimers: 3.33 Å intradimer and 3.54 Å interdimer. However the  $\pi$ - $\pi$  overlap is almost uniformly offset showing that its cooperative action with double hydrogen bonding may win over the stronger zinc chelation.

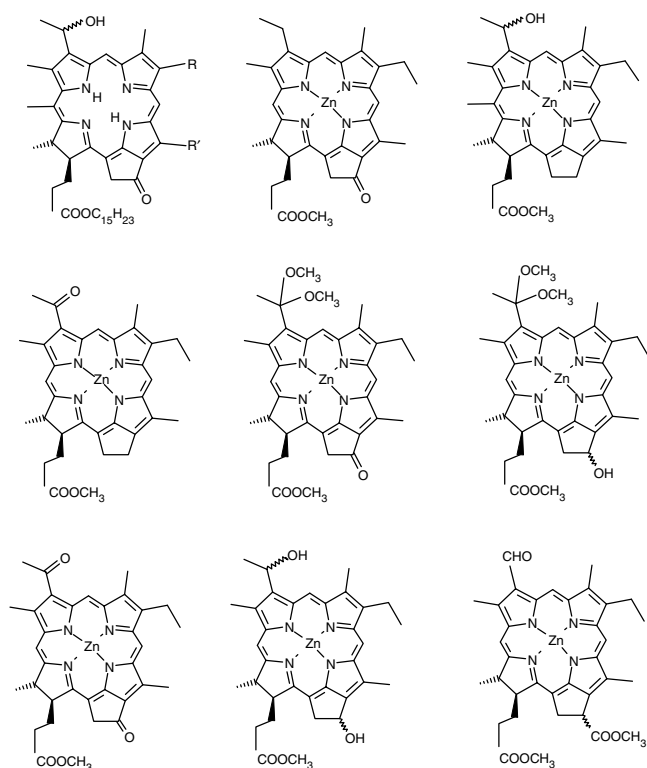

### Cooperative Interactions between Porphyrinic Chromophores Using Metal Ligation and Hydrogen Bonding

When a ligand binds to a metal atom and at the same time the ligand can function as a hydrogen bonding group, cooperativity effects may occur. This is the case presently believed to operate for the natural light-harvesting systems of green photosynthetic bacteria, the chlorosomes, discussed before (see Section 3.1.1) which involve BChl *c*, *d* and *e*. Numerous studies of the natural system first in collaboration with Schaffner and Holzwarth [39–47] were then continued independently by Tamiaki and Balaban with nonnatural systems. While Tamiaki has used exclusively semisynthetic compounds derived either from Chl *a* (usually isolated from algae such as *Spirulina geitleri*) or BChl *a* (isolated for example from the purple bacterium *Rhodobacter sphaeroides*), Balaban has taken a fully synthetic approach with robust pigments such as porphyrins or phthalocyanines. In view of applications, the latter way is better yielding and does not rely on culturing and tedious isolation techniques, usually involving high performance liquid chromatography (HPLC) separations.

Jesorka et al. were the first to show that the BChl *c* and *d* skeleton is tolerant to rather wide variations and can still be induced to self-assemble [304]. Thus when the positions of the 3<sup>1</sup>-hydroxy groups and 13<sup>1</sup> carbonyl groups are interchanged self-assembly still occurs. However, if the central metal atom (zinc or magnesium) is missing (i.e., the corresponding free base chlorins) or if either the hydroxyl and/or the carbonyl groups are removed or protected the ability to form a light-harvesting system by self-assembly is inhibited. Thus the simultaneous presence of a metal atom, carbonyl group, and hydroxyl group on a macrocyclic scaffold capable of  $\pi$ -stacking is essential. Scheme 2 presents structures which cannot self-assemble.

Scheme 3 shows the semisynthetic mimics of BChl *c*, *d*, and *e* (for their formulas see Scheme 1) which can self-assemble and have large redshifted and usually broad absorption maxima, reminiscent of J-aggregates [41, 304–306].

Newer studies from Tamiaki's laboratory include the asymmetric reduction of the 3-acetyl group using oxazaborolidines as chiral auxiliaries [307] or insertion in the 3-position of  $\omega$ -hydroxyalkyl groups [308] instead of the hydroxy(m)ethyl group. Also synthesized were similar compounds having a tertiary 3<sup>1</sup>-hydroxy group [309] or "inverted" compounds having a tertiary hydroxy group in the

**Scheme 2.** BChl analogs which do not self-assemble.

13<sup>1</sup>-position and a 3-acetyl group [310]:

Important proof that functional devices can be obtained by self-assembly was made by generating light-harvesting

**Scheme 3.**

nanostructures with such BChl *c* (or *d*) mimics which had additionally incorporated an energy trap of BChl *a* type [75–77]:

These covalent linked dyads have the BChl *a* energy trap (left moiety) bound to the semisynthetic chlorin mimic (right part) which, having the same functional groups, inserts itself within the self-assembling antenna formed only from the right half molecules. The energy absorbed by the self-assembled chlorins present in large excess (100 to 1) is efficiently transferred to the bacteriochlorin trap. If the covalent linkage is absent there is no energy transfer except when the two components are confined within liposomes. This is in accord with the Förster excitation energy transfer mechanism.

Very recently Balaban et al. could synthesize by different methods, some of them novel to porphyrin chemistry, the following porphyrin mimics of BChls which are able to self-assemble [193]:

A systematic variation was performed of the positions where the carbonyl group (either formyl or acetyl) and the hydroxy group (either as an achiral hydroxymethylene group or the chiral 1-hydroxyethyl group) are appended onto the porphyrin ring. The zinc metalated compounds ( $M = \text{Zn}$ ) self-assemble in nonpolar solvents and their optical properties can be fine tuned due to variations of the  $\pi$ - $\pi$  overlap. Furthermore, by separating the enantiomers of

the hydroxyethyl substituted compounds by means of chiral HPLC and then inducing these to self-assemble, chiral nanostructures are obtained which are enantiomorphic having mirror imaged CD spectra. Thus the chirality of the monomeric building block induces the chirality of the supramolecular assembly.

Another interesting example, where also crystallographic proof of the structure could be provided for the self-assembly combining Zn ligation with simultaneous hydrogen bonding and  $\pi$ - $\pi$  interactions, was provided by means of 2-aminopyrimidine groups which were appended in *meso*-porphyrinic positions [192]. For the first time a pyrimidine ligand was found to coordinate the central Zn atom of a porphyrin, thereby inducing the preferential formation of a closed tetramer (Fig. 32).

Inside the tetramer two 2-aminopyrimidine groups  $\pi$ -stack in an offset manner. The other two 2-aminopyrimidine groups pointing outward are involved in double hydrogen bonding (dotted lines) to neighboring tetramers which appear thus as beads on a hydrogen bonded string. Between the strands solvent molecules (cyclohexane) interact favorably with the bulky *t*-butyl groups.

If water molecules complex the central zinc atom within porphyrins, their ability to serve as hydrogen bond donors is enhanced. An interesting dimer could be crystallized from a 10,20-dioxoporphyrin having pendant ester groups whose carbonyl oxygens serve as the hydrogen bond acceptors [351].

**Assembly of Porphyrinic Nanostructures by Other Weak Interactions** In the absence of other stronger intermolecular interactions, even hydrophobic (or dispersive) forces can be used to assemble nanostructures which can perform light harvesting. An example was provided by Kobuke and co-workers who have prepared liposomes as small unilamellar vesicles of about 30 nm by sonicating dispersions in water of the following imidazolyl-substituted

porphyrins [311]:

It is also probable that  $\pi$ - $\pi$  interactions occur within these micellar assemblies which can include other fluorescent molecules such as pyranine. In polar media, in this case water, no imidazolyl-imidazolyl hydrogen bonding is expected to occur.

Porphyrin containing nanoparticles having average hydrodynamic radii in the 10–70 nm range were recently described and imaged by AFM [312]. In this case J-aggregates were formed, which are typical also for other chromophores. For some representative examples of J-aggregates see [313–317] and other references cited therein.

## 5. CONCLUSIONS: ARTIFICIAL PHOTOSYNTHESIS—PERSPECTIVES AND FUTURE GOALS

I have tried to give a broad overview of light-harvesting both in natural systems and in synthetic systems built by chemists. The vision is to engineer manmade compounds into devices capable of photosynthesis (i.e., to be able to use sunlight, even under low light illumination conditions, to produce useful energy). Plants and bacteria do this optimally due to evolution which has helped them optimize the quantum yields of each step involved so that the overall efficiency is stunning. In artificial photosynthesis the generated energy form maybe either direct photocurrent, as in photovoltaic devices, or producing reactive chemical species which thus store the light energy in a chemical form. Photocatalytic water splitting is a goal that is actively pursued by several research groups, both in academia and industry. The present state-of-the-art silicon based photovoltaic cells, although they represent a working technology, due to the high production cost and relatively low photocurrent efficiency (under 15%), have reached an evolutionary plateau

**Figure 32.** Self-assembled tetramer in the crystal. The dotted lines indicate hydrogen bonds to adjacent tetramers.

so that large scale applications are not yet envisageable. One of the most efficient nonsilicon based solar cell is the so-called “dry Grätzel cell” which uses nanotechnology to make an interpenetrating network of mesoporous nanocrystalline titanium dioxide. This wide band semiconductor cannot be directly excited by the solar spectrum but can be photosensitized with a chromophore, initially a ruthenium (II) bipyridine complex [318]. A hole transporting molecule, such as a spiro-bis-fluorene derivative, allows the hopping of electrons from a gold electrode to the dye which, after photoexcitation and charge separation, has injected an electron into the conduction band of the  $\text{TiO}_2$  semiconductor. Conversion of photons to current occurs with over 30% efficiency. The interested reader is referred to the excellent reviews by Grätzel et al. describing newer advances since the “wet Grätzel cell” which was based on electrolytes [319–321].

Several trials to improve with other light-harvesting chromophores the photosensitization of titanium dioxide have been undertaken. These include modified phthalocyanines [322], aggregated cyanines [323], porphyrins [324], or other ruthenium pyridyl complexes [325–327]. Sandwich-type structures were achieved by incorporating different dyes into zeolites, thus preventing the usual fluorescence quenching due to aggregation effects, and bidirectional cascade-type energy transfer could be observed [328]. An excellent review has been very recently published [352].

Newer technologies, based on organic solar cells, although the working principle has been proven, are still in their infancy with efficiencies around 3% [329–331]. In this case however, cheap production costs, as expected from the polymer industry, could be a trade-off for higher photocurrent yields. Addition of a polythiophene regioregular polymer as a hole conducting material gives enhanced photocurrents in organic solid-state cells employing Mg tetraphenylporphyrin or its free base [332]. Light-harvesting porphyrin-substituted polythiophenes which were electropolymerized were investigated for their performance in both photoelectrochemical cells and Schottky junction devices [333].

Highly efficient artificial models for the photosynthetic reaction center have been designed and synthesized, using amazing chemistry by Sauvage and co-workers. Very long charge separated states, entering the  $\mu\text{s}$  range, can be obtained with some porphyrinic systems which are mechanically interlocked into catenanes [334–336]. The principles for the construction of mechanical interlocked compounds where there are no bonds between electron donors and acceptors have been reviewed [337].

Finally, the recent achievements of the Arizona researchers led by Devens Gust together with Thomas and Anna Moore deserve special mention. An artificial reaction center formed from a tetrathiafulvalene–porphyrin–fullerene triad was shown to exhibit a very long-lived charge separated state (660 ns) [338]. In collaboration with the Lindsey group an efficient artificial photosynthetic antenna–reaction center covalent hybrid was synthesized and its photophysics were studied [339].

This hexad is formed from three peripheral antenna Zn porphyrins ( $\text{P}_{\text{ZP}})_3$ , a central Zn porphyrin ( $\text{P}_{\text{ZC}}$ ), a free base porphyrin (P) which acts as an energetic trap, and a fullerene ( $\text{C}_{60}$ ) as an electron acceptor. Depending on the substitution pattern of the free base porphyrin which influences the oxidation potentials and thus the driving force for generating a charge separated state, very different quantum yields and lifetimes could be determined. The best performing hexad has *meso*-mesityl-groups, being thus a tetraaryl free base porphyrin and not an octaalkyl one. Light is gathered by the peripheral Zn porphyrins and the energy is transferred to the central one generating its singlet excited state  $(\text{P}_{\text{ZP}})_3^{-1}\text{P}_{\text{ZC}}-\text{P}-\text{C}_{60}$  with a time constant of 50 ps. Part of this energy is then further trapped by the artificial reaction center part of the hexad generating the  $(\text{P}_{\text{ZP}})_3-\text{P}_{\text{ZC}}^{-1}\text{P}-\text{C}_{60}$  state with a time constant of 32 ps. The latter decays within 25 ps by means of a photoinduced electron transfer pathway to the fullerene forming thus the primary charge separated state  $(\text{P}_{\text{ZP}})_3-\text{P}_{\text{ZC}}-\text{P}^+-\text{C}_{60}^{\bullet-}$ . This state can also be accessed (with quantitative quantum yield) by exciting directly the free base porphyrin P. Secondary, long lived charge separated states,  $((\text{P}_{\text{ZP}})_3-\text{P}_{\text{ZC}})^{\bullet+}-\text{P}-\text{C}_{60}^{\bullet-}$  are subsequently formed with a rate constant of  $2.3 \times 10^9 \text{ s}^{-1}$  and an exceptional lifetime of 240 ns (for the mesityl-substituted P) and an extremely high quantum yield of 0.86. Almost every photon which is absorbed leads thus to charge separation and the long lifetime would in principle make such hexads suitable as components in solar cells or optoelectronic devices. The overall efficiency is, however, still lower than in natural photosynthesis which uses much larger antennas for each reaction center enabling them to harvest light in higher yields across the entire solar spectrum. Future improvements reside thus in increasing the size of the artificial antenna. We have recently presented a biomimetic approach of how this can be achieved by using synthetic porphyrins which have been equipped with the same groups that induce self-assembly as in the chlorosomal antenna [193, 194]. By using pigments other than porphyrins, with higher extinction coefficients, even better antennas are envisageable. A simple model exhibiting ultrafast energy transfer from a carotenoid to a covalently bound chlorin has already been described [340].

Another recent and interesting application consists of devising switches for energy and electron transfer. An initial

porphyrin–spiropyran dyad showed photoswitching ability of the energy transfer [341]. The spiro[indoline–benzopyran] moiety (Sp) can be present in a “closed” form which does not absorb light over 400 nm and upon irradiation in the near-UV valence tautomerizes to a “ring-opened” merocyanine form (Sp<sub>o</sub>) which absorbs strongly in the visible region (500–700 nm). Reclosure can occur either thermally (slowly with a time constant of 20 s) or more rapidly by irradiation into the 600 nm band. Excitation of the porphyrin present in the merocyanine form produces <sup>1</sup>P<sub>Zn</sub>–Sp<sub>o</sub> which decays to the P<sub>Zn</sub>–<sup>1</sup>Sp<sub>o</sub> within 130 ps with a quantum yield of 0.93 for the energy transfer. In the closed state, the porphyrins (either as free base or Zn-metalated) are unperturbed having much longer lifetimes. This provided light-activated control of the porphyrin excited states by means of gated energy transfer. A more recent photonic switch based on the Irie-type dithienylethene scaffold [342–344] allowed control of the photoinduced electron transfer from a porphyrin to a fullerene [345]:

Model compounds where R is H or a tetararylporphyrin were synthesized besides the active device which has the fullerene attached to the porphyrin. In the colorless, open form of the dithienylethene (DTE<sub>o</sub>), when the porphyrin is excited the charge separated state DTE<sub>o</sub>–P<sup>•+</sup>–C<sub>60</sub><sup>•-</sup> is generated with quantum yield of unity. In contrast, upon irradiation with UV light and conversion to the closed conjugated form (DTE<sub>c</sub>) the singlet excited state of the porphyrin (<sup>1</sup>P) is quenched by energy transfer to DTE<sub>c</sub> within ~2 ps thus inhibiting any electron transfer (quantum yield of the charge separated state < 0.09) to the fullerene. Irradiation with visible light returns the very stable perfluorocyclopentene DTE to its colorless open form DTE<sub>o</sub>. These two examples demonstrate that both energy and electron transfer processes can be photoswitched.

Definite proof that artificial photosynthesis is not only a dream has been brought forth by combining in a liposomal construct which mimics the natural photosynthetic membrane, an artificial reaction center assembled into a light driven proton pump which is used to drive an incorporated ATP-synthase to fabricate ATP [346]. For an excellent recent review on mimicking photosynthetic solar energy transduction see [347]. Very recently, transport of Ca<sup>2+</sup> ions against a thermodynamic gradient was demonstrated to be possible within a liposomal artificial photosynthetic membrane [348].

We hope that the present chapter might stimulate other researchers to enter this field and help the established

groups in finding solutions on improving artificial light harvesting and energy conversion. Paraphrasing Richard Feynmann with his famous phrase “there is plenty of room at the bottom,” which has forecasted the boom in nanoscience and nanotechnology, we can say that “there is plenty of room for perfecting artificial photosynthesis” from the current status to what Nature has achieved through evolution. Even imperfect solutions might become economically viable.

## GLOSSARY

**Antenna** A collection of natural or artificial molecules capable of absorption of electromagnetic radiation.

**Blueshift** Shift of the absorption maximum towards shorter wavelengths (i.e., to higher energy), also called *hypsochromic* shift.

**Catenane** Bi- or polycyclic molecular species which has mechanically interlocked parts, similarly to the rings within a chain.

**Chlorosome** Light-harvesting organelle of green photosynthetic bacteria *Chlorobiineae* and *Chloroflexaceae* appended on the inner side of the cytoplasmic membrane.

**Dendrimer** Monodisperse, usually highly branched, covalent molecular species formed by a repetitive sequence of chemical reactions which enable the transformation of one generation (G<sub>n</sub>) into the next one (G<sub>n+1</sub>).

**Electron transfer (eT)** A process by which an electron from a donor molecule is passed to an orbital of an acceptor molecule. If the process is activated by light one speaks of photoinduced eT.

**Energy trap** A pigment, or collection of pigment molecules (e.g. dimers) that can collect the energy from a light-harvesting apparatus, similarly to the focal point of a parabolic antenna or an optical lens. Usually, but not necessarily, the energetic traps are the most redshifted antenna pigments.

**Excitation energy transfer (EET)** A process by which the energy of a photon which brings one chromophore to its (usually singlet) excited state can be passed to another (usually adjacent) chromophore. Thereby the donor chromophore relaxes to the ground state while the acceptor chromophore becomes excited, becoming thus a potential new energy donor chromophore. The EET and can occur by different mechanisms: Förster (or dipolar) EET operates over a long range (1 to 8, or even 10 nm) between weakly coupled chromophores while the Dexter (or exchange) EET mechanism operates between strongly coupled chromophores, at short distances, and is actually a double electron transfer process.

**Exciton** An electron-hole pair which can be tightly coupled and residing in a confined portion of space (Frenkel exciton) or can be delocalized over larger regions (Wannier–Mott exciton).

**Nanostructure** Molecular, supramolecular, or ensemble of species with dimensions between 1 and 100 nm which has distinct properties as its components and which usually fulfills a specific function.

**Reaction center** Complex of molecules which after receiving the excitation energy from an energetic trap (which may

or not be part of the reaction center itself) is capable of charge separation (i.e., formation of an exciton) and of stabilizing it through subsequent electron transfer steps. If charge recombination is inhibited so that the exciton is sufficiently long-lived, it can be transformed into biochemical, electrochemical, or a photovoltaic potential.

**Redshift** Shift of the absorption maximum towards longer wavelengths (i.e. to lower energy), also called *bathochromic* shift.

**Recognition groups** Chemical groups, usually having complementary supramolecular binding sites, which decorate tectons in view of inducing self-assembly.

**Self-assembly** An enthalpy driven process, usually associated with an entropic loss, by which a supramolecular species is formed.

**Supramolecular species** A discrete ensemble of tectons which are held together by noncovalent interactions such as: ion pairing (or salt bridges), metal chelation, hydrogen bonding,  $\pi$ - $\pi$  interactions, hydrophobic or dispersive forces.

**Tecton** Molecular entity (or brick) programmed for self-assembly, i.e., which stores within its molecular architecture the information needed to construct supramolecular species.

## ACKNOWLEDGMENTS

Mihaela Carmen Balaban is thanked for help in preparation of the figures, retrieval of the PDB structural information, and reference database management, and for coping with the stress of the family related to writing reviews. Niels-Ulrik Frigaard is thanked for the design and elaboration of the chlorosome figure. Some of the work reviewed in this chapter from the author's laboratory was partially supported by the Center for Functional Nanostructures (CFN) of the Deutsche Forschungsgemeinschaft (DFG) within project C3.2.

## 1. INTRODUCTION

The electronic and optical properties of semiconducting crystallites with a size of a few nanometers (often called nanocrystals or quantum dots) differ considerably from those of the corresponding bulk material. Systems with nanoparticles represent a new class of materials with promising properties due to their nonlinear optical, photoconductivity, photoemission, and electroluminescence behaviors. They have been thoroughly investigated during the last two decades for their promising practical applications, for instance, in solar energy conversion, optical processing devices, and photocatalytic processes.

The bulk crystalline structure is preserved in nanocrystals. However, due to quantum confinement nanocrystals have molecule-like discrete electronic states which exhibit strong size dependence. Semiconductor nanocrystal systems are often synthesized in oxide glass hosts or prepared in the form of dispersed colloids. Among numerous other methods that have been developed we mention the preparation of

nanocrystals in polymers, zeolites, and micelles. By electrochemical anodic oxidation of crystalline semiconductor substrates porous nanostructures or free standing columns can be produced.

Most of the light scattered by a particle is elastically scattered without an energy shift. A small part, a few orders weaker in intensity, is scattered inelastically. This inelastic scattering carries information about energetic levels of the particle. In a Raman scattering process with incident photon energy  $\hbar\omega_L$  the scattered photon  $\hbar\omega_S$  has lost (Stokes scattering) or gained (anti-Stokes scattering) the energy  $\hbar\omega$  of an elementary excitation (phonons, electronic transitions, etc.) of the particle:

$$\hbar\omega_S = \hbar\omega_L \mp \hbar\omega \quad (1)$$

The Raman scattering is sensitive for probing the local atomic arrangement. Crystalline and amorphous phases or the influence of strain can be detected in the Raman vibrational spectra. Light couples to phonons intermediate through electronic excitations by either the deformation potential interaction or the Fröhlich interaction. The deformation interaction is present in polar crystals such as the compound semiconductors as well as in nonpolar crystals such as Si and Ge. In polar crystals the electric fields induced by vibrations interact with electronic excitations via the Fröhlich mechanism. When the Raman scattering process involves real intermediate electronic states by excitation with energy near gaps of the electronic band structure, the scattering cross section may be resonantly enhanced [1]. The Raman scattering probes the electron–phonon interaction as well as the confinement of the phonons and contains information about the confined vibrational and electronic states.

The light-scattering process in an infinite crystal obeys the pseudo-momentum conservation relation

$$\hbar\vec{k}_S = \hbar\vec{k}_L \mp \hbar\vec{q} \quad (2)$$

where  $\vec{k}_s(\vec{k}_L)$  denote the wavevectors of the plane waves of the scattered (incident) light,  $\vec{q}$  is the wavevector transferred to the excitation. The energies of crystalline vibrations probed by Raman scattering are about  $<0.1$  eV and those of the exciting visible laserlight are about 2.5 eV (corresponding to the wavelength  $\lambda_L \approx 500$  nm). Therefore, from Eq. (1) we get  $\omega_s \approx \omega_L$  and the wavevector in a typical backscattering experiment will be on the order of  $|\vec{q}| \approx 4\pi n/\lambda_L$  and much smaller than the wavevector  $q = 2\pi/a$  at the boundary of the Brillouin zone,  $a$  is the lattice constant, and  $n$  denotes the refractive index of the sample. That means that only excitations near the center of the Brillouin zone ( $\Gamma$ -point) will contribute to the Raman scattering.

If the process of light scattering by excitations is limited to the finite space occupied by the nanoparticle, an uncertainty of the transferred wavevector  $\vec{q}$  occurs and excitations with wavevectors from the whole Brillouin zone contribute to the scattering. This effect will vary with size as well as with the eigenfrequencies of acoustic and optical phonons and the electron–phonon interaction in small particles. The vibrational Raman spectra of nanoparticles can therefore be used for size determinations. This is important because one of the major goals in the field of preparation is the synthesis of monodisperse nanocrystals with a narrow size distribution and with well-defined surfaces. Size effects will be discussed in Sections 3, 4, and 6.

In addition to acoustic and optical phonon modes, surface-related modes appearing in polar crystals will be discussed in Section 5. They are observable for particle sizes smaller than the wavelength of the exciting laser light inside the particle.

The pioneering work was the first observation of confined acoustic modes with low-frequency Raman scattering in nanocrystals embedded in glasses by Duval et al. [2] and the unambiguous observation of surface-related modes in semiconductor nanoparticles by Hayashi and Kanamori [3].

It is relatively easy to produce nanocrystals of II–VI compounds embedded in different media such as glasses, polymers, or solutions. Besides potential applications of such systems the possibility of growing isolated nanoparticles in glasses with desired size and narrow size distribution and nearly spherically shaped particles makes such systems interesting for light-scattering investigations in comparison with theoretical calculations.

The observation of strong visible photoluminescence at room temperature from porous Si [4] with the possibility of optoelectronic applications has initiated intensive research on nanostructured silicon (e.g., reviewed in [5]).

Intensive light emission from Ge nanocrystals has also been found.

Within the last few years there has also been progress in the fabrication of nanostructured compound semiconductors with desired structures, especially porous III–V semiconductors.

Nanostructuring provides important degrees of freedom for phonon engineering. It may change considerably the density of phonon states, induce surface-related vibrations, and spatially confine the bulk phonon modes.

Although not expected by use of the term “quantum dots” for nanoparticles, many properties of confined vibrations

and surface modes can be understood by applying classic physics developed about 100 years ago [6, 7].

Inelastic light scattering also has been very intensively investigated in two-dimensionally layered semiconductor structures exhibiting one-dimensional confinement in growth direction. Readers may refer to reviews in Refs. [8, 9].

## 2. QUANTUM CONFINEMENT IN SEMICONDUCTORS

Semiconductor crystals with sizes of a few nanometers typically contain several hundreds to several thousands of atoms; they are too small to have bulk electronic properties. Quantum confinement in such crystals arises due to the finite size of the crystal, which limits the motion of electrons, holes, and excitons. In a small nanocrystal with size comparable to the Bohr radius of the corresponding bulk material, spatial confinement effects on the electron–hole system become significant. At very small crystal sizes, the character of the exciton starts disappearing and the electrons and holes become individually confined, because the kinetic energies of the electrons and holes become dominant and the Coulomb interaction between electrons and holes starts losing its significance. Theoretical models predict [10] that the energy spectrum of such a material consists of a series of discrete lines, which change their positions with particle size, and a blueshift of the band gap with respect to the corresponding bulk material is observed. This blueshift gives a measure of the confinement, which can be observed, for example, in absorption [11] or photoluminescence (PL) [12] experiments.

For a bulk crystal, the electron wavelength can extend to infinity, facilitating  $\vec{k}$  to take all values including zero and, hence, the band structures are parabolic. Electrons (holes) can occupy any position on the parabolic conduction (valence) band. The band gap is defined as the energy difference between the conduction and the valence band at  $\vec{k} = 0$ . On the other hand, in the case of a nanocrystal, the electron wavelength is confined to the size of the crystal and, hence,  $\vec{k}$  takes only nonzero discrete values, depending on the particle size. The electrons and the holes with minimum energy can only take a position where  $\vec{k} \neq 0$ , and the band gap for a nanocrystal has to be defined as the energy difference between the conduction and the valence band at this nonzero value of  $\vec{k}$ , which is higher than the band gap of the corresponding bulk. This can be understood from the illustration presented in Figure 7 of Ref. [13]. The band gap for nanocrystals can be expressed as

$$E = E_g + \Delta E \quad (3)$$

where  $E_g$  is the bulk band gap. The energy difference  $\Delta E$  is referred as the confinement energy. The value of  $\Delta E$  depends on the crystal size and becomes zero for bulk. The confinement can be classified into two categories, depending upon the size of the crystal. If the Bohr radius of the exciton is  $a_B$  and  $R$  is the particle radius, then the system is said to have strong confinement if  $R \ll a_B$  and weak confinement if

$R \gg a_B$ . In the simplest approach, the confinement energy in the case of strong confinement is given by [10, 14–17]

$$\Delta E = \frac{\hbar^2 \chi^2}{2\mu R^2} \quad \text{with} \quad \frac{1}{\mu} = \frac{1}{m_e} + \frac{1}{m_h} \quad (4)$$

In the case of weak confinement the confinement energy is

$$\Delta E = \frac{\hbar^2 \chi^2}{2MR^2} \quad \text{with} \quad M = m_e + m_h \quad (5)$$

Here,  $m_e$  and  $m_h$  are the electron and the hole mass, respectively, and  $\chi$  are roots of the spherical Bessel functions; the first root for the lowest energy transition is  $\chi = \pi$ . The simple effective mass model was improved by empirical pseudopotential [18] and tight-binding [19, 20] methods with application to II–VI semiconductors. The first-principles pseudopotential method was also applied to silicon [21]. For more details see, for example, the review in Ref. [22].

The II–VI nanoparticles are the most investigated materials, and PL spectroscopy is widely used to measure the confined energy [12, 23]. A typical PL spectrum from nanoparticles contains a sharp structure corresponding to the band edge, and some broad structures related to shallow and deep traps. The structure corresponding to the band edge is usually asymmetrically broadened, partially due to the temperature and the shallow traps very close to the band edge. However, under careful experimental conditions, the luminescence at the band edge can still be used with sufficient accuracy to estimate the band gap of the material. As discussed above, the effective band gap of a nanoparticle system is increased due to confinement. This can be easily observed in PL spectra, in the form of a blueshift of the band-edge luminescence. Because this shift depends on particle size, and the samples usually have an asymmetric particle size distribution, the band-edge luminescence is also partially asymmetrically broadened due to the particle size distribution. It has been observed [13] that in some cases the peak position of the band-edge luminescence strongly depends on the probing laser power and, hence, it is important to measure the luminescence at very low probing power-density to avoid other causes, which may shift the luminescence peak. By measuring the peak position of this band-edge luminescence, one can estimate the effective band gap  $E = E_g + \Delta E$  of the material. By substituting the bulk band gap  $E_g$  and by using the above-mentioned equation for the confinement energies, one can estimate the particle size. Although the absolute particle size estimation using PL experiments alone may not give a very accurate value of the particle size, it gives a good estimation of the confinement energy, especially when one wants to compare the confinements due to changing particle sizes. A comparison with Raman scattering also shows satisfactory agreement for the particle size estimation.

### 3. ELECTRON–PHONON COUPLING

Electron–longitudinal optical (LO) phonon coupling, governed by the Fröhlich interaction, is very important in the electronic and optical properties of a nanoparticle system, and its investigation has attracted a lot of attention. The

coupling between free charge carriers and vibrational excitations plays a central role in determining the transport properties and the energy relaxation rates of the excited carriers. One of the interesting points is that the electron–phonon interaction in small nanoparticles can be investigated experimentally beyond the bulk approximations. In this system, the confinement effects influence not only the electronic and vibrational states, but also the coupling between them. Although the effect of size dependence on the electron–phonon coupling has inspired a lot of work, the initial studies have produced contradicting results. In the early work, Schmitt-Rink et al. [24] theoretically suggested that, if electron and hole charge distributions are identical, then exciton–LO phonon coupling should vanish in small nanoparticles. Klein et al. [25] predicted size-independent coupling, if the dimensions of the charge distribution scales as the particle size. However, other authors [26–28] suggested that electron–phonon coupling increases with decreasing particle size for small particles. Here, the electron–hole correlation, the valence band degeneracy, the conduction band nonparabolicity, and proper confined phonon wavefunctions were considered. Experimentally, absorption spectroscopy [29] and photoluminescence [30] measurements indicated that the electron–phonon coupling increases with decreasing particle size. On the other hand, in some resonant Raman scattering experiments, in which in principle the electron–phonon interaction can be directly probed, either a size-independent coupling [25] or a decrease of electron–phonon coupling with decreasing particle size was detected [31, 32]. Later, Scamarcio et al. [33] unambiguously demonstrated that the electron–LO phonon coupling increases with increasing confinement in the strong confinement region. This was experimentally demonstrated through the size dependence of the ratio between the two-phonon and the one-phonon Raman cross sections in the resonant Raman scattering of a prototype system. These experiments were done under improved conditions, with constant resonance conditioning being maintained for all the particle sizes investigated. It was experimentally shown that, as the nanoparticle size changes from about 3 to 2 nm, the electron–phonon interaction increases more than two times. They also suggested that the electron–phonon coupling governed by the Fröhlich interaction increases stronger than that governed by the deformation potential with decreasing particle size.

Resonant Raman scattering up to the third order was studied by Rodríguez-Suárez et al. [34]. The observed relative intensities of the overtones were found to be very sensitive to the particle size, in accordance with calculations considering the Fröhlich interaction between excitons and phonons.

For exciton–acoustic phonon interaction the deformation potential coupling mechanism was shown to predominate in semiconductor nanocrystals [35, 36].

## 4. ACOUSTIC PHONONS

### 4.1. Confinement

The finite size of nanoparticles restricts the motion of phonons inside a nanocrystal; hence the confinement effects on the phonons can be observed. For a bulk

crystal, the phonons can extend up to infinity, which allows  $\vec{q}$  to take any value in the reciprocal lattice, including zero. Owing to the scattering selection rules, phonons at the  $\Gamma$ -point ( $\vec{q} = 0$ ) are the only observable phonons in the first-order Raman scattering. Therefore, the acoustic phonons, with vanishing energy at the  $\Gamma$ -point, are not observed in the first-order Raman scattering of a bulk crystal. On the other hand, because of the uncertainty of momentum transfer for small particles, acoustic phonons in nanocrystals become observable in first-order Raman spectra. They are called “confined acoustic phonons.” The vibrational frequencies of these phonons are very close to zero. They appear in the low-frequency range of the Raman spectra, with frequencies inversely proportional to the diameter of the nanoparticles.

One way to understand these acoustic phonons is to consider the possible vibrations of the whole particle. To calculate these vibrations, the particle can be considered as an elastic sphere and elastic continuum theory can be used, along with the proper boundary conditions at the surface of the nanoparticle. More than 100 years ago, Lamb [6] discussed the vibrations of a homogeneous elastic body of spherical shape under stress-free boundary conditions. This model, which was extended later (see, e.g., Tamura et al. [37]), is valid if the wavelengths of the acoustic phonons sufficiently exceed those of the lattice constants. It has been proved to be useful as an approximation for the calculations of vibrational confinement in nanoparticles. The eigenfrequencies of the elastic body can be obtained by solving the differential equation

$$\partial^2 \vec{s} / \partial t^2 = v_t^2 \Delta \vec{s} + (v_l^2 - v_t^2) \text{grad div } \vec{s} \quad (6)$$

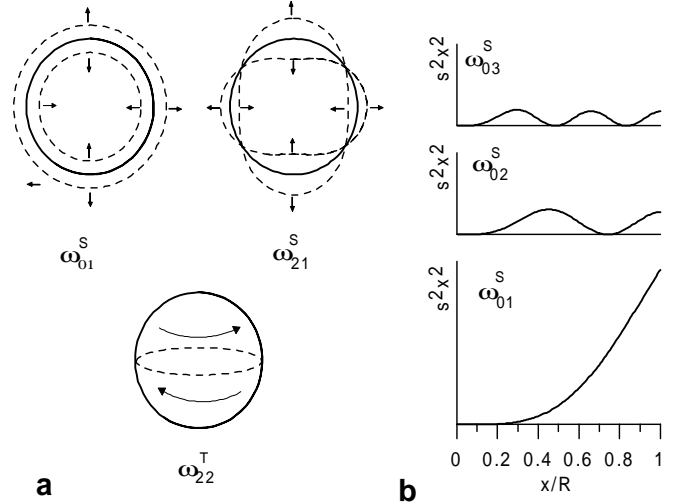

under the corresponding boundary conditions. Here,  $\vec{s}$  is the lattice displacement vector, and  $v_t$  and  $v_l$  are the transverse and the longitudinal sound velocities, respectively. By classifying the eigenfrequencies according to the symmetry group of the sphere, two types of vibrational modes can be obtained, spheroidal modes  $\omega^S$  and torsional modes  $\omega^T$ . The torsional modes are dilatation-free vibrations without a volume change of the sphere and the spheroidal modes are curl-free.

The eigenvalues are characterized by the angular quantum number  $\ell$  and by another quantum number  $p$ , which gives the order of the zeroth of the radial part of the wavefunction. The torsional mode is only defined for  $\ell \geq 1$  because the mode with  $\ell = 0$  has no displacement. The eigenvalues determine the quantized vibrational frequencies  $\omega_{\ell p}^S$  and  $\omega_{\ell p}^T$  for the particle with the radius  $R$  from the relations

$$\omega_{\ell p}^S = \frac{\xi_{\ell p}^S}{R} v_l \quad \omega_{\ell p}^T = \frac{\eta_{\ell p}^T}{R} v_t \quad (7)$$

where  $\xi$  and  $\eta$  are the eigenvalues of Eq. (6).

The “wavevectors” of acoustic phonons in nanoparticles are also quantized and are described by the two sets  $\xi_{\ell p}^S/R$  and  $\eta_{\ell p}^T/R$ . Figure 1a illustrates the deformations of the vibrating sphere for the eigenfrequencies with lowest indices. The total symmetric spheroidal mode or the “breathing” mode is denoted by  $\omega_{01}^S$ ,  $\omega_{21}^S$  indicates the quadrupolar symmetric spheroidal mode, and  $\omega_{21}^T$  is a torsional mode. Only the lowest modes  $\omega_{\ell p}^S$  with  $p = 1$  have large amplitudes

**Figure 1.** Some vibrational modes of an elastic isotropic sphere. (a) Spheroidal “breathing” mode  $\omega_{01}^S$  with  $\ell = 0$  and  $p = 1$ , spheroidal quadrupolar mode  $\omega_{21}^S$ , and torsional mode  $\omega_{21}^T$ . (b) Radial distribution of the energy density  $s^2 x^2$  of the spheroidal breathing mode  $\omega_{01}^S$  (surface mode) and the first two overtones  $\omega_{02}^S$  and  $\omega_{03}^S$  (inner modes) for spherical particles with free surface.

near the surface of the nanocrystals; the higher modes with  $p > 1$  correspond to inner modes. Figure 1b shows the radial distribution of the energy density  $s^2 R^2$  of the spheroidal breathing mode  $\omega_{01}^S$  (also called surface mode) and the first two overtones  $\omega_{02}^S$  and  $\omega_{03}^S$  (inner modes).

As shown by Duval [38], only the spheroidal modes with angular quantum numbers  $\ell = 0$  and  $\ell = 2$  are Raman active. The total symmetric mode  $\ell = 0$  is polarized, and the quadrupolar symmetric mode  $\ell = 2$  is depolarized. The simplest case  $\ell = 0$  with the eigenvalue equation

$$\sin(\xi) = 4\alpha^2 j_1(\xi) \quad (8)$$

can be analyzed easily. Here,  $j_1(x) = (\sin(x) - x \cos(x))/x^2$  is the spherical Bessel function of first order. Eigenvalue equations for higher quantum numbers are given, for example, in [37, 39, 40].

For a free particle, the parameter  $\alpha$  in Eq. (8) is given by the ratio of the transverse and longitudinal sound velocities  $v_t/v_l$ . In the case of an embedded particle, the relations for the continuity of the displacement and of the stress vectors at the spherical surface result in a generalized eigenvalue [41]. The parameter  $\alpha$  then additionally depends on the sound velocities in the matrix and on the ratio of the mass densities of the particle and the matrix. Further,  $\alpha$  is obtained as a complex number, sound emission into the matrix occurs, and therefore the particle vibrations are damped.

## 4.2. Raman Scattering

### 4.2.1. Scattering Efficiency

The Raman scattering is caused by fluctuations in the dielectric susceptibility due to the elastic waves. The Raman scattering efficiency can be expressed as a function of the

elasto-optic coefficients [1, 42]. The wavevector dependence of an acoustic mode is given by

$$d\sigma/d\Omega \sim (n(\omega) + 1)q \left[ \int_V \exp[-i(\vec{k}_L - \vec{k}_S - \vec{q}) \cdot \vec{r}] dV \right]^2 \quad (9)$$

where  $n(\omega) = (\exp(\hbar\omega/kT) - 1)^{-1}$  is the Bose-Einstein population factor. For bulk materials, corresponding to large dimensions of the scattering volume  $V$  in comparison with  $1/q$ , the integral in Eq. (9) can be replaced by the  $\delta$  function  $\delta(\vec{k}_L - \vec{k}_S - \vec{q})$ . This expresses the momentum conservation: The wavevectors of the scattered light  $\vec{k}_S$  and of the exciting light  $\vec{k}_L$  are very small. Therefore, only phonons near the center of the first Brillouin zone with wavevectors  $q = |\vec{k}_L - \vec{k}_S| \sim 0$  contribute to the light scattering which hinders the observation of Raman scattering by acoustic phonons in bulk material. By assuming nanoparticles to be spherically shaped with radius  $R$  and by integrating over the sphere volume, the Raman scattering efficiency results in

$$d\sigma/d\Omega \sim (n(\omega) + 1)qS(q, R) \quad (10)$$

with

$$S(q, R) = \left[ \frac{3j_1(qR)}{qR} \right]^2 \quad (11)$$

The scattering function  $S(q, R)$  replaces the  $\delta$  function. In this case, the wavevector selection rules are relaxed. Phonons with larger wavevectors contribute to the Raman scattering, and the observation of the confined acoustic phonons is allowed. For particles embedded in a matrix, the elastic excitations are exponentially damped due to complex eigenvalues. Therefore, we assume for the phonon modes  $\omega_{\ell p}^S$  Lorentzian bands  $L(\omega, \omega_{\ell p}, b_{\ell p}) \sim (1 + (2(\omega - \omega_{\ell p})/b_{\ell p})^2)^{-1}$  with the maximum at  $\omega_{\ell p}$  and half-width  $b_{\ell p}$  describing the damping. Further, we take into account the density of states  $\sim q^2$  and a size distribution  $c(R)$ . Then the Raman scattering intensity is obtained as

$$d\sigma/d\Omega \sim (n(\omega) + 1)\omega^3 \int S(q, R)c(R)V(R)L(\omega, \omega_{\ell p}^S, b_{\ell p})dR \quad (12)$$

with the wavevector  $q = \omega_{\ell p}^S/v_l$  and the particle volume  $V(R)$ .

The homogeneous line broadening due to the matrix effect is considerable and must be taken into account if one wants to deduce the particle size distribution from the Raman spectra [41].

#### 4.2.2. II–VI Semiconductors

Figure 2 represents as an example low-frequency Raman spectra of  $\text{CdS}_x\text{Se}_{1-x}$  nanoparticles with a mean radius of  $R = 3.1$  nm embedded in a silicate glass matrix. The spectra were excited with a Ti:sapphire laser operating at a wavelength far from resonance. The curves (a) and (b) correspond to polarized and depolarized configurations, respectively. For comparison, curve (c) shows an unpolarized spectrum of the base material, which contains no nanoparticles. The broad band with maximum at about  $50 \text{ cm}^{-1}$ , which

**Figure 2.** Low-frequency Raman scattering spectra of  $\text{CdS}_{0.67}\text{Se}_{0.33}$  nanocrystals embedded in borosilicate glass excited at the wavelength  $\lambda = 857$  nm below the absorption band. The mean particle radius is 3.1 nm. The quadrupolar mode is indicated by 1; the phonon modes 3 and 4 are overtones of the breathing mode 2. (a) Polarized spectrum; (b) depolarized spectrum; (c) base material of the sample. In the inset the polarized spectra in the anti-Stokes and in the Stokes regions are shown.

is typical for glass vibrations and is known as the Boson peak [43, 44], is also present in the spectra (a) and (b). Band 1 in curve (a) at  $8.5 \text{ cm}^{-1}$  corresponds to the depolarized spheroidal vibration with  $\ell = 2$  and  $p = 1$  and band 2 at  $17.5 \text{ cm}^{-1}$  corresponds to the polarized spheroidal vibration with  $\ell = 0$  and  $p = 1$ . Weaker bands 3 and 4 at about 40 and  $55 \text{ cm}^{-1}$  can be assigned to the inner modes with  $\ell = 0$  and  $p = 2$  and  $p = 3$ , respectively. The frequencies of the bands scale with  $1/R$ , as can be seen in Figure 3 where results for  $\text{CdS}_x\text{Se}_{1-x}$  nanoparticles with different sizes are shown. Such doped semiconductor glasses are used as sharp cutoff filters, the absorption edge being adjusted by changing the particle size. The value obtained experimentally agree well with calculations based on the continuum theory. The influence of the composition  $x$  is small as can be seen by the three curves for each phonon mode calculated for  $x = 0.8, 0.5$ , and  $0.2$ .

Nanocrystals of II–VI semiconductors are conventionally synthesized either in oxide glass hosts or by colloidal precipitation. The synthesis of quantum dots in polymer films has also been reported. For more information see, for example, Woggon [22], Herron [45], Kamat et al. [46], and references therein.

In the case of semiconductor-doped oxide glasses, precipitation of the semiconducting dots from the solid solution is obtained by annealing the glass after quenching. Silicate glasses containing  $\text{CdS}_x\text{Se}_{1-x}$  mixed crystals have been extensively investigated. Particle sizes have been obtained by Raman scattering of acoustic modes in

**Figure 3.** Measured low-frequency peaks in dependence on  $1/R$  for various filter glass samples.  $\omega_{ep}$  indicates various polarized modes, depolarized modes, and their overtones. The experimental values for the corresponding phonons are shown by full circles. The dashed, solid, and dotted lines correspond to the theoretical values calculated with  $x = 0.8, 0.5,$  and  $0.2,$  respectively. It can be seen that the influence of the composition  $x$  on the phonon frequencies is small. Reprinted with permission from [41], P. Verma et al. *Phys. Rev. B* 60, 5778 (1999). © 1999, American Physical Society.

$\text{CdS}_x\text{Se}_{1-x}$  [41, 47–52],  $\text{CdS}$  [49, 53, 54],  $\text{CdSe}$  [39, 55],  $\text{Zn}_x\text{Cd}_{1-x}\text{S}$  [49] crystals in silicate glass matrix,  $\text{CdS}$  [56], and  $\text{CdSe}$  [39] crystals in  $\text{GeO}_2$  glass matrix.

Other methods used to determine the particle sizes were transmission electron microscopy (TEM) [23, 47, 56–61], optical absorption [47, 49, 51, 59, 62], small angle scattering of neutrons (SANS) [63], small angle scattering of X-rays (SAXS) [13, 50, 53, 55, 64, 65], and photoluminescence [59, 66].

In addition to size-dependent shifts of the photoluminescence peaks, the discrete acoustic phonon modes could also be observed in photoluminescence spectra [67].

Saviot et al. [53, 54] observed size and excitation dependence of resonant low-frequency Raman scattering in  $\text{CdS}$  nanocrystals embedded in glass. They reported size-selective excitation, when the exciting laser wavelength was changed within the absorption band. With variation of the excitation within the absorption band, they observed dependence of the low-frequency band position and changes of its depolarization. The low-frequency band was 100% polarized for excitation below the absorption edge while it was depolarized when excited above the absorption.

#### 4.2.3. Si and Ge

Low-frequency Raman modes of nanometric Si crystallites were first observed in porous Si [65, 68]. Gregora et al. [68] found a well-defined peak at  $37 \text{ cm}^{-1}$  in the low-frequency spectra of porous silicon layers produced by electrochemical

etching in hydrofluoric acid solution of heavily boron-doped silicon wafers. With the assumption of spherical particles, on the basis of Eq. (7),  $2R = 6.5 \text{ nm}$  is obtained. However, due to the columnar morphology of the porous structure a model with particles of elongated nonspherical shapes is more realistic. For long cylinders this model yields  $2R \approx 4.1 \text{ nm}$ ,  $2R$  corresponds to the diameter of the columns. A similar value was deduced from the observed downshift and broadening of the  $520 \text{ cm}^{-1}$  one-phonon peak (see Section 6).

Liu et al. [65] succeeded in preparing Si clusters embedded in a porous Si skeleton. The Si clusters were produced by evaporation and inert gas condensation [69, 70], and the cluster size was controlled by adjusting the evaporation temperature, the Ar gas pressure, and the distance between the substrate and the W boat containing the Si powder. The cluster size was determined with TEM measurements. The strongest peaks in the low-frequency region of the Raman spectra were observed at  $29 \text{ cm}^{-1}$  (particle size  $3.8 \text{ nm}$ ) and at  $28 \text{ cm}^{-1}$  (particle size  $3.9 \text{ nm}$ ), respectively.

Raman scattering from acoustic phonons confined in Si nanocrystals which were dispersed in  $\text{SiO}_2$  thin films have been observed by Fujii et al. [71]. The samples were prepared by a radiofrequency cosputtering method [72, 73]. The sizes of the particles were determined from high-resolution electron microscopic observations. It was found that the Si nanocrystals are single crystals with good crystallinity. Raman spectra are shown in Figure 4. As the size decreases, the peaks shift to higher frequencies. The intensity ratio of the peaks in the polarized and depolarized spectra is about 0.25 for samples with  $d = 3.1$  and  $3.5 \text{ nm}$ ; for  $d = 5.5 \text{ nm}$  a distinct peak was not observed in the depolarized spectrum. However, the quantitative comparison between the experiment and the theory based on the continuum model is not successful. This will be discussed in Section 4.3.

Low-frequency Raman measurements on Ge microcrystals with sizes of  $5 \text{ nm}$  and greater embedded in a  $\text{GeO}_2$  glass matrix have been performed by Ovsyuk and Novikov [40, 74]. The crystals were grown using the reaction  $2\text{GeO}(\text{gas}) = \text{Ge} + \text{GeO}_2$  [74]. The low-frequency Raman scattering data

**Figure 4.** Low-frequency Raman scattering of Si nanocrystals embedded in  $\text{SiO}_2$  matrices. (a) Polarized spectra; (b) depolarized spectra. Reprinted with permission from [71], M. Fujii et al. *Phys. Rev. B* 54, R8373 (1996). © 1996, American Physical Society.

were used to show that the vibrations of the Ge nanocrystals differ considerably from those of free particles and that the influence of the matrix is considerable. Using the theory of Tamura et al. [37] the influence of the matrix on the spheroidal and torsional modes of nanocrystals was analyzed. It was found that surface vibrations were caused by the restoring force which limits the free rotation of microcrystals.

#### 4.2.4. Other Compounds

While in semiconducting nanoparticles the spheroidal breathing mode with  $\ell = 0$  and  $p = 1$  is the strongest in the Raman spectra, the scattering intensity of this mode is very low for metallic nanocrystals, for example, consisting of Ag or Au, and the light scattering of the quadrupolar mode dominates the Raman spectra. The reason is that in the latter case the inelastic light scattering is induced by the phonon-plasmon coupling. The electric dipole moment of the surface plasmon is modulated by the vibrational modes. As noted by Gersten et al. [75], the breathing mode ( $\ell = 0$ ) will produce no significant modulation; however, the quadrupolar vibrations ( $\ell = 2$ ) will be strongly coupled to the dipolar plasmon. A depolarization ratio of 0.75 was determined for the  $\ell = 2$  modes [76].

Light scattering is sensitive to the size and the shape of the nanoparticles. For ellipsoidally distorted shapes, the threefold degenerate dipolar plasmon splits into a lower-energy plasmon oscillating along the long axis of the ellipsoid and a twofold degenerate higher-energy plasmon oscillating perpendicular to this axis. Further, the fivefold degeneracy of the  $\ell = 2$  mode ( $m = 0, \pm 1, \pm 2$ ) is lifted. The observed large inhomogeneous width of the plasmon absorption of Ag clusters may be explained by ellipsoidal distortions because the plasmon energy very weakly depends on the size [77]. The shape of the clusters can even be selected by Raman scattering: Palpant et al. [78] investigated thin films consisting of small Ag clusters embedded in a porous alumina matrix. Most clusters were roughly spherical, but a noticeable amount of clusters, generally the larger ones, were found with a prolate ellipsoidal shape, as shown by TEM investigations. By excitation with the 457.9 nm Ar laser line close to the absorption maximum at 420 nm, the low-frequency peaks of spherical nanoclusters were observed with a depolarization ratio close to  $\frac{3}{4}$ . By shifting the excitation to the red region, the low-frequency peak was shifted to lower frequency with a depolarization ratio close to  $\frac{1}{3}$ . This can be explained by selective enhanced excitation of the nondegenerate plasmon along the long axis of the ellipsoidally distorted particles by excitation in the low-energy wing of the absorption band.

Silver nanocrystals embedded in  $\text{SiO}_2$  [79], alkali halide [76], and porous alumina matrix [78] were investigated too. It was shown that the observed low-frequency peaks agree fairly well with calculations based on Lamb's theory if the particle size is less than about 4 nm [79]. Courty et al. [80] performed low-frequency Raman measurements on silver nanocrystals self-organized on a hexagonal compact array on highly oriented pyrolytic graphite substrate. Besides the quadrupolar vibration mode, two weaker bands were observed at larger frequency shifts. They were attributed to

the spheroidal breathing modes  $\ell = 0$ , and  $p = 1, 2$ , and their observation was made possible by the high crystallinity and the narrow size distribution of the particles. Recently, low-frequency Raman measurements of Au particles supported on  $\text{CeO}_2$  and  $\text{Fe}_2\text{O}_3$  catalytic matrixes were performed [81, 82] with the aim of measuring their grain size. Supported by measurements of the depolarization ratio, it was concluded that the observed bands are due to the  $\ell = 0$  and  $\ell = 2$  spheroidal modes [82].

Confined acoustic phonons were investigated in Sn nanoparticles embedded in a  $\text{SiO}_x$  thin film, the inelastic scattered light was measured by a Sandercock interferometer [83]. The observed low-frequency modes scale with the inverse of the particle size in accordance with Lamb's theory. The vibrational modes of the smallest particles were overdamped. A similar result was obtained with femtosecond pump-and-probe spectroscopy measurements, where oscillations with comparable frequencies were detected for the big particles but not for the smaller ones. By increasing the temperature, clear effects of particle melting on the acoustic and the optical modes could be observed [84].

For  $\text{SnO}_2$  nanoparticles grain size and distribution deduced from Raman scattering were found in agreement with TEM measurements, especially for the smaller particles [85].

#### 4.3. Size Determination

In this section we will discuss other methods that are used for particle size determination and often correlated with Raman scattering measurements.

The average sizes calculated from the frequencies at the low-frequency peak maxima in the Raman spectra are overestimated if a size distribution is present because the scattering intensity is proportional to the particle volume. This is true for perfect lattice structure; however, lattice defects may reduce the scattering intensity due to spatial coherence effects as discussed by Duval et al. [86].

- (a) *Transmission electron microscopy.* TEM is often used to deduce a mean particle size and size distributions from a limited number of particle images. Preparation techniques are often pretentious and may affect the observation; the particle sizes are underestimated.

The lattice images of nanocrystals observed with high-resolution TEM are produced by interference of diffracted beams; different types of lattice images are found, depending on the orientation of the particle relative to the electron beam. They are visible when the crystal thickness exceeds a threshold value  $t_0$ . For the case of CdSe in glass, Champagnon et al. [47] estimated a threshold thickness of  $t_0 \approx 3$  nm. Therefore, the lattice is visible only in particles larger than the threshold thickness. Further, for larger particles the lattice image is produced from the central parts but may be invisible (below a threshold intensity) near the surface over a width  $w \approx t_0^2/4R$ , depending on the particle radius  $R$ . The deviation of the apparent size from the real size, therefore, is much more important at small sizes. This effect could be one possible reason for discrepancies in the observed sizes of very small

particles determined with different methods [47]; see Figures 6 and 7.

- (b) *Absorption, luminescence.* The energetically lowest optical transition can be used to determine the particle size. The corresponding absorption is often not a well-defined narrow peak. Some authors used the second derivative of the absorption spectrum [62] to locate the band edge; other authors took the energy at which the absorption appears to extrapolate to zero [87]. A clear inverse square size dependence in both the absorption edge and in the photoluminescence was observed in most cases, at least for II–VI compounds. Potter and Simmons [59] studied CdS crystals at sizes between 4 and 40 nm and obtained good agreement with the case of strong confinement [Eq. (4)]. The bulk Bohr radius in CdS is 2.8 nm. In general, the determination of size values from absorption and luminescence measurements depends on the model used and requires knowledge of parameters such as exciton masses.
- (c) *X-ray diffraction (XRD).* The finite crystallite size leads to a broadening of the peaks in the XRD spectra. This can be understood if one considers that in a finite crystal the number of rays reflected from successive lattice planes that add up in constructive or destructive interference is finite. Therefore, they do not reinforce or cancel out completely. The determination of the crystallite size from the XRD peaks is discussed in several books [88–90], mostly the Scherrer formula is used. The peak broadening gives a weighted average of the mean grain size, but the grain size may be considerably less than the particle size [91]. Variations in the lattice constant, for instance, from one crystallite to another and structural defects will also broaden the peaks. Several methods have been described to separate crystalline size- and distortion-induced broadenings. Further the XRD spectra can be influenced by particle shape effects. For prolate nanoparticles with more planes contributing to the diffraction in the direction of the prolate axis the corresponding XRD peaks can be increased in intensity and reduced in width as shown for CdSe nanocrystals [92] with sizes of about 8 nm and for Si nanocrystals [93] with sizes of about 50 nm. In the last case the peak-dependent linewidth broadening was used as evidence for pressure-induced diamond-to-hexagonal structure phase transition accompanied by shape changes from spherical to prolate.
- (d) *Small angle scattering (SAXS and SANS).* The size as well as the size distribution can be obtained with SAXS or SANS. We will discuss here as an example SAXS. The central scattering of X-rays due to the presence of nanoparticles having dimensions from several tens to several hundred times the X-ray wavelength  $\lambda$  is analogous to the well-known phenomenon of optical diffraction, where a halo is produced by the passage of a light ray in a powder with grain dimensions on the order of a hundred times the light wavelength. Let us consider a particle in a beam of X-rays; then all the electrons are sources of scattered

waves. The scattered waves are all in phase when the scattering direction is the same as that of the incident beam. As the scattering angle increases, the difference in phase between the various scattered waves also increases and the intensity of the resultant scattered wave decreases because of destructive interference. The intensity becomes zero when there are as many waves between 0 and  $\pi$  as between  $\pi$  and  $2\pi$ ; this will occur for a scattering angle of about  $2\vartheta \approx \lambda/L$ , where  $L$  is an average size of the particle. The scattering cross section for spherical particles with radius  $R$  and size distribution  $c(R)$  embedded in a matrix can be expressed as [94, 95]

$$\frac{d\sigma}{d\Omega}(q, E) \sim A(\Delta\rho(E)) \int S(q, R)c(R)V^2(R) dR \quad (13)$$

where  $q = (4\pi/\lambda) \sin(\vartheta)$  is the magnitude of the scattering vector,  $E$  is the X-ray energy, and the scattering function  $S(q, R)$  was defined in Eq. (11). The expression  $A$  depends on the electronic contrast  $\Delta\rho$  between the particle and the matrix. Figure 5 shows the scattering curve of a sample with  $\text{CdS}_{0.67}\text{Se}_{0.33}$  nanocrystals. The corresponding Raman spectrum is given in Figure 2. The solid line has been fitted by assuming spherically shaped particles with asymmetric size distribution as shown in the inset. The dashed line was calculated for a size distribution with a  $\delta$ -function-like profile.

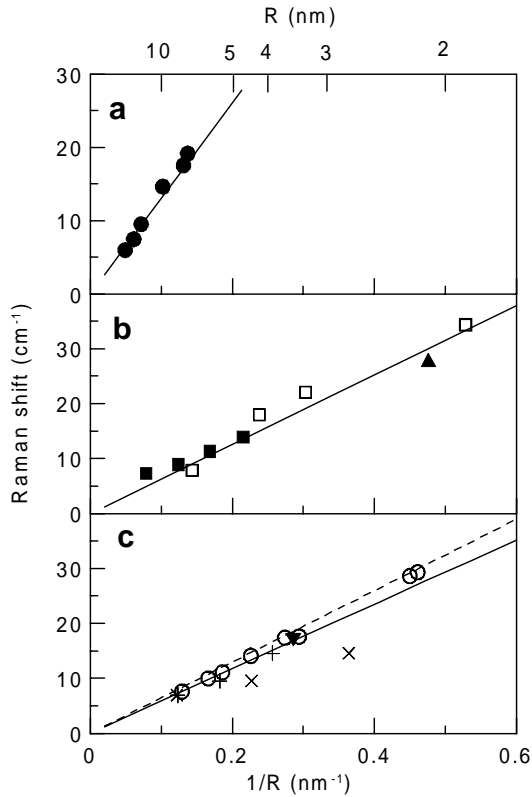

From Eq. (13) it can be seen that particles with larger radius contribute much more to the scattering cross section than smaller ones. Therefore, average size values could be overestimated if Guinier plots and not a complete fit procedure are used.

In Figure 6 results of Raman measurements of nanocrystals in glass matrices are plotted against the inverse radius

**Figure 5.** Small angle X-ray scattering curve of the sample with  $\text{CdS}_{0.67}\text{Se}_{0.33}$  nanocrystals described in Figure 2. The solid line has been fitted by assuming spherically shaped particles with asymmetric size distribution as shown in the inset. The dashed line was calculated for a size distribution with a  $\delta$ -function-like profile. Reprinted with permission from [95], G. Irmer et al. *J. Appl. Phys.* 88, 1873 (2000). © 2000, American Institute of Physics.

**Figure 6.** Position of the spheroidal mode  $\omega_{01}^s$  as a function of the inverse of the particle radius as observed by other scattering methods or TEM, respectively. as determined by other scattering methods (SAXS, anomalous SAXS, or SANS) or TEM, respectively. The straight full lines are calculated with Lamb's theory for spheres with free surfaces, and the dotted line in Figure 6c takes into account the matrix effect. The agreement between various scattering methods is good; however, for smaller particles deviations from results of TEM measurements can be observed [47].

Large discrepancies between experimental results and the theory based on the continuum model were obtained for Si nanocrystals, as shown in Figure 7. Because the formulae in Section 4.1 are based on the isotropic elastic medium approximation, mean values for the sound velocities  $v_l$  and  $v_t$  were used for the calculation of the size dependence of the polarized spheroidal mode  $\omega_{01}$  and the depolarized spheroidal mode  $\omega_{21}$  of a free particle. The calculated values are much larger than those of the measured peaks, even if the large anisotropy of the elastic constants in Si is taken into account. The influence of the SiO<sub>2</sub> matrix [71] is discussed as one possible reason for the deviation between experiment and theory. However, quantitative estimations are still lacking and further theoretical studies are necessary. For instance, opposite predictions were made for the influence of SiO<sub>2</sub> matrices on Ag particles. Montagna and Dusi [96] predicted very small and negligible influences, while Ovsyuk and Novikov [40] reported that the phonon modes

**Figure 7.** Position of the spheroidal mode  $\omega_{01}^s$  as a function of the inverse of the particle radius of Si nanocrystals. The radii were obtained by ●, TEM measurements [71]; ○, TEM measurements [65]; □, estimation of the size analyzing the shift and shape of the optical phonon band assuming a columnar structure (column radius  $R$ ) [68]. The straight lines were calculated based on Lamb's theory for particles with free surfaces: solid line, spheres; dotted line, columns, assuming isotropic elastic medium. The hatched region indicates the range of theoretical values when the elastic anisotropy of Si is taken into account. For comparison theoretical results (+) obtained with lattice dynamical calculations on Si clusters are included [170].

due to matrix effects shift to lower frequencies by considerable amounts.

## 5. SURFACE PHONONS

### 5.1. Surface Modes of Small Particles

The classical electromagnetic theory for the absorption and scattering of a sphere was given a century ago by Mie [7]. About 60 years later Mie's theory was applied to spherical ionic crystallites [99–102] characterized by the frequency-dependent dielectric function  $\varepsilon(\omega)$  which also describes the optical behavior of a polar semi-insulating cubic semiconductor in the infrared (IR) region:

$$\varepsilon(\omega) = \varepsilon_\infty \left[ \frac{\omega_{LO}^2 - \omega^2 - i\omega\gamma}{\omega_{TO}^2 - \omega^2 - i\omega\gamma} \right] \quad (14)$$

Here,  $\omega_{TO}$  and  $\omega_{LO}$  are the frequencies of the transverse and longitudinal optical bulk phonons, respectively,  $\varepsilon_\infty$  is the dielectric constant at high frequencies, and the constant  $\gamma$  takes damping into account. The bulk phonons in small particles have properties similar to those of the corresponding phonons in an infinite crystal; however their wavefunctions are adapted to the geometry of the small particle. For spherical geometry, for example, the phonon wavefunctions can be described by orthogonal eigenfunctions consisting of products of spherical Bessel functions  $j_\ell(q_{ln}r)$  with spherical harmonics  $Y_{\ell m}$ , classified by the quantum numbers

$\ell$ ,  $m$ , and  $n$ . The radial wavevectors  $q_{\ell n}$  are size-quantized due to the boundary conditions with  $q_{\ell n} = \nu_{\ell n}/R$ , where  $\nu_{\ell n}$  are the  $\ell$ th order spherical Bessel function roots [103].

In addition to the bulk phonons in small particles, there exist surface phonon modes, which have no counterpart in infinite crystals. Their frequencies  $\omega_\ell$  are intermediate between  $\omega_{\text{TO}}$  and  $\omega_{\text{LO}}$ . They can be obtained by solving the equation

$$\varepsilon(\omega) + \varepsilon_1 \cdot (\ell + 1)/\ell = 0, \quad \ell = 1, 2, 3, \dots \quad (15)$$

where  $\varepsilon_1$  is the dielectric constant of the embedding medium and  $\ell$  is an angular quantum number. Unlike bulk phonons, the surface phonons have nonvanishing electrical fields outside the particle; inside the electrical field changes with  $r^{\ell-1}$  radial dependence. The surface mode with the lowest index  $\ell = 1$  has a constant amplitude inside the sphere (therefore, the restriction of the notation ‘‘surface mode’’ to modes with  $\ell > 1$  is also in use). This mode of homogeneous polarization has a frequency  $\omega_F$  given by the solution of  $\varepsilon(\omega) + 2\varepsilon_1 = 0$  and is often called the Fröhlich mode [104]. With each surface mode a surface charge distribution is associated, which generates the polarization field inside the sphere. The Fröhlich mode with  $\ell = 1$  corresponds to a dipolar charge distribution, the mode with  $\ell = 2$  to a quadrupolar, and the inner modes with higher  $\ell$  to higher multipolar surface charge distributions. For particles that are small compared with the wavelength, the electrostatic approximation can be used and the mode with  $\ell = 1$  dominates [105].

Up to now we have considered a spherical particle. However, the shape has an important influence on the surface mode frequencies. As an example, we consider an ellipsoid of homogeneous polarization (Fröhlich mode). Three frequencies are obtained instead of one, given by the solutions of the equations

$$\varepsilon(\omega) + \varepsilon_1 \cdot (1/n_i - 1) = 0, \quad i = 1, 2, 3, \dots \quad (16)$$

where  $n_i$  are the so-called depolarization factors corresponding to the  $i$ th axis of the ellipsoid. The depolarization factors obey the relations  $0 \leq n_i \leq 1$  and  $n_1 + n_2 + n_3 = 1$ . The inverse of  $n_i$  is approximately proportional to the  $i$ th axis. Note, that for  $n_1 = n_2 = n_3 = \frac{1}{3}$  the case  $\varepsilon(\omega) + 2\varepsilon_1 = 0$  of the sphere is obtained; for an infinite long cylinder with  $n_1 = n_2 = \frac{1}{2}$ ,  $n_3 = 0$  the surface frequency is determined by  $\varepsilon(\omega) + \varepsilon_1 = 0$ . The electromagnetic theory was extended to cylindrical [106], cubic [107], and other nonspherical particles; reviews are given in Refs. [102, 105, 108].

Roca et al. [109] and Chamberlain et al. [110] extended the treatment of polar optical phonons in quantum dots by including mechanical boundary conditions. Phonon dispersion up to quadratic terms in the wavevector and the coupling between the mechanical displacement and the electrostatic potential were taken into account. Their model gives (1) uncoupled transverse optical (TO) modes with purely transverse character and (2) coupled modes with in general mixed LO–TO character.

$\ell = 0$ : The most important contribution to Raman scattering corresponds to the modes with  $\ell = 0$ . These LO modes

of longitudinal type are purely radial with the mechanical displacement vector

$$\vec{s}_{\ell=0,n} = A j_1(\nu_n r/R) \vec{e}_r \quad (17)$$

where  $\nu_n$  is the  $n$ th zero of the spherical Bessel function  $j_1$ . Assuming a quadratic negative bulk LO phonon dispersion, the eigenfrequencies of the modes with  $\ell = 0$  are given by

$$\omega_n^2 = \omega_{\text{LO}}^2 - \beta_L^2 (\nu_n/R)^2 \quad (18)$$

Here,  $\beta_L^2$  is a parameter describing the dispersion of the LO phonon in the bulk [109, 111]. For large  $R$ ,  $\omega_n \rightarrow \omega_{\text{LO}}$  is obtained. For example, for GaAs quantum dots embedded in AlAs, the  $n = 1$  mode was calculated to occur basically at the  $\omega_{\text{LO}}$  frequency of bulk GaAs for radii  $> 2.5$  nm.

$\ell \geq 1$ : The frequencies of these surface modes are more difficult to obtain [109]. However, for large  $R$  the frequencies are again solutions of Eq. (15), meaning that the effect of mechanical boundary conditions becomes important only for small  $R$ .

The theories mentioned above concern the optical response of an isolated particle embedded in a homogeneous medium characterized by a dielectric constant  $\varepsilon_1$ ; particle interactions are not included. However, in practice the particles are often not separated and light-scattering experiments have to be performed on collections of particles like powders or nanosized porous media. As mentioned above, the surface modes in polar semiconductors are accompanied by electrical fields. For instance, the Fröhlich mode of an particle with its dipole field will interact with those of other particles via dipole–dipole interaction. A theory that accounts approximately for the interactions is the effective medium theory.

## 5.2. Effective Medium Theory

For visible light interacting with semiconducting nanoparticles (characteristic size  $L$  and dielectric function  $\varepsilon_2$ ) distributed in a medium with the dielectric constant  $\varepsilon_1$  in the limit  $\lambda \gg L$  the heterogeneous composite can be treated as a homogeneous medium, and the so-called effective medium theory applies.

The effective dielectric function  $\varepsilon_{\text{eff}}$  is defined by

$$\langle \vec{D} \rangle = \varepsilon_{\text{eff}} \langle \vec{E} \rangle \quad (19)$$

where  $\langle \vec{D} \rangle$  and  $\langle \vec{E} \rangle$  denote spatial averages of the dielectric displacement and the electric field, respectively. For a composite of two materials with the dielectric functions  $\varepsilon_1$  and  $\varepsilon_2$  we get

$$(1-f)\varepsilon_1 \langle \vec{E} \rangle_1 + f\varepsilon_2 \langle \vec{E} \rangle_2 = \varepsilon_{\text{eff}} [(1-f)\langle \vec{E} \rangle_1 + f\langle \vec{E} \rangle_2] \quad (20)$$

where the averages are taken over the volumes occupied by the material with the dielectric function  $\varepsilon_1$  or  $\varepsilon_2$ , respectively. The parameter  $f$  is the relative volume  $V_2/V$  occupied by the material with  $\varepsilon_2$ . If the fields have the same directions in the two media (which has to be proved), the

dielectric function can be expressed as a function of the field ratio  $\beta = \langle E \rangle_2 / \langle E \rangle_1$ :

$$\varepsilon_{\text{eff}} = \frac{(1-f)\varepsilon_1 + f\varepsilon_2\beta}{(1-f) + f\beta} \quad (21)$$

The field ratio  $\beta$  can be obtained by solving the electrostatic equations  $\text{rot } \vec{E} = 0$  and  $\text{div } \vec{D} = 0$  under the appropriate boundary conditions. Exact solutions exist only in a few cases:

- (a) The medium consists of parallel slabs of both materials; the applied electrical field is parallel to the slabs (perpendicular to their common normal). Continuity of the tangential electric field components requires  $\beta = 1$  and we get from Eq. (21)

$$\varepsilon_{\text{eff}} = \varepsilon_{\text{upp}} = (1-f)\varepsilon_1 + f\varepsilon_2 \quad (22)$$

the so-called upper Wiener limit [112], because it can be proven to be the absolute upper limit for  $\varepsilon_{\text{eff}}$  for a two-material composite.

- (b) The medium consists of parallel slabs of both materials; the applied electrical field is perpendicular to the slabs (parallel to their common normal). Continuity of the normal displacement field components requires  $\beta = \varepsilon_1/\varepsilon_2$  and we get from Eq. (21) the so-called lower Wiener limit [112] as the absolute lowest limit for  $\varepsilon_{\text{eff}}$  for a two-material composite:

$$\frac{1}{\varepsilon_{\text{eff}}} = \frac{1}{\varepsilon_{\text{low}}} = \frac{(1-f)}{\varepsilon_1} + \frac{f}{\varepsilon_2} \quad (23)$$

- (c) An exact solution is also possible for the case of an external electrical field applied along an axis of an ellipsoid (e.g., dielectric function  $\varepsilon_2$ ) embedded into an infinite matrix (of dielectric function  $\varepsilon_1$ ); see, for example, Ref. [105]. Here, we restrict ourselves to the special case of a sphere. The field ratio is then  $\beta = 3\varepsilon_1/(\varepsilon_2 + 2\varepsilon_1)$ , often derived in textbooks of electrodynamics. From Eq. (21) we obtain the Maxwell–Garnett (MG) I result [113]; see Table 1,

three-dimensional case. The result is exact for the  $f \rightarrow 0$  limit (and for the trivial case  $f = 1$ ). Therefore, the application of the formula is justified if the matrix contains only a few well-separated spheres ( $f \rightarrow 0$ ), but often it is used as interpolation formula for all  $f$ . The formula, for example, describes the case of semiconducting spheres with concentration  $f$  and dielectric function  $\varepsilon_2 = \varepsilon(\omega)$  embedded in air ( $\varepsilon_1$ ). The replacements  $\varepsilon_1 \leftrightarrow \varepsilon_2$  and  $f \leftrightarrow 1-f$  result in the Maxwell–Garnett II formula  $\varepsilon_{\text{eff}} = \varepsilon_{\text{MGII}}$  (see Table 1) corresponding to the “swiss cheese” case of spherical air inclusions ( $\varepsilon_1$ ) in the semiconducting material with  $\varepsilon_2 = \varepsilon(\omega)$ . It can be shown that (if  $\varepsilon_1 < \varepsilon_2$ )  $\varepsilon_{\text{MGI}}$  and  $\varepsilon_{\text{MGII}}$  are the absolute lowest and the absolute upper limit, respectively, for the effective dielectric function  $\varepsilon_{\text{eff}}$  for isotropic or cubic two-material composites [114]:

$$\varepsilon_{\text{low}} < \varepsilon_{\text{MGI}} \leq \varepsilon_{\text{eff}} \leq \varepsilon_{\text{MGII}} < \varepsilon_{\text{upp}} \quad (24)$$

The replacements  $\varepsilon_1 \leftrightarrow \varepsilon_2$  and  $f \leftrightarrow 1-f$  do not result in  $\varepsilon_{\text{MGI}} = \varepsilon_{\text{MGII}}$ ; such a topology is called a matrix topology. If one of the phases is strongly diluted, the Maxwell–Garnett formulae are good approximations. Examples are semiconductor doped glasses with filling factors  $f$  of about 0.01 discussed in the next sections.

If phases 1 and 2 are equivalent, a so-called aggregate topology has to be described. An example is the Bruggeman expression [115] (see Table 1, first row). The solution  $\varepsilon_{\text{eff}}$  of the Bruggeman formula is invariant under the replacements  $\varepsilon_1 \leftrightarrow \varepsilon_2$  and  $f \leftrightarrow 1-f$ , characteristic of an aggregate topology. The Bruggeman formula can be derived by generalizing Eq. (21) for three materials, spherical inclusions  $\varepsilon_1$  and  $\varepsilon_2$  with volume fractions  $f_1 = V_1/V$  and  $f_2 = V_2/V$  embedded in a matrix  $\varepsilon_m$ :

$$\frac{\varepsilon_{\text{eff}} - \varepsilon_m}{2\varepsilon_m + \varepsilon_{\text{eff}}} = f_1 \frac{\varepsilon_1 - \varepsilon_m}{2\varepsilon_m + \varepsilon_1} + f_2 \frac{\varepsilon_2 - \varepsilon_m}{2\varepsilon_m + \varepsilon_2} \quad (25)$$

**Table 1.** Effective dielectric functions.

Topology	3D	2D
Matrix	Maxwell–Garnett I $\varepsilon_{\text{eff}} = \varepsilon_{\text{MGI}} = \varepsilon_1 \frac{2(1-f)\varepsilon_1 + (1+2f)\varepsilon_2}{(2+f)\varepsilon_1 + (1-f)\varepsilon_2}$	Maxwell–Garnett I $\varepsilon_{\text{eff}}^\perp = \varepsilon_1 \frac{(1-f)\varepsilon_1 + (1+f)\varepsilon_2}{(1+f)\varepsilon_1 + (1-f)\varepsilon_2}$
	Maxwell–Garnett II $\varepsilon_{\text{eff}} = \varepsilon_{\text{MGII}} = \varepsilon_2 \frac{(3-2f)\varepsilon_1 + 2f\varepsilon_2}{f\varepsilon_1 + (3-f)\varepsilon_2}$	Maxwell–Garnett II $\varepsilon_{\text{eff}}^\perp = \varepsilon_2 \frac{(2-f)\varepsilon_1 + f\varepsilon_2}{f\varepsilon_1 + (2-f)\varepsilon_2}$
Aggregate	Bruggeman $0 = (1-f) \frac{\varepsilon_1 - \varepsilon_{\text{eff}}}{2\varepsilon_{\text{eff}} + \varepsilon_1} + f \frac{\varepsilon_2 - \varepsilon_{\text{eff}}}{2\varepsilon_{\text{eff}} + \varepsilon_2}$	Bruggeman $0 = (1-f) \frac{\varepsilon_1 - \varepsilon_{\text{eff}}}{\varepsilon_{\text{eff}} + \varepsilon_1} + f \frac{\varepsilon_2 - \varepsilon_{\text{eff}}}{\varepsilon_{\text{eff}} + \varepsilon_2}$
	Monecke $\varepsilon_{\text{eff}} = \frac{\varepsilon_1 + 4f\varepsilon_1(\varepsilon_2 - \varepsilon_1)/(2\varepsilon_1 + \varepsilon_2)}{1 + f(\varepsilon_2 - \varepsilon_1)/(2\varepsilon_1 + \varepsilon_2)} + \frac{2f^2(\varepsilon_2 - \varepsilon_1)^2/(2\varepsilon_1 + \varepsilon_2)}{1 + f(\varepsilon_2 - \varepsilon_1)/(2\varepsilon_1 + \varepsilon_2)}$	

If, in a self-consistent way as the matrix material  $\varepsilon_m$  the effective medium  $\varepsilon_{\text{eff}}$  itself is chosen, with  $f_1 = (1 - f)$  and  $f_2 = f$ , the Bruggeman expression is obtained. It is often considered to be the best possible interpolation formula for an aggregate topology. It has, however, the following essential shortcoming. Let us consider a few semiconducting inclusions with the dielectric function  $\varepsilon_2(\omega)$  in a matrix of constant  $\varepsilon_1$ . In the IR region between the transverse and the longitudinal optical phonon,  $\varepsilon_2(\omega)$  is negative and  $2\varepsilon_1 + \varepsilon_2$  may become zero at the Fröhlich frequency  $\omega_F$ . For  $f \rightarrow 0$  the Maxwell–Garnett I formula is correct and results in a pole at  $2\varepsilon_1 + \varepsilon_2 = 0$ , giving rise to the Fröhlich mode [104]. This exact result is not reproduced for  $f \rightarrow 0$  by the Bruggeman formula. To overcome this deficiency, another interpolation formula for an aggregate topology has to be found. An isotropic aggregate topology is given, for example, by spherical  $\varepsilon_2$  inclusions in a matrix  $\varepsilon_1$  for  $f \rightarrow 0$  interpolated to spherical  $\varepsilon_1$  inclusions in a matrix  $\varepsilon_2$  for  $f \rightarrow 1$ . In both limits the field ratios are exactly known as  $\beta_{f \rightarrow 0} = 3\varepsilon_1 / (2\varepsilon_1 + \varepsilon_2)$  or  $\beta_{f \rightarrow 1} = [3\varepsilon_2 / (2\varepsilon_2 + \varepsilon_1)]^{-1}$ , respectively. The simplest interpolation for  $\beta$  is given by

$$\beta = \frac{3(1-f)\varepsilon_1 + f(2\varepsilon_2 + \varepsilon_1)}{3f\varepsilon_2 + (1-f)(2\varepsilon_1 + \varepsilon_2)} \quad (26)$$

By inserting  $\beta$  into Eq. (16), a new expression for  $\varepsilon_{\text{eff}}$  is obtained [116, 117]; see Table 1.

Often two-dimensional (2D) effective functions more adequately describe materials with nanosized structures. Examples are porous semiconductor structures produced by electrochemical etching with cylindrical pores, porous membranes with columnar semiconductor structures, and materials with quantum wires.

A typical porous polar semiconductor can be described as a heterogeneous material consisting of, for example, air-filled ( $\varepsilon_1 \approx 1$ ) cylindrical pores in the  $z$  direction, which are randomly distributed in the  $xy$  plane and embedded in the semiconducting matrix with  $\varepsilon_2 = \varepsilon(\omega)$ . The symmetry of the material is reduced. For a diatomic semiconductor with zincblende structure, the cubic point group  $T_d$  is changed to an uniaxial one [ $D_{2d}$  for a (100) surface and  $C_{3v}$  for a (111) surface]. In both cases the effective dielectric function becomes a tensor

$$\tilde{\varepsilon}_{\text{eff}} = \begin{pmatrix} \varepsilon_{\text{eff}}^{\perp} & 0 & 0 \\ 0 & \varepsilon_{\text{eff}}^{\perp} & 0 \\ 0 & 0 & \varepsilon_{\text{eff}}^{\parallel} \end{pmatrix} \quad (27)$$

For the electric field component parallel to the pores,  $\varepsilon_{\text{eff}}^{\parallel}$  is given exactly by the upper Wiener limit [Eq. (22)]. For  $\varepsilon_{\text{eff}}^{\perp}$  a two-dimensional variant of the Maxwell–Garnett model I can be used (see Table 1). The formula describes the morphology of the porous structure as an interpolation between two boundary cases: cylindrical voids in the semiconducting matrix (large material concentration) and a skeleton of intercrossing semiconductor plates (large void concentration). Being correct in both limits  $f \rightarrow 1$  and  $f \rightarrow 0$ , it can be used in the entire range  $f \in [0, 1]$ .

For columnar nanostructures it is more appropriate to use the two-dimensional equivalent of the Maxwell–Garnett

II formula. Single columns ( $f \rightarrow 0$ ) would then result in a Fröhlich mode given by  $\varepsilon(\omega_F) + \varepsilon_1 = 0$ .

Any dielectric function has to obey the Bergman spectral representation [118]. It can be shown that the effective dielectric functions given above fulfill the corresponding conditions. Additionally, in the two-dimensional case the Keller theorem [119] has to be fulfilled. This is the case for both Maxwell–Garnett formulae and for the Bruggeman expression.

The behavior of the effective dielectric function in the region of the optical phonons is illustrated in Figure 8. Parameters for GaP ( $\omega_{\text{TO}} = 366 \text{ cm}^{-1}$ ,  $\omega_{\text{LO}} = 402 \text{ cm}^{-1}$ ,  $\gamma = 1 \text{ cm}^{-1}$ ,  $\varepsilon_{\infty} = 8.5$ , and  $f = 0.7$ ) and the model interpolating between I and II were used. Phonons of transverse (longitudinal) character appear at the poles (zeros) of the real part  $\text{Re}(\varepsilon)$  of the effective dielectric function; see Figure 8c (the poles are smoothed due to the finite damping constant  $\gamma$  used). Between the pole corresponding to the TO phonon and the zero corresponding to the LO phonon an additional pole and an additional zero appear. They can be assigned to the Fröhlich mode. The unusual sequence, the longitudinal Fröhlich mode being below the transverse one, results from the fact that in any dielectric function poles should alternate with zeros in the sequence  $T \rightarrow L \rightarrow T \rightarrow L$ , etc., with increasing frequency. The Raman scattering efficiency is  $\propto \text{Im}(\varepsilon)$  for TO phonons and  $\propto \text{Im}(-1/\varepsilon)$  for LO phonons; the corresponding imaginary parts are plotted in Figure 8a and Figure 8b in arbitrary units. Although a strong Fröhlich mode phonon of longitudinal character can be seen, the transverse Fröhlich mode at  $\omega_{F-T}$  is very weak (not shown in Fig. 8b; its intensity is  $< 1\%$  of that of the TO

**Figure 8.** Effective dielectric function model: interpolation between three-dimensional (3D) MGI and 3D MGII [117]. Parameters:  $\omega_{\text{TO}} = 367 \text{ cm}^{-1}$ ,  $\omega_{\text{LO}} = 402 \text{ cm}^{-1}$ ,  $\gamma = 1 \text{ cm}^{-1}$ , and  $f = 0.74$  (closely packed spheres). (a) Imaginary part  $\text{Im}(\varepsilon)$ ; (b)  $\text{Im}(-1/\varepsilon)$ ; (c) real part  $\text{Re}(\varepsilon)$ ; (d) reflectivity  $R(\varepsilon)$ .

phonon) and should be not observable in the Raman spectra. However, the L–T splitting of the Fröhlich mode gives rise to a reflectivity minimum; see Figure 8d. The reflectivity is easy to calculate according to the standard formulae

$$R(\omega) = \frac{(n(\omega) - 1)^2 + \kappa(\omega)^2}{(n(\omega) + 1)^2 + \kappa(\omega)^2} \quad (28)$$

with  $n(\omega) = \sqrt{\sqrt{a^2 + b^2} + a}$ ,  $\kappa(\omega) = \sqrt{\sqrt{a^2 + b^2} - a}$ ,  $a = \text{Re}(\varepsilon_{\perp}(\omega))$ , and  $b = \text{Im}(\varepsilon_{\perp}(\omega))$ .

### 5.3. Raman Scattering

#### 5.3.1. III–V Semiconductors

Hayashi and Kanamori [3] were the first to observe Raman spectra by surface modes in polar semiconductors unambiguously. The GaP microcrystals they investigated were prepared by a gas evaporation technique. Figure 9 shows Raman spectra of samples with different particle sizes in the range between 51 and 430 nm. The surface peak can be clearly seen between the TO and the LO phonon peaks, when the microcrystals are about 1 order of magnitude smaller than the wavelength of the incident laser. For the samples used the surrounding medium was air. A frequency shift of the surface mode for different sizes was not reported. The frequency shifted to lower frequencies when the dielectric constant of the surrounding medium was increased.

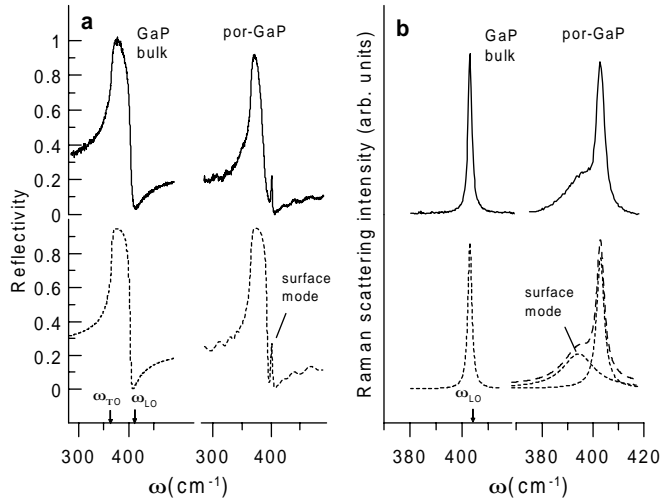

**Figure 9.** Light-scattering spectra of the surface mode of GaP nanoparticles.  $\bar{d}$  is the average particle size. Reprinted with permission from [3], S. Hayashi and H. Kanamori, *Phys. Rev. B* 26, 7079 (1982). © 1982, American Physical Society.

This was realized by embedding the microcrystals in the liquids nujol ( $\varepsilon_1 = 2.00$ ), aniline ( $\varepsilon_1 = 2.56$ ), and methylene iodide ( $\varepsilon_1 = 3.10$ ). The lineshape of the peaks attributed to an ellipsoidal particle shape was calculated using effective-medium theory [120]. It was observed that the intensity of the surface phonon peak increases as the average particle size decreases. An explanation was given based on calculations of Ruppin [103] for Raman scattering efficiencies of bulk and surface phonons in very small spherical crystals.

Watt et al. [121] investigated Raman spectra from arrays of GaAs cylinders fabricated by lithographic techniques with radii in the range of 30–100 nm and heights of 140–570 nm. Those with radius  $\leq 40$  nm showed a well-defined feature between the TO and LO phonons. The position of the additional peak was found to be in agreement with calculations based on the model developed by Ruppin and Englman [102] for the case of an infinite cylinder embedded in a dielectric medium. Wang et al. [122] reported Raman measurements of GaAs dots, fabricated by electron beam lithography and dry etching. It was found that the surface phonon intensity increased dramatically with decreasing dot sizes. da Silva et al. [123] observed the surface phonon at 287.6  $\text{cm}^{-1}$  in 6–10  $\mu\text{m}$  long wire-like crystals of GaAs with radii of 30 nm. The GaAs crystals were epitaxially grown on porous Si. They did not observe a dependence of the Raman intensity on the angle of the incident light, in contradiction to the observations of Watt et al. [121].

In recent years, in addition to porous silicon, increasing attention has been paid to porous III–V semiconductor materials [124–130] due to their potential applications in the field of electronics and photonics [131]. The nano-sized structures of such polar porous media (not in the case of the nonpolar Si) allow investigations of the surface modes. Their properties strongly depend on the morphology (i.e., symmetry, structural geometry, effective size, etc.) and on the constituents. The analysis of these modes helps to characterize the porous structure by the comparison of experimental results with theoretical calculations based on the effective-medium theory. Although for powders or nanocrystals embedded in homogeneous media 3D models of the effective-medium theory are successfully applied, 2D models are more appropriate to describe the morphology of porous semiconductors. The morphology of the porous structures fabricated by electrochemical etching of III–V materials depends mainly on the doping level of the bulk material, on the defect density on the surface and on the crystal orientation for given etching conditions [126, 127, 132–134]. A surface-related phonon mode in porous GaP at 397  $\text{cm}^{-1}$  observed by Tiginyanu et al. [135] was interpreted in terms of a Fröhlich mode on the basis of an effective medium approach [128]. It was shown that its frequency decreases with increasing anodization current. The fabrication of free-standing porous membranes, detached from the substrate, described in [136], enabled the investigation of the surface modes in porous membranes filled with liquids [137] and infrared reflectance measurements [134]. Figure 10 shows infrared reflectance spectra (a) and Raman scattering spectra (b) of a porous (111) GaP membrane. The pores of about 30 nm diameter exhibit a column-like shape, stretching into the sample perpendicularly to the initial crystal surface. The experimental spectra (upper row)

**Figure 10.** Surface modes in GaP with columnar nanosized pores. (a) Fourier transform infrared reflectivity spectra and (b) Raman spectra of porous and of bulk material. The lower row shows results of calculations based on the effective dielectric function corresponding to the 2D MGII model.

can be interpreted theoretically (lower row) using a two-dimensional effective dielectric function 2D MGII; see Table 1, which describes the morphology of the porous structures as an interpolation between two cases: cylindrical voids in the semiconducting matrix ( $f \rightarrow 1$ ) and a skeleton of intercrossing semiconductor plates ( $f \rightarrow 0$ ). The wave-like structures in the reflectance spectra of the porous membrane are interferences of light reflected at the membrane boundaries. The effect of hydrostatic pressure on the surface modes in porous GaP was investigated in [138] and the temperature influence in [139].

Sarua et al. [133, 134] studied the influence of free charge carrier in porous GaAs and porous InP on the surface phonons. It could be shown that the Fröhlich mode, like the LO phonon mode, couples to the plasmon modes induced by vibrations of the free carrier plasma of electrons. As the LO phonons, the Fröhlich modes were shifted to higher frequencies with increasing carrier density. In porous InP this effect could be observed both by light-scattering and by infrared reflectance measurements; in porous GaAs the F-T-F-L splitting is too small to be observed in the Fourier transform infrared experiment.

In GaN columnar nanostructures a new mode near  $716 \text{ cm}^{-1}$  was found by Raman scattering measurements [140]. The columnar structures with the thickness of about  $1.5 \mu\text{m}$  were fabricated by electrochemical dissolution of bulk material. Scanning electron microscope images proved that the columns with transverse dimensions of about 50 nm or less were oriented perpendicular to the initial surface. By Raman lineshape analysis based on the effective dielectric function for a composite of GaN columns in an air matrix (2D MGI; see Table 1) the new mode could be attributed to Fröhlich vibrational modes.

Electron–phonon coupling due to Fröhlich interaction has been considered by Efros et al. [26]. They investigated resonance Raman scattering of GaP nanocrystals embedded in glass. With laser excitation near the direct gap a strong LO

phonon and a surface mode approximately 10 times smaller in intensity were observed, in agreement with calculations based on the Fröhlich interaction and taking into account a degenerate valence band. Varying the excitation energy below the direct gap the LO phonon band decreases dramatically, whereas the intensity of the surface mode band is not much changed. This could be evidence that besides the Fröhlich interaction other scattering mechanisms like deformation potential scattering contribute to the surface mode scattering. However, up to now calculations on the electron–phonon interaction concentrated only upon the Fröhlich interaction.

### 5.3.2. II–VI Semiconductors

Surface modes in II–VI compounds were first observed by Scott and Damen [141] in cylindrical microcrystallites ( $\ll 1 \mu\text{m}$ ) of CdS in a polycrystalline film using Raman scattering. Pan et al. [142] studied Raman scattering of CdS nanocrystals (size  $< 30 \text{ nm}$ ) by surface modes in different organic media. Most Raman scattering experiments were performed with nanocrystals embedded in a glassy matrix: CdS [143], CdSe [25],  $\text{CdS}_x\text{Se}_{1-x}$  [34, 144–146], and ZnS [147]. As an example, we discuss here the case of  $\text{CdS}_x\text{Se}_{1-x}$  nanoparticles.

It is known that in the mixed crystal  $\text{CdS}_x\text{Se}_{1-x}$  the optical phonons show the so-called two-mode behavior, meaning that a CdS-like mode ( $\text{TO}_1$  and  $\text{LO}_1$ ) and a CdSe-like mode ( $\text{TO}_2$  and  $\text{LO}_2$ ) can be attributed to two oscillators which contribute with different oscillator strengths depending on the composition  $x$ .

The dielectric function of the mixed crystal can be described by

$$\varepsilon(\omega, x) = \varepsilon_\infty(x) \left( \frac{\omega_{\text{L}1}^2(x) - \omega^2 - i\gamma_1\omega}{\omega_{\text{T}1}^2(x) - \omega^2 - i\gamma_1\omega} \right) \times \left( \frac{\omega_{\text{L}2}^2(x) - \omega^2 - i\gamma_2\omega}{\omega_{\text{T}2}^2(x) - \omega^2 - i\gamma_2\omega} \right) \quad (29)$$

with  $\omega_{\text{L}1}(x) = 266 + 55x - 19x^2$ ,  $\omega_{\text{T}1}(x) = 266 - 28x$ ,  $\omega_{\text{L}2}(x) = 211 - 25x$ ,  $\omega_{\text{T}2}(x) = 168 + 17x$ , and  $\varepsilon_\infty(x) = 5.3x + 6.3(1 - x)$ . The parameters were taken from bulk measurements [148]. The phonon frequencies that depend on the composition  $x$  are plotted in Figure 11. The symbols correspond to measurements on  $\text{CdS}_x\text{Se}_{1-x}$  nanoparticles embedded in glass. Below both LO phonons additional modes can be observed (Fig. 12). In comparison with calculations on the basis of the effective dielectric function according to the 3D MGI model (dotted curve in Fig. 11), they can be attributed to Fröhlich modes.

To study the influence of the particle size on the optical phonons and the surface modes, a semiconductor doped glass slab was annealed in a furnace with an applied temperature gradient with temperatures between 850 and 1100 K. With increasing temperature the  $\text{CdS}_{0.6}\text{Se}_{0.4}$  particles grow to larger sizes. The composition  $x = 0.6$  was estimated from the position of the LO phonons [148]. The positions of the LO phonons and the surface mode were obtained by fitting with Lorentzian bands. The dotted lines in Figure 13a correspond to the calculated frequency of the Fröhlich modes

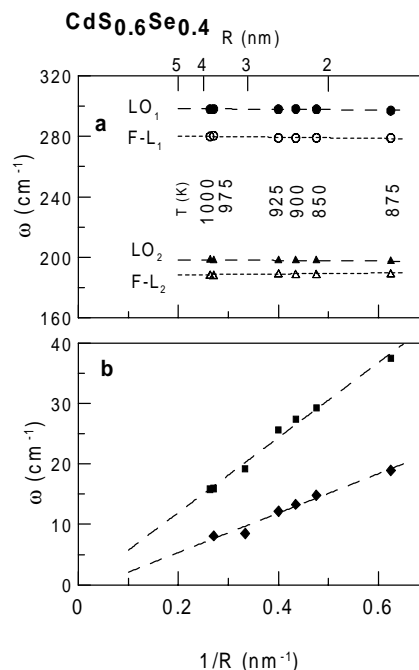

**Figure 11.** Dependence of the optical phonons and surface modes on the composition  $x$  of  $\text{CdS}_x\text{Se}_{1-x}$  nanoparticles embedded in borosilicate glass. The lines were calculated with the effective dielectric function of the 3D MGI model.

assuming spherical particles. Contrary to the acoustic vibrations (Fig. 13b), the optical phonons and the Fröhlich modes are nearly not size dependent. The effect of small shifts due to confinement effects for small particle sizes is discussed in Section 6.2.2.

The electron–phonon coupling in the case of the Fröhlich interaction between the field induced by the vibrational motion and the charge distribution was studied by several authors theoretically with different approximations and partly contradicting results (see Section 3). Klein et al. [25] observed surface modes in CdSe. Their calculations were based on a classical dielectric model. They concentrated their investigations on the  $1s-1s$  electronic transition and assumed that only the electron wavefunction is confined

**Figure 12.** Surface modes in  $\text{CdS}_{0.6}\text{Se}_{0.4}$  nanoparticles embedded in borosilicate glass.

whereas the hole resides near the center of the sphere. Their result is that the radial charge distribution in the spherical box does not couple to surface modes. As a possible reason for the observation of surface modes in the Raman spectra they assume deviations from the spherical particle shape. Efros et al. [26] included holes in a four-fold degenerate valence band in their calculation and showed that surface modes with  $\ell = 2$  are allowed due to a mixing of the valence bands even for perfectly spherical nanocrystals. Chamberlain et al. [110] considered the mechanical as well as the electrostatic boundary conditions in their model. In addition to the dipole approximation they considered the quadrupole contribution of the Fröhlich interaction, proportional to the wavevector. They showed that this term dominates for intersubband scattering and occurs only via  $\ell = 1$  phonons. Because they used a one-band effective mass model, the phonon modes are restricted to  $\ell = 0$  when the dipole approximation is used. The published calculations are based on the Fröhlich interaction, but other scattering mechanisms could contribute to the light scattering by surface modes, too. More detailed theoretical investigations are necessary and more experiments should be performed, analyzing the dependence on the excitation wavelength (near and far of resonance), on the polarization of the scattered light, and on the particle size to bring to light the properties of the surface modes.

The selection rules for Raman scattering of optical phonons in a homogeneous sphere are similar to those obtained for the acoustic vibrations discussed by Duval [38]. The vibrational modes must belong to the irreducible representations  $D_g^{(\ell)}$  and  $D_u^{(\ell)}$  of the three-dimensional rotation–inversion group  $O(3)$  ( $g$  and  $u$  mean even or odd upon inversion). The coupled optical (and the spheroidal acoustic)

modes transform according to  $D_g^{(0)}$ ,  $D_u^{(2)}$ , ... and the uncoupled optical (torsional) modes transform according to  $D_g^{(1)}$ ,  $D_u^{(2)}$ ,  $D_u^{(3)}$ , ... The Raman transition operator for dipole-allowed scattering is the polarizability tensor. Its components transform like  $D_g^{(0)}$  and  $D_g^{(2)}$ . The IR absorption is electric dipolar; the dipole operator transforms according to  $D_u^{(1)}$ . Therefore, the uncoupled transverse optical (torsional acoustic) modes are not expected to be optically active.

It should be noted that the considerations above do not reflect the crystal symmetry inside the sphere. For zincblende-type materials belonging to the point group  $T_d$  or wurtzite-type materials with point group  $C_{6v}$  the inversion symmetry is absent. For binary compounds such as GaAs, InP, and GaP, upon lowering of the symmetry from  $O(3)$  to  $T_d$  the representation  $D_g^{(0)}$  becomes  $\Gamma_1$  [109]. Scattering by optical phonons due to the so-called dipole forbidden Fröhlich interaction with diagonal Raman tensor belongs to this representation and will be visible. However, both representations  $D_g^{(2)}$  and  $D_u^{(1)}$  convert into  $\Gamma_{15}$ . The scattering by optical phonons due to deformation potential and electro-optic mechanisms belongs to this Raman activity and  $D_u^{(1)}$  surface modes are thus Raman active. The question of when, upon increasing  $R$ , the sphere will behave as a piece of bulk material, is discussed in more detail in [109], considering the coherence length of phonons.

### 5.3.3. Other Compounds

A reflectivity gap corresponding to surface modes in a polar porous semiconductor was first observed by Danishevskii et al. [149] in porous SiC and interpreted by McMillan et al. [150] on the basis of the effective medium theory. Sasaki et al. [50] measured Raman spectra from SiC fibers consisting of microcrystalline SiC about 50 nm in size embedded in amorphous SiC and carbon. They attributed features in the spectra between the TO and LO phonon frequencies to surface modes. The features observed were very weak and very broad, perhaps due to a high free carrier concentration and high plasmon damping of the SiC microcrystals and therefore difficult to interpret.

DiGregorio and Furtak [151] investigated commercially available 6H-SiC particles with an average size of about 3  $\mu\text{m}$ . The particles were irregular in shape with an average aspect ratio of about 2. They obtained a weak band in the Raman spectra below the LO phonon. However, scattering by surface modes is expected to be negligible in crystals that are larger than the wavelength of the exciting light. The appearance of weak surface modes was qualitatively explained as being caused by a decrease of the effective particle radius in irregularly shaped particles, enhancement of the intrinsic electric fields, and localization of surface modes near sharp corners and facets on the particles [152]. The observed mode frequencies 947  $\text{cm}^{-1}$  for the particles in air and 928  $\text{cm}^{-1}$  for particles embedded in KBr ( $\epsilon_1 = 2.33$ ) are near the solutions 932.3 and 948.8  $\text{cm}^{-1}$  of the equation  $\epsilon(\omega) + \epsilon_1 = 0$  for cylinder-like particles.

Raman scattering spectra in [50, 151] were obtained from SiC microcrystals of irregular shape and/or large size and, hence, weak surface phonon structures. This suggests the presentation here of Raman measurements of nanosized

particles nearly spherically shaped with an average diameter of about 30 nm as proved by XRD measurements. In the Raman spectra from these particles in air below the LO phonon a band at 937  $\text{cm}^{-1}$  was observed (Fig. 14c). Its position was found to be in agreement with calculations based on the effective medium theory. The observed half-width of the band is much larger than the half-width of the LO phonon. One reason could be local changes in the particle packing density. The theoretical curves (dotted lines in Fig. 14) were obtained with the 3D Mo model (Table 1), assuming a distribution of  $f$  values around  $f = 0.7$  with standard deviation  $\sigma = 0.3$ . The sensitivity of the surface mode to the environment of the particles was proved by embedding them into amorphous silica ( $\epsilon_1 \approx 2$ ). This was achieved by heating the powder in a laser beam. The temperature was controlled by measurement of the intensity ratio of the Stokes and anti-Stokes TO and LO phonons and by the frequency shift of the phonons. At about 1200 °C the oxidation of the SiC crystals starts, resulting in a  $\text{SiO}_2$  oxide layer around the particles [154, 155]. The  $\text{SiO}_2$  observed in the Raman spectra could be assigned to amorphous silica [156]. The corresponding peaks at about 500 and 600  $\text{cm}^{-1}$  are shown in Figure 14a. The small peak below the strong TO phonon is a weak phonon of TO character, indicating the 6H polytype of SiC.

**Figure 14.** Influence of the embedding medium on the surface modes of SiC nanoparticles. (a) Raman spectrum of SiC nanoparticles embedded in an amorphous silica matrix. (b) Detail of spectrum (a) with surface mode F-L and phonon. (c) Raman spectrum of the SiC nanoparticles embedded in air. Calculations (dotted lines) were based on the effective dielectric function interpolated between 3D MGI and 3D MGII [153].

The surface mode is located at about  $909\text{ cm}^{-1}$  between the TO and LO phonons of SiC, shown in Figure 14a and in the inset (Fig. 14b). The theoretical curve in Figure 14b was calculated with  $f = 0.65$  and  $\sigma = 0.15$ .

In the optical phonon Raman spectra of SiC nanorods (diameters range from 3 to 30 nm; lengths are  $>1\ \mu\text{m}$ ) with a high density of defects, bands at 791, 864, and  $924\text{ cm}^{-1}$  were observed [157]. By comparison with calculations it was found that the Fröhlich enhanced effective density of states of the optical phonons, which becomes important because of the broken translation symmetry induced by defects, is responsible for the features in the Raman spectra.

Observations of surface phonon modes have also been reported for ZnO [158], SiO<sub>2</sub> [159], and Si [65].

## 6. OPTICAL PHONONS

### 6.1. Confinement Models

In the Raman spectra of nanocrystalline materials with particle sizes of a few nanometers, peak-position shifts, broadenings, and asymmetries of optical phonon bands appear. In most cases the Raman peak shifts to progressively lower energies and the lineshape gets progressively broader and asymmetric (on the low-energy side) as the particle size gets smaller. This effect can be used to determine the particle size. A typical Raman spectrum of the optical phonons of nanocrystals with about 3 nm diameter is shown in Figure 15,

**Figure 15.** Raman scattering of confined optical phonons in nanocluster Si with crystals of about 3 nm size. The inset shows for comparison the Raman spectrum of an optical phonon in bulk Si. The dashed curve was calculated with the confinement model CM-II for spheres.

together with the Raman spectrum of a single crystal. The upper dashed curve in the inset shows a calculated profile. Different confinement models are in use to determine particle sizes and size distributions from the measured spectra.

### Confinement Model CM-I, Phenomenological Phonon Confinement Model

To characterize and interpret the observed bands, a phenomenological phonon-confinement model is very widely used; therefore, it is briefly outlined below. This model, originally proposed by Richter et al. [160], was later extended by Campbell et al. [161]. In a Stokes scattering process in an infinite crystal the wavevector difference  $\vec{k} = \vec{k}_L - \vec{k}_S$  is transferred to a phonon with wavevector  $\vec{q}_0$ . The wavefunction of a phonon with wavevector  $\vec{q}_0$  in an infinite crystal is

$$\Phi(\vec{q}_0, \vec{r}) = u(\vec{q}_0, \vec{r})e^{-i\vec{q}_0\vec{r}}, \quad (30)$$

where  $u(\vec{q}_0, \vec{r})$  has the periodicity of the lattice. The vibrational wavefunction of the nanocrystal is approximated by

$$\Psi(\vec{q}_0, \vec{r}) = W(\vec{r}, L)\Phi(\vec{q}_0, \vec{r}) = \Psi'(\vec{q}_0, \vec{r})u(\vec{q}_0, \vec{r}), \quad (31)$$

where the localization of the phonon in a microcrystal is taken into account by the weighting function  $W(\vec{r}, L)$ . A Gaussian weighting function  $W(r, R) \sim \exp(-\xi r^2/R^2)$ , introduced in [160] is mostly used in the traditional approach to bandshape analysis. The parameter  $\xi$  is fixed arbitrarily to get a small value at the sphere boundary  $R$ . Some other weighting functions were also applied [161–163].  $\Psi'(\vec{q}_0, \vec{r})$  can be expanded in a Fourier series, the Fourier coefficients being

$$C(\vec{q}_0, \vec{q}) = \frac{1}{2\pi^3} \int d^3r \Psi'(\vec{q}_0, \vec{r})e^{-i\vec{q}_0\vec{r}}. \quad (32)$$

The Raman scattering intensity is then described by a continuous superposition of Lorentzian curves with bandwidth  $\Gamma$  centered at the wavenumbers  $\omega(q)$  of the phonon dispersion curve and weighted by the  $|C(\vec{q}_0, \vec{q})|^2$  factor. By assuming a spherical Brillouin zone, isotropic dispersion curve, and  $\vec{q}_0 = \vec{k}_L - \vec{k}_S \approx 0$  for one-phonon scattering, the Raman intensity can be written as

$$I(\omega) \propto \int d^3q \frac{|C(\vec{q})|^2}{(\omega - \omega(q))^2 - (\Gamma/2)^2}. \quad (33)$$

The Fourier coefficients for the Gaussian weighting function are  $C(q) \sim \exp(-q^2L^2/4\xi)$ . This formula has been often used to fit Raman spectra to obtain mean particle sizes. However, there is no physical reason to use a Gaussian weighting function or in the assumption that the phonon wavefunction amplitude differs from zero at the crystalline boundary. For the fit parameter  $\xi$  the value  $\frac{1}{2}$  was originally used by Richter et al. [161]. Campbell et al. [160] found the best agreement with experiments setting  $\xi = 2\pi^2$ ; this value has been used by the most authors afterwards. With  $W^2(r, R) \sim \exp(-4\pi^2r^2/R^2)$  strong confinement of the phonons to the core is obtained:  $W^2(r, R)$  decreases from 100% at  $r = 0$  to 5% at  $r = 0.28R$  which means that the phonon energy is concentrated in only 2% of the sphere volume. Although the phonon confinement model is practicable to estimate particle sizes, it is theoretically not well founded.

**Confinement Model CM-II** This model uses the scattering function, which is well established in the analysis of SAXS experiments on small particles [164] (see Section 4.3). The application of similar expressions to light-scattering processes on small particles was also proposed in [48, 49, 96]. To derive the structure factor we follow Nemanich et al. [165], who presented an evaluation of the susceptibility function over a limited spatial extent. The results indicate that spectral changes are related to the phonon dispersion, and the photon wavevector uncertainty is accounted for.

The light-scattering cross section is proportional to the space-time Fourier transform of the correlation function of the fluctuations in the polarizability  $\delta\chi(\vec{r}, t)$  [42]:

$$I(\omega, \vec{k}) \propto \int d^3r \int d^3r' \int dt \langle \delta\chi^*(\vec{r}, t) \delta\chi(\vec{r}', 0) \rangle \times \exp(-i\vec{k} \cdot (\vec{r} - \vec{r}') - i\omega t) \quad (34)$$

The fluctuations  $\delta\chi(\vec{r}, t)$  can be expressed by the atomic displacements  $\delta\chi(\vec{r}, t) = \frac{\partial\chi}{\partial u} u(\vec{r}, t)$ .

In the absence of interaction between different phonon eigenmodes the displacements of modes with different  $\vec{q}$  are uncorrelated, and we obtain

$$\langle u^*(\vec{r}, t) u(\vec{r}', 0) \rangle = (1/V) \sum_{\vec{q}} \langle u^*(\vec{q}) u(\vec{q}) \rangle \times \exp(i\vec{q} \cdot (\vec{r} - \vec{r}') + i\omega_0 t) \quad (35)$$

where  $\omega_0(\vec{q})$  describes the dispersion of the phonon mode. The correlation function in Eq. (35) depends only on the difference  $\vec{r} - \vec{r}'$ . Therefore, the integrals can be factorized. Further, the displacement correlation function is expressed in terms of the Bose–Einstein factor  $n(\omega)$ , and Eq. (34) can be written

$$I(\omega, \vec{k}) \propto \frac{n(\omega) + 1}{\omega} \sum_{\vec{q}} A(\vec{q}, \omega) S(\vec{q}, \vec{k}) \delta(\omega - \omega_0(\vec{q})) \quad (36)$$

where the scattering function  $S$  is obtained by

$$S(\vec{q}, \vec{k}) = \left[ (1/V) \int_V d^3r \exp(i(\vec{q} - \vec{k}) \cdot \vec{r}) \right]^2 \quad (37)$$

The function  $S(\vec{q}, \vec{k})$  is a measure of the uncertainty of the wavevector  $\vec{q}$ . For an infinite transparent crystal with  $S(\vec{q}, \vec{k}) \sim \delta(\vec{q} - \vec{k})$  wavevector conservation is obtained. Before we discuss the scattering function for small particles, some remarks concerning absorption are needed. For a crystal that is opaque to light, the effective scattering volume is limited by the penetration depth, which is on the order of  $1/\alpha$ , where  $\alpha$  is the absorption coefficient. The effect of absorption can be described by assuming complex wavevectors  $\vec{k}_L = \vec{k}'_L + i\vec{k}''_L$  and  $\vec{k}_S = \vec{k}'_S + i\vec{k}''_S$ . By integration of Eq. (37) over the half-space  $z \leq 0$  we obtain a Lorentzian function  $S(\vec{q}) \propto ((q_z - (k'_L - k'_S))^2 + \alpha^2)^{-1}$ , where we have used  $\alpha \approx k''_L + k''_S$ . This means that the wavevector component  $q_z$  has a Lorentzian distribution centered at  $k = k'_L - k'_S$  with a half-width of  $2\alpha$ . Lorentzian distributions were successfully used to interpret Raman scattering of LO phonon–plasmon excitations [9] and Brillouin

scattering [10] in opaque semiconductors. However, because we have to deal with very small scattering volumes of particles with characteristic lengths  $L \ll 1/\alpha$ , the absorption can be neglected in general.

For finite scattering volumes the coupling of light to excitation modes with wavevectors  $\vec{q}$  in a range about  $\vec{k}$  is allowed and the function  $S(\vec{q}, \vec{k})$  describes the range of wavevectors that take part in the light-scattering process. For optical phonons we assume small frequency changes along the dispersion curves and we will use the approximation of a constant term  $A(\vec{q}, \omega)$ . The finite lifetime of the phonons is taken into account by replacing the  $\delta$ -function by a Lorentzian function and the sum is approximated by an integral over a spherical Brillouin zone. With  $\vec{k} = \vec{k}_L - \vec{k}_S \approx 0$  we obtain

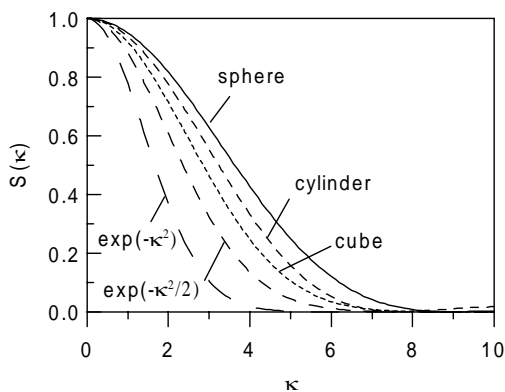

$$I(\omega, \vec{k}) \propto \int d^3q \frac{S(\vec{q})}{(\omega - \omega(q))^2 - (\Gamma/2)^2} \quad (38)$$

an expression similar to Eq. (33) but with  $S(\vec{q})$  instead of  $|C(\vec{q})|^2$ . Table 2 presents the function  $S(q)$  for some differently shaped particles and for a layer. In Figure 16 these functions are shown in dependence on the dimensionless parameter  $\kappa$ :  $\kappa = q \cdot 2R$  for spheres with radius  $R$ ,  $\kappa = q_p \cdot 2R$  for long cylinders (length  $L \gg$  radius  $R$ ), and  $\kappa = q_x \cdot L$  for a cube (edge length  $L$ ). The function  $S(\kappa)$  describes the range of wavevectors that take part in the light-scattering process. For example, for spheres the curve  $S(q)$  diminishes from the value 1 at  $\kappa = 0$  ( $q = 0$ ) to a weight of  $\frac{1}{2}$  at about  $\kappa = 4$ , corresponding to a wavevector of  $q = 2/R$ ; wavevectors with less weight contribute up to about  $\kappa = 8$  corresponding to  $q = 4/R$ . The wavevector corresponds to a momentum  $p = \hbar q$ ; therefore, we can discuss these equations in terms of Heisenberg's uncertainty relation  $\Delta x \cdot \Delta p \geq \hbar/2$  correlating the uncertainties of the coordinate  $x$  and the momentum  $p$ . A Gaussian distribution of  $x$  values corresponds to a Gaussian distribution of  $p$  values. For Gaussian distributions only the lower limit  $\Delta p = \hbar/2\Delta x$  of Heisenberg's uncertainty relation is obtained [168]. In our case of  $x$  values strongly restricted to the particle volume the uncertainty is larger. Using the example of the sphere we estimate that  $\Delta p \approx 4\hbar/\Delta x$ , setting  $\Delta x = 2R$  and  $\Delta q \approx 2/R$ .

For comparison two Gaussian weighting functions used in the phonon confinement models CM-I are also shown ( $\xi = 1$

**Table 2.** Scattering functions  $S(q)$ .

Shape	$S(q)$	
Sphere	$9 \frac{j_1^2(qR)}{(qR)^2}$	$R$ : radius $j_1$ : spherical Bessel function
Cylinder	$\frac{4J_1^2(q_p R)}{(q_p R)^2} \cdot \frac{\sin^2(q_z L/2)}{(q_z L/2)^2}$	$R$ : radius $L$ : length in $z$ direction $J_1$ : Bessel function
Rhomboeder	$\prod_{i=x,y,z} \frac{\sin^2(L_i q_i/2)}{(L_i q_i/2)^2}$	$L_i$ : lengths of the edges
Layer	$\frac{\sin^2(L q_z/2)}{(L q_z/2)^2}$	$L$ : layer thickness in $z$ direction

**Figure 16.** Scattering functions  $S(\kappa)$  for light scattering of differently shaped particles. The parameter  $\kappa$  is the dimensionless product of a characteristic length  $L$  ( $2R$  for spheres and cylinders; edge length for the cube) times the corresponding wavevector component.

and  $\xi = 1/4$ ). The two formulae [Eq. (33) and Eq. (38)] look similar, but their interpretations are different. It should be noted that the model CM-II does not involve arbitrary fitting parameters.

To take the phonon confinement into account, we should consider that the largest possible wavelength of the phonons in the particle is restricted by their size. For example, in a sphere the corresponding smallest wavevector is  $4.49/L$ , the wavevectors allowed are approximately  $4.49/L$ ,  $7.72/L$ , and  $10.90/L \dots 2\pi/a$ , where  $a$  is the lattice constant. For  $L \gg a$  the approximation of the sum over  $q$  values by an integral in Eq. (33) or (38) is justified.

The phonon dispersion curves often are approximated on the basis of a linear chain model by  $\omega(q) = -A + \sqrt{A^2 - B(1 - \cos(aq))}$ . The parameters  $A$  and  $B$  are chosen to fit neutron scattering data or theoretical calculations, and  $a$  is the lattice constant. Other approximation formulae are given in Ref. [109, 111, 145, 169].

**Other Confinement Models** Raman shifts of nanocrystals versus size were studied theoretically by a bond polarizability model [170]. In the first step the vibrational properties of clusters of some hundred atoms were calculated. The force constants and the atom positions were taken to be the same as those in the bulk. The force constants were considered up to the fifth order; a partial density approach [171] was adopted to calculate them. The vibrational eigenfrequencies and eigenfunctions were calculated for Si spheres and Si columns consisting of up to 657 atoms. Then the Raman spectra were calculated by a bond polarizability model [172, 173] as a sum of independent contributions from each bond. It was found that the Raman shifts due to the confinement effect could be described by  $\Delta\omega = \omega_0 - \omega(L) = A(a/L)^\gamma$ , where  $\omega(L)$  is the phonon frequency of the nanocrystal with size  $L$ ,  $\omega_0$  is the frequency of the optical phonon in bulk material at the Brillouin zone center, and  $a$  is the lattice constant. The fitted parameters were  $A = 47.41(20.92) \text{ cm}^{-1}$  and  $\gamma = 1.44(1.08)$  for spheres (cylinders), respectively.

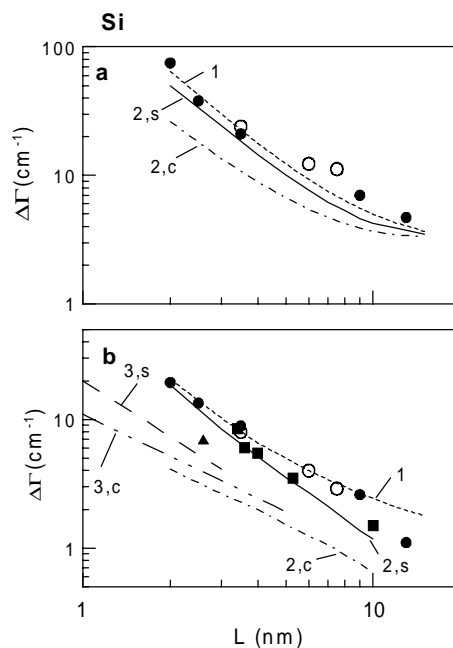

A simple microscopic calculation using a one-dimensional linear chain model with bond polarizabilities to calculate the

Raman intensities was applied to different porous Si structures with connected or isolated Si structures [174]. Comparing the experimental spectra with those simulated by models the results were consistent with cylindrical nanocrystals of 3:1 length-to-diameter ratio and diameters of  $\sim 5 \text{ nm}$ , measured by TEM.

## 6.2. Size Determination by Raman Scattering

### 6.2.1. Si and Ge

The confinement of optical phonons has been investigated by Raman scattering in Si nanocrystals prepared by the plasma transport method [160, 175], the gas-evaporation technique [176], the reactive sputtering technique [177], molecular beam deposition [178], laser annealing of a-Si:H samples [179], plasma-enhanced chemical vapor deposition [180], and surface modification by implantation [181] and in porous Si layers [68, 162, 163, 174, 181–187]. From the observed phonon shifts the particle sizes have been estimated using the confinement model CM-I [Eq. (33)] with Gaussian weighting functions [169, 179, 180, 181, 185, 187] or with the weighting function  $W(r, L) = \sin(ar)/ar$ , by analogy with the ground state of an electron in a hard sphere [162, 163]. In some cases the particle sizes were determined independently by other methods. In Figure 17 observed frequency shifts and half-width broadenings are plotted versus the particle size determined by TEM [169] or XRD [177, 180]. For comparison calculated results were included, obtained with the phonon confinement model CM-I using

**Figure 17.** Observed frequency shifts and half-widths of the Raman bands of the optical phonon in nanocluster Si (○ [188], ▲ [177], ■ [180]) and porous Si (● [169]) depending on the particle size  $L$ . The curves are results of calculations: (1) confinement model CM-I, parameters taken from [169]; (2) confinement model CM-II; s, spheres; c, long cylinders; (3) microscopic calculations [170]; s: spheres; c: cylinders.

a Gaussian weighting function (parameters taken from Ref. [169]), with the model CM-II (spheres and cylinders), and results calculated with the bond polarizability model [170] (spheres and cylinders). For the following reasons the confinement models cannot be used without taking some care.

- (i) The particle shapes are often not well defined and the particles have a size distribution.  
A lineshape analysis of Raman spectra of porous Si by assuming that the crystallite sizes obey a log-normal distribution has been performed in [163], assuming two nanocrystalline components with Gaussian distributions in [187].
- (ii) Strain-induced changes in the phonon frequencies have to be taken into account [162, 180, 184]. It is known that in nanoporous Si the Raman peak can be shifted by strain to lower energies ( $\leq 2 \text{ cm}^{-1}$ ) [189, 190]. Stress inhomogeneities on a nanometer scale can be expected to broaden the Raman signal.
- (iii) The structure of the particles is not perfect crystalline.

In some cases spectral features were observed which consist of two or more bands [169, 176, 180, 187, 191–193]. Although a broad band at about  $475 \text{ cm}^{-1}$  can be assigned to amorphous Si, we supposed that the origin of two bands between this band and  $520 \text{ cm}^{-1}$  (bulk phonon frequency) is due to a splitting of the optical phonon (degenerate for  $q = 0$  in the Brillouin zone center) in TO and LO modes for larger  $q$  values [192] or to a combined contribution of two types of nanocrystallites [184, 187, 193, 194] or to a shell structure of the particles with modified vibrational contributions of the near-surface atoms. Xia et al. [180] observed one band for crystalline sizes  $L \leq 2.2 \text{ nm}$  and  $L \geq 5.3 \text{ nm}$  in hydrogenated nanocrystalline Si films. For samples with  $2.2 \text{ nm} \leq L \leq 5.3 \text{ nm}$  the Raman spectra were composed of two bands: one peaked at  $505\text{--}509 \text{ cm}^{-1}$  and the other at  $512\text{--}517 \text{ cm}^{-1}$ . A spherically shaped cluster with two shells was used to model the nanocrystals, and the observed Raman spectra were analyzed by combining the confinement model CM-I and strain effects. The size dependence of the relative intensity of the two bands corresponds to the ratio of the near-surface region and the crystalline core. It should be noted that a hexagonal phase of Si with Raman peak at about  $500 \text{ cm}^{-1}$  has also been found in pressure-treated Si [196] and in wear debris from dicing of silicon wafers [197].

For  $L \leq 1.5 \text{ nm}$  (corresponding to about 200 atoms) reported Raman spectra of Si clusters are to some extent similar to those of amorphous Si films. A new aspect is the observation of Raman bands around  $550 \text{ cm}^{-1}$  extending up to  $600 \text{ cm}^{-1}$ , well above the highest peaks of bulk Si in Si-rich  $\text{SiO}_2$  films with clusters [198]. The observed spectral shapes are in qualitative agreement with the density of states spectra calculated by Feldman et al. [199] for  $\text{Si}_{33}$  and  $\text{Si}_{45}$  clusters. Raman spectra of molecular clusters  $\text{Si}_4$ ,  $\text{Si}_6$ , and  $\text{Si}_7$  have been successfully measured by Honea et al. [200] by applying a technique of surface-enhanced Raman scattering. Si cluster ions were produced by laser vaporization, size-selected in a quadrupole mass spectrometer and co-deposited with an  $\text{N}_2$  matrix onto a liquid helium-cooled

substrate. By comparison of the observed very sharp vibrational lines with *ab initio* calculations they could determine the cluster structures.

In comparison with Si nanoparticles of the same size the observed frequency shifts and half-width broadenings in Ge nanoparticles are much smaller. A smaller shift is expected due to the position of the optical phonon in crystalline-Ge at the lower frequency of about  $300 \text{ cm}^{-1}$ , the main reason could be the smaller dispersion of the optical phonons, which was observed by neutron scattering for Ge [201] compared with measurements for Si [202–204]. Kanata et al. [205] investigated gas-evaporated Ge particles with sizes of 10–60 nm, as determined by Raman measurements and by XRD measurements. Good agreement was obtained by applying the CM-I model ( $\xi = 25/8$ ) and assuming spheres with a single-crystalline core and a coating amorphous shell. The confinement effect in Ge dots in the size range  $L = 2.6\text{--}13 \text{ nm}$  has been studied systematically by Bottani et al. [206] with Raman scattering, TEM, and absorption measurements. The samples were grown by an evaporation-condensation self-organization technique that allows obtaining nearly spherically shaped nanoparticles with a narrow size dispersion [207]. As the size decreases an inhomogeneous broadening, a redshift and a softening of the optical phonon peak were observed. The measurements were found to be in agreement with confinement model calculations (CM-I), taking into account the size distribution as measured by TEM. Sasaki and Horie [208] investigated gas-evaporated Ge nanocrystals in the size range 2.6–13 nm with resonant Raman scattering. They found that the size as deduced from the frequency shift and half-width broadening is about half of that obtained from the lowest electronic excitation energy measured in the resonant Raman scattering. Additional anharmonicity is assumed to be associated with a decay process including surface vibrational states. They used a confinement model with phonon waves confined to a cube and vanishing amplitudes at the surface.

Intensive photoluminescence around 2 eV has been observed by formation of Ge nanocrystals in  $\text{SiO}_2$  [209–211]. The phonon confinement measured by Raman scattering was used to show that the crystalline phase formed consists of Ge nanocrystals. If Si substrates are used, the analysis of the experimental results has to be done with extreme care, because an observed peak at about  $300 \text{ cm}^{-1}$  could originate from the two-phonon peak of the Si substrate and not from Ge ([211–213]; see also Fig. 15). To tackle this problem resonant Raman scattering with excitation laser energy at 2.4 eV and polarized Raman scattering can be used [214].

### 6.2.2. II–VI Semiconductors

In polar semiconductors the confinement effect of the optical phonons in particles of a few nanometers in size can be more difficult to observe due to the simultaneous appearance of surface modes between the LO and the TO phonons [145].

Small frequency shifts (up to about  $3 \text{ cm}^{-1}$ ) of the LO phonon of small quantum dots of II–VI compounds in comparison with the bulk value were observed for decreasing radii (down to  $\approx 2 \text{ nm}$ ) in glass matrices. Redshifts for CdSe dots [39, 54, 110, 146] blueshifts [61] as well as redshifts [52, 145] for  $\text{Cd}_x\text{Se}_{1-x}$  dots, and size-independent LO

phonon frequency for CdS dots [32] are reported. Obviously the shifts depend also on the glass matrix used [215]. To explain the observed phonon shifts and broadenings some authors, in addition to the confinement models, introduced lattice contraction caused by the mismatch of the thermal expansion between the quantum dots and their host material and surface tension increasing with decreasing dot size [61, 215]. Shiang et al. [32] estimated with a confinement model the observed asymmetric band shape, the increase in bandwidth, and the frequency downshift with decreasing size. They assumed that surface pressure effects nearly compensate for the confinement effect in such a way that no size dependence of the LO frequency results. For small CdSe nanoparticles embedded in glass, an asymmetrical broadening of the LO phonon band toward the low-frequency side for nanocrystals with  $R = 2.1$  and 1.8 nm and a decrease to lower frequencies was observed [111]. This was attributed to confinement of the LO phonons. The dispersion of the observed LO phonon frequencies was compared with *ab initio* calculations [111].

### 6.2.3. Other Compounds

Phonon confinement effects were also studied on self-assembled GaN quantum dots of 2–3 nm height [216], crystalline As precipitates in GaAs [217], in CeO<sub>2-y</sub> nanoparticles [218], diamond nanoparticles [219, 220] and in BN micro- and nanoparticles [165]. The latter case is interesting because an upward shift of the high frequency mode E<sub>2g</sub> was observed with decreasing particle size similar to that for small particles of graphite. Calculations were performed with the confinement model CM-II using phonon dispersion curves reported in [221].

Redshift or blueshift in dependence on the coating was observed in coated TiO<sub>2</sub> nanoparticles [222].

## 7. NEW INSTRUMENTATION AND METHODS

**High-Throughput Devices** Many applications of Raman spectroscopy benefit from developments to measure the usually weak signals more efficiently. For recording scattered light, charge-coupled devices (CCD) have become very widespread during the last 10 years and are now used in the most multichannel Raman spectrometers. They have a very high quantum efficiency over a broad spectral range and a very low dark count level when cooled. The separation of the Raman signals from the much stronger elastically scattered light has been achieved in the past by use of double or triple monochromators. Another technical solution, now used more and more, are Raman spectrometers consisting of a holographic notch filter for stray light suppression and a single grating spectrograph. Such spectrometers have up to 10 times larger optical throughput, are more compact with fewer optical components, and are less expensive than triple monochromators. The notch filters suppress the incident laser light by a factor of more than 10<sup>6</sup> while the rest of the spectrum is transmitted with a high efficiency of about 80%. The small edgewidth of less than 4 nm allows measurements of frequencies as low as 50 cm<sup>-1</sup>. The application of this new generation of Raman spectrometers is

attractive for measurements on nanoparticles with low signals, too. However, for low-frequency Raman measurements on acoustic modes closer to the laser line, better stray light rejection is required. This can be realized by application of a triple monochromator and a photomultiplier as detector or by using a double monochromator in the configuration as a cutoff filter followed by a single spectrograph and CCD as detector.

**Surface-Enhanced Raman Scattering** An enhancement of Raman scattering intensity was observed for molecules deposited on silver surfaces. A large increase in the local electric field intensity occurs when the wavevector of the surface plasmon mode of the silver film is matched to that of the incident laser [223–226]. Vibrational Raman spectra of small Si clusters, size-selected in a quadrupole mass spectrometer and co-deposited with an N<sub>2</sub> matrix onto a liquid helium-cooled silver film were measured with a signal enhancement of about 50 at the surface plasmon-polariton resonance [200].

The Raman scattering intensity of molecules can be enhanced in SERS processes by 5 to 6 orders of magnitude when they are adsorbed on a roughened silver surface.

Although all details of the origin of the signal enhancement are not yet understood, two main mechanisms are usually assumed to be responsible. The so-called electromagnetic effect is considered by most authors to be the major contributor to SERS. The electromagnetic effect was explained in terms of the excitation of localized surface plasmons in silver nanostructures (and nanostructures of a few other metals), which enhances the electromagnetic fields near the nanoparticle's surface. Resonance of the exciting/scattered fields with the surface plasmons is assumed. The second mechanism discussed, the so-called chemical enhancement effect, is attributed to resonant Raman processes involving charge transfer between the adsorbed molecule and the metal surface. Although the average enhancement factor has been normally measured to lie in the 10<sup>5</sup>–10<sup>6</sup> range, it has been shown recently that the enhancement is laterally highly inhomogeneous and concentrated at hot spots at the surface of the metallic nanostructures where the SERS enhancement can be as large as 10<sup>10</sup> [227, 228]. The lateral resolution is thus not determined by the diffraction limit, but by the spatial confinement of the local fields. Over the last 5 years it was shown that SERS can be observed even from single molecules [229–233]. The fact that enhancements large enough to allow single-molecule spectra to be detected have only been observed for some adsorbates (generally dye molecules) suggests that resonance processes are involved.

The target species are in local electromagnetic fields of high intensity and, in particular, also very strong field gradients. These effects could explain some observed results of SERS measurements on single carbon nanotubes, not seen with conventional Raman scattering, for example, exchange in scattering intensity between phonon modes and changes of the depolarization ratios [234, 235].

**Near-Field Optical Microscopy** In conventional Raman microscopy a pixel size no smaller than 1 μm is common. Resolutions of 100 nm or even substantially smaller can be realized by combining Raman scattering with the near-field

optical microscopy [236]. A laser beam is coupled into an optical fiber that is sharpened to a very small tip with conical shape at the end. The dimensions of the tip are much smaller than the wavelength of the exciting laser light. Initially, the major obstacles for obtaining Raman spectra were arising from the weak light intensity given by the excitation and the detection through small apertures and by the Raman scattering process. The principle of the method was demonstrated, for example, by the measurement of the phonon spectra of diamond with a fiber probe of 100 nm diameter [237]. In measurements of Raman spectra from liquid  $\text{CCl}_4$  the sampling volume of 70 nm diameter and 10 nm depth contained only about 250,000 molecules [238]. For applications with weaker scatterers a considerable improvement of the signals obtained is necessary. One way to enhance the Raman cross section is resonant excitation, which was already used in some cases. Another technique is the combination of near-field optical microscopy with SERS, with which strong enhancement of the Raman signals by many orders of magnitude was obtained [239, 240].

**Tip-Enhanced Near-Field Raman Spectroscopy** Tip-enhanced near-field Raman scattering is one of the forthcoming characterization techniques, which can be effectively used to understand the vibronic and electronic properties of a material at nanoscale. This technique can also be used even for a single molecule detection, because it allows for the detection of molecular vibration spectra with a resolution smaller than the diffraction limit of the light. It has recently been demonstrated [241] that the near-field detection of Raman scattering using a metallized tip achieves high spatial resolution beyond the known limits of surface-enhanced Raman scattering and reveals new weak vibrational modes, which cannot be seen in usual far-field measurements. It has been demonstrated that because of the local field enhancement, the Raman scattering is enhanced by a factor of 40 and the spectra could be measured at a spatial resolution of several tens of nanometers. By using this technique, single nanoparticle detection could be possible. Also, single molecule detection could be much more precise and accurate compared to SERS, where the spatial resolution is diffraction limited. For near-field detection, it is possible to observe the dynamics of a molecule with spatial resolution on a molecular scale. In these experiments, a metallic tip with a size of a few tens of nanometers is approached to the sample where the source light is tightly focused. The localized surface plasmon-polariton is excited at the tip apex. The area of the field localized at the tip corresponds to the diameter of the tip, which works as the near-field light source and attends the super-resolving capability. Molecules soaked in this localized field around the tip scatter inelastically through Raman scattering. The Raman spectra recorded contain useful information about molecular vibrations at the nanoscale level, which cannot be detected through other techniques. In this way, it is possible to understand the special behavior of molecules, excitons, and electron-phonon interaction inside a nanoparticle, which can reveal new understanding about the confinement and the effect of confinement on the electron-phonon system.

## GLOSSARY

**Effective medium theory** The properties (e.g., the dielectric function) of a composite are described by averaging over local inhomogeneities introducing suitable effective media models.

**Quantum confinement** In nanometer-sized structures (quantum wells, wires, and dots) the allowed energy states and the density of states are modified in comparison with the corresponding bulk material. Onset occurs when one or more dimensions of a structure become comparable to the characteristic length scale of an elementary excitation.

**Raman scattering process** Inelastic light scattering. The scattered photon has lost (Stokes process) or gained (anti-Stokes process) the energy of an elementary excitation (e.g., a phonon) compared with the energy of the incident photon.

**Rayleigh scattering process** Elastic light scattering. The scattered and the incident photon have the same energy.

**Small angle X-ray scattering (SAXS), small angle neutron scattering (SANS)** Scattering at small angles in the vicinity of the primary beam. The scattering features at these angles correspond to structures ranging from nanometers to submicrometers.

**X-ray diffraction (XRD)** Technique for characterizing crystalline materials. It provides information on structures, phases, average grain size, crystallinity, strain, crystal defects.

## ACKNOWLEDGMENTS

The authors acknowledge fruitful cooperation with Professor I. M. Tiginyanu (Technical University of Moldova), Dr. A. Sarua (University of Bristol), and Dr. W. Cordts (Technical University Bergakademie Freiberg) who contributed to many illustrative results presented in this chapter and express their gratitude to them for stimulating discussions.

## 1. INTRODUCTION

One of the most spectacular phenomena discovered in recent years in magnetic artificially layered structures is the giant magnetoresistance (GMR) effect. The essence of the effect is the dependence of electrical resistance of a magnetic metallic multilayer on its magnetic configuration [1,2]. Such a configuration can be changed, for example, with an external magnetic field applied to the system. A typical structure in which the effect occurs is a multilayer with adjacent ferromagnetic films coupled antiferromagnetically across a nonmagnetic spacer [3,4] so that they have antiparallel magnetizations in the vanishing magnetic field. The magnetizations then rotate in an external field from the antiparallel configuration to the parallel one, and this rotation is accompanied by a decrease in the electrical resistance of the multilayer (an increase is also possible [5]). The effect exists for electric current flowing in the film plane [1,2,6], as well as for electric current flowing perpendicularly to the film plane [7–9]. The antiparallel alignment can also be obtained by other means. If, for instance, a multilayer consists of two types of ferromagnetic films (which have different coercive fields), then there is a range of magnetic fields during scan through the hysteresis loop where the magnetizations are antiparallel (being parallel above a certain saturation field) [6]. The GMR effect itself is a classical effect, and also exists at room temperature. Therefore, most of the experimental works on electronic transport in magnetic structures were done in this temperature range.

Whereas the transport properties of magnetic systems in the high-temperature regime are more interesting from

the application point of view, the low-temperature regime seems to be more interesting from the point of view of fundamental physics. This is because various quantum phenomena have peculiar contributions to transport characteristics, particularly in systems of reduced dimensionality. In such structures, usually one or more characteristic dimensions are in the nanometer range. When electrons propagate in a disordered system with the electron coherence length comparable to its (one or more) dimensions, the conductivity corrections due to quantum interference and electron–electron (e–e) interaction may play a significant role. Moreover, analysis of the phase-coherent effects in spin-polarized materials, particularly their dependence on the magnetic field and temperature, provides a sensitive way to investigate the degree and role of structural (morphological) and magnetic (domain walls) inhomogeneities. One may also expect that future spin electronics (spintronics) will take advantage of the phase-coherent transport in spin-polarized systems.

Localization effects in the transport properties of nonmagnetic metals and semiconductors were investigated very extensively during the last three decades, starting from the paper by Anderson [10]. The main results of these investigations have been summarized in several review articles [11–15]. The best developed seems to be the weak localization (WL) theory [11, 12], which gives a way to rigorously calculate localization corrections to the conductivity of disordered metals or degenerate semiconductors in the limit of  $\varepsilon_F \tau / \hbar \gg 1$ , where  $\varepsilon_F$  is the Fermi energy and  $\tau$  is the momentum relaxation time of electrons. These corrections turn out to be strongly dependent on the temperature and magnetic field, and therefore they have been clearly observed in many experiments (see [15] for a review). The interaction theory of disordered systems [13, 14], which accounts for the quantum corrections to conductivity due to e–e interaction, has been developed in the same spirit as WL. Even though these two theories are constructed as perturbation theories, and thus are restricted to relatively small quantum corrections to conductivity, they explained a great number of experiments on disordered metals, heavily doped semiconductors, and amorphous metallic films. One of the most surprising properties of disordered systems is the effect of dimensionality in films and wires, and in small metallic particles. The essential point is that disordered systems are characterized by two characteristic lengths—the electron mean-free path  $l$  and the phase coherence length  $L_\phi$  (or the Thouless length  $L_T$  in the interaction theory). The latter length scale corresponds to the distance at which the electron preserves its phase coherence, and this scale is associated with inelastic processes like scattering from phonons. When the geometrical size of a sample becomes smaller than  $L_\phi$ , its transport properties are drastically changed since the quantum corrections for systems of different effective dimensionality are significantly different too. When the sample size is smaller than  $L_\phi$ , the system is called *mesoscopic*. The origin of WL corrections to conductivity can be understood as a quantum effect due to the interference of electron waves propagating in a disorder potential [15, 16]. The quantum interference enhances the probability of an

electron to return back to the starting point, which results in a tendency of the electron to localize. The external magnetic field and inelastic scattering from phonons suppress the quantum interference, which effectively decreases the magnitude of localization corrections. A different response of WL and e–e interaction to the magnetic field usually allows us to distinguish between the localization and e–e contributions [17]. The relevant theoretical formalism makes use of *diffusons* (particle–hole propagator) and *cooperons* (particle–particle propagator) [11, 12]. They describe propagation in space and time of the electron density and of the fluctuations of superconductive density, respectively. The effects of temperature, magnetic field, and spin–orbit (SO) interaction can be accounted for theoretically by considering the corresponding influence on the diffusons and cooperons.

The quantum corrections to conductivity due to WL and e–e interactions are usually limited to low temperatures. However, e–e interaction can lead to other phenomena, which in certain systems also have a significant influence on electronic transport at high temperatures. An example of such systems are tunnel junctions. Broad interest in magnetic tunnel junctions was initiated by successful applications of the GMR effect in read/write heads and magnetic field sensors [18]. Indeed, an effect qualitatively similar to GMR was also observed in magnetic tunnel junctions. Now, the junction resistance varies when the magnetizations of the ferromagnetic electrodes rotate from an antiparallel to a parallel alignment. The effect is commonly known as the tunnel magnetoresistance (TMR) effect, and was first observed in Co/Ge/Fe junctions by Julliere [19]. It results from the spin-dependent electronic band structure of the ferromagnetic electrodes and spin-dependent tunneling rates. The effect occurs not only in simple planar junctions [20], but also in more complex ones, like double magnetic junctions with ferromagnetic outer electrodes and magnetic or nonmagnetic central ones. In the latter case, the TMR effect in the sequential tunneling regime results from spin accumulation in the central electrode, which in turn is a consequence of spin-dependent tunneling rates across the barriers [21]. However, it also may occur in the coherent tunneling regime, where an electron is in a coherent state of the whole double-barrier system, and therefore is sensitive to the magnetic configuration of the outer electrodes.

In the case of double-barrier planar junctions, the central electrode (called also an island in the following) is sufficiently large to neglect the effects due to electrostatic interaction of an electron tunneling to this electrode with other electrons already being there. When the island becomes small, the electrostatic interaction of the excess electrons with the other ones may play a crucial role in electronic transport, leading to Coulomb blockade phenomena [22]. In asymmetric junctions, transport characteristics then form the well-known Coulomb staircase. Interplay of the charging phenomena and ferromagnetism of the electrodes [23] are briefly reviewed too.

The review then summarizes the results of experimental and theoretical studies of localization in ferromagnets, magnetic layers, and multilayers, as well as in mesoscopic

magnetic structures. It also includes recent results on the e–e correction to conductivity in disordered ferromagnetic structures, and the results on electrostatic charging effects in double magnetic junctions.

## 2. EARLY EXPERIMENTS

The low-temperature anomaly in electrical conductivity of ferromagnetic metals and thin films was reported in several experimental works. These works clearly demonstrate that the localization and interaction corrections to conductivity occur not only in nonmagnetic systems, but also in ferromagnets. However, interpretation of the results was not quite certain because the corresponding theory was not developed at that time. Here, we review some of these early experimental works. Kobayashi et al. [24] studied the temperature and magnetic field dependence of the electrical conductivity of highly resistive thin Ni films (film thickness of 40 and 60 Å). The samples were prepared in the following way [25, 26]. First, vacuum deposition of ferromagnetic metal (Ni of an amount which corresponded to 1 nm) onto quartz substrate was carried out, followed by oxidation at  $6.5 \cdot 10^{-2}$  torr for a few minutes. At the next stage, this procedure was repeated two times with two more deposited Ni layers, each oxidized again. The resistance of the samples was controlled by changing the oxidation time. By analyzing electron micrographs, it was found that the film consisted of an ensemble of Ni nanoparticles with diameter of 1 nm (distribution of the size within  $\pm 5$  Å) dispersed on the substrate. The stack of three layers of the particles formed a well-connected two-dimensional network of particles having only little overlap in the direction normal to the substrate. The third layer was covered with 50 nm thick SiO for protection. Kobayashi et al. [24] observed that the sheet conductivity  $\Delta\sigma_{\square} \simeq [R_{\square}(T_0) - R_{\square}(T)]/R_{\square}^2(T_0)$  (here,  $R_{\square}(T)$  is the sheet resistance) as a function of temperature has the form  $\sigma_{\square} = \sigma_0 + A \ln T$ . They also found the parameter  $A$  to be close to  $e^2/(2\pi^2\hbar)$ , and to be almost independent of the film thickness below 60 Å. Magnetoconductivity was positive, independent of temperature, and as small as 0.1% at 10 kOe. These results are in agreement with the WL theory in the effectively 2-D case. Some conclusions about the importance of spin–orbit (SO) interaction in ferromagnets were also drawn there.

The magnetoresistance (MR) of thin  $\text{Pd}_{1-y}\text{Ni}_y\text{H}_x$  films of thickness 25, 50, and 100 Å was measured by Raffy et al. [27] between 1 and 5 K and in magnetic fields up to 1 T. With no hydrogen ( $x = 0$ ) and for  $y > 0.025$ , the alloys are ferromagnetic, and display localization behavior in a zero magnetic field. Hydrogenation suppresses ferromagnetism in these materials, and for ( $x \rightarrow 1$ ), the ground state is dominated by magnetic fluctuations. It was shown that MR for 25 Å  $\text{Pd}_{0.94}\text{Ni}_{0.06}\text{H}_x$  film could be fitted rather well by the 2-D form

$$\frac{\Delta R_{\square}}{R_{\square}^2} = \frac{e^2}{2\pi^2\hbar} (\beta - \alpha) Y\left(\frac{H}{H_0}\right) \quad (1)$$

where  $Y(x) = \ln x + \psi(1/2 + 1/x)$ , and  $\psi(x)$  is the digamma function, which has the property  $\psi(x) \simeq \ln(x)$  for  $x \gg 1$  [28]. This is the formula for quantum correction in nonmagnetic metals, where the coefficient  $\beta$  is due to the Maki–Thompson correction [29] and  $\alpha$  is due to the WL corrections, respectively, whereas  $H_0$  is the phase-breaking field determined by spin-flip scattering and inelastic processes. MR was positive, and therefore accounted for by the suppression of the antilocalization correction in a magnetic field. The antilocalization effect was attributed to strong SO scattering. It should be noted that Pd and Ni alloys are close to the ferromagnetic transition at low temperatures. Introducing hydrogen into ferromagnetic Pd turns it into the paramagnetic state, whereas a relatively small concentration of Ni atoms leads to the presence of large-moment localized magnetic impurities or small magnetic clusters. The fact that the system is close to the phase transition point makes the interpretation of experimental results much more complex.

The resistivity of thin Fe films (for thickness above 60 Å) grown epitaxially on GaAs was studied by Fuller et al. [30] and Rubinstein et al. [31]. The iron films were grown on GaAs substrates by the molecular beam epitaxy (MBE) method. The substrate face orientation was chosen to be (110) in order to obtain within the film plane the following three different crystalline axes: the magnetically easy [001], hard [111], and intermediate [110] ones. It is known that epitaxial few monolayer Fe films can be obtained on MgO [32] and GaAs substrates [33, 34] because the corresponding nearest neighbor distances are close (within less than 1%) to that of bcc iron. The deposition of Fe on GaAs is of special importance because magnetic films deposited on semiconductors are important for application in spintronics. However, in this particular experiment on weak localization phenomena in Fe, specially prepared highly insulating substrates were used to allow studying transport properties of the iron films. These specially doped with chromium ( $6 \cdot 10^{16}$  atoms  $\cdot$  cm $^{-3}$ ) and tin ( $2 \cdot 10^{16}$  atoms  $\cdot$  cm $^{-3}$ ) GaAs substrates remained highly insulating, even when heated to 625 °C in a vacuum for about 30 min. Several samples, grown with thicknesses from 60 to 200 Å, were photolithographically patterned to three conducting stripes, aligned along one of three different magnetic axes: easy, intermediate, and hard. The temperature dependence shows a shallow minimum at approximately 15 K, and at lower temperatures, obeyed the log law  $\sigma_{\square} = \sigma_0 + A \ln T$ , with the coefficient  $A$  very close to  $e^2/(2\pi^2\hbar)$  [30, 31]. It was shown that the anomalous temperature dependence did not vary with the current and sample orientation [31]. This temperature dependence was not affected by magnetic fields up to 600 G. A small negative MR was observed only at magnetic fields larger than 30 kG. No anomaly in the low-temperature conductivity was observed for films of thickness larger than 100 Å, which excludes the Kondo effect as a possible explanation of the experimental results. A comparison of the temperature dependence of the resistivity and of the normal Hall effect did not allow to distinguish between the interaction and WL corrections, mainly because of the experimental error. Finally, at 4.2 K, the high-field MR appeared to be negative, and varying linearly with the magnetic field between 30 and 130 kG. This is inconsistent

with the e-e interaction and WL theories, which predict the  $\ln H$  and  $-\ln H$  dependence in this regime, respectively.

Aprili et al. [35] measured the low-temperature conductivity of inhomogeneous Ni films near the percolation threshold. Homogeneous layers of thickness  $d = 6$  nm were first evaporated using electron guns in ultra high vacuum ( $10^{-9}$  torr). Percolating Ni films were prepared by controlled coalescence due to the annealing of homogeneous films at temperatures from 500 to 550 °C in ultrapure He vapor. The annealing process was controlled by resistance measurements, which provided an accurate method for following the evolution of the inhomogeneous state. Moreover, the annealing allowed a reduction of the amount of atomic size effects, leading to relatively large-scale topological disorder only. The metallic coverage ( $p$ ) was deduced by analyzing transmission electron microscopy images after annealing. A percolation coverage of about  $p_c = 0.56$  and a fractal dimensionality  $d_f = 1.8$  were found to be in good agreement with theoretical predictions [35]. Assuming the diffusion coefficient  $D = 5 \cdot 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$ , found in Ni-based percolation alloys [27], the authors estimated that, for temperatures below 30 K, the scale on which the phase coherence is preserved,  $L_T = \sqrt{D\hbar/k_B T}$ , should become larger than a typical film thickness, indicating possible two-dimensional quantum transport. Indeed, the  $\log T$  anomaly was found experimentally, which was well fitted with the formula  $\Delta\sigma_{\square} = (e^2/2\pi^2\hbar)[1 + 2(1 - F)]\log T - K_d T^\alpha/dR_{\square}$ , where the first two terms account for quantum transport (WL contributes to the coefficient 1 and e-e interaction to the factor  $2(1 - F)$ ,  $F$  being a screening factor). The second term reflects ordinary inelastic scattering with  $K_d$ , the coupling coefficient. It was also observed that the external magnetic field of 4 T did not affect  $\Delta\sigma_{\square}(T)$ , indicating that the quantum correction was mainly due to e-e interaction in 2-D. Moreover, from the  $\log T$  fit, one can obtain  $F = 0.55$ , which was close to the screening factor of 0.53 estimated theoretically. For percolating films, the logarithmic slope was found to be partially suppressed. Moreover, a signature of a modified dimensionality at  $T < 4$  K was reported, reflecting the transition to the regime, where the phase-coherent scale becomes close to the percolation length. Magnetoresistivity measurements performed by subtracting data obtained at 20 K (i.e., in the classical regime) showed that some contribution due to WL is also present. The dependence of a small additional (positive) contribution to the conductivity on the external magnetic field became logarithmic at high fields (above 3 T), and can be approximated by formula (1).

### 3. EFFECTS OF MAGNETIC FIELD ON THE LOCALIZATION CORRECTIONS

An analysis of the localization corrections in ferromagnetically ordered metals or semiconductors was carried out in [36–38], where the results were also compared to the corresponding ones derived for nonmagnetic materials [11, 12]. It was shown that there were two main sources which affect the localization corrections: the internal induction  $\mathbf{B}$  and the magnetization field  $\mathbf{M}$ . For theoretical analysis [36–38],

a model described by the following Hamiltonian

$$H = -\frac{\hbar^2}{2m} \left( \frac{\partial}{\partial \mathbf{r}} - \frac{i e \mathbf{A}}{\hbar c} \right)^2 - \mathbf{M} \cdot \boldsymbol{\sigma} \quad (2)$$

was used, where the vector potential  $\mathbf{A}$  is related to the magnetic induction  $\mathbf{B}$  by  $\mathbf{B} = \text{rot } \mathbf{A}$ ,  $\mathbf{M}$  has the dimensionality of energy, and  $\boldsymbol{\sigma}$  is the vector of Pauli matrices. The first term in Eq. (2) describes electrons moving in the magnetic field  $\mathbf{B}$ , whereas the second one takes into account the Zeeman splitting of spin-up and spin-down electron bands. Both factors in the Hamiltonian affect the localization corrections. It is known that the first term suppresses the cooperons, whereas the second one suppresses singlet cooperons and singlet diffusons [11, 12]. In good metallic ferromagnets, the magnitude of the spin-splitting  $M$  related to the second term of Eq. (2) is of the order of Fermi energy  $\varepsilon_F$ . On the other hand, there is a general condition,  $\varepsilon_F \tau / \hbar \gg 1$ , on which the WL theory is valid (i.e., when the localization corrections can be considered as small corrections). Therefore, one can assume that, in good ferromagnetic metals, the condition  $M\tau / \hbar \gg 1$  is also fulfilled. It can be shown [37] that when this condition is fulfilled, the contribution of singlet diffusons and cooperons can be neglected. Bearing this in mind, one can find the localization corrections to conductivity by direct generalization of the results derived for nonmagnetic metals [11, 12].

In the three-dimensional case, the localization correction to the conductivity, which includes only triplet cooperons and takes into account the magnetic induction  $B$ , can be written in the following form:

$$\begin{aligned} \Delta\sigma(B) = \Delta\sigma(0) - \frac{e^2}{16\pi^2\hbar l_B} \\ \times \sum_{n=0}^{\infty} \left[ \frac{1}{(n + 1/2 + \delta_{\uparrow})^{1/2}} - 2(n + 1 + \delta_{\uparrow})^{1/2} \right. \\ \left. + 2(n + \delta_{\uparrow})^{1/2} + \frac{1}{(n + 1/2 + \delta_{\downarrow})^{1/2}} \right. \\ \left. - 2(n + 1 + \delta_{\downarrow})^{1/2} + 2(n + \delta_{\downarrow})^{1/2} \right] \quad (3) \end{aligned}$$

where  $\sigma(0)$  does not include the effects due to magnetic induction, and is given by

$$\begin{aligned} \Delta\sigma(0) = C + \frac{e^2}{4\pi^2\hbar} \left[ \frac{1}{D_{\uparrow}^{1/2}} \left( \frac{1}{\tilde{\tau}_{\text{so}\uparrow}} + \frac{1}{\tau_{\varphi\uparrow}} \right)^{1/2} \right. \\ \left. + \frac{1}{D_{\downarrow}^{1/2}} \left( \frac{1}{\tilde{\tau}_{\text{so}\downarrow}} + \frac{1}{\tau_{\varphi\downarrow}} \right)^{1/2} \right] \quad (4) \end{aligned}$$

with the following notations introduced:

$$C \simeq -\frac{e^2}{2\pi^2\hbar l}, \quad \delta_{\uparrow(\downarrow)} = \frac{l_B^2}{4D_{\uparrow(\downarrow)}} \left( \frac{1}{\tilde{\tau}_{\text{so}\uparrow(\downarrow)}} + \frac{1}{\tau_{\varphi\uparrow(\downarrow)}} \right) \quad (5)$$

Here,  $D_{\uparrow(\downarrow)} = v_{F\uparrow(\downarrow)}^2 \tau_{\uparrow(\downarrow)} / 3$  are the diffusion coefficients, and  $v_{F\uparrow(\downarrow)}$  are the Fermi velocities for spin-up and spin-down electrons. Apart from this,  $l_B = (c\hbar/eB)^{1/2}$  is the magnetic length, and  $l$  is the electron mean-free path. Spin-orbit

interaction is included, and is described by the SO relaxation time of cooperons  $\tilde{\tau}_{\text{so}\uparrow(\downarrow)}$  and the phase relaxation time  $\tau_{\varphi\uparrow(\downarrow)}$ , related to the inelastic scattering of electrons from phonons. The dependence of  $\tau_{\varphi}$  on  $T$  results in the temperature dependence of conductivity at low  $T$ . Formula (3) was found by Kawabata's method [39], and is limited to weak magnetic induction, when  $l_B \gg l$ . The magnetoresistivity is found to be *negative* due to the suppression of the negative localization correction by magnetic induction  $\mathbf{B}$ . In the case of  $l_B < l$ , the localization correction vanishes, being completely suppressed by the magnetic induction. At  $\delta_{\uparrow}, \delta_{\downarrow} \ll 1$  (i.e., for low temperatures or strong magnetic induction), the sum in Eq. (3) is a constant  $C_2 = -0.13$  [39], which leads to the  $\sqrt{B}$  dependence of the localization correction on  $B$ . In the opposite limit of weak magnetic induction, one has  $\delta_{\uparrow}, \delta_{\downarrow} \gg 1$ , and the correction is proportional to  $B^2$ . The derived formulas describe the dependence on the total magnetic induction, which in turn depends on the external magnetic field.

In the effectively 2-D case, the localization correction has the form

$$\Delta\sigma(B) = -\frac{e^2}{4\pi^2\hbar} \left[ \psi\left(\frac{1}{2} + \frac{1}{\tau_{\uparrow}a_{\uparrow}}\right) - \psi\left(\frac{1}{2} + \frac{1}{\tilde{\tau}_{\text{so}\uparrow}a_{\uparrow}} + \frac{1}{\tau_{\varphi\uparrow}a_{\uparrow}}\right) + \psi\left(\frac{1}{2} + \frac{1}{\tau_{\downarrow}a_{\downarrow}}\right) - \psi\left(\frac{1}{2} + \frac{1}{\tilde{\tau}_{\text{so}\downarrow}a_{\downarrow}} + \frac{1}{\tau_{\varphi\downarrow}a_{\downarrow}}\right) \right] \quad (6)$$

where  $a_{\uparrow,\downarrow} = 4eBD_{\uparrow,\downarrow}/c\hbar$ . In the limit of  $B \rightarrow 0$ , the localization correction has a form similar to that in the nonmagnetic case:

$$\delta\sigma(0) = \frac{e^2}{4\pi^2\hbar} \ln \left[ \tau_{\uparrow}\tau_{\downarrow} \left( \frac{1}{\tilde{\tau}_{\text{so}\uparrow}} + \frac{1}{\tau_{\varphi\uparrow}} \right) \left( \frac{1}{\tilde{\tau}_{\text{so}\downarrow}} + \frac{1}{\tau_{\varphi\downarrow}} \right) \right] \quad (7)$$

In both effective 3-D and effective 2-D cases, the localization correction to conductivity is *negative*, and the magnitude of this correction decreases with increasing  $\mathbf{B}$ . The latter takes into account both the internal magnetic induction and the effect of the external magnetic field. Thus, the localization can be observed only in the case of a weak suppression of the localization correction by the internal induction.

The key question for quantum corrections is: how long is the phase coherence length? Tataru and Barbara [40] theoretically considered the Aharonov–Bohm effect in a disordered ferromagnetic ring. The Aharonov–Bohm effect is a macroscopic manifestation of the quantum interference of electron waves. It shows up as oscillations of electric current in a small metallic ring as a function of the external magnetic field. In the case of superconductors or pure nonmagnetic metals, the oscillation factor in the dependence of electric current on the magnetic field is known to be  $\cos(2\pi\phi/\phi_0)$ , where  $\phi$  is the magnetic flux penetrating through the ring, and  $\phi_0 = hc/e$  is the magnetic flux quantum. The corresponding theory for disordered normal metals was developed by Altshuler et al. [41], and it was shown that, in disordered metals, the corresponding factor should be  $\cos(4\pi\phi/\phi_0)$  instead of  $\cos(2\pi\phi/\phi_0)$ . This is because the cooperon contributing to the current in the ring carries the double electron charge  $2e$ , and therefore the effective magnetic quantum is half of the usual value  $hc/e$ . The theoretical prediction of [41] was later confirmed

in experiments with gold rings [42]. Due to the internal magnetization and internal induction in ferromagnets, the Aharonov–Bohm effect was shown [40] to be different from the analogous effect in nonmagnetic disordered metallic rings. The main difference is related to the influence of magnetization on the components of the cooperon. Each spin component contributes to the Aharonov–Bohm effect, with a damping factor depending on the scattering of electrons in each spin channel. Due to the possibility of a large difference in the mean-free paths of spin-up and spin-down electrons, only electrons of a specific spin orientation contribute to the effect. Thus, ferromagnetism does not suppress the Aharonov–Bohm effect, even if the difference in the spin-up and spin-down relaxation times is large (as, for example, in Fe).

Aliev et al. [43] measured MR of 17 nm thick Co wires with a width of 200 nm and a length of 1  $\mu\text{m}$  at temperatures from 4 K down to 100 mK, and in magnetic fields up to 15 T perpendicular to the structure. The polycrystalline wire structures were grown at room temperature by molecular beam epitaxy, followed by electron lithography patterning. Electric measurements were performed in a dilution He<sup>3</sup>–He<sup>4</sup> refrigerator by using the standard ac bridge technique (LR700), which assured low dissipation at low temperatures. The low-temperature resistivity (30  $\mu\Omega \cdot \text{cm}$ ) confirmed the polycrystalline structure of the sample, and indicated that the elastic mean-free path was slightly smaller than the strip cross-section dimensions. Figure 1 presents the data obtained at 100 mK at different values of electric currents between 10 and 1  $\mu\text{A}$ , and for magnetic fields well outside the region where the anisotropic MR (AMR) could affect the results. One can clearly see reproducible conductance fluctuations with an amplitude of the order of  $0.01e^2/h$  at the lowest currents and temperatures. Strong suppression of the resistance fluctuations with the current above 10  $\mu\text{A}$  and temperature  $T > 4$  K indicates that these anomalies are not induced by a reproducible rearrangement of the internal magnetic structure. These conductance fluctuations also indicate the phase-coherent transport.

**Figure 1.** Reproducible magnetoresistance fluctuations in 17 nm thick Co line structures with width of 200 nm and length 1 of  $\mu\text{m}$  observed at ultralow temperatures (100 mK) at different electric currents from 10 to 1  $\mu\text{A}$ .

Recently, Kasai et al. [44] observed the Aharonov–Bohm effect in a ferromagnetic permalloy nanoring. The sample consisted of a nanoscale ring with leads made of permalloy ( $\text{Fe}_{19}\text{Ni}_{81}$ ) and patterned by using the lift-off technique and electron-beam lithography. First, a thin photoresist of 100 nm was spin coated onto a thermally oxidized Si substrate. The resist mask was then patterned with a 20 keV electron beam. After development, permalloy was deposited by an electron-beam evaporator with 0.5 nm/s. The sample was then obtained after the resist mask had been lifted off in solvent. A scanning electron microscope was used to image and determine the dimensions of the sample. For resistance measurement, Cu electrodes were attached to the leads. The distance between the two voltage electrodes was 2.5  $\mu\text{m}$ . The outer and inner diameters were, respectively, equal to 500 and 420 nm, whereas the thickness was 20 nm. The magnetoresistivity of the ring was measured from 30 mK to 4 K in a magnetic field perpendicular to the ring plane. For magnetic fields large enough to exclude AMR, the authors [44] observed aperiodic fluctuations and periodic resistance oscillations. The aperiodic fluctuations, similar to those found for Co line structures [43], have been identified as being due to the universal conductance fluctuations. By calculating the power spectrum from the Fourier transform of the MR data obtained in the range from 3 to 4 T, it was concluded that the Aharonov–Bohm oscillations had a period  $\Delta B = 0.0266$  T, which was consistent with the estimated range of  $0.0209T < \Delta B < 0.0299T$ , given by the inner and outer diameters of the ring. The oscillation period was found to be dependent on the magnetic field tilting angle. The amplitude of oscillations was estimated to be about  $0.001e^2/h$ , which was almost three orders of magnitude smaller than one might expect for the fully phase-coherent diffusive conductor. The reduced value of the conductance oscillations was explained by a small (as compared to paramagnetic metals) phase-coherence length (500 nm). In ferromagnets, the phase-coherence length is significantly reduced by spin-flip scattering.

#### 4. ELECTRON–ELECTRON INTERACTION IN SPIN QUANTUM WELLS

Contrary to WL, the e–e interaction corrections in ferromagnets are not suppressed by the internal magnetic induction. This is because the interaction corrections are described mainly by the diffusons, which are not affected by the magnetic induction. The main difference between nonmagnetic and ferromagnetic metals, as concerns the interaction corrections, is the suppression of the contribution due to singlet diffusons. Thus, taking into account only triplet diffusons, one finds the following form for the exchange term in the interaction correction [36, 38]:

$$\Delta\sigma_{ex} = \frac{e^2}{2\pi^2\hbar(\nu_{\uparrow} + \nu_{\downarrow})} \left[ \nu_{\uparrow} \ln\left(\frac{T\tau_{\uparrow}}{\hbar}\right) + \nu_{\downarrow} \ln\left(\frac{T\tau_{\downarrow}}{\hbar}\right) \right] \quad (8)$$

where  $\nu_{\uparrow(\downarrow)}$  is the density of states of spin-up (down) electrons at the Fermi level, and  $T$  is taken in the energy units.

The Hartree term in the correction, on the other hand, is given by the formula

$$\Delta\sigma_{Har} = -\frac{e^2}{4\pi^2\hbar} \left[ F_{\uparrow} \ln\left(\frac{T\tau_{\downarrow}}{\hbar}\right) + F_{\downarrow} \ln\left(\frac{T\tau_{\uparrow}}{\hbar}\right) \right] \quad (9)$$

The above expression contains the constants  $F_{\uparrow}$  and  $F_{\downarrow}$ , which are determined by the average ratio of the Coulomb interaction matrix elements with the momentum  $k$  to the matrix element with  $k = 0$  [13, 12]. Here,  $k$  is the momentum transferred due to e–e interaction for the electrons at the Fermi surface. The difference between  $F_{\uparrow}$  and  $F_{\downarrow}$  is due to the different Fermi surfaces of spin-up and spin-down electrons.

Experimentally, the interaction corrections to the conductivity were observed by Aliev et al. [45] in Co/(Cr/Ag)/Co multilayers. The multilayers were prepared on MgO(100) substrates in a molecular beam epitaxy (MBE) deposition system using electron-beam guns and a mass spectrometer control system to stabilize the growth rate. In order to vary the thickness systematically, the Cr and Ag films were grown in a wedge shape. Then the system was cut into long stripes. The following multilayer composition was studied: Co(45 Å)/Cr(0–15 Å)/Ag(0–20 Å)/Co(45 Å), covered by 20 Å of Ag as a protection layer. The sample surface and structure were studied in detail by atomic force microscopy (AFM), X-ray diffraction (XRD), and magnetic force microscopy (MFM) [45]. The AFM measurements on the thinnest part of the wedge gave an rms roughness of 0.4 nm over a  $2.5 \cdot 2.5 \mu\text{m}^2$  area, while for the thickest part of the wedge, an rms roughness of 1.5 nm was obtained for the same area. The average grain diameter observed using AFM images was 50 nm. Low-angle specular XRD spectra clearly showed a series of well-defined finite-size oscillations, again an indication of low film roughness. The temperature dependence of conductivity at  $T < 20$  K shows the logarithmic dependence on  $T$ , fitted by the formula  $\rho = A \log T + C$  (see Fig. 2). Possible reasons for the observed logarithmic increase of the resistivity at low temperatures could be: (1) the Kondo effect, (2) WL effects, (3) disorder-enhanced two-dimensional e–e interactions, or (4) the interaction of conduction electrons with two-level systems. The first two effects are sensitive to low magnetic fields, and give rise to negative MR. They can be distinguished from the other interactions by applying a sufficiently strong magnetic field. The estimated upper limit for the Kondo temperature was  $T_K = 7$  K, defined as the middle point of the temperature interval, where the resistivity grows logarithmically. Therefore, for the usual Kondo effect, the temperature dependence of the resistivity should be substantially changed by the field  $H = 110$  kG. Characteristic fields which suppress WL effects are usually lower than 1 kG. However, it was found [45] that even the magnetic field of 110 kG had almost no influence on the logarithmic slope. The lack of saturation of the resistivity down to ultralow temperatures, both for  $H = 0$  and in the magnetic field of 110 kG, implies that the logarithmic term in the resistivity is likely due to the 2-D type e–e interactions in the presence of disorder. However, the experimental data [45] do not allow to exclude some additional contribution to the resistivity due to scattering on two-level systems. The indication of such a possibility comes

**Figure 2.** Logarithmic dependence of resistivity at  $T < 20$  K ( $\rho = A \cdot \log T + C$ ) for two Co (45 Å)/(Cr/Ag)/Co (45 Å) trilayers with different thicknesses of Cr/Ag spacer. Inset shows plot  $(-A/C)$  as a function of the Cr/Ag spacer thickness.

from the deviation from the  $\log$ - $T$  behavior in the resistivity at ultralow temperatures [46].

The thickness dependence of the observed normalized logarithmic term in the resistivity,  $A/C$ , was found to be rather unusual (see the inset in Fig. 2). For the elastic scattering times  $10^{-9}$ – $10^{-13}$  s within an accuracy of 0.01, the ratio  $A/C$  in the  $\log$ - $T$  fit is proportional to the product of the e–e interaction coefficient  $F$  and the residual resistivity [45]. For all studied strips, the coefficient  $F$  turned out to be strongly dependent on the thickness  $L$  of the (Cr/Ag) spacer layer. At some values of  $L$ , however, resonance-like peaks of  $F$  were observed. An explanation of this intriguing observation, given by Aliev et al. [45], was related to a change of disorder at the Cr/Ag interface with increasing thickness of the Cr/Ag spacer. The observed periodicity of 5 Å indeed corresponds roughly to 2.1 Å for Cr and 2.9 Å for Ag. An atomic monolayer of Cr in the preferential (110) direction is around 2.04 Å thick, which is in good agreement with the 2.1 Å estimated above. It is worth noting that interface-morphology-induced oscillations with a one monolayer periodicity also were observed in the magnetic properties and in the in-plane lattice spacing of cobalt [47–49] and gold ultrathin films [50].

Another possible explanation of this phenomenon is based on the screening effects in spin-separated quantum wells created by the multilayer structure [36]. In a simplified model, one may assume two different quantum wells, respectively for spin-up and spin-down electrons. Correspondingly, there are two different spin channels for the localization corrections. The coupling constant of e–e interaction is also associated with each of the spin channels. However, the screening of e–e interaction may include electrons with both spin orientations, provided that the corresponding matrix

elements obey certain selection rules. The resonance effect occurs when the ratio of the spin-up and spin-down quantum well widths is an integer. Physically, this corresponds to a commensurability of the wavefunctions of electrons with different spin orientations.

## 5. ROLE OF SPIN–ORBIT INTERACTION

The SO interaction plays an important role in the localization phenomena. It is well known that, in nonmagnetic metals, the presence of SO interaction can change the sign of the localization correction. As a result, the low-temperature conductivity of metals with strong SO interactions increases with decreasing temperature, what is known as the weak antilocalization effect. The change of the sign of localization correction is associated with the suppression of triplet cooperons by the SO interaction. In nonmagnetic metals, there are contributions from singlet and triplet cooperons, which have different signs and which enter with coefficients reflecting the multiplicity of the corresponding states: +1 for the singlet and  $-3$  for the triplet [13, 12]. Without SO interaction, this results in a negative correction since each component of the triplet gives the same contribution as one component of the singlet. By switching on a sufficiently strong SO interaction, one suppresses the triplet cooperon, and only the singlet cooperon is then relevant. This results in the sign reversal of the localization correction.

The situation is different in ferromagnetic metals, where the relatively strong internal magnetization completely excludes the singlet cooperons. Thus, the localization correction is negative, that is, there is no weak antilocalization. On the other hand, the SO interaction affects the triplet cooperons, decreasing the localization correction, making it smaller than in nonmagnetic metals. That is why the SO interaction is of main importance for the localization corrections in ferromagnets.

The SO interaction occurs as a relativistic effect in electron scattering from impurities and defects. It also occurs as the Rashba terms due to the interfaces [51], and the Dresselhaus terms [52] due to the higher order  $k$  terms in the electron Hamiltonian. The effects of SO interaction on the cooperons, related to the scattering from impurities and to the Rashba terms, have been studied theoretically in the case of bulk and effectively 2-D ferromagnets [37]. The most important result is that the SO interaction entering the cooperons turns out to be strongly dependent on the orientation of magnetization vector  $\mathbf{M}$  in 2-D structures. More precisely, the inverse SO relaxation time  $\tilde{\tau}_{so}^{-1}$  vanishes when the magnetization is in the plane of the layers.

It is worth noting that the SO interaction should be even more pronounced in the case of multilayered structures than in single films. As we pointed out before, the potential steps at the interfaces in combination with the relativistic terms in the Hamiltonian may produce strong SO scattering. The corresponding theory for the interface SO interaction was proposed by Bychkov and Rashba [51]. In the case of Fe/Cr multilayers, the potential steps are about 2.5 eV for the majority of electrons, and one can expect a significant SO scattering from the interface.

## 6. LOCALIZATION CORRECTIONS TO THE ANOMALOUS HALL EFFECT

Theoretical and experimental investigation of the anomalous (or extraordinary) Hall effect (AHE) in ferromagnets has a long history [53]. Recently, this effect has attracted much interest because it can be used to determine the magnitude and orientation of the magnetization in some magnetic materials, structures, and devices. AHE can be measured as a Hall voltage induced by an electric current flowing in the direction perpendicular to the magnetization  $\mathbf{M}$ . In contrast to the usual Hall effect, AHE does not require any external magnetic field. Two different mechanisms leading to AHE have been studied thoroughly: the so-called *side-jump* and *skew-scattering* mechanisms. They both essentially involve the SO interaction. The physical reason for AHE is a spin-dependent lateral displacement of the electron wave packet during the scattering from impurity (side jump) and a spin-dependent anisotropy of the scattering amplitude (skew scattering) [54].

The calculation of the off-diagonal conductivity  $\sigma_{xy}$  in a ferromagnet can be performed using the diagram technique. Considering a loop diagram with the SO correction to the vertex part (this is the side-jump mechanism), Crépieux and Bruno [54] found the following formula for  $\sigma_{xy}$ :

$$\sigma_{xy}^{(sj)} = \frac{e^2 \lambda_0^2}{6} (\nu_{\downarrow} k_{F\downarrow} v_{F\downarrow} - \nu_{\uparrow} k_{F\uparrow} v_{F\uparrow}) \quad (10)$$

where  $k_{F\uparrow, \downarrow}$ ,  $v_{F\uparrow, \downarrow}$ , and  $\nu_{\uparrow, \downarrow}$  are the electron momentum, electron velocity, and the density of states for spin-up and spin-down electrons at the Fermi surfaces. The constant  $\lambda_0$  measures the strength of the SO interaction. It has the dimensionality of length, and for nonrelativistic electrons in vacuum,  $\lambda_0 = \lambda_c/2\pi$ , where  $\lambda_c = 2\pi\hbar/m_0c$  is the Compton wavelength of electrons and  $m_0$  is the free electron mass. The magnitude of  $\lambda_0$  in crystals is changed due to crystalline fields.

Within the skew-scattering mechanism, one takes into account the loop diagrams with the third-order corrections due to scattering from impurities, keeping the first order in SO interaction [54]. The result of relevant calculation is

$$\sigma_{xy}^{(ss)} = \frac{\pi \langle V^3 \rangle \lambda_0^2 a_0^3}{6 \langle V^2 \rangle} [\sigma_{xx, \downarrow} k_{F\downarrow}^2 \nu_{\downarrow} - \sigma_{xx, \uparrow} k_{F\uparrow}^2 \nu_{\uparrow}] \quad (11)$$

where  $\sigma_{xx, \uparrow, \downarrow}$  are the diagonal conductivities in the spin-up and spin-down channels, and  $a_0$  is the lattice parameter. Here,  $V$  measures the amplitude of disorder, and the angle brackets mean averaging over disorder. The dimensionless ratio  $\langle V^3 \rangle / \langle V^2 \rangle^{3/2}$  depends only on the distribution  $P(V)$  of the random field  $V(\mathbf{r})$ , whereas  $\nu a_0^3 \langle V^2 \rangle^{1/2}$  characterizes the relative strength of the potential.

Localization correction to the anomalous Hall effect has been studied experimentally on several amorphous ferromagnetic Fe films with thickness from two to ten atomic layers [55]. The films were prepared *in-situ* by quenched condensation onto a crystalline quartz substrate held at helium temperature in a vacuum better than  $10^{-11}$  torr. Homogeneous amorphous iron films of less than two monolayers thickness could be obtained by this method if they were deposited on an insulating Sb buffer layer with a thickness of

ten monolayers. An additional indication on the amorphous structure of the films was the resistively detected irreversible transformation to the crystalline state for films of thickness of more than 18 monolayers, when they were heated to above 40 K. Details of the sample preparation are described in [56]. It has been found [55] that the quantum correction to the off-diagonal (Hall) conductance  $\Delta\sigma_{xy}$  is negligibly small in the low-temperature region, in which the correction to the conductance  $\Delta\sigma_{xx} \sim \log T$  is clearly seen. In other words, the quantum corrections due to localization and e-e interaction to the off-diagonal conductance vanish in ferromagnetic films. This result is in contrast to what is known of the localization corrections to the usual Hall effect [11, 12], for which the localization correction to the off-diagonal conductance is nonzero, and this exactly compensates the effect of localization correction in diagonal conductance for the Hall constant. As a result, the localization correction to the Hall constant is exactly zero, but the correction to  $\sigma_{xy}$  is not zero. The theoretical analysis for ferromagnets has been done in [57–60]. It was shown that the results are different for different mechanisms of AHE. Namely, the localization correction to  $\sigma_{xy}$  is nonzero for the skew scattering [57, 58], but it vanishes for the side-jump mechanism [58]. In the latter case, exact cancellation of the contributions from different diagrams takes place. In addition, the exchange interaction correction for the skew-scattering mechanism was shown to vanish too [57]. Thus, the experiment of Bergmann and Ye [55] can be interpreted either as the localization correction strongly suppressed by the SO interaction within the skew scattering [57], or as the localization correction within the side-jump mechanism [58]. The latter interpretation is better justified for an alloy-like type of disorder described by the Gaussian distribution of random fields. Such a type of disorder (alloys, amorphous systems) is in contrast to the impurity disorder (doped semiconductors).

## 7. INTERPLAY BETWEEN LOCALIZATION AND BAND MAGNETISM

The above discussion of the WL and e-e interaction corrections to conductivity applies to systems far from the critical point of ferromagnetic transition, where the magnetic fluctuations are very weak. An important issue is the influence of localization on the magnetic ordering in itinerant ferromagnets. This effect should be of key importance near the critical point, where the magnetic fluctuations are affected by the localization effects. In other words, magnetic fluctuations, cooperons, and diffusons should be considered at the same footing. This problem was studied in [61, 62]. Fukuyama [61] considered a ferromagnet in the framework of the Hubbard model and in the presence of random short-range impurities. He found that the Curie temperature  $T_c$  depends substantially on the disorder which leads to an increase in  $T_c$ . The reason for this is that the Coulomb interaction leading to ferromagnetism is effectively enhanced due to the diffusive motion of electrons.

A similar model, with two coupling constants describing the Hubbard interaction in a disordered electron system, was studied by Singh and Fradkin [62]. They found that the effect of enhancement of the e-e interaction by the localization can be so strong that the electrons can be localized, and

at the same time, the ferromagnetic ordering can persist. The authors called such a system the *ferromagnetic Anderson insulator*. The other important aspect of the self-consistent calculation in their work was *no suppression of the singlet cooperon* by the spontaneous magnetization. This resulted from an interplay of different types of fluctuations in the vicinity of the magnetic phase transition point.

Recently, Kim and Millis [63] predicted a singular renormalization of the amplitude of backscattering from impurities, when the correlation length near the ferromagnetic magnetic quantum critical point exceeds the mean-free path. In other words, long wavelength fluctuations may dramatically increase the backscattering by spinless impurities. This effect leads to an enhancement of the Altshuler–Aronov correction to conductivity from  $\log(1/T)$  to  $\log^2(1/T)$ . Besides, peculiar Friedel oscillations in the electron density near the impurities should occur for a magnetic-field-induced quantum-phase transition. Due to a nonzero magnetic field, the spin-up and spin-down Fermi surfaces are characterized by different wavevectors. Accordingly, two superimposed oscillations in the electron density may be expected near any impurity.

On the experimental side, localization effects due to the magnetically tuned quantum-phase transition were observed in synthetic antiferromagnet (Fe/Cr) [64] and natural quasi two-dimensional metal  $\text{Sr}_3\text{Ru}_2\text{O}_7$  [65]. The ruthenate  $\text{Sr}_3\text{Ru}_2\text{O}_7$  is the  $n = 2$  member of the series of layered perovskites  $\text{Sr}_{n+1}\text{Ru}_n\text{O}_{3n+1}$ . The end members of the series are the pseudocubic and itinerant ferromagnet  $\text{SrRuO}_3$  ( $n = \infty$ ) [66] and the strongly two-dimensional unconventional superconductor  $\text{Sr}_2\text{RuO}_4$  [67]. The high-quality single crystals were grown using methods described in [68]. It was found that critical fluctuations near the metamagnetic phase transition in quasi two-dimensional metal  $\text{Sr}_3\text{Ru}_2\text{O}_7$  strongly enhance the residual resistivity  $\rho_{\text{res}}$  as the temperature is lowered below a few kelvin [65]. The low-temperature resistivity, however, varies as  $\rho = \rho_{\text{res}} + AT^\alpha$ , with  $\alpha \simeq 1$ . Similar conclusions have been drawn from the study of the magnetic-field-tuned quantum-phase transition in antiferromagnetically coupled Fe/Cr multilayers (see the next section and [64] for details of the sample growth and characterization). The difference is that, in the latter case, the maximum in the residual resistivity is overshadowed by a strong magnetic-field-dependent resistance, that is, by the GMR effect.

## 8. LOCALIZATION CORRECTIONS ASSOCIATED WITH DOMAIN WALLS

It has been known for a long time that magnetic domain walls (DWs) contribute to MR (DWMR). Electron transport through a narrow DW is predominantly ballistic [69], whereas for thick DWs it is rather diffusive. In the latter case, the quantum corrections due to WL and e–e interaction in the presence of disorder can also play a significant role, leading to interesting MR phenomena [70–72]. Recent interest in the DW contribution to resistivity is stimulated by intriguing physics which underlies the DWMR effect [73–77], and also by possible applications. Indeed, DWs can have a significant influence on the electrical noise

and operation of magnetoelectronic devices [78]. Although the number of DWs was controlled and directly observed, for example, in Fe [77] and Co films [75] at room temperature, where DW formation is relatively well understood, no clear picture emerged which could allow an understanding of the results. AMR dominates the low-field MR, and complicates the extraction of the true DW contribution to the resistivity [79]. In order to minimize the AMR contribution, thin films with reduced magnetization and special DW configurations have been studied [80].

The localization corrections in the presence of DWs are affected by a specific perturbation, which can be described as an effective gauge field arising in the vicinity of DWs. This problem has been studied theoretically in several works [70–72]. Tataro and Fukuyama [70] showed that, using a local spin transformation, the problem of a smooth DW with a spatially varying magnetization  $\mathbf{M}(z)$  can be considered as a problem with constant magnetization, but with an additional spin-dependent gauge field. The effect of the gauge field on the cooperon is similar to that of the vector potential associated with a magnetic field, that is, the gauge field suppresses the cooperons. Thus, DWs cause suppression of the localization corrections, which leads to an increase in the conductivity in the presence of DWs. When the external magnetic field removes DWs, then the conductivity decreases, giving rise to positive magnetoresistivity. This effect should be observed in the low-temperature region, where the localization corrections are not negligible. Recently, Jonkers [81] predicted that, for a 2-D ferromagnetic wire with impurity scattering independent of the spin orientation, the suppression of WL by DWs increases with increasing impurity concentration and decreases with increasing width of the wall.

The theory described above [70, 71] was revised and further developed by Lyanda-Geller et al. [72]. They showed that, actually, the gauge field does not equivalently suppress all of the cooperon components. Strictly speaking, some components can be unaffected by this field, which means that the effect is smaller than that predicted in [70, 71].

One of the ways to quantify the effect of the domain walls on resistance of ferromagnetic films is to pattern high-quality thin (100 nm thick) epitaxially grown (110) oriented bcc Fe films [77]. These films, grown on sapphire substrates [82], display a large in-plane uniaxial magnetocrystalline anisotropy, with the easy axis parallel to the [001] direction. The films were patterned using projection optical lithography and ion milling to produce micron scale wires oriented perpendicular to the magnetic easy axis. The residual resistivity ratio of 30 and low residual resistance indicate the high crystalline quality of these films. The competition among magnetocrystalline, exchange, and magnetostatic interactions results in a pattern of regularly spaced stripe domains perpendicular to the wire axis. Variation of the wire width changes the ratio of these energies, and hence the domain size. The magnetic domain configurations were strongly affected by the magnetic history of the samples. Before imaging, the wires were magnetized to saturation with a magnetic field transverse or longitudinal to the wire axis. In the transverse case, the mean stripe domain length was 1.6  $\mu\text{m}$ —much larger than in the longitudinal case, where it was 0.4  $\mu\text{m}$ . The negative DW contribution to the

resistivity, which was extracted from the low-field MR of these epitaxial Fe films after taking into account the AMR contribution, was explained [77] as a possible indication for the localization corrections in the presence of DWs. However, the fact that the WL effect survived at elevated (77 K) temperatures is rather against such an explanation. A negative contribution to resistivity due to DWs was also reported by Hong and Giordano [83] in Ni wires at  $T < 20$  K. Very narrow strips were patterned from Ni films evaporated onto glass substrates. The patterning was accomplished using a step-edge method [84], with typical thicknesses and widths of 200–400 Å, and sample lengths of  $10 \mu\text{m} \cdot \text{km}$ . The elastic mean-free path, estimated from low-temperature resistivity (10–20  $\mu\Omega \cdot \text{cm}$ ) was comparable to, or slightly smaller than, the strip cross section. Further experimental details are given in [85]. These experiments [83], however, did not study the temperature dependence of the effect, and considered AMR as an alternative origin of the observation. In the following, we review recent experimental results on the localization corrections in antiferromagnetically coupled Fe/Cr multilayer structures in the presence of DWs [86, 87].

Antiferromagnetically (AF) coupled magnetic multilayers (MMLs) are systems of reduced magnetization, and therefore have strongly suppressed AMR. Weak pinning of DWs at high temperatures is expected to suppress the DWMR. For a fixed magnetic field, DWMR should occur at sufficiently low temperatures, where DWs become strongly pinned and their configuration is not affected by thermal fluctuations or electrical current. The GMR effect (see Section 1) in this system is dominated by realignment of the magnetization direction in adjacent magnetic layers [88]. The presence of DWs should result in a small additional in-plane MR [89]. While the GMR effect is known to saturate at low temperatures [90], the temperature dependence of DWMR is still a matter of controversy.

Epitaxial  $[\text{Fe}/\text{Cr}]_{10}$  multilayers with ten bilayers were prepared in an MBE system on MgO (100)-oriented substrates held at 50 °C and covered by a 12 Å thick Cr seed layer. *In-situ* high-energy electron diffraction and *ex-situ* X-ray diffraction measurements were used to control the structural quality of the multilayers. The thickness of the Cr layers was typically 12–13 Å, which corresponds to the first antiferromagnetic peak in the interlayer exchange coupling for the Fe/Cr system [91], and gives rise to maximum GMR, which is about 20% at 300 K and 100% at 4.2 K. The antiferromagnetic fraction exceeds 80%, and the bilinear AF coupling dominates the biquadratic exchange coupling [92]. A detailed description of the sample preparation and structural characterization is given in [93].

Typical magnetic images at  $T = 4.2$  K and room temperature [86, 87] reveal different irregularly shaped domains of micrometer size (which is a characteristic feature of strong AF coupling [88, 94]). The susceptibility data point toward a weak pinning of the DWs at room temperature and a strong pinning at low temperatures [87]. Figure 3a shows the temperature dependence of the electrical resistivity  $\rho$  for an  $[\text{Fe}(12 \text{ Å})/\text{Cr}]_{10}$  MML and for different magnetic fields ( $|H| \leq 300$  Oe). The magnetic field was applied in the plane of the film and parallel to the current flowing along the (110) axis. For  $|H| > 100$  Oe, the  $\rho(T)$  dependence reveals a

**Figure 3.** (a) Temperature dependence of the resistivity for  $[\text{Fe}(12 \text{ Å})/\text{Cr}]_{10}$  multilayer in different magnetic fields. Both the field and the current are along the (110) axis. (b) Temperature dependence of the DW contribution to the resistivity.  $\rho_{\text{DW}} = \rho(T, H) - \rho(T, H_S)$  determined from the data shown in (a) for  $H = 0$  and 200 Oe and  $H_S = -300$  Oe. The solid lines correspond to the fits which are described in the text. Vertical bar indicates maximum influence which could cause the GMR effect as on the estimated DW contribution.

metallic behavior, while for  $|H| \leq 100$  Oe, there is a shallow minimum in the  $\rho(T)$  curves.

In order to separate the DW contribution to magnetoresistivity from the GMR effect, the authors of [87] estimated the DW resistivity as  $\rho_{\text{DW}} = \rho(T, H) - \rho(T, H_S)$ , with  $|H_S| \leq 300$  Oe. Although this method may underestimate the magnetoresistivity due to DWs, because some of the domains may not be removed by the applied field  $H_S$ , it provides a possibility to determine the temperature dependence of the DW magnetoresistivity. Figure 3b shows  $\rho_{\text{DW}}(T, H)$  between 1.9 and 50 K for two magnetic fields (0 and –200 Oe) and zero field when  $H_S = -300$  Oe. In contrast to GMR, the DW magnetoresistivity is strongly temperature dependent at low temperatures, with no sign of saturation. The vertical bar indicates maximum influence, which could be caused by the GMR effect. This estimation was obtained from the temperature dependence of the magnetoresistivity measured for two different magnetic fields sufficiently large to remove all DWs. It is known from other measurements that, for Fe/Cr epitaxial multilayers, the GMR effect is weakly temperature dependent below 50 K; it saturates as  $T^2$ , and changes less than 7% [64]. The authors of [86, 87] also demonstrated that neither AMR (which depends on the relative orientation of the magnetization and the current  $I$ ) nor the ordinary magnetoresistivity caused by the Lorentz

force (which depends on the relative orientation of  $I$  and the magnetic induction  $B$ ) contributes to  $\rho_{\text{DW}}$ .

The ballistic approach to electron transport through DWs [69] requires that the mean-free path  $l$  in the epitaxial layers exceeds the DW width  $D$ , with  $20 < D < 200$  nm for Fe/Cr/Fe trilayers [95]. Therefore, the condition for ballistic transport may only be fulfilled at sufficiently low temperatures [93]. Although nonballistic effects have not yet been incorporated into the theory [69], it is clear that they cannot account for the strong variation of  $\rho_{\text{DW}}$  down to 1.9 K because the mean-free path is expected to saturate at low temperatures. Moreover, the strong pinning of DWs at low temperatures [87] implies that a distortion of the current lines by domain walls [73] or a change of the DW configuration cannot account for the observed strongly temperature-dependent low-field contribution to MR in antiferromagnetically coupled magnetic multilayers.

In order to explain the strong variation of the DW magnetoresistivity at low temperatures, one has to go beyond the classical approach [69]. A certain possibility is to link the observed phenomena either to standard, disorder-related, WL effects or to scattering by isolated spins. Experimental results [86, 87] are in conflict with both scenarios because the resistivity corrections with and without a magnetic field are different when a magnetic field is applied along the hard or easy axis. We note that both [70, 71] and [72] theoretical works predicted a destruction of WL by DWs, although the details of the destruction mechanism are different. Direct application of these models results in a sign of the DW magnetoresistivity, which is opposite that observed experimentally. However, the sign of the localization correction may be reversed due to strong spin-orbit scattering (antilocalization) [96]. The suppression of WL corrections by DWs, predicted in [70–72], is related to the associated effective gauge potential. In contrast to the electromagnetic vector potential corresponding to an external magnetic field, the gauge field depends on the electron spin giving rise to a different influence of DWs on the different components of the cooperon [72].

Measurements of Aliev et al. [86, 87] are consistent with the antilocalization effect in the absence of DWs ( $H > 300$  Oe) and its suppression in the presence of DWs ( $H = 0$ ). It is quite natural to assume the presence of a strong SO scattering in the vicinity of the interfaces of MMLs (Rashba term [97]). In the case of strong SO scattering, MR is caused by the destruction of the singlet cooperon by the gauge field associated with DWs.

When  $l \ll D$ , the system can be characterized in terms of the local conductivity, which is defined as an average over distances larger than  $l$ , but smaller than  $D$ . The localization correction for a particular DW is then determined by smaller diffusive trajectories with size  $L < D$ , as well as by large trajectories  $D < L < L_\varphi$ . The localization corrections associated with the small trajectories are suppressed by the gauge field since they are located within the DW. The contribution of large trajectories to localization is small, and for strong SO scattering, the local conductivity within a DW is

$$\sigma_{\text{DW}} \simeq \sigma_0 + \frac{e^2}{4\pi^2\hbar} \left[ \frac{1}{l} - \left( \frac{1}{L_{\text{DW}}^2} + \frac{1}{L_\varphi^2} \right)^{1/2} \right] \quad (12)$$

where  $L_{\text{DW}}$  is the characteristic length which is determined by the influence of the gauge potential  $A$ . Its magnitude can be estimated as  $A \sim 1/D$ , and consequently,  $L_{\text{DW}} \sim D$ .

Since the antilocalization correction without DW is

$$\sigma \simeq \sigma_0 + \frac{e^2}{4\pi^2\hbar} \left( \frac{1}{l} - \frac{1}{L_\varphi} \right) \quad (13)$$

one can estimate the difference in magnetoresistivity due to the DWs as

$$\sigma_{\text{DW}} - \sigma \simeq -\frac{e^2}{4\pi^2\hbar} \left[ \left( \frac{1}{L_{\text{DW}}^2} + \frac{1}{L_\varphi^2} \right)^{1/2} - \frac{1}{L_\varphi} \right] \quad (14)$$

The most important feature of this evaluation of the antilocalization effects is the fact that the correction to the local conductivity is determined by the gauge field inside DWs. If the current crosses a particular DW, the correction to the local conductivity, calculated for a narrow region inside the wall, shows up in the sample resistance.

One can also estimate the influence of an external magnetic field of 300 Oe and of the internal magnetization on the localization corrections. These effects are small when the magnetic length  $l_H \equiv \sqrt{\hbar c / (eH)} \gg l$ . For  $H = 300$  Oe,  $l_H \simeq 1.4 \cdot 10^{-5}$  cm. Assuming the internal magnetic induction  $B = 2$  T (a typical value for Fe), we obtain the corresponding length  $l_H \simeq 1.8 \times 10^{-6}$  cm. On the other hand, the mean-free path  $l \simeq 10^{-7}$  cm. Thus, both the external magnetic field and the magnetization are rather unable to effectively suppress the antilocalization corrections in these structures.

It is possible to fit the data [86, 87] to Eq. (14) by assuming that  $L_{\text{DW}}$  is independent of temperature, and that the phase-breaking length  $L_\varphi$  varies with temperature according to a power law  $L_\varphi \propto T^{-3/2}$  [12]. On the other hand, one has to introduce an additional (constant) shift of the data which takes into account the change of the resistance due to the variation of the angle between magnetic layers. It is important to note that the three different fits presented in Figure 3b correspond to the same fitting parameters, except for the parameter which describes the magnetic contrast ( $L_{\text{DW}}$ ). It is found that the effective DW width  $L_{\text{DW}}$  becomes about 2.5 times larger when the magnetic field is increased from 0 to 200 Oe. Thus, the detailed analysis shows that the experiments [86, 87] can be explained in terms of the suppression of antilocalization corrections by DWs.

As already mentioned, the dephasing effect may be induced, not only by the DWs, but also by the boundary magnetic field when a nonmagnetic conductor is sandwiched between two ferromagnetic layers. Tatara and Fukuyama [98] also found that spin mixing induced by SO interaction may suppress the antilocalization effect. This suppression is especially enhanced when the magnetizations of two layers are parallel.

## 9. LOCALIZATION CORRECTIONS TO MAGNETIC INTERACTIONS IN MULTILAYERS

The problem of magnetic interactions in magnetic multilayer structures is of high importance from the application point of view. It is closely related to the possibility of an

effective control of magnetization by an external magnetic field. Such a control is essential for the magnetoelectronic-device-based GMR effect [1,2]. During the last decade, the interlayer exchange coupling has been the subject of intensive study, both experimentally [3,4,99] and theoretically [100–104]. The main physics of the coupling is now well understood, and many experimental observations have been successfully explained by the existing theoretical models. There are several excellent review articles on the phenomenon [105–108].

The starting point of the analysis of magnetic coupling in the multilayer structures is the RKKY mechanism of *exchange interaction* between magnetic impurities in metals [109–111]. The indirect exchange interaction is mediated by itinerant electrons, which transfer the information about spin polarization from a particular impurity to another one. The key point of the RKKY mechanism is magnetic polarization of the electron gas by an impurity. Such a cloud of polarization couples to the spin of the other impurity. The effective exchange parameter varies with the distance  $R$  between magnetic impurities, and is proportional to  $\cos(2k_F R)/R^3$ , where  $k_F$  is the Fermi momentum of electrons in metal. Thus, the RKKY interaction changes sign with increasing  $R$ , and the corresponding oscillation period is  $\pi/k_F$ .

In contrast to the RKKY interaction between magnetic impurities, the magnetic interlayer coupling involves a collective interaction of a distributed magnetization within the magnetic layers. This makes the problem more complex for theoretical analysis because the application of perturbative methods is not well justified in this case. It also should be noted that both the homogeneity of the magnetization in the film plane and the finite layer thickness are of importance. This was shown in a number of works accounting for the oscillatory dependence of magnetic coupling on the layer thickness. The interlayer coupling generally depends on the spacer thickness as  $J = \sum_{\alpha} A_{\alpha} \sin(k_{\alpha} R)/R^2$ , where the index  $\alpha$  distinguishes different oscillatory components [108].

It turns out that the above-mentioned difference in the magnetic coupling between impurities and magnetic layers is crucial for the localization effects in the magnetic interaction. The problem concerns a range of the exchange interaction related to disorder. It was suggested in the past by de Gennes [112] that an inevitable disorder should impose a damping factor  $\exp(-R/l)$  on the exchange interaction between magnetic impurities, where  $l$  is the mean-free path of electrons in metal. However, a careful analysis of the interaction between magnetic impurities in disordered metals shows [113–115] that the exponential factor should be dropped in many cases. Namely, the result essentially depends on what physical quantity, determined by the interaction, is under averaging over possible realizations of the disorder.

Such a dependence is a manifestation of a nonself-averaging property of some physical quantities in the theory of disordered systems. A general rule is that we should average a physically observable quantity such as, for example, the magnitude of electric current (in many cases, it is the same as the averaging conductivity), depending on a specific realization of disorder. Correspondingly, to find the critical temperature  $T_c$  of a spin glass transition in a metallic system

with magnetic impurities, we should average the expression for the transition temperature, which contains  $J^2$ . The main result of [113,114] is that, without averaging over disorder (i.e., for any specific realization of disorder), the coupling between magnetic impurities does not contain any damping factor at all. Moreover, the averaged quantity  $\langle J^2 \rangle$  does not contain it either. The reason is that there is an exact compensation of the impurity contributions in diagrams describing the second power of coupling  $J$ .

However, the same approach to the theory of interlayer coupling [116] in magnetic structures with a disorder produced by nonmagnetic impurities and/or interface roughness shows that the effective interaction gains a damping factor  $\exp(-R/a)$ . However, the value of the interaction range  $a$  is not equal to  $l$ , and it can be considerably longer than the mean-free path of electrons in the spacer. In particular, the interfacial roughness does not change the damping factor, whereas it affects the electron mean-free path  $l$ . The nonvanishing damping factor in the interlayer coupling shows the self-averaging character of the magnetic interaction in magnetic structures, in contrast to the interaction between ions [116].

## 10. LOCALIZATION CORRECTIONS TO SPIN CONDUCTIVITY

The investigation of the transport properties of magnetic systems quite naturally invokes the problem of spin currents induced by some external fields (for instance, an electric field or the gradient of a magnetic field). A general theory of the spin-current response to external perturbations has been developed by Levy [117]. This approach distinguishes between the charge and spin currents, even though there is no real separation of spin and charge (both are related to the same particle). Nevertheless, in many cases, such an approach is better justified than the assumption of separated spin channels. In particular, the approach is justified for systems with large spin-orbit coupling, where a strong mixing of spin channels takes place, or for systems with strong Coulomb interaction which acts differently on the total charge and on the total spin (exchange interaction). The importance of the separation of charge and spin currents is also related to the conservation laws; there is a rigorous conservation law only for the total charge.

In the case of small perturbations, the corresponding linear response theory for the spin current can be easily developed. Such a linear response is described in terms of the spin conductivity. It can be shown that the spin conductivity and the spin diffusion coefficient obey Einstein's relation. The separation of spin and charge currents also allows us to separately study the localization effects on the spin and charge conductivities. Here, the spin conductivity is considered as a linear response of the system to an electric field. Physically, a nonvanishing spin current is possible in systems with some asymmetry in the transport properties of spin-up and spin-down electrons. The electric current in ferromagnets is usually associated with both the charge transfer and spin transfer.

The quantum corrections to spin conductivity can be derived using the same methods as in the case of corrections to charge conductivity. The localization correction to

the spin conductivity was analyzed in [118, 119], where it was shown that the correction vanishes in the absence of SO interaction. However, even if the SO interaction is present, the correction is rather small, which is due to cancellation of the contributions to spin conductivity from the spin-up and spin-down channels. It should be noted that this result is applicable to the disorder associated with localized impurity scatterers.

In the 3-D case (bulk ferromagnet), the correction to the spin conductivity has the following form:

$$\Delta\sigma_{\text{spin}}^{3\text{-D}} = \frac{e}{4\pi^2\hbar} \left[ \frac{1}{D_{\uparrow}^{1/2}} \left( \frac{1}{\tilde{\tau}_{\text{so}\uparrow}} + \frac{1}{\tau_{\varphi\uparrow}} \right)^{1/2} - \frac{1}{D_{\downarrow}^{1/2}} \left( \frac{1}{\tilde{\tau}_{\text{so}\downarrow}} + \frac{1}{\tau_{\varphi\downarrow}} \right)^{1/2} \right] \quad (15)$$

whereas in the effectively 2-D case, one finds

$$\Delta\sigma_{\text{spin}}^{2\text{-D}} = -\frac{e}{4\pi^2\hbar} \ln \left[ \frac{D_{\uparrow}(\tilde{\tau}_{\text{so}\downarrow}^{-1} + \tau_{\varphi\downarrow}^{-1})}{D_{\downarrow}(\tilde{\tau}_{\text{so}\uparrow}^{-1} + \tau_{\varphi\uparrow}^{-1})} \right] \quad (16)$$

The main contributions to the correction, originating from the shortest time  $\tau_{\sigma}$ , are exactly canceled. Thus, the correction to the spin conductivity is determined by the SO relaxation time and the phase relaxation rate.

## 11. LOCALIZATION EFFECTS IN LOW-CARRIER-DENSITY MAGNETS

The quantum corrections to low-temperature resistivity have been studied recently in perovskite-type manganites  $\text{La}_{1-x}\text{Pb}_x\text{MnO}_3$  [120] and bilayer manganites  $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$  [121]. The interest in these compounds is mostly related to the colossal MR (CMR), which is usually attributed to the magnetic-field-controlled scattering from localized magnetic moments. The physics of manganites is very interesting and complex because of the interplay of magnetic effects, disorder, and strong electron–electron correlations leading to Mott-type phase transitions. This results in a complex character of the temperature dependence of resistivity, with a distinguished region of prevailing scattering from magnons. Single-crystalline  $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$  manganites, used for studies of quantum interaction effects, were grown from sintered rods of the same nominal composition by the floating-zone method using a mirror furnace, described in detail in [122]. High-quality single crystals  $\text{La}_{1-x}\text{Pb}_x\text{MnO}_3$  were grown by the flux growth using the accelerated crucible rotation technique. The detailed preparation process and composition analysis are described in [123]. A temperature dependence for  $\text{La}_{1-x}\text{Pb}_x\text{MnO}_3$  perovskite manganites [120] clearly shows an increasing resistivity with decreasing temperature for  $T < 50$  K. This increase obeys the low  $T^{1/2}$  characteristic for quantum correction due to e–e interactions in 3-D metals or due to WL with the phase relaxation time  $\tau_{\varphi}$  depending on the temperature as  $\tau_{\varphi} \sim T^{-1/2}$  [12, 13]. The latter dependence is characteristic of the inelastic e–e scattering, which results in dephasing of the electrons. The key role of e–e interactions seems to be

quite natural for these compounds, which have typical characteristics of strongly correlated electron systems. MR was found to be positive and relatively large, up to 20% at 4.2 K. The positive sign of MR has been attributed to the e–e interaction in the presence of disorder [120]. The temperature dependence of the resistivity correction for  $\text{La}_{1.2}\text{Sr}_{1.8}\text{Mn}_2\text{O}_7$  was studied by Zhang et al. [121], who found the same  $T^{-1/2}$  dependence. The authors proposed the explanation in the framework of WL with the dephasing time  $\tau_{\varphi} \sim T^{-1/2}$ .

Another interesting example was the observation of quantum interference effects in  $\text{Fe}_{1-y}\text{Co}_y\text{Si}$  ferromagnets [124]. This system is peculiar because the two limiting compounds (for  $x = 0$  and  $x = 1$ ) are both nonmagnetic, whereas for almost all intermediate compositions, it is magnetic [125]. Polycrystalline pellets or small single crystals grown from Sb and Sn were produced from high-purity starting materials by arc melting in an argon atmosphere. Annealing of  $\text{Fe}_{1-y}\text{Co}_y\text{Si}$  ( $\text{Fe}_{1-x}\text{Mn}_x\text{Si}$ ) in evacuated quartz ampoules for 24 h at 1280 °C (four days at 1000 °C) improved the homogeneity of the samples. The linearity of the lattice constants with Co and Mn concentration indicates that Co or Mn successfully replaces Fe over the entire concentration range ( $0 < x < 1$ ;  $0 < y < 1$ ). Energy dispersive X-ray microanalysis confirmed the nominal concentrations. The Hall effect data established the sign and density of the carriers, and demonstrated a systematic increase in the carrier density ( $n$ ) proportional to the Co and Mn concentration at small  $x$  and  $y$  [124]. It was shown that  $n$  does not change when the Curie temperature is surpassed. Spontaneous magnetization determined from the saturated value of the magnetization at high magnetic fields corresponds to approximately  $1 \mu_B$  per Co atom. These materials are highly disordered low-carrier-density ferromagnets, where the same electrons are responsible for both the magnetic properties and the electric conduction. One should note, however, the rather low coercive magnetic field, as may be determined from the analysis of the magnetization hysteresis [124]. This implies either weak ferromagnetic crystalline anisotropy and/or weak domain wall pinning. A large positive and weakly temperature-dependent MR was observed at  $T < 35$  K (below the Curie temperature). Due to the similarity between the low-temperature magnetotransport for paramagnetic Al- and Mn-doped FeSi and  $\text{Fe}_{1-x}\text{Co}_x\text{Si}$ , the authors [124] concluded that the low-temperature MR in ferromagnetic  $\text{Fe}_{1-x}\text{Co}_x\text{Si}$  is due to e–e interaction enhanced by disorder. Indeed, the dependence of the correction on the magnetic field is in good agreement with the interaction theory of magnetoconductivity in nonmagnetic 3-D systems [12, 13], provided the magnetic field is substituted by an effective field  $H_{\text{eff}} = H + \alpha M$ , where  $\alpha$  is a constant and  $M$  is the internal magnetization. The temperature dependence of the correction to conductivity obeys the  $T^{-1/2}$  law. The temperature scaling  $(\sigma - \sigma_0)/T^{1/2}$  versus  $H_{\text{eff}}/T$  has been observed for temperatures up to 100 K in some alloys, which demonstrates the strong quantum interference effects at rather high temperatures. The experimental results of the above-described works are in rough agreement with our previous analysis. Indeed, in the case of strong ferromagnets, the magnetization completely suppresses the singlet cooperons and diffusons. The effect of an external magnetic field can be seen only on the triplet

cooperons, for which the magnetic field dependence appears as in the case of nonmagnetic metals with the magnetic field  $H$  replaced by the magnetic induction  $B$ . Finally, we note that the enhanced e–e interaction effects and WL were also reported in the conductivity of ferromagnetic glasses [126,127]. However, the presence of a minimum in resistivity at rather high temperatures (above 200 K) indicates the electron interaction with two-level systems as the most probable explanation of the effect [128].

## 12. COULOMB INTERACTIONS IN FERROMAGNETIC DOUBLE JUNCTIONS

When the central electrode (island) of a double-barrier junction is small, the addition of one extra electron may cost a significant amount of energy. This addition energy includes a contribution following from the quantization of the energy levels of the island, and also a term due to the electrostatic interaction of the extra electron with other electrons being on the island. These two contributions may be comparable. In a few-electron quantum dot, the discreteness is important. In metallic islands (grains) of nanometer size, on the other hand, the quantization of the energy levels is less important, and in that case, the energy related to the electrostatic interaction plays a dominant role. In the simplest case, one may approximate the electrostatic energy by a phenomenological charging energy  $E_c = e^2/2C$ , where  $C$  is the capacitance of the island. The charging energy defined in this way is independent of the distribution of electrons between different discrete levels. This phenomenological model describes the transport characteristics rather well for the energy relaxation time on the island smaller than the injection time (time between the following tunneling events). When the capacitance  $C$  is sufficiently small, one can then reach the regime where the charging energy  $E_c$  is larger than the thermal energy  $k_B T$ . If this is the case, discrete charging of the island with single electrons modifies the junction current–voltage characteristics, leading to a Coulomb blockade of the electric current below a certain threshold voltage and to characteristic Coulomb steps above the threshold [22]. When the system is in the blocked state, then the blockade can be removed by applying a gate voltage to the island. The system then acts like a transistor, in which, however, electrons are transmitted in a correlated way one by one, and therefore the device is called a single-electron transistor (SET).

There are two methods of magnetic control of the Coulomb blockade phenomena. First, one can apply a relatively strong magnetic field which, owing to the Zeeman splitting of the energy states and spin asymmetry in the density of electron states, induces a shift of the chemical potential in the ferromagnetic electrodes (external and/or central), and therefore effectively acts as a magnetic gate. This method, however, is limited to rather small charging energies and, consequently, to low temperatures (due to the small Zeeman energy) [23].

Another method of magnetic control of the Coulomb blockade effects follows from the sensitivity of the charging effects to the relative orientation of the magnetic moments of the grain (if it is magnetic) and external electrodes

[129,130]. This technique is not limited to low temperatures, and for realistic parameters, can also work at room temperatures. We will restrict our further considerations to this method and to a double junction, in which both external electrodes are ferromagnetic, while the island is nonmagnetic.

Generally, one can distinguish three relevant time scales in electronic transport through ferromagnetic (FM) or nonmagnetic (NM) double junctions: (1) spin-conserving energy relaxation time on the island  $\tau_\epsilon$ , (2) current injection time  $\tau_I$ , and (3) spin-flip relaxation time  $\tau_{sf}$ . In real systems,  $\tau_\epsilon$  is usually the shortest time scale,  $\tau_\epsilon < 10^{-9}$  s, whereas  $\tau_{sf}$  can be in the range  $10^{-9}$ – $10^{-6}$  s. On the other hand, for a current of 1 nA, the injection time is of the order of  $10^{-9}$  s. Thus, the slow spin relaxation limit is experimentally accessible. Accordingly, one may assume that the shortest time scale in many systems is the spin-conserving energy relaxation time. As concerns the other two time scales, we will distinguish two regimes. The first is the slow spin relaxation regime, where the longest time scale is the spin-flip relaxation time  $\tau_{sf} \gg \tau_I \gg \tau_\epsilon$ . In this regime, an electron tunneling to the island relaxes to the relevant Fermi level before the next tunneling processes occur. However, the electron can preserve its spin orientation for a time much longer than the time between successive tunneling events (injection time). This means that the electrons on the island in a steady state can be described by two Fermi levels corresponding to opposite spin orientations [131–133]. The second regime is the so-called fast spin relaxation regime, where  $\tau_{sf}$  becomes of the order of  $\tau_I$  or even shorter. In that case, there is a common Fermi level for different spin orientations [129,130]. In this limit, the two external electrodes become magnetically decoupled, and when the central electrode is nonmagnetic, the total current flowing through the system is independent of the magnetic configuration. In the following, we assume spin-conserving tunneling through the barriers, and define positive bias  $V$  as the one corresponding to current flowing from the left to the right (electrons flow in the opposite direction).

### 12.1. Limit of Continuous Density of States

Assume that the effects due to the quantization of energy levels on the island are negligible. Such an assumption is reasonable when the separation between discrete energy levels is much smaller than the charging energy, and also significantly smaller than the thermal energy  $k_B T$ . When the barrier resistances are larger than the quantum resistance  $R_q$  ( $R_q \approx 26$  k $\Omega$ ), one can use the “orthodox” tunneling theory to describe electronic transport. In the sequential tunneling regime, an electron tunnels to the island through one barrier, and later another electron leaves the island through the second barrier (or vice versa). These processes are suppressed below a certain threshold voltage, and therefore are dominant only above the first Coulomb step. The electric current  $I$  in the sequential tunneling regime can be calculated from the formula

$$\begin{aligned} I &= -e \sum_N P(N) \sum_\sigma \{ \Gamma_{l\sigma}^+(N) - \Gamma_{l\sigma}^-(N) \} \\ &= e \sum_N P(N) \sum_\sigma \{ \Gamma_{r\sigma}^+(N) - \Gamma_{r\sigma}^-(N) \} \end{aligned} \quad (17)$$

where  $e$  is the absolute value of electron charge ( $e > 0$ ),  $\Gamma_{\alpha\sigma}^{\pm}(N)$  ( $\alpha = l$  for the left junction and  $\alpha = r$  for the right junction) are the tunneling rates for electrons with spin  $\sigma$ , which tunnel to the island (+) from the lead  $\alpha$  or back (-), whereas  $P(N)$  is the probability of finding  $N$  excess electrons on the island.

The probability  $P(N)$  is usually calculated from the master equation

$$\begin{aligned} \partial P(N)/\partial t = 0 = & -\Gamma(N)P(N) + P(N-1) \sum_{\sigma} \Gamma_{\sigma}^{+}(N-1) \\ & + P(N+1) \sum_{\sigma} \Gamma_{\sigma}^{-}(N+1) \end{aligned} \quad (18)$$

where  $\Gamma_{\sigma}^{\pm}(N) = \Gamma_{l\sigma}^{\pm}(N) + \Gamma_{r\sigma}^{\pm}(N)$  and  $\Gamma(N) = \sum_{\sigma} \{\Gamma_{\sigma}^{+}(N) + \Gamma_{\sigma}^{-}(N)\}$ . From this follows that, in a steady state, the net transition rate between the states with  $N$  and  $N+1$  excess electrons on the island is equal to zero, which can be used to calculate the probability  $P(N)$  [134].

The transition rate  $\Gamma_{r\sigma}^{+}(N)$  is given by

$$\begin{aligned} \Gamma_{r\sigma}^{+}(N) = & \frac{2\pi}{\hbar} \int dE |T_{r\sigma}(E)|^2 D_{r\sigma}(E - E_F^{(r)}) D_{i\sigma}(E - E_{F\sigma}^{(i)}) \\ & \times f(E - E_F^{(r)}) [1 - f(E - E_{F\sigma}^{(i)})] \end{aligned} \quad (19)$$

where  $T_{r\sigma}(E)$  is an average transition matrix element for electronic states of energy  $E$ , while  $E_{F\sigma}^{(i)}$  and  $E_F^{(r)}$  are the Fermi levels, respectively, for the island and right electrode. Due to spin accumulation on the island in a general case, the Fermi level  $E_{F\sigma}^{(i)}$  is spin dependent. The difference between  $E_{F\sigma}^{(i)}$  and  $E_F^{(r)}$  depends on the applied voltage and the number of excess electrons on the grain, and can be written as  $E_{F\sigma}^{(i)} - E_F^{(r)} = E_c + \Delta E_{\sigma}^{(i)} - eV_r(N)$ . Here,  $E_c = e^2/2(C_l + C_r)$ , and  $V_r(N) = C_l V / (C_l + C_r) - Ne / (C_l + C_r)$ , with  $C_l$  and  $C_r$  the capacitances of the two junctions ( $C_l + C_r = C$ ). Apart from this,  $\Delta E_{\sigma}^{(i)}$  is a shift of the chemical potential of the grain for spin  $\sigma$ , which is caused by spin accumulation.

Generally, the spin dependence of the transition rates  $\Gamma_{\alpha\sigma}^{+}(N)$  and  $\Gamma_{\alpha\sigma}^{-}(N)$  ( $\alpha = 1, 2$ ) follows from the spin dependence of the matrix elements, the spin dependence of the density of electron states, and the spin dependence of the Fermi level. For constant (independent of energy) matrix elements and density of states in the electrodes, the transition rate  $\Gamma_{r\sigma}^{+}(N)$  can be written as

$$\Gamma_{r\sigma}^{+}(N) = \frac{1}{e^2 R_{r\sigma}} \frac{+eV_r(N) - E_c - \Delta E_{\sigma}^{(i)}}{1 - \exp\{[-eV_r(N) + E_c + \Delta E_{\sigma}^{(i)}]/kT\}} \quad (20)$$

where  $R_{r\sigma}$  is the resistance of the right junction for the spin channel  $\sigma$ . Formulas similar to Eq. (20) also can be written for  $\Gamma_{r\sigma}^{-}(N)$  and for the tunneling rates  $\Gamma_{l\sigma}^{+}(N)$  and  $\Gamma_{l\sigma}^{-}(N)$  through the left junction.

For arbitrary  $\tau_{sf}$ , the chemical potential shifts  $\Delta E_{\sigma}^{(i)}$  can be determined from the relevant balance equation which, for the case of a nonmagnetic island, takes the form

$$\frac{1}{e} (I_{\uparrow}^{(r)} - I_{\uparrow}^{(l)}) - \frac{2D}{\tau_{sf}} \Delta E_{\uparrow}^{(i)} = 0 \quad (21)$$

where  $I_{\uparrow}^{(\alpha)}$  ( $\alpha = l, r$ ) is the current of spin-up electrons through the  $\alpha$ th junction,  $D$  is the density of electron states in the island per spin, and the condition  $\Delta E_{\sigma}^{(i)} = -\Delta E_{-\sigma}^{(i)}$  was used (valid for nonmagnetic islands). The chemical potential shifts and electric current flowing through the junction have to be calculated self-consistently.

Typical transport characteristics of a double-barrier junction with a nonmagnetic island are shown in Figure 4 for both parallel and antiparallel magnetic configurations, and for the slow spin relaxation limit on the island. In both cases, the electric current is blocked below a certain threshold voltage, which is determined by the charging energy and the ratio of capacitances  $C_l/C_r$ . Current flows above the threshold voltage and a typical Coulomb staircase then can be observed. Each step corresponds to a new charge state of the island, and consequently, to a new channel for electron tunneling. The Coulomb steps are well resolved for an asymmetric junction, when the resistances of both barriers are significantly different. However, the steps of the Coulomb “staircase” above the threshold voltage are qualitatively different in the parallel and antiparallel configurations. This difference is due to spin accumulation and associated shifts of the chemical potentials. When the electrodes are of the same ferromagnetic material, there is no spin accumulation on the island in the parallel configuration, and consequently, no spin splitting of the chemical potential. Thus, the current–voltage curves in this configuration are similar to those for nonmagnetic junctions. In contrast, in the antiparallel configuration, the spin asymmetries for both junctions are different, and a nonequilibrium magnetic moment builds up on the island (spin accumulation) until the tunneling rates for a given spin orientation become equal for both junctions. The additional kinks on the  $I$ – $V$  curve for the antiparallel configuration correspond to the local maxima of spin accumulation. Since the  $I$ – $V$  characteristics are different in the parallel and antiparallel configurations, transition

**Figure 4.** Typical current–voltage characteristics in the parallel and antiparallel configurations, calculated for the long spin-flip relaxation time limit. The junction consists of two identical ferromagnetic outer electrodes, two nonmagnetic barriers, and a nonmagnetic metallic central electrode. The parameters assumed are:  $E_c = 40$  meV,  $kT = 1$  meV,  $R_{1+} = 2$  M $\Omega$ ,  $R_{1-} = 0.5$  M $\Omega$ ,  $R_{2+} = 200$  M $\Omega$ ,  $R_{2-} = 50$  M $\Omega$ , and  $C_1/C_2 = 1$ . Here,  $\sigma = \pm$  corresponds to the majority (minority) electrons.

from one configuration to the other results in a nonvanishing TMR effect, which varies with the bias voltage reflecting the features in the corresponding  $I$ - $V$  curves.

When the spin-flip relaxation time for the island becomes shorter, the TMR effect decreases. In the case of a nonmagnetic island, no TMR appears in the fast spin relaxation limit. The transition from slow to fast spin relaxation was considered in [135], where it was shown that TMR drops relatively fast to almost zero when the spin relaxation time approaches the injection time.

Sequential tunneling processes are suppressed below the threshold voltage. However, there are still processes of higher order (cotunneling), which can transport charge between the source and drain electrodes [130]. In the cotunneling processes, two tunneling events are correlated in time, and are not blocked by the charging energy. Being of higher order, they are less effective, and therefore the electric current in the cotunneling regime is smaller than in the sequential one. Close to the threshold voltage, however, both currents may be comparable.

The cotunneling processes can be calculated perturbatively. The lowest order perturbation description is valid sufficiently well below the threshold voltage. However, a more general description has been worked out, which is also valid in the transition regime. Such a description was formulated in terms of closed-time path Green functions [136] for nonmagnetic SETs. This description was extended recently to magnetic systems [137]. It includes the double-barrier cotunneling processes directly contributing to electric current, and the single-barrier cotunneling processes which—although do not contribute directly to the flowing current—give an indirect contribution via modification of the magnetic state of the island. Other cotunneling processes lead to vertex and propagator renormalization. When the spin relaxation time on the island is long, the cotunneling processes—similarly as the sequential ones—lead to spin accumulation on the island.

## 12.2. Role of Discreteness

When  $kT \ll \Delta E$ , the size quantization of energy levels on the island must be taken into account [138–140]. To describe the transport properties, the “orthodox” tunneling theory [141] was generalized by taking into account the electron spin [140]. The electric current in a stationary state is now given by the formula [140]

$$I = -e \sum_{\sigma} \sum_{N_{\uparrow}, N_{\downarrow}} P(N_{\uparrow}, N_{\downarrow}) \{ \Gamma_{l\sigma}^{+}(N_{\uparrow}, N_{\downarrow}) - \Gamma_{l\sigma}^{-}(N_{\uparrow}, N_{\downarrow}) \} \\ = e \sum_{\sigma} \sum_{N_{\uparrow}, N_{\downarrow}} P(N_{\uparrow}, N_{\downarrow}) \{ \Gamma_{r\sigma}^{+}(N_{\uparrow}, N_{\downarrow}) - \Gamma_{r\sigma}^{-}(N_{\uparrow}, N_{\downarrow}) \} \quad (22)$$

where  $\Gamma_{\alpha\sigma}^{\pm}(N_{\uparrow}, N_{\downarrow})$  are the tunneling rates for electrons with spin  $\sigma$  tunneling to the island (+) from the lead  $\alpha = l, r$  or back (−), and  $P(N_{\uparrow}, N_{\downarrow})$  is the probability to find  $N_{\uparrow}$  and  $N_{\downarrow}$  excess electrons on the island with the spin  $\sigma = \uparrow$  and  $\sigma = \downarrow$ , respectively. The total number of excess electrons on the island is  $N = N_{\uparrow} + N_{\downarrow}$ , while its magnetic moment is determined by  $M = N_{\uparrow} - N_{\downarrow}$ . As before, only spin-conserving tunneling processes are taken into account in Ex. (22).

The probability  $P(N_{\uparrow}, N_{\downarrow})$  can be calculated from the following master equation [140]:

$$\partial P(N_{\uparrow}, N_{\downarrow}) / \partial t \\ = 0 = - [ \Gamma(N_{\uparrow}, N_{\downarrow}) + \Omega_{\uparrow, \downarrow}(N_{\uparrow}, N_{\downarrow}) + \Omega_{\downarrow, \uparrow}(N_{\uparrow}, N_{\downarrow}) ] \\ \times P(N_{\uparrow}, N_{\downarrow}) + \Gamma_{\uparrow}^{+}(N_{\uparrow} - 1, N_{\downarrow}) P(N_{\uparrow} - 1, N_{\downarrow}) \\ + \Gamma_{\downarrow}^{+}(N_{\uparrow}, N_{\downarrow} - 1) P(N_{\uparrow}, N_{\downarrow} - 1) + \Gamma_{\uparrow}^{-}(N_{\uparrow} + 1, N_{\downarrow}) \\ \times P(N_{\uparrow} + 1, N_{\downarrow}) + \Gamma_{\downarrow}^{-}(N_{\uparrow}, N_{\downarrow} + 1) P(N_{\uparrow}, N_{\downarrow} + 1) \\ + \Omega_{\uparrow, \downarrow}(N_{\uparrow} - 1, N_{\downarrow} + 1) P(N_{\uparrow} - 1, N_{\downarrow} + 1) \\ + \Omega_{\downarrow, \uparrow}(N_{\uparrow} + 1, N_{\downarrow} - 1) P(N_{\uparrow} + 1, N_{\downarrow} - 1) \quad (23)$$

where  $\Gamma_{\alpha\sigma}^{\pm}(N_{\uparrow}, N_{\downarrow}) = \sum_{\alpha=l,r} \Gamma_{\alpha\sigma}^{\pm}(N_{\uparrow}, N_{\downarrow})$  and  $\Gamma(N_{\uparrow}, N_{\downarrow}) = \sum_{\sigma} [ \Gamma_{\sigma}^{+}(N_{\uparrow}, N_{\downarrow}) + \Gamma_{\sigma}^{-}(N_{\uparrow}, N_{\downarrow}) ]$ . The tunneling rates  $\Gamma_{\alpha\sigma}^{\pm}(N_{\uparrow}, N_{\downarrow})$  include tunneling process between the lead  $\alpha$  and all discrete levels  $E_{n\sigma}$  of the island. The  $\Omega$  terms, on the other hand, take into account the spin-flip process on the island. For a nonmagnetic island, one may assume that the discrete energy levels  $E_{n\sigma}$  are independent of the spin orientation. One can also simplify the description further by assuming that the levels are equally separated, with the level spacing  $\Delta E$ . The tunneling rates  $\Gamma_{\alpha\sigma}^{\pm}(N_{\uparrow}, N_{\downarrow})$  can be then expressed in terms of the bare tunneling rates  $\gamma_{n\sigma}^{\alpha} = \Delta E / e^2 R_{\alpha\sigma}$  [141]. When the level separation  $\Delta E$  becomes of the order of  $k_B T$  or larger, but still smaller than  $E_c$ , the effects due to the discrete structure become visible in the transport characteristics as additional small steps [140].

## 13. TRANSPORT THROUGH QUANTUM DOTS WITH ELECTRON CORRELATIONS

Further features appear when  $E_c \leq \Delta E$ . A limiting case is when tunneling takes place through a single discrete level. The system consisting of a single-level nonmagnetic quantum dot coupled to two ferromagnetic leads can be described by the Hamiltonian  $H = H_l + H_r + H_d + H_t$ , where the first two terms,  $H_l$  and  $H_r$ , describe the left and right electrodes (in the noninteracting particle approximation, for simplicity), whereas the term  $H_d$  describes the dot, and can be taken in the Hubbard form  $H_d = \sum_{\sigma} \epsilon_d c_{\sigma}^{+} c_{\sigma} + U c_{\uparrow}^{+} c_{\uparrow} c_{\downarrow}^{+} c_{\downarrow}$ , in which  $\epsilon_d$  is the energy of the discrete level,  $U$  is the electron correlation parameter, and  $c_{\sigma}^{+}$  ( $c_{\sigma}$ ) are the creation (annihilation) operators for the dot. The energy level  $\epsilon_d$  includes the electrostatic part,  $\epsilon_d = \epsilon_d^0 + eU_e$ , where  $\epsilon_d^0$  is the level energy at zero bias, and  $U_e$  is the electrostatic potential of the dot. The last term,  $H_t$ , is the tunneling part of the Hamiltonian, where only spin-conserving tunneling processes are taken into account.

When the tunneling rates are small, the transport characteristics can be calculated within the master equation technique [142, 143]. In a more general situation, such a description is not sufficient since it does not properly take into account the electron correlations on the dot. It also breaks down in the strong tunneling regime and at low temperatures, where many body effects become important and lead to the Kondo effect. A more accurate description

is based on the nonequilibrium Green's functions (NGFs) [144, 145].

The tunneling current  $J_\sigma$  can be calculated from the formula [144–146]

$$J_\sigma = \frac{ie}{\hbar} \int \frac{d\epsilon}{2\pi} [f_l(\epsilon) - f_r(\epsilon)] \frac{\Gamma_\sigma^r(\epsilon)\Gamma_\sigma^l(\epsilon)}{\Gamma_\sigma^r(\epsilon) + \Gamma_\sigma^l(\epsilon)} \times [\langle\langle c_\sigma; c_\sigma^+ \rangle\rangle_\epsilon^r - \langle\langle c_\sigma; c_\sigma^+ \rangle\rangle_\epsilon^a] \quad (24)$$

where  $\langle\langle c_\sigma; c_\sigma^+ \rangle\rangle_\epsilon^r$  and  $\langle\langle c_\sigma; c_\sigma^+ \rangle\rangle_\epsilon^a$  are the retarded and advanced Green's functions,  $f_l(\epsilon)$  and  $f_r(\epsilon)$  are the Fermi distribution functions for the left and right electrodes, whereas  $\Gamma_\sigma^l(\epsilon)$  and  $\Gamma_\sigma^r(\epsilon)$  are the contributions to the half width of the discrete level due to electron tunneling to the left and right electrodes, respectively. The formula (26) is valid when  $\Gamma_\sigma^l(\epsilon)$  and  $\Gamma_\sigma^r(\epsilon)$  are proportional,  $\Gamma_\sigma^l(\epsilon) = \lambda\Gamma_\sigma^r(\epsilon)$ .

Equations of motion for the retarded and advanced Green's functions contain the occupation numbers  $n_\sigma = \langle c_\sigma^+ c_\sigma \rangle$ , which in turn are determined by the lesser Green's function  $\langle\langle c_\sigma; c_\sigma^+ \rangle\rangle_\epsilon^<$  via the formula,  $n_\sigma = \int (d\epsilon/2\pi) \times \text{Im}\langle\langle c_\sigma; c_\sigma^+ \rangle\rangle_\epsilon^<$ . Thus, to find the electric current, one needs to calculate self-consistently all of the Green's functions, occupation numbers, and the electrostatic potential. When the Kondo effect is irrelevant, the Green's functions can be calculated in the Hartree–Fock approximation.

When the temperature is sufficiently low, the Kondo resonance in the density of states is formed, which has a dramatic influence on transport through the dot. The Kondo effect occurs in quantum dots containing an odd number of electrons, and is related to screening of the dot spin by conduction electrons in the leads. This screening is a many-body effect which occurs due to exchange coupling between the electrons on the dot and in the leads. In the case of quantum dots connected to nonmagnetic leads, the Kondo effect was extensively studied in the past decade. However, some new interesting questions arise when the leads are ferromagnetic and the conduction electrons are spin polarized. Recent theoretical results show that the Kondo effect still persists in such systems, although its characteristics are significantly modified [147, 148].

## 14. SUMMARY

The localization and interaction corrections to electrical conductivity can be significant not only in nonmagnetic, but also in ferromagnetic disordered metals or nanoscopic structures. As ferromagnetism diminishes localization corrections (and generally suppresses the singlet cooperon leading to the absence of weak antilocalization), the interaction corrections are rather unaffected by the ferromagnetism, and therefore can be easily observed in ferromagnetic systems. The corrections are important only at relatively low temperatures. Generally, there are some experimental works which confirm the importance of the WL and e–e interaction corrections. These data were usually accounted for on the basis of the theoretical results obtained for nonmagnetic systems. Even though the physical origin of quantum corrections in ferromagnets is substantially the same as in nonmagnetic

systems, there is an important difference due to the presence of internal magnetization and magnetic induction in ferromagnets.

Electron–electron interaction also leads to significant effects in ferromagnetic mesoscopic double-barrier tunnel junctions, which are also observable at high temperatures. In the case of a sufficiently large central electrode, this interaction can be described by a phenomenological charging energy. This charging energy leads to a Coulomb blockade of electric current below a certain threshold voltage, and also to Coulomb steps at higher voltages. The interplay of ferromagnetism and charging effects leads to some new features in the transport characteristics. Some of these features result from nonequilibrium spin accumulation at the small central electrode. When the central electrode is a quantum dot, the Coulomb correlation on the dot can be described in terms of the Hubbard model. Electronic transport then takes place through a small number of discrete levels (or even through a single level), which leads to additional features.

Coherent transport in the low-temperature range as well as ferromagnetic tunnel junctions (also operating at high temperature) are of potential importance for applications in magnetoelectronics and spintronics devices. The ferromagnetic systems or ferromagnetic components of a more complex device can be either metallic or semiconducting. Recently, huge efforts have been undertaken to grow ferromagnetic semiconductors with room-temperature ferromagnetism. The phenomena described in this review apply to ferromagnetic semiconductors too.

## GLOSSARY

**Anisotropic magnetoresistance (AMR)** Magnetoresistance observed in ferromagnetic metals which depends on relative orientation of electric current and magnetization.

**Anomalous hall effect (AHE)** Transverse current induced by the electric field in ferromagnets in the absence of external magnetic field.

**Giant magnetoresistance (GMR)** Magnetoresistance in magnetic multilayer system related to the switch from antiferromagnetic to ferromagnetic ordering in magnetic layers by weak magnetic field.

**Magnetic multilayers (MMLs)** Alternating thin layers of magnetic and nonmagnetic metals.

**Magnetoresistance (MR)** Variation of the resistance of metals and semiconductors in magnetic field.

**Molecular beam epitaxy (MBE)** Technology of the epitaxial growth of thin films using molecular beams.

**Ruderman–Kittel–Kasuya–Yosida interaction (RRKY)** Magnetic interaction due to the exchange between magnetic impurities via free electron gas.

**Spin–orbit interaction (SO)** The interaction affecting the spin state of a particle due to its orbital motion.

**Tunneling magnetoresistance (TMR)** Magnetoresistance in tunneling systems with magnetic overlayers.

**Weak localization (WL)** Theory of weak corrections to conductivity in metals and heavily doped semiconductors induced by disorder.

## ACKNOWLEDGMENTS

V. K. Dugaev is grateful to P. Bruno for many stimulating discussions. F. G. Aliev thanks R. Villar for critical reading of the manuscript. This work was supported by the Polish Committee for Scientific Research under Grants 5 P03B 091 20 and PBZ/KBN/044/P03/2001, and also by Spanish MCyT (BFM2000-0016) and CM (07N/0050/2002).

## 1. INTRODUCTION

Nanostructured semiconductors with a size range of 1–100 nm have been the focus of recent scientific research because of their important nonlinear optical properties [1], luminescent properties [2, 3], quantum size effects [4, 5], and other important physical and chemical properties [6]. In past decades, low-dimensional materials such as nanometer-size inorganic dots, tubes, and wires have exhibited a wide range of electronic and optical properties that depend sensitively on both size and shape, and are of both fundamental and technological interest [7, 8]. They are potentially ideal building blocks for nanoscale electronics and optoelectronics [9]. The ability to control the shapes of semiconductor nanocrystals affords an opportunity to further test theories of quantum confinement and yields samples with desirable optical characteristics from the point of view of application [10, 11].

The exciting emerging important applications of low-dimensional semiconductor nanocrystals include using QDs in biological assays [12–15], building blocks for assembly semiconductor nanodevices [16], hybrid nanorod-polymer solar cells that combine semiconducting polymers and nanoparticles in useful photovoltaic devices with relatively high conversion efficiencies [17], room-temperature ultraviolet lasing using ZnO nanowire (NW) arrays [18], light-emitting diodes (LEDs) [9], and nanosensors for biological and chemical species [19–21].

One of the current hottest issues in nanotechnology and nanoscience is how to control the size, shape, and dimensionality of nanocrystals because of their important applications in the design of new materials and devices in

various fields such as catalysis, electronics, medicine, ceramics, pigments, cosmetics, and biotechnology [11–22]. For example, shape control is of significant importance in the fabrication of semiconductor nanocrystals [11], metal nanocrystals [24], and other inorganic materials [25], which may add alternative variables in the tailoring of properties of nanomaterials and provide more possibilities in the fabrication of nanodevices. The key issue in the study and application of 1D materials is how to assemble individual atoms into 1D nanostructures in an effective and controllable way [23]. Scheme 1 shows a schematic illustration of ideal semiconductor nanocrystals with well-defined shapes and sizes, and the relationship of the band gap to nanoparticle size [26].

Considerable progress and a lot of effort have been made in the synthesis of technologically important semiconductors from the group II–VI, III–VI, and IV families of crystallites or nanocrystallines, which have been reviewed recently [27, 28]. However, all of these methods can only produce nanocrystallites with shapes never very far from spherical [23, 27–33]. Although several examples have been demonstrated, shape control has been more difficult to achieve. An intensive recent review by Yang et al. summarized the general strategies for the synthesis of various kinds of one-dimensional NWs or nanorods (NRs) [23]. In addition, a review by Nesper et al. [34] of the synthesis of oxide NR and nanotube (NT) materials appeared very recently.

This chapter will give a general overview of the state of the art for the variety of different synthesis routes of low-dimensional nanocrystals, with a focus on 1D NRs/NWs by solution pathways and emerging new approaches. Since the synthesis of NTs and oxide NWs/NRs has been reviewed very recently [23, 34], we will focus more on the synthesis of nonoxide low-dimensional nanocrystals by mild solution processes and introduce some promising new strategies for self-assembly of 1D, 2D nanocrystals and more complex structures.

The chapter is organized into the following parts: in the first part, a grand survey of research activities and progress

**Scheme 1.** Schematic illustration of the preparation of semiconductor nanocrystals with ideal shapes and sizes, and the relationship of the band gap to nanoparticle size. Reprinted with permission from [26], S. H. Yu, *J. Ceram. Soc. Jpn.* 109, S65 (2001). © 2001, Ceramic Society of Japan.

on the various low-dimensional nanocrystals was summarized in the form of tabulation.

The second part will discuss the main methodologies and emerging promising approaches for the synthesis of various important inorganic NWs/NRs, hierarchical nanostructures, and more complex superstructures with strong application potential. Generally, the synthetic strategies can be classified into two types, the “hard” and “soft” approaches, according to the preparation characteristics and reaction conditions. Among the “hard” approaches, usually foreign hard templates or drastic reaction conditions are needed; for example, the reaction medium is usually gas phase, and a high vacuum system and high temperature are applied. The main existing “hard” approaches for synthesis of 1D nanomaterials include four types: (i) The template-directed growth method, in which hard templates such as carbon nanotubes [7, 8, 35, 36] and porous aluminum template [37–40] are used. (ii) The vapor-liquid-solid (VLS) mechanism, which was previously proposed by Wagner in the 1960s [41]. This mechanism has been applied for the synthesis of various semiconductor NWs [42–47]. A laser ablation-based VLS catalytic growth process (LCG) makes it possible to synthesize semiconductor NWs with many different compositions [48]. (iii) The vapor-solid (VS) mechanism [49], in which NWs are generated directly from vapor condensation onto a substrate. Various metal oxides such as MgO, Al<sub>2</sub>O<sub>3</sub>, ZnO, and SnO<sub>2</sub> NWs or nanobelts (NBs) have been grown by either a carbon-thermal reduction process [50, 51] or direct thermal evaporation [52, 53]. (iv) The oxide-assisted NW growth route [54–59] was reported by Lee’s group for growing GaAs, GaN NWs and Si NWs with the advantages of not having to use a metal catalyst or a template.

In contrast, the “soft” approaches are based on solution reactions and do not need a foreign hard template. They do not involve the use of drastic conditions, and the reaction is usually initiated under mild conditions or under natural conditions. The emerging main approaches also include four types: (i) A solvothermal process, which has been emerging as a versatile solution route for the synthesis of various semiconductor nanocrystals with different sizes and shapes [26, 34, 60–65]. (ii) A solution-liquid-solid

(SLS) mechanism, which is used for growing III–V group nanofibers in hydrocarbon solvents at relatively low temperatures [60, 66–69] (group IV Ge, Si NWs can also be generated by a supercritical fluid solution-phase approach [70, 71]). (iii) Capping agent/surfactant-assisted synthesis [11, 25, 72–79]. Well-defined nanostructures can be obtained under hot conditions or natural/mild conditions. (iv) A bio-inspired approach for complex superstructures [73, 80–95]. In this approach, soft templates such as polymers, organic additives, or supramolecular templates are employed as crystal growth modifiers [88–90] and templates [94]. (v) An oriented attachment growth mechanism [96–103]. The spontaneous aggregation of smaller nanoparticles into well-structured nanocrystals has been reported in the case of TiO<sub>2</sub> [97–99], ZnO [100, 102], and CdTe [103]. These main strategies will be discussed in more detail with specific examples in the following parts after the general grand survey on the synthesis methodologies. Finally, we will give our own perspectives.

## 2. SYNTHETIC ROUTES FOR LOW-DIMENSIONAL NANOCRYSTALS

The intensive research and ongoing advances in the synthesis of various nanomaterials make it more and more difficult to keep up to date with all of the new achievements. However, in this section, we will try our best to briefly summarize various low-dimensional nanocrystals with strong application potentials synthesized by different routes in the past decade. We will focus more on the synthesis of 1D, 2D nanocrystals and more complex structures built up based on simple synthesis strategies, which we call “emerging and promising approaches” here.

Since intensive reviews on the synthesis of semiconductor nanodots (0D) have been published very recently [27, 28], we only focus on 1D and 2D nanomaterials such as NWs, NRs, NBs, nanoribbons, NTs, nanosheets (2D), and more complex structures. Table 1 is a general survey of various oxide NRs, NWs, NTs, and NBs or other novel/new nanostructures prepared by different strategies. Table 2 gives an intensive survey of nonoxide inorganic nanomaterials such as metal, semiconductor, and carbide- or nitride-based nanomaterials (NRs, NWs, NTs, nanoribbons, NBs, etc.).

### 2.1. Templated-Directed Growth Method

Template-based synthesis of low-dimensional nanomaterials has been widely employed in past decades. The characteristic of this method is the use of various templates to limited reactions to a confined nanoscale space such as channels or on a surface. Conventional templates include porous solid-state materials such as carbon NTs, anode aluminum oxide, zeolites, MCM-41 mesoporous silica, and porous polymers. Representative examples are given below to illustrate the application of these templates in the formation of various kinds of one-dimensional nanocrystals.

**Table 1.** Synthetic routes for oxide low-dimensional nanocrystals (published since 1995).

Nanomaterials	Synthetic method	Ref.
BaTiO <sub>3</sub> NRs	Solution-phase decomposition of bimetallic alkoxide precursors in the presence of coordinating ligands	[104]
SrTiO <sub>3</sub> NRs		[104]
BaSO <sub>4</sub> NWs and superstructures	Mineralization from aqueous solution in the presence of polymers	[88, 89]
BaCrO <sub>4</sub> NWs and chain structures	Reversed micelle templating method	[25, 75]
BaCrO <sub>4</sub> NWs and superstructures	Mineralization from aqueous solution in the presence of polymers	[89–91]
BaCO <sub>3</sub> NWs	A reverse micelle-based approach	[77]
BaWO <sub>4</sub> NRs	Reversed micelle templating method	[78]
BaWO <sub>4</sub> NWs	Cationic reverse micelles	[79]
BaWO <sub>4</sub> NWs arrays	Langmuir-Blodgett assembly of 1D nanostructures	[105, 106]
CaSO <sub>4</sub> NWs	A water-in-oil microemulsions route	[107]
CdO NBs	Evaporation of metal oxide powders at high temperatures, VS	[52]
CdWO <sub>4</sub> Nanosheets	Hydrothermal treatment in the presence of block copolymers	[92]
CdWO <sub>4</sub> NBs	Double jet reaction at room temperature	[92]
CdWO <sub>4</sub> NRs	Hydrothermal treatment of CdCl <sub>2</sub> and Na <sub>2</sub> WO <sub>4</sub>	[108]
Co <sub>3</sub> O <sub>4</sub> NRs	Template method with alumina membranes	[109]
Co <sub>3</sub> O <sub>4</sub> NRs	Calcination of precursor powders prepared in a novel inverse microemulsion	[110]
CuO NRs	Room-temperature reaction of CuCl <sub>2</sub> · 2H <sub>2</sub> O and NaOH with PEG 400	[111]
CuO NRs	Heating copper substrates in air	[112]
Eu <sub>2</sub> O <sub>3</sub> NRs	Sonication of an aqueous solution	[113]
Fe <sub>2</sub> O <sub>3</sub> NRs	Thin-film processing method	[114]
Fe <sub>2</sub> O <sub>3</sub> NRs	Grown onto a polycrystalline (or single-crystalline) substrate from an aqueous solution of ferric salts	[115]
Fe <sub>3</sub> O <sub>4</sub> NRs	Sonication of aqueous iron(II) acetate in the presence of β-cyclodextrin	[116]
Fe <sub>4</sub> [Fe(CN) <sub>6</sub> ] <sub>3</sub> · xH <sub>2</sub> O NWs	Electrodeposition with two-step anodizing anodic aluminum oxide films	[117]
Ga <sub>2</sub> O <sub>3</sub> NRs	Catalytic growth by arc discharge of GaN powders in Ar/O <sub>2</sub> mixture	[118]
Ga <sub>2</sub> O <sub>3</sub>	Gas reaction method starting from Ga and O <sub>2</sub>	[119]
Ga <sub>2</sub> O <sub>3</sub>	Physical evaporation at 300 °C from a bulk gallium target	[120]
Ga <sub>2</sub> O <sub>3</sub>	DC arc discharge (GaN, graphite, nickel powder)	[121]
Ga <sub>2</sub> O <sub>3</sub>	Electric arc discharge of GaN powders mixed with Ni and Co	[122]
Ga <sub>2</sub> O <sub>3</sub>	Heat treatment of Ga with SiO <sub>2</sub> powder and a Fe <sub>2</sub> O <sub>3</sub> catalyst	[123]
Ga <sub>2</sub> O <sub>3</sub> NTs, NWs Nano-paintbrushes	Molten gallium and microwave plasma containing a mixture of monatomic oxygen and hydrogen	[124]
Ga <sub>2</sub> O <sub>3</sub> NWs	Heating raw materials in N <sub>2</sub> or Ar without metal catalysts	[125]
GeO <sub>2</sub> NRs	Carbon-NT confined reaction of metallic Ge	[126]
GeO <sub>2</sub> NWs	Carbothermal reduction reaction between germanium dioxide and active carbons	[127]
GeO <sub>2</sub> NWs	Thermal oxidation of suboxide at high temperature	[128]
In <sub>2</sub> O <sub>3</sub> NBs	Evaporation of metal oxide powders at high temperatures, VS	[52]
In <sub>2</sub> O <sub>3</sub> NWs	A rapid heating process on Au-coated InP substrates in oxygen	[129]
IrO <sub>2</sub>	Templating against carbon NTs	[130]
K <sub>2</sub> Ti <sub>6</sub> O <sub>13</sub>	Calcination of KF and TiO <sub>2</sub>	[131]
LaPO <sub>4</sub> :Eu NWs	Hydrothermal synthesis	[132]
LaPO <sub>4</sub> :Ce NWs	Hydrothermal synthesis	[132]
MgO NRs	Vapor-solid growth process with <i>in-situ</i> generated Mg vapor	[51]
MgO NWs	Oxide-assisted catalytic growth method	[133]
MgO NWs	Vapor-phase method using MgB <sub>2</sub> as precursor	[134]
MgO NRs	Heating of MgCl <sub>2</sub> at 750 °C in mixture gas (Ar/H <sub>2</sub> )	[135]
Mg(OH) <sub>2</sub> NRs	Hydrothermal reaction of Mg, H <sub>2</sub> O, and ethylenediamine	[136]
MnO <sub>2</sub> NRs	Template method with alumina membranes by a sol-gel approach	[137]
MnO <sub>2</sub> NRs	Hydrothermal synthesis	[138]
Mn <sub>3</sub> O <sub>4</sub> NWs	Thermolysis of carbonates in NaCl flux and a surfactant NP9 at 850 °C	[139]
Mg <sub>2.11</sub> Mn <sub>5.46</sub> O <sub>12</sub> · xH <sub>2</sub> O nano-ribbons	A combination of techniques consisting of a sol-gel process for tetraethylammonium manganese oxide layered material, an ion-exchange method to a thin-film Mg-buserite precursor, and a hydrothermal reaction to transform the Mg-buserite to nanoribbonlike Mg-todorokite material	[140]
MoO <sub>3</sub> NRs	Template-directed reaction of molybdic acid and subsequent leaching process	[141]
MoO <sub>3</sub> NRs	Templating against carbon nanotubes	[130]
MoO <sub>2</sub> NRs	Templating against carbon NTs	[130]
Ni(OH) <sub>2</sub> NRs	Hydrothermal synthesis and deposition in a carbon-coated anodic alumina film	[142]

Sb <sub>2</sub> O <sub>3</sub> NRs	Templated against carbon NTs	[147]
Sb <sub>2</sub> O <sub>5</sub> NRs	Microemulsion method for the system AOT-water-toluene	[145]
SnO <sub>2</sub> NRs	Calcining precursors that are produced in inverse microemulsions	[148, 149]
SnO <sub>2</sub> NBs	Evaporation of metal oxide powders at high temperatures, VS	[52]
SnO <sub>2</sub> NWs, nanoribbons, NTs	Elevated temperature synthesis techniques using layered mixtures of Sn foil and SnO powder or simply SnO powder, VS	[150]
SnO <sub>2</sub> diskettes	Evaporating techniques using SnO or SnO <sub>2</sub> powders, VS	[151]
SnO nanoribbons	Evaporating SnO powders, VS	[152]
SiO <sub>2</sub> NWs	Helical mesostructured tubules from the Taylor vortex-assisted surfactant templates	[153]
SiO <sub>2</sub> NWs	Oxidation of Si wafer induced by molten gallium	[154]
SiO <sub>2</sub> NWs and bunches	Vapor-liquid-solid (VLS) process using molten gallium as a catalyst	[155]
SiO <sub>2</sub> NTs, NWs	Pyrolysis of mixed Si and SiO <sub>2</sub> powders	[156]
SiO <sub>2</sub> NWs	Using Au nanoparticle catalysts on a silicon substrate	[157]
SiC/SiO <sub>2</sub> helical core-shell NWs	Chemical vapor deposition technique	[158]
TiO <sub>2</sub> NWs	Electrochemically preparation using nanochannel alumina	[159]
TiO <sub>2</sub> NWs	Sol-gel template method employing alumina membranes	[160]
TiO <sub>2</sub> NWs	Electrochemically induced sol-gel preparation	[161]
TiO <sub>2</sub> NTs	Sol-gel-derived fine TiO <sub>2</sub> -based powders were treated with NaOH aqueous solution	[162]
TiO <sub>2</sub> NTs	Solution growth method by hydrolyzing TiF <sub>4</sub> under acidic condition	[163]
TiO <sub>2</sub> NTs	Sol-gel method and removing the polymer thermally	[164]
TiO <sub>2</sub> NTs	Calcination of an organic gelator prepared from supramolecular assemblies	[165]
VO <sub>x</sub> NTs	Hydrothermal using long-chain amine as templates	[166–168]
V <sub>2</sub> O <sub>5</sub> NRs	Vanadium pentoxide gels	[169]
V <sub>2</sub> O <sub>5</sub> NRs	Templating against carbon NTs	[130]
WO <sub>3</sub> NRs	Templating against carbon NTs	[130]
WO <sub>3</sub> NRs	Direct oxidation of tungsten metal	[170]
YBCO NRs	Laser ablation of a high T <sub>c</sub> superconductor YBa <sub>2</sub> Cu <sub>3</sub> O <sub>7</sub>	[171]
ZnO NRs	Gas reaction employing Zn and H <sub>2</sub> O	[172]
ZnO NWs	Heating Zn in N <sub>2</sub> or Ar without metal catalysts	[125]
ZnO NWs	Catalytic growth by vapor transport, VLS	[45, 173]
ZnO NBs	Evaporation of metal oxide powders at high temperatures, VS	[52]
ZnO NWs	Thermal evaporation, VS	[174]
ZnO NWs	Catalyzed epitaxial growth, VLS	[46]
ZnO NRs	Catalyst-free CVD method	[175]
ZnO NRs	Thermal decomposition of the precursor of ZnC <sub>2</sub> O <sub>4</sub> in the presence of surfactant nonyl phenyl ether and NaCl flux	[176]
ZnO NWs	Site-specific growth by catalysis-driven molecular beam epitaxy	[177]
ZnO NWs arrays	Electrodeposited in the pores of anodic alumina membranes	[178]
ZnO NWs on CNTs	Multiwall carbon NTs were treated with Zn	[179]
ZnO NRs	Oriented attachment growth from ZnO nanoparticles from solution	[102]
ZnO hierarchical nano-structures	Vapor transport and condensation process on In <sub>2</sub> O <sub>3</sub> core NWs	[53]
ZnO helical NRs	Biomimetic controlled nucleation and growth on ZnO NR arrays	[95]

Carbon NTs, which were discovered in 1991 [352], are a good candidate for template-induced growth. The first example using carbon NTs as templates came from the synthesis of metal carbide NRs [35]. In this approach, carbon NTs as a reactant were directly converted into MC<sub>x</sub> NRs by the reactions of volatile metal oxide species. Herein, MO should be a metal oxide or nonmetal oxide with a relatively high vapor pressure at the desired reaction temperature.

Similarly, GaN NRs were fabricated through the reaction of carbon NTs with MO (metal oxide) under an ammonia atmosphere [36]. Figure 1 shows typical TEM images of the original C NTs and GaN NRs templated from C NTs. Herein, MO should be a metal oxide or nonmetal oxide with a relatively high vapor pressure at the desired reaction temperature. The total reaction formula could be expressed as the following:

**Table 2.** Synthetic routes for nonoxide low-dimensional nanocrystals (published since 1995).

Nanomaterials	Synthetic method	Ref.
Ag ultrathin NWs	Grow inside the pores of self-assembled calyx [4] hydroquinone NTs by electro/photochemical redox reaction in an ambient aqueous phase	[180]
Ag NWs	Templated from the mesoporous silica	[181, 182]
Ag NWs	Metal NW formation using $\text{Mo}_3\text{Se}_3^-$ as reducing and sacrificing templates	[183]
Ag NRs and dendrites	Ultraviolet photoreduction technique at room temperature using poly(vinyl-alcohol) (PVA) as protection agent	[184]
Ag NRs, NWs	Seed-mediated growth in a rodlike micellar medium	[185]
Ag nanoprisms	A photoinduced method for converting large quantities of silver nanospheres into triangular nanoprisms	[186]
Ag NWs	Electron-beam-induced growth from zeolite crystallites	[187]
Ag NWs	Templated from AgBr nanocrystals	[188]
Ag nanoarrays	Formed inside micellar arrays of a template consisting of a (dendritic polyisobutylene)/polyisocyanide block copolymer reduced under the TEM electron beam	[189]
Ag NWs	Solid-liquid phase arc discharge method	[190]
Ag truncated triangular nanoplates	A solution phase method in the presence of cetyltrimethylammonium bromide micelles	[191]
Ag nanodisc	Mixing two reverse micellar solutions	[192]
Ag nanoprisms	Boiling $\text{AgNO}_3$ in <i>N,N</i> -dimethyl formamide, in the presence of poly(vinylpyrrolidone)	[193]
Ag NWs	Solvothermal reaction using Pt nanoparticles as seeds in ethylene glycol at 160 °C	[194]
2D Ag NWs arrays	Evaporating a drop of chloroform-dispersed dodecanethiol-capped prolate Ag nanocrystals on a carbon substrate, which were synthesized in the presence of tetraoctylammonium bromide	[195]
Au NRs	Electrochemical oxidation/reduction within a simple two-electrode-type cell in the presence of cationic surfactant $\text{C}_{16}\text{TAB}$	[196]
Au NWs	Templated from the mesoporous silica	[182]
Au NWs	Metal NW formation using $\text{Mo}_3\text{Se}_3^-$ as reducing and sacrificing templates	[183]
Au NRs	A solution seeding growth approach in the presence of an aqueous micellar template CTAB	[197, 198]
Au NRs	UV irradiation of $\text{HAuCl}_4$ solutions with 253.7-nm light in the presence of rodlike micelles of hexadecyltrimethylammonium chloride	[199]
Au NWs	DNA-directed assembly of gold NWs on complementary surfaces	[200]
2D Au NWs	Self-assembly of gold nanoparticles on water surfaces in the presence of surfactants	[201]
Au NWs	Ultrahigh vacuum TEM with the electron beam thinning technique	[202]
3D aggregates of Au NRs	DNA-driven self-assembly of gold NRs	[203]
$\text{Au}_{\text{core}}\text{Ag}_{\text{shell}}$ NRs	Reducing $\text{AgCl}_4^{3-}(\text{aq})$ with $\text{NH}_2\text{OH}$ selectively on the surface of gold NRs	[204]
Co NRs	The early stage of the thermal decomposition of $\text{Co}_2(\text{CO})_8$ in a mixture of oleic acid and trioctylphosphine oxide (TOPO)	[205]
Co NW array	Vertical arrays of Co NWs with high densities through direct current electrodeposition created by using ultra-high-density arrays of nanopore of diblock copolymer templates	[206]
Co NWs	The potentiostatic electrochemical template synthesis of NWs in polycarbonate track-etched membranes with nominal pore diameters	[207]
Cu NWs	The potentiostatic electrochemical template synthesis of NWs in polycarbonate track-etched membranes with nominal pore diameters	[207]
Fe NRs	Thermal decomposition of organometallic precursor ( $\text{Fe}(\text{CO})_5$ ) in the presence of a stabilizing surfactant TOPO at 340 °C under an argon atmosphere	[208]
In NWs	Room-temperature organometallic route using long-chain amines (hexadecylamine) as templates	[209]
$\text{In}_3\text{Sb}$ NWs	Room-temperature organometallic route using long-chain amines (hexadecylamine) as templates	[209]
Ni NRs	Surfactants hexadecylamine (HDA) or TOPO as capping agents in THF	[210]
Pb NWs	The NWs were embedded in tracked-etched polycarbonate membranes by electrodeposition	[211]
Pb NWs	Electrodeposition into anodic alumina membranes	[212]
Pd tetrahedras and octahedras	Reduction of metal ions in sodium dodecyl sulfate (SDS)/poly(acrylamide) gel by UV irradiation	[213]
Pd NWs	Using a mesoporous silica template via chemical vapor infiltration	[214]
Pd dendrites	Ultrasonically assisted synthesis using skeleton nickel as templates	[215]
Pt tetrahedra	Tetrahedral, cubic, irregular-prismatic, icosahedral, and cube-octahedral particle shapes were prepared with sodium polyacrylate as a capping agent	[216]
Mo NWs	A two-step process involving the electrodeposition of $\text{MoO}_2$ NWs on a highly oriented pyrolytic graphite (HOPG) surface followed by reduction	[217]

PbSnS <sub>3</sub> NRs	An iodine transport hydrothermal route	[351]

The templating effect can be confirmed by a series of experiments. The mixture of Ga<sub>2</sub>O<sub>3</sub> and Ga was used to produce gaseous Ga<sub>2</sub>O, which is about 1 torr at 880 °C [353]. The powder mixture was separated from carbon NTs

by porous alumina membrane, which can ensure that only gaseous Ga<sub>2</sub>O flows up toward the side of carbon NTs to participate in the reaction. In such a reaction, carbon NTs act as templates to confine the reaction on NTs, which led

**Figure 1.** (A) TEM image of carbon nanotubes. (B) TEM image of GaN nanorods. Reprinted with permission from [36], W. Q. Han et al., *Science* 277, 1287 (1997). © 1997, American Association for the Advancement of Science.

to the formation of NRs. If carbon NTs are not present in this reaction, GaN powders still can be obtained by another reaction:

However, no GaN NRs were observed in this product [354]. On the other hand, carbon NTs did not change without Ga-Ga<sub>2</sub>O<sub>3</sub> mixtures, in spite of the presence of ammonia. The results confirmed the evidence that the formation of GaN NRs took place on the surface of carbon NTs according to Eq. (2).

Other examples include GaP NWs [252], AlN NRs [258], SiC NRs, and B<sub>x</sub>C NRs [35]. The carbon NT-templated oxide NRs include GeO<sub>2</sub> [126], IrO<sub>2</sub> [130], V<sub>2</sub>O<sub>5</sub>, WO<sub>3</sub> [130], MoO<sub>3</sub>, MoO<sub>2</sub> [130], Sb<sub>2</sub>O<sub>3</sub> [147], and ZnO [179].

Recently, the range of the compounds, which can be prepared by the use of carbon NTs as templates, has been extended widely [258, 355]. Now, not only ternary NRs/NWs such as CoFe<sub>2</sub>O<sub>4</sub> [355], but also disulfide NTs ReS<sub>2</sub> [356], NbS<sub>2</sub> [357], HfS<sub>2</sub>, ZrS<sub>2</sub>, and TiS<sub>2</sub> [343] can be fabricated with the use of carbon NTs as templates. However, in the case of the synthesis of disulfide NTs, carbon NTs do not participate in the reactions and just act as deposition substrates of disulfides.

In contrast to the above vapor-phase synthesis by hard template, another versatile methodology was solution-phase electrodeposition for the formation of various NWs with anode aluminum oxide (AAO) as a template. This methodology was first pioneered by Martin and Moskovits [37–40]. Since the electrodeposition is caused by electron transfer from the surface of the conducting material, the wires nucleate at the bottom of the channels of the AAO and grow continuously along the channels. Achieving continuous wires is a key advantage of electrodeposition, particularly for applications in which conductivity is important (e.g., thermoelectric devices, opto-electronic devices). On the other hand, porous alumina is a good choice for a template, because the pore diameters are easily adjusted (down to 9 nm) to sizes enabling quantum confinement. Moreover, the pore densities (10<sup>10</sup> pores/cm<sup>2</sup>) and aspect ratio (>100) are high, which is appropriate for the growth of NWs. Figure 2 shows that Bi<sub>2</sub>Te<sub>3</sub> NW arrays were electrodeposited in anode alumina oxide channels [320, 321]. A lot of inorganic NWs have been fabricated through this approach, such as Ag, Au, Pt,

**Figure 2.** (Left) SEM image of a top view of Bi<sub>2</sub>Te<sub>3</sub> nanowires electrodeposited in AAO. Reprinted with permission from [321], A. L. Prieto et al., *J. Am. Chem. Soc.* 123, 7161 (2001). © 2001, American Chemical Society. (Right) SEM image of a side view of Bi<sub>2</sub>Te<sub>3</sub> nanowires in AAO. Reprinted with permission from [320], M. S. Sander et al., *Adv. Mater.* 14, 665 (2002). © 2002, Wiley-VCH.

TiO<sub>2</sub>, MnO<sub>2</sub>, ZnO, SnO<sub>2</sub>, CdS, and CdSe [358]. It should be pointed out that most of the wires are polycrystalline by the electrodeposition process, which could limit its applications in electronic transport study [23].

A report by Zhu et al. [229] shows that large-area silicon NW arrays can be fabricated on silicon wafers without the use of a template, but based on a so-called micro-electrochemical process that occurs at the surface of the silicon wafer in ionic metal (such as Ag<sup>+</sup>) HF solution. However, the applicability of this method must be further extended.

The above templates have to be removed by heating carbon NTs in air or by dissolving the anode aluminum oxide in a strong basic solution to get pure NWs. It is worth noting that such post-treatments will more or less affect the as-prepared NWs.

## 2.2. Vapor-Liquid-Solid Mechanism

Another extensive method is one-dimensional growth based on the VLS mechanism. Initially, the VLS mechanism was proposed by Wagner [41] to explain the growth of crystal whiskers. In 1992, Yazawa et al. demonstrated that high densities of InAs nanowhiskers with diameters of 20–30 nm can be epitaxially grown on InAs (111) substrates onto which one monolayer of Au atoms have been deposited [42]. They argued that the wirelike growth appears to be induced by ultrafine alloy droplets generated by the reactions between Au clusters and InAs substrates. Again, silicon NWs were grown on Si(111) via the VLS reaction, with silane as the Si source gas and Au as the mediating solvent [43].

Lieber's group [7, 8] proposed a general mechanism to illustrate the growth process of the nanowires. The main points of the mechanism are the orientation growth directed by the metal droplet on the tip of crystals. The metal droplet acts as an energetically favored site for absorption of gas-phase reactants. When the clusters dissolve in the metal droplet supersaturates, they will crystallize and grow one-dimensional nanowires. The process is illustrated in Scheme 2.

This group made a great contribution to the improvement of the application of this mechanism to the synthesis of various semiconductor NWs by employing the laser ablation technique to produce nanosized metal catalysts, which

**Scheme 2.** Schematic illustration on the catalytic growth based on the VLS mechanism, including three stages: alloying, nucleation, and axial growth. Reprinted with permission from [7], J. T. Hu et al., *Acc. Chem. Res.* 32, 435 (1999). © 1999, American Chemical Society.

defines the diameter of NWs grown by the VLS mechanism. A pulsed Nd-yttrium-aluminum-garnet laser (wavelength 532 nm) was used to bombard targets, which were composed of NWs and catalysts. The laser ablation on  $\text{Si}_{0.9}\text{Fe}_{0.1}$  generated NWs with a uniform diameter on the order of 10 nm and a length on the order of micrometers (Fig. 3A) [44]. Element analysis revealed that these NWs were Si cores coated by an amorphous  $\text{SiO}_2$  shell as shown in Figure 3B. All of the nanowires terminated at one end in metal nanoparticles, which have a slightly larger diameter than that of NWs. The appearance of these metal nanoparticles on the tips of NWs confirmed that the growth of NWs relies on the VLS mechanism. The authors proposed that the main composition of the catalyst solid should be  $\text{FeSi}_2$ , because  $\text{FeSi}_2$  is stable at the Si-rich region of the phase diagram. In addition, the NWs will stop growing when the temperature is below  $1207^\circ\text{C}$ , since there will be no liquid catalyst at such a low temperature. The agreement between experimental data and theoretical predictions indicates that it is possible to rationally design new catalysts and appropriate growth conditions for other NWs.

It should be noted that the metal selected as a catalyst has a certain solubility with reactants. Meanwhile, since the catalyst should become liquid at the desired reaction temperature, the melting point of the catalyst should be taken into account. The known phase diagrams of binary compounds will be helpful for the design of reactions and selection of catalysts; however, we still know little about the ternary phase diagrams.

**Figure 3.** (A) TEM image of the nanowires produced following ablation of a  $\text{Si}_{0.9}\text{Fe}_{0.1}$  target. The white scale bar corresponds to 100 nm. (B) TEM image of a typical nanowire with crystalline Si core and an amorphous  $\text{SiO}_x$  sheath. The scale bar corresponds to 10 nm. Inset: Electron diffraction recorded along the [211] zone axis. Reprinted with permission from [44], A. M. Morales and C. M. Lieber, *Science* 279, 208 (1998). © 1998, American Association for the Advancement of Science.

This idea has been successfully implemented by the preparation of a broad range of binary NWs and ternary NWs such as III–V materials (GaAs, GaP, GaAsP, InAs, InP, InAsP), II–VI compounds (ZnS, ZnSe, CdS, CdSe), and SiGe alloys, with LCG, based on the VLS mechanism [48]. However, the mechanism also has its inherent weaknesses. First, to ensure that the catalyst remains liquid, the reaction temperature has to be relatively high ( $700\text{--}1200^\circ\text{C}$ ). This impedes the application of this approach with compounds that are unstable at high temperatures. Second, the products based this approach are not pure materials, because of the metal catalyst attached to the tip of the NWs. It is difficult to remove these catalysts from the as-prepared NWs. Third, the size distribution of these NWs is not ideal. Because the metal catalyst clusters tend to aggregate at high temperatures, this will lead to the decentralization of the size distribution of the NWs.

Yang et al. combined the conventional epitaxial crystal growth technique with the VLS mechanism to achieve precise orientation control during NW growth [46]. The result shows that this vapor-liquid-solid epitaxy (VLSE) is particularly powerful in controlling the synthesis of NW arrays. This group successfully epitaxially grew the highly oriented and well-aligned NW arrays on a patterned substrate by using a Au thin film as the catalyst for NW growth. Typical scanning electron microscopy (SEM) images of NW arrays grown on sapphire (110) substrates with patterned Au thin film fabricated by photolithography (Fig. 4) confirm that the ZnO NWs grow only in the Au-coated areas. The diameters of these wires range from 20 to 150 nm, whereas more than

**Figure 4.** (A through E) SEM images of ZnO nanowire arrays grown on sapphire substrates. A top view of the well-faceted hexagonal nanowire tips is shown in (E). (F) High-resolution TEM image of an individual ZnO nanowire showing its  $\langle 0001 \rangle$  growth direction. For the nanowire growth, clean (110) sapphire substrates were coated with a 10- to  $35\text{-\AA}$ -thick layer of Au, with or without TEM grids as shadow masks (micro-contact printing of thiols on Au followed by selective etching has also been used to create the Au pattern). Equal amounts of ZnO powder and graphite powder were ground and transferred to an alumina boat. The Au-coated sapphire substrates were typically placed 0.5 to 2.5 cm from the center of the boat. The starting materials and the substrates were then heated to  $880^\circ$  to  $905^\circ\text{C}$  in an Ar flow. Zn vapor is generated by carbothermal reduction of ZnO and transported to the substrates where the ZnO nanowires grew. The growth generally took place within 2 to 10 min. Reprinted with permission from [46], M. Huang et al., *Science* 292, 1897 (2001). © 2001, American Association for the Advancement of Science.

95% of them have diameters of 70 to 100 nm. The room temperature ultraviolet lasing was successfully demonstrated within ZnO NW arrays [46]. More recently, Yang et al. [21] discovered that certain superstructures of ZnO NWs can readily be formed with Zn as vapor source. A large yield of comb-like structures made of ZnO NWs can be synthesized, in which the NWs are uniformly distributed on the side of the comb stem. Other interesting structures such as tetrapods and tapered NWs can also be synthesized by varying the vapor conditions [21].

This approach can also be extended to the synthesis of carbide materials such as TiC NWs [279] and  $B_xC$  nano-springs [277].

### 2.3. Vapor-Solid Mechanism

In fact, NWs can also be achieved in the absence of catalysts, with the classical VS mechanism [49]. Compared with the VLS mechanism, this route can avoid problems with the purity of products, because of the absence of catalysts. However, it is hard to find a strong and obvious driving force for the formation of NWs by this approach. So far, the researchers are inclined to assign the formation of NWs to the anisotropic growth rates of nanocrystals in different directions. However, these growth rates are related to many specific experimental conditions. The specific requirements for 1D crystal growth, such as the presence of a dislocation at the vapor-solid interface, are still controversial. One of the key factors is the control of supersaturation, the degree of which determines the prevailing growth morphology. The size of NWs can be controlled by supersaturation, nucleation sizes, and the growth process.

MgO,  $Al_2O_3$ , ZnO, and  $SnO_2$  NWs have been synthesized by a carbon-thermal reduction process by Yang's group [50, 51]. Recently, Wang's group has shown an elegant example of the application of the VS mechanism to the synthesis of semiconductor NWs and NBs [52]. In a typical experimental procedure, oxide powders were placed in an alumina tube. The products were collected by an alumina substrate at the downstream end of the tube. The pressure in the alumina tube, the reaction time, and the flow rate of Ar were kept at 300 torr, 2 h, and 50 sccm, respectively, for all of the experiments. The evaporation temperatures were determined by the melting points of individual oxides. The as-obtained hexagonal ZnO exhibits a unique belt-like shape as shown in Figure 5. The detailed structure characterization shows uniform structure, single crystals, and two different growth directions ( $[0001]$  and  $[0110]$ ). The subsequent success with  $SnO_2$ ,  $In_2O_3$ , and CdO NBs indicates that this method is not a minor approach to NBs. The crystal growth was governed by a vapor-solid process. Oxide vapor was generated by the oxide powders, was deposited on a substrate at a lower temperature zone, and grew into NBs.

More recently, Ren's group has shown that a variety of novel hierarchical ZnO nanostructures with 6-, 4-, and 2-fold symmetries can be grown by a vapor transport and condensation technique from a mixture of ZnO,  $In_2O_3$ , and graphite powders as raw materials, as shown in Figure 6 [53]. Since

**Figure 5.** TEM and HRTEM images of ZnO nanobelts, showing their geometrical shape. Pan et al., *Science* 291, 1947 (2001). © 2001, American Association for the Advancement of Science.

no catalyst is used in such a system, the  $In_2O_3$  NW growth should be based on the VL mechanism. It was found that the major core NWs are single-crystal  $In_2O_3$  with six, four, and two facets, and the secondary NRs are single-crystal hexagonal ZnO and grow either perpendicularly on or slanted to all of the facets of the core  $In_2O_3$  NWs (Fig. 4). The growth of ZnO NRs could also grow based on the VS mechanism because the  $In_2O_3$  core is covered by a ZnO layer that can be the basis for further ZnO NR growth. The high vapor pressure is necessary for the growth of the hierarchical structures compared with the aligned ZnO grown by the VLS mechanism [46]. The growth conditions, such as temperature, pressure, and source component ratios, are correlated to affect the supersaturation rate and the structure formed. This intriguing method could be extended for growing other oxide, carbide, and nitride materials with novel hierarchical nanostructures.

Based on the VS mechanism, various novel metal oxide nanostructures can also be synthesized, such as  $Sb_2O_3$  NRs [146],  $SnO_2$  NWs/nanoribbons/NTs [150],  $SnO_2$  nanodiskettes [151], SnO nanoribbons [152], and  $MoS_2$  NT bundles [337].

## 2.4. Oxide-Assisted Growth Route

The oxide-assisted growth mechanism of NWs was recently developed by Lee's group [54]. It is somewhat like the VLS mechanism, but with the metal droplets in VLS replaced by an oxide in this mechanism. Therefore, this process has an advantage of being free of a metal catalyst or a template compared with the VLS mechanism.

GaE (E = N, P, As) NWs were fabricated by laser ablation of the corresponding powders mixed with gallium oxide ( $\text{Ga}_2\text{O}_3$ ) under the flow of a carrier gas consisting of Ar and  $\text{H}_2$  [55–57]. The diameter of GaAs core wires and the thickness of the  $\text{GaO}_x$  sheath was in the range of 10–120 nm and 2–10 nm, respectively. The interface between the crystal core and amorphous sheath has an undulant contour. The following reactions were suggested during the growth process:

The results show that if a target made of pure GaAs powder without  $\text{Ga}_2\text{O}_3$  was used for laser ablation, no NWs were found in the products. This indicates that the presence of the oxide  $\text{Ga}_2\text{O}_3$  in the target is critical for the reaction in Eq. (6). Similar results were also observed in GaP, GaN NWs prepared by the same method, indicating that these NWs were grown by an oxide-assisted mechanism.

This mechanism can be further extended for the synthesis of Si NWs [58, 59]. Freestanding quasi-two-dimensional silicon nanoribbons have been realized in the present work with an oxide-assisted growth method (Fig. 7). Two kinds of morphology of the nanoribbons have been observed (Fig. 1A). Most of the ribbons have rippling edges (Fig. 1B), and a small portion of the ribbons has smooth edges (Fig. 1C). The thickness of the ribbons was estimated to be 10–20 nm. The rippling and curling features at the edge of most ribbons also further confirm that the nanoribbons are a quasi-two-dimensional structure and are distinctly different in shape from the one-dimensional silicon NWs with a smooth surface.

The oxide-assisted growth model is illustrated in Figure 8 with Si NWs as an example. Silicon oxide ( $\text{Si}_x\text{O}$ ) was deposited from the vapor phase and generated silicon nanoparticles on the surface (Fig. 8a). Because the surface melting temperatures of nanoparticles can be much lower than that of their bulk materials, this enhances atomic absorption, diffusion, and deposition in a growth process. At the same time, the  $\text{SiO}_2$  shell around silicon can effectively retard the radial growth of nanoparticles and impede the aggregation of nanoparticles. The structure defects at the tip of NWs provide favorable conditions for the faster axial growth of NWs (Fig. 8b). A detailed description of this mechanism and its application to Si NWs have been reported recently [58]. The characteristic of the product generated

**Figure 7.** TEM images of (A) silicon nanoribbons collected from the substrate. Arrows 1 indicate the edge-on position, and arrows 2 indicate silicon nanowires grown together with nanoribbons. (B) Some rippling-edge ribbons. (C) A smooth-edge ribbon. The thicknesses of the ribbons estimated from the arrows indicating parts in B and C are 13 and 14 nm, respectively. Scale bars: 1  $\mu\text{m}$  in A and 100 nm in B and C. Reprinted with permission from [59], W. S. Shi et al., *J. Am. Chem. Soc.* 123, 11095 (2001). © 2001, American Chemical Society.

by this mechanism is that the desired NW materials were surrounded by an amorphous oxide sheath.

## 2.5. Solvothermal Process

A challenging trend in synthetic chemistry and materials science is determining how the traditional solid-state reaction can be conducted in round-bottom flasks (i.e., turning down the heat for the fabrication of crystals) [60, 67]. Recent developments in soft solution processing may provide an alternative, convenient, lower-temperature, and environmentally friendly pathway for the fabrication of advanced ceramic materials with desirable shapes and sizes [359]. As

**Figure 8.** Schematic illustration of the oxide-assisted mechanism of nanowires. The parallel lines indicate the (112) orientation. one kind of solution-based chemical process, the hydrothermal process has been widely used for the synthesis of a vast range of solid-state compounds such as oxides, sulfides, and halides [26, 34, 360–363] and molecular, zeolite, and other microporous phases [363], since the pioneering work from the 1960s to the 1980s.

Hydrothermal synthesis can be defined as the use of water as a solvent in a sealed reaction container when the temperature is raised above 100 °C. Under these conditions, the autogenous pressure (i.e., self-developing and not externally applied) is developed. The pressure within the sealed reaction container is found to increase dramatically with temperature, but it will also depend on other experimental factors, such as the percentage fill of the vessel and any dissolved salts. Figure 9 shows these data and demonstrates first the dramatic rise in pressure when a high percentage fill of the reaction vessel is used, and second how the pressure inside the reaction container can be controlled by choice of temperature and/or the volume of solvent used. Below the critical point of water, and even below 200 °C, a high percentage fill allows access to pressures of hundreds of atmospheres [365].

The use of hydrothermal conditions can exert significant effects on the reactivity of inorganic solids and the solubility of the compounds under conditions of elevated pressure and temperatures. The chemical reactivity of usually insoluble reagents can be much enhanced, and many sluggish solid-state reactions can be initiated under hydrothermal conditions. Usually hydrothermal synthesis occurs at higher temperatures (above 300 °C) and often takes place in the supercritical regime. However, even milder reaction conditions (temperature < 250 °C) can be applied not only to provide a convenient low-temperature route to materials with practical application, but also in the exploratory synthesis of new solids [364, 365].

The concepts embodied in the hydrothermal process have been extrapolated to nonaqueous system; therefore, its counterpart, the so-called solvothermal process, has

**Figure 9.** Pressure as a function of temperature and percentage fill of water in a sealed vessel. Reprinted with permission from [365], R. I. Walton, *Chem. Soc. Rev.* 31, 230 (2002). © 2002, Royal Society of Chemistry. Adapted from [361], A. Rabenau, *Angew. Chem., Int. Ed. Engl.* 24, 1026 (1985). © 1985, Wiley-VCH.

emerged, in which an organic solvent is used as the reaction medium instead of water, at an elevated temperature near its boiling point. As the counterpart of the hydrothermal process, the solvothermal process has emerged in recent years and has received great attention in synthetic chemistry and materials science.

Solvothermal reactions are usually performed in a Teflon-lined, stainless steel autoclave, as shown in Figure 10. The use of an autoclave is necessitated by the pressures developed in the solvothermal reactions, and the inert liner is used to protect the stainless steel outer shell from the corrosive reagents and solvents typically used in the synthesis. Such autoclaves can be used at up to 270 °C, and, depending on the engineering specifications of the steel walls, pressures of ~150 bar can be maintained [365]. The synthetic procedure is simple; however, the rational design of the reaction requires multidisciplinary and interdisciplinary knowledge.

There are several advantages of the solvothermal technique that distinguish it from the traditional solid-state reactions and hydrothermal process. First, many inorganic precursors can be solubilized in a suitable solvent similar to that in which reactants were solubilized in the molten flux of the solid-state reaction at high temperatures [366]. Second, the solvothermal technique removes diffusion control by the use of a suitable solvent under mild conditions [366]. Third, the conventional hydrothermal method is confined to the conditions that some reactants will decompose in the presence of water or the precursors are very sensitive to water, or some reactions will not happen in the presence of water, resulting in the failure of the synthesis of the desired compounds. By the substitution of nonaqueous solvents (both polar and apolar solvents) such as alcohols,  $C_6H_6$ , polyamines,  $NH_2NH_2$ , or liquid  $NH_3$  for water, solvothermal process allows many possibilities for the preparation of various nanocrystalline compounds and the initiation of some conventional solid-state reactions in organic media under mild conditions [26]. It can even be used to prepare carbonides, nitrides, phosphides, silicides, chalcogenides, and so on.

In the solvothermal process, one or several kinds of precursors are dissolved in nonaqueous solvents. The reactants are dispersed in solution and become more active. The reactions happen in the liquid phase or under supercritical status. The solvothermal process is relatively simple and easy

**Figure 10.** Left: A schematic of a Teflon-lined, stainless steel autoclave typically used in the laboratory to perform subcritical solvothermal synthesis. Reprinted with permission from [365], R. I. Walton, *Chem. Soc. Rev.* 31, 230 (2002). © 2002, Royal Society of Chemistry. Right: A set of autoclaves.

to control with several changeable parameters such as solvents, temperature, and reaction time. The sealed system can effectively prevent the contamination of the toxic and air-sensitive precursors. With the substitution of nonaqueous solvents such as polar and nonpolar solvents for water, the so-called solvothermal process can be widely extended to prepare various kinds of nonoxide nanocrystalline materials whose precursors are very sensitive to water.

In the past two decades, a trend toward very mild conditions (100–200 °C) has become increasingly apparent for inorganic synthesis chemistry and materials synthesis. The potential of this technique for preparative solid-state chemistry has been intensively reviewed [365–368]. Various oxide ceramic ultrafine powders were prepared by the solvothermal process [367]. Morris and Weigel [368] summarized some of the results of the recent works in the synthesis of molecular sieves from nonaqueous solvents.

In recent years, rational solution routes to nanocrystals have been extensively explored [26, 34]. Various nonoxide compound nanocrystals such as metal chalcogenides [61–65, 310, 323, 369, 370, 372–379], phosphides [380], and metal nitrides can be synthesized [381–383]. The results showed that the physicochemical properties of the solvents have strong effects on the reactivity, shapes, sizes, and phases of the particles, since solvent properties such as polarity, viscosity, and softness will strongly influence the solubility and transport behavior of precursors under solvothermal conditions. Various kinds of inorganic NRs/NWs/NTs can be synthesized by solvothermal/hydrothermal processes as listed in Tables 1 and 2.

In the following sections, the latest development of the fabrication of nonoxide low-dimensional semiconductor nanocrystals with different shapes, sizes, and phases by mild solution routes will be reviewed with a focus on the emerging solvothermal processing of 1D NRs/NWs. Specific examples will be given to illustrate the reaction activity, the principle, and key parameters that dominated the synthesis process.

### 2.5.1. Fabrication of II–VI Group Low-Dimensional Nanocrystals

#### Shape, Size, and Phase Control of CdE Nanocrystals

Several solvothermal routes were designed for the synthesis of CdS nanoparticles with different shapes, sizes, and phases [61, 62, 369]:

The reaction was conducted in a Teflon-lined autoclave with a 40-ml capacity (as shown in Fig. 10), which was filled with a solvent up to 80% of the total volume. The autoclave was maintained at 80–180 °C for 3–12 h and air-cooled to room temperature. Different solvents were chosen to investigate the influence on the reactivity, crystal shape, size, and phase.

The shape, particle size, and phase of II–VI group semiconductor nanoparticles can be synthesized conveniently with high yield by the solvothermal process [61]. A CdS sample synthesized in ethylenediamine (en) via the reaction shown in Eq. (8) at 160 °C for 12 h can be indexed as the hexagonal phase of CdS (wurtzite structure) with cell constants  $a = 4.140 \text{ \AA}$ ,  $c = 6.72 \text{ \AA}$ , which are close to the reported data for CdS (JCPDS card file no. 41-1049). The TEM image in Figure 11A shows that the CdS crystallites synthesized in ethylenediamine are uniform NRs with diameters of 20–50 nm and lengths of 200–1300 nm. In addition, CdS crystallites synthesized in other polyamines such as diethylene triamine (dien) and triethylene tetraamine (trien) under the same experimental conditions display the same morphology. The CdS powders obtained in dien consist of uniform NRs with diameters of 30–60 nm and lengths of 200–4800 nm. Wurtzite CdSe NRs with diameters of 6–20 nm and lengths up to 100–500 nm can also be synthesized in en, dien, and trien. Similarly, CdTe NRs with a zinc-blende structure were obtained in en.

Solvent effects on the morphology of the products were investigated. Disc-like particles with a size of 40 nm were produced in pyridine (py) as shown in Figure 11B. A lower temperature is unfavorable for the growth of CdE NRs. The CdS particles formed in en at 120 °C for 12 h consist of both uniform spherical particles and shorter NRs. If the temperature is lower than 120 °C, the reaction is incomplete and may not even occur. These results suggest that relatively higher temperature and pressure in the system are necessary for the oriented growth of the NRs. The results indicate that the morphology of CdS, CdSe, and CdTe crystallites can be controlled by choosing different solvents.

Remarkable control over the shape, size, and phase of CdS can be readily realized with the choice of different solvents and reaction conditions and other modified solvothermal reactions as expressed in Eqs. (9) and (10) [62, 369]. The widths and sizes of CdS NRs can be varied by controlling the temperature and reaction time. The TEM image

**Figure 11.** TEM images and ED patterns for the obtained CdS samples. (A) CdS synthesized in en at 160 °C for 12 h. (B) CdS nanoparticles synthesized in pyridine at 160 °C for 12 h. Reprinted with permission from [61], S. H. Yu et al., *Chem. Mater.* 10, 2309 (1998). © 1998, American Chemical Society.

in Figure 12a shows that the CdS powders obtained at 100 °C for 12 h consist of uniform NRs with diameters of 6–13 nm and lengths up to 140–480 nm. As the temperature approached 180 °C, the product was found to be uniform NRs with widths of 30–40 nm and lengths up to 280–900 nm (Fig. 12b). The CdS NRs show [001] preferential orientation as shown in a typical high-resolution transmission electron microscopy (HRTEM) image in Figure 12c, corresponding to a stronger and sharper (002) diffraction peak in the X-ray diffraction (XRD) pattern. The SEAD inserted in Figure 12c indicated the CdS NRs are polycrystalline with a wurtzite structure. Further results show that single-crystal CdS NRs can also be obtained at higher temperatures [63].

In addition to the shape control, both sizes and the phase of CdS nanocrystals can be controlled. A modified solvent thermal process as expressed in Eq. (10) was applied to prepare spherical CdS nanocrystals with different sizes via the reaction of CdSO<sub>4</sub> with Na<sub>2</sub>S<sub>3</sub> in benzene at 80–120 °C. It was found that solvent, temperature, and reactant have significant effects on the crystal structure and particle size of CdS nanocrystals. Increased temperature and use of a solvent with a low dielectric constant benefit the preparation of CdS nanocrystals with hexagonal structure. The water content in the system not only induces the presence of cubic phase CdS nanocrystals, but also leads to increasing particle size. Compared with the result from the solvothermal process, pure cubic CdS nanocrystals with an average size of 7 nm were obtained via the hydrothermal process at 100 °C for 12 h, with CdSO<sub>4</sub> · 8/3H<sub>2</sub>O and Na<sub>2</sub>S as reactants [369].

It is well known that the free energy difference between cubic and hexagonal structures for CdS is small [384, 385]. It is believed that solvents with a lower dielectric constant may minimize the free energy difference between the hexagonal and cubic phases and thus favor the formation of hexagonal phase CdS. In addition, the solvent has a significant effect on the shifting of the following equilibrium:

**Figure 12.** TEM and HRTEM images of CdS nanowires synthesized by a solvothermal reaction of Cd<sup>2+</sup> with thiourea in ethylenediamine (a) at 100 °C for 12 h. (b) 180 °C for 12 h. (c) HRTEM image indicating a typical CdS nanorod with a diameter of ~12 nm and well-resolved (002) lattice planes, which was obtained under condition (a). An inserted electron diffraction pattern (ED) shows that the CdS nanorods are of polycrystalline nature and can be indexed as the wurtzite structure. Reprinted with permission from [26], S. H. Yu, *J. Ceram. Soc. Jpn.* 109, S65 (2001). © 2001, Ceramic Society of Japan.

In this route, the presence of benzene, with a lower dielectric constant than water, will shift the equilibrium (11) to the left and slows the dissolution rate of CdS crystallites. Thus, it will lead to a difference in particle size of the final products. The effects of the solvent on crystal structures and particle size are also consistent with those reported by Ramsden et al. [386].

A modified solvothermal process produced CdTe crystals with different sizes, phase, and morphologies, with CdCO<sub>3</sub> reacting with Te in the presence of N<sub>2</sub>H<sub>4</sub> · H<sub>2</sub>O in the different solvents [370]. More interestingly, the meta-stable wurtzite CdTe phase and its conversion to the stable cubic CdTe phase under mild conditions were observed.

**Shape and Phase Control Synthesis of ZnS Nanocrystals** A rational design of the solvothermal reaction makes it possible to control both the dimensionality (dots, rods, and sheets) of ZnS nanocrystals and the phase. The solvothermal reaction of zinc salts such as Zn(CH<sub>3</sub>COO)<sub>2</sub> · 2H<sub>2</sub>O or ZnCl<sub>2</sub>, and with thiourea in en at 120–180 °C for 6–12 h, results in a white precipitate with the composition ZnS · (en)<sub>0.5</sub> [64].

The XRD pattern in Figure 13a shows that a new molecular precursor was obtained at 180 °C. It has been confirmed that either a solvothermal reaction of Zn<sup>2+</sup> with thiourea or a similar reaction between Zn (or Zn<sup>2+</sup>) and sulfur in en medium at 120–180 °C resulted in the same product. The SEM image in Figure 14a shows that all of the particles are sheet-like. EDX analysis of this lamellar precursor gave a Zn:S ratio of 1.00:0.98, indicating that this sulfide had the expected composition. In addition, both N and C signals were detected in the EDX spectrum. After removal of the en template, no N signal was detected in the EDX

**Figure 13.** XRD patterns of the products. (a) A lamellar precursor ZnS · (en)<sub>0.5</sub> obtained by solvothermal reaction of Zn(CH<sub>3</sub>COO)<sub>2</sub> · 2H<sub>2</sub>O with thiourea in ethylenediamine (en) at 180 °C for 12 h. (b) and (c) Wurtzite ZnS nanoparticles obtained by thermal decomposition of lamellar ZnS · (en)<sub>0.5</sub> precursor at 250 °C, 500 °C for 0.5 h under vacuum, respectively. Mater.* 14, 296 (2002). © 2002, Wiley-VCH.

**Figure 14.** SEM images of (a) the lamellar precursor  $\text{ZnS} \cdot (\text{en})_{0.5}$  obtained by solvothermal reaction at 180 °C for 12 h and (b) ZnS nanosheets obtained by thermal decomposition of the precursor in vacuum at 250 °C for 0.5 h. Reprinted with permission from [64], S. H. Yu et al., *Adv. Mater.* 14, 296 (2002). © 2002, Wiley-VCH.

spectrum. TG-DTA analysis shows that the decomposition events of the precursor obtained at 120–180 °C happened at 362 °C, accompanying the weight loss of en. The net weight loss for the precursor obtained at 120 °C and 180 °C in this stage is 23.5%, which suggests a molecular precursor with a composition of  $\text{ZnS} \cdot (\text{en})_{0.5}$  (theory: 23.62%).

Pure wurtzite ZnS (W) was produced by removing the en by thermal decomposition at 250–500 °C under vacuum as confirmed by the XRD patterns in Figure 13c and d. The SEM image in Figure 14b and TEM images in Figure 15a show that ZnS nanoparticles are sheet-like with rectangle lateral dimensions in a range of 0.3–2 μm. The oxidation of the lamellar molecule in air produced wurtzite ZnO flake-like dendrites [64]. The nanosheets are well-crystallized single crystals with a growth direction along the *a* and *c* axes, as indicated by the SAED pattern in Figure 15a. The sharp nature of the (002) peak in Figure 13b and c suggests that the nanosheets grow along the *c* axis. The HRTEM image shows well-resolved (100) lattice planes with a lattice spacing of 3.3 Å, indicating that the preferred orientation is along the *a* axis (Fig. 15b). EDX analysis shows that the weight composition of Zn and S in the product is 67.24% and 32.76%, which is in good agreement with the stoichiometric composition of ZnS.

The synthetic method is both flexible and reproducible for controlling the phase, shape, and sizes of ZnS nanocrystals. By a similar solvothermal reaction at 120 °C, with

**Figure 15.** (a) TEM images and SAED patterns for wurtzite ZnS single-crystal nanosheets obtained by thermal decomposition of lamellar  $\text{ZnS} \cdot (\text{en})_{0.5}$  precursor at 500 °C for 0.5 h in vacuum. The inserted SAED pattern was recorded along the  $\langle 010 \rangle$  zone. (b) Well-resolved HRTEM image of the wurtzite ZnS single-crystal nanosheet. Reprinted with permission from [64], S. H. Yu and M. Yoshimura, *Adv. Mater.* 14, 296 (2002). © 2002, Wiley-VCH.

ethanol instead of en as a solvent, sphalerite ZnS (S) nanoparticles with a size of ~3 nm can easily be synthesized. Furthermore, wurtzite ZnS NRs can also be synthesized by using *n*-butylamine, a monodentate amine, as a solvent [65]. A typical TEM image is shown in Figure 16. In addition, the NRs could be aligned together to form bundle structures or arrays under limited experimental conditions. The further oxidation of ZnS NRs can generate ZnO wurtzite NRs. The general synthetic strategies for ZnS nanocrystals with different phases and shapes and ZnO dendrites are shown in Scheme 3. The results show that both shape and phase of the ZnS nanocrystals can be well controlled by choosing solvents.

These facile mild solution-based methods shed light on the possibility of controlling shape, dimensionality (0D, 1D, 2D), size, and phase. The unusual 1D, 2D wurtzite ZnS single-crystal NRs and nanosheets, flake-like ZnO dendrites, and ZnO NRs can easily be generated based on the solvothermal reactions. This synthetic strategy implies that other semiconductor nanocrystals could also be synthesized along the same line by using a suitable “shape controller” under solvothermal conditions that we will discuss in next section.

#### Formation Mechanism and General Synthesis of II–VI Nanorods

As stated above, only CdS nanocrystals prepared by the solvothermal reactions in en display a rod-like shape. If en were replaced by other organic molecules as solvents, CdS nanocrystals would be irregular or spherical. What dominates this process and results in the formation of NRs? If this mechanism is revealed, one can expect to make use of it to control the shape and size of nanocrystals. Moreover, this mechanism can be expanded to design a general and rational pathway to other 1D semiconductors. In this section, the detailed formation process of CdS NRs under solvothermal conditions was discussed at first. Then a general solvothermal synthesis of II–VI NRs was presented.

CdS nanocrystals were prepared with a previous synthetic method [62]. In a typical procedure, an appropriate amount of  $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$  and  $\text{NH}_2\text{CSNH}_2$  (molar ratio 1:3) was added to a Teflon-lined stainless steel autoclave that had been filled with en to 80% of its capacity. Samples (a), (b), (c), and (d) were taken out of the autoclave after the reaction had been carried out at 120 °C for 1 h, 1.5 h, 2.5 h, and 3.5 h, respectively. Then the mixtures were cooled to room temperature immediately. The precipitates were filtered and

**Figure 16.** Wurtzite ZnS nanorods synthesized in *n*-butylamine at 250 °C for 12 h.

**Scheme 3.** Illustration of the controlled synthesis of ZnS nanocrystals with different dimensionalities and phases: ZnS dots, nanosheets, nanorods, and bundles. Partially adapted with permission from [64], S. H. Yu and M. Yoshimura, *Adv. Mater.* 14, 296 (2002). © 2002, Wiley-VCH.

washed repeatedly with distilled H<sub>2</sub>O and absolute ethanol to remove the excessive thiourea and other impurities. Finally the samples were dried in vacuum at 70 °C for 0.5 h.

The crystallinity of the samples is improved with the reaction time prolonged during the whole process, as shown in Figure 17. Furthermore, a preferential orientation and a rod-like shape were observed in the samples after a longer reaction time. TEM photographs show that there is an accordion-like folding process in the morphology evolution of the samples. The poorly crystallized sample (a) displayed a lamellar shape, as shown in Figure 18a, whereas the SAED pattern (inset of Fig. 18a) indicates that it was poorly crystallized, as confirmed by the XRD pattern in Figure 17a. A TEM photograph (Fig. 18b) of sample (b) reveals that the number of folds increased and these folds spontaneously agglomerated together. It seems that the shrinkage of the lamellae leads to both the increase and the agglomeration

**Figure 18.** TEM images of the morphology evolution of CdS samples obtained at 120 °C in ethylenediamine. (a)–(d) With time prolonged by 1, 1.5, 2.5, and 3.5 h, respectively. Reprinted with permission from [63], J. Yang et al., *Chem. Mater.* 12, 3259 (2000). © 2000, American Chemical Society.

of the folds. Subsequently, there was an interesting shape change in the sample (c). The previously agglomerated folds broke into needle-like fragments as shown in Figure 18c, which is very critical in the formation process of CdS NRs. The SAED pattern shows a preferential orientation along (002), which coincides with the result from the XRD pattern. The sample (d) is composed of short NRs with widths of 12–17 nm and lengths of 40–160 nm.

According to these results, the formation of the obtained NRs can be divided into several steps. First cadmium nitrate and thiourea reacted to produce the lamellar CdS with many folds. After that, the folds on the lamellae agglomerated together. Then these folds broke into needle-like fragments. Finally these needles further grew into well-crystallized NRs. This transition process is interesting and is obviously different from the known 1D growth mechanisms. It is believed that en molecules adsorbed to the samples determined this morphology transition, and en molecules in the solution were not relevant to this transition process. If the sample (a) after filtering but without washing was put in a solvent such as absolute ethanol and solvothermally treated at 120 °C for 10 h, the products obtained were composed of CdS needles exclusively. However, if en molecules adsorbed to sample (a) were removed by washing several times with distilled H<sub>2</sub>O, most of the products prepared under the same conditions were uniform spherical particles. The results suggested that the transition process depends on en molecules adsorbed to the initial sample.

Although the close relationship between en molecules adsorbed to the surface and the formation of one-dimensional nanocrystals has been proved according to the above results, it is still not clear how en molecules control the formation of NRs. The IR spectrum of the starting solution was similar to that of  $[\text{Cd}(\text{en})_3]^{2+}$ , which is similar to the data reported in the literature [387]. This implies that the en molecule in the starting solution uses a *gauche* conformation to chelate with  $\text{Cd}^{2+}$  just like that in  $[\text{Cd}(\text{en})_3]^{2+}$  [388]. Although there is thiourea in the solution, the coordination capacity of thiourea is much smaller than that of the en molecule [389]. Therefore, a complex between thiourea and the  $\text{Cd}^{2+}$  ion was not observed in the IR spectra. The IR spectra of the CdS samples were close to that of  $\text{Cd}(\text{en})\text{Cl}_2$ , in which an en molecule uses a *trans* conformation to bridge an adjacent cadmium ion [391, 392]. This result indicates that the en molecule probably uses a *trans* conformation to coordinate with  $\text{Cd}^{2+}$  on the surface of CdS, which we assume to be due to the fact that sulfur bonded with  $\text{Cd}^{2+}$  impeded the formation of the chelate structure between the en molecule and  $\text{Cd}^{2+}$  on the surface of the CdS.

The *trans* conformation of the en molecule adsorbed to the surface of CdS is important for the formation of CdS NRs through this process. To certify this conclusion, *o*-phenanthroline was chosen as the solvent to prepare CdS powders by the same reaction at 210 °C for 36 h, since it merely forms the chelate structure with  $\text{Cd}^{2+}$  and its chelate ability is close to that of en [389]. Only irregularly shaped particles were observed in the product. This result demonstrates the importance of the conformation of the en molecule from the back. Reetz and co-workers also reported a nonchelating mode of coordination for  $\alpha$ -hydroxy carboxylates on the metal surface, which is likely to be the morphology-determining factor in the shape-selective preparation [393].

Although the IR spectra of the samples obtained at the different times were similar to each other, it was noted that the intensity of absorption peaks of the en molecules adsorbed to the surface of the CdS gradually decreased with regard to the adsorption peak of  $\text{NO}_3^-$  at  $1384.6\text{ cm}^{-1}$ . This indicates that the en molecule dissociates from the surface of CdS nanocrystallites during the morphology transition. The high temperature weakens the interaction between the en molecule and  $\text{Cd}^{2+}$  on the surface of CdS, which leads to the dissociation of en molecules from the CdS surface. When the obtained samples without post-treatment were heated in a vacuum at 70 °C for 1 h, the absorption peaks that belonged to the en molecule adsorbed to the surface of CdS greatly decreased in intensity. However, there was no shift in the position of the IR peaks, indicating that the interaction between the en molecule and  $\text{Cd}^{2+}$  on the surface of the CdS was destroyed.

If the dissociation of the en molecule adsorbed to the surface of CdS is restrained, the morphology transition will slow down and even stop. For example, when sample (a) without post-treatment was put into benzene at 120 °C for 10 h, the products kept almost their original morphology. This can be attributed to the fact that the low solubility of the en molecule in benzene limits the dissociation of the en molecule. The result confirmed that the dissociation of the en molecule adsorbed to the surface of CdS leads to the

morphology transition of CdS. This result also indicates that the dissociation of the en molecule in an apolar solvent is much slower than that in a polar solvent. In other words, the physicochemical properties of solvents have a great influence on the dissociation of the en molecule from CdS.

Based on all of these results, the whole forming process of CdS NRs can be expressed as follows:

First, the  $\text{Cd}^{2+}$  ion coordinated with the en molecule to form  $\text{Cd}(\text{en})_3^{2+}$  [387]. Thiourea decomposed to produce  $\text{S}^{2-}$  at low temperatures in the base environment. Then the reaction between  $\text{Cd}(\text{en})_3^{2+}$  and  $\text{S}^{2-}$  produced CdS powder with its surface-adsorbed en molecule. Meanwhile, the conformation of the en molecule coordinated with  $\text{Cd}^{2+}$  changed from the *gauche* conformation to the *trans* conformation. However, the interaction between the en molecule and  $\text{Cd}^{2+}$  on the surface of CdS was weak when the en molecule was used in the *trans* conformation. Therefore, this structure was destroyed at higher temperatures. This dissociation of the en molecule from the surface of CdS resulted in the evolution process of the morphology. In fact, the en molecule with the *trans* conformation acted as an intermediate.

There are still two questions to be resolved. One is to further ascertain the coordination mode between  $\text{Cd}^{2+}$  on the surface and the en molecules. Because it is difficult to judge whether the coordination mode between  $\text{Cd}^{2+}$  on the surface and the en molecules is monodentate (Scheme 4a) or bridging (Scheme 4b) based only on IR data, the en molecules in both cases are in the *trans* configuration. The other is to expand the controlling mechanism to the syntheses for other important one-dimensional semiconductors.

In as much as *n*-butylamine can act only as a monodentate ligand, the coordination between it and metal ions must be in a monodentate mode, as shown in Scheme 4c. Thus, it is employed as the solvent to answer the first question. CdS nanocrystals were chosen as the target to examine whether the same reaction in a monodentate ligand can produce NRs. In the IR spectrum of the as-prepared CdS nanocrystals, the characteristic absorption peak at  $1573.0\text{ cm}^{-1}$  can be undoubtedly assigned to the  $-\text{NH}_2$  bending vibration, which shifts to lower frequencies as compared with pure *n*-butylamine [394]. At the same time, the red shift of C-N bending vibration caused by this coordination is also observed in the IR spectrum [394]. These results indicate

**Scheme 4.** Illustration of the possible coordination mode on the surface (a) monodentate mode of en molecules, (b) polydentate mode of en molecules, (c) monodentate mode of *n*-butylamine. Reprinted with permission from [65], J. Yang et al., *Angew. Chem. Ed. Int.* 41, 4697 (2002). © 2002, Wiley-VCH.

that *n*-butylamine also uses the nitrogen atom to coordinate with metal ions on the surface of CdS nanocrystals in a monodentate mode.

As shown in Figure 19a, the XRD pattern of CdS obtained at 220 °C for 12 h can be identified as a hexagonal phase CdS (JCPDS card no. 41-1049). The crystal size, which can be roughly estimated by using the Scherrer equation, are 50 nm and 9 nm, based on the (002) and (110) diffraction peaks, respectively. The great difference between the coherence length in the [002] direction and that in the [110] direction implies the unusual shape of the products [394]. Short NRs 7–10 nm in width and 30–55 nm in length can be readily observed in Figure 19b. It is believed that plenty of (002) planes in NRs and the anisotropic shape of NRs result in a remarkable increase in the intensity and narrowing of the FWHM of the (002) diffraction.

That a number of rod-like CdS nanoparticles can be obtained in *n*-butylamine indicates that one anchor atom in a ligand is necessary and adequate to the formation of NRs, even though more anchor atoms may be present in a ligand. The close interaction between anchor atoms in ligands (Lewis base) and metal ions on the surface (Lewis acid) is another prerequisite for the formation of NRs, because the result of this weak interaction will be that ligand molecules will not impose effective influence on the nucleation and growth of nanoparticles [62]. Altering this kind of interaction strength between ligands and metal ions could control the shape and size of various chalcogenide nanocrystals, as demonstrated previously in the synthesis of CdS nanocrystals [62].

To verify whether a monodentate ligand can be used as a “shape controller” for the synthesis of other semiconductor NRs, a series of similar solvothermal reactions were performed in *n*-butylamine. A mixture of hexagonal phase CdSe and cubic phase CdSe was obtained at 160 °C for 12 h. The TEM image in Figure 20a shows that the CdSe nanocrystals are composed of NRs 12–16 nm in width and 200–400 nm in length. Similarly, wurtzite ZnSe nanoparticles can also be obtained at 220 °C for 12 h. The ZnSe nanocrystals are composed of NRs with diameters in the range of 25–50 nm and lengths up to 1000 nm. A well-crystallized single ZnSe NR with a growth direction along the *c* axis is presented in Figure 20b. Wurtzite ZnSe NRs were achieved for the first

**Figure 19.** (a) XRD pattern and (b) TEM image of CdS nanocrystals obtained at 220 °C for 12 h. Reprinted with permission from [65], J. Yang et al., *Angew. Chem. Ed. Int.* 41, 4697 (2002). © 2002, Wiley-VCH.

**Figure 20.** TEM images of (a) CdSe nanocrystals (160 °C, 12 h), (b) ZnSe nanocrystals (220 °C, 12 h), and (c) PbSe nanocrystals (80 °C, 12 h). Reprinted with permission from [65], J. Yang et al., *Angew. Chem. Ed. Int.* 41, 4697 (2002). © 2002, Wiley-VCH.

time in a solution system under mild conditions. Again, cubic PbSe NRs 12–20 nm in width and 200–450 nm in length as shown in Figure 20c can be obtained at 80 °C for 12 h. The growth direction of the NRs was along  $\langle 200 \rangle$ . These results indicate that selecting the proper experimental conditions is important for the formation of NRs, although NRs can be synthesized in *n*-butylamine.

This solvent-mediated controlling mechanism has been demonstrated to be successful in the synthesis of a variety of semiconductor NRs/NWs. In this mechanism, ligands control the shape of nanocrystals through the interaction between ligands and metal ions on the surface of nuclei. One anchor atom in a ligand such as *n*-butylamine is necessary and sufficient for the formation of 1D nanocrystals, even though more anchor atoms may be present in a ligand. The close interaction between anchor atoms in ligands and metal ions on the surface is another important prerequisite for NR formation. Furthermore, this route provides not only a possible general route to other chalcogenide NRs on a large scale but also a guide for further rational design of 1D chalcogenides.

### 2.5.2. Fabrication of Group V–VI Low-Dimensional Nanocrystals

$A_2B_3^{VI}$  ( $A = \text{Sb, Bi, As}$  and  $B = \text{S, Se, Te}$ ) semiconductor compounds find applications in television cameras with photoconducting targets, thermoelectric devices, electronic and optoelectronic devices, and IR spectroscopy [395]. Bismuthinite ( $\text{Bi}_2\text{S}_3$ ) and stibnite ( $\text{Sb}_2\text{S}_3$ ) are direct band-gap materials that are useful for photodiode arrays or photovoltaics [396, 397].  $\text{Bi}_2\text{S}_3$  and  $\text{Sb}_2\text{S}_3$  also belong to a family of solid-state materials with applications in thermoelectric cooling technologies based on the Peltier effect [398]. These materials may be a starting material for the synthesis of semiconductors based on sulfo salts of bismuth and related compounds and sulfoantimonates of antimony and related compounds such as  $\text{M}(\text{NH}_3)_6\text{Cu}_8\text{Sb}_3\text{S}_{13}$  ( $M = \text{Mn, Fe, Ni}$ ) [399].

Conventionally,  $\text{Bi}_2\text{S}_3$  and  $\text{Sb}_2\text{S}_3$  can be prepared by direct reaction of elements and sulfur vapor in a quartz vessel at high temperature [395, 400]. The liquid solution syntheses of  $\text{Bi}_2\text{S}_3$  and  $\text{Sb}_2\text{S}_3$  generally yield products that are mostly amorphous, poorly crystallized, or colloidal particles [401]. Thermal degradation of metal complexes with sulfur-containing ligands seems to be an attractive method for the synthesis of metal sulfides [398, 402]; however,

high temperature is required to decompose the complex. In contrast, chemical solution reaction methods that do not involve sophisticated vacuum systems and heating apparatus have some advantages for the preparation of  $\text{Bi}_2\text{S}_3$  and  $\text{Sb}_2\text{S}_3$ .

To avoid the hydrolysis of the bismuth and antimony salts in the presence of water, a so-called solvothermal decomposition process (SPD) was developed for the fabrication of  $\text{Bi}_2\text{S}_3$  and  $\text{Sb}_2\text{S}_3$  NWs (or NRs) [314–316], with  $\text{BiCl}_3$  or  $\text{SbCl}_3$  and thiourea (Tu) or thioacetamide (TAA) as starting reactants in polar solvents:

$\text{Bi}_2\text{S}_3$  nanoparticles can also be prepared by a hydrothermal crystallization method, by using ethylene diamine tetraacetic acid (EDTA) as a chelating agent to prevent the hydrolysis of  $\text{Bi}^{3+}$  in water:

The methods make it possible to produce  $\text{Bi}_2\text{S}_3$  and  $\text{Sb}_2\text{S}_3$  NRs/NWs conveniently with yields as high as 95%. The particle sizes can be well controlled through the choice of different solvents or different processes. The influence of solvents, reaction temperature, and reaction time on the formation of  $\text{Bi}_2\text{S}_3$  NWs was investigated. Since many metal ions can complex with thiourea or selenurea, the present technique is expected to synthesize other nanostructured metal chalcogenides.

The controllable synthesis of  $\text{Bi}_2\text{S}_3$  nanocrystals is illustrated in Scheme 5.  $\text{Bi}_2\text{S}_3$  NWs/NRs with controllable sizes can be selectively synthesized conveniently by the solvothermal decomposition process (SDP) and the hydrothermal process under suitable conditions, as shown in Figure 21.

Pure  $\text{Bi}_2\text{S}_3$  can be easily obtained in high yield in several polar solvents. The products can be indexed orthorhombic structure with cell constants  $a = 11.127$ ,  $b = 11.265$ ,  $c = 3.976$  Å, which are in agreement with the reported data (JCPDS card file 17-320). Different solvents were chosen for the investigation of the solvent effects on the

formation of  $\text{Bi}_2\text{S}_3$ . The solvents used included ethanol (eth), pyridine (py), ethylene glycol (EG), water, tetrahydrofuran (THF), en, 1,2-dimethoxyethane (DME), *N,N*-dimethylformamide (DMF), diethyl ether (DEE), benzene, and toluene. The effects of solvents on the synthesis of  $\text{Bi}_2\text{S}_3$  and their physicochemical properties are listed in Table 3. The results confirmed that the  $\text{Bi}_2\text{S}_3$  phase can be obtained in many polar solvents such as eth, py, EG,  $\text{H}_2\text{O}$ , DME, THF, en, and DMF. However, pure  $\text{Bi}_2\text{S}_3$  nanowires can only be obtained in eth, py, EG,  $\text{H}_2\text{O}$ , and DME. Some unidentified phases besides the  $\text{Bi}_2\text{S}_3$  phase in the products prepared in THF, en, and DMF were detected by XRD. In contrast, the Bi-Tu complex is difficult to form because of its poor solubility in apolar solvents such as DEE, benzene, and toluene due to the poor solubility of  $\text{BiCl}_3$  and thiourea in apolar solvents. Both  $\text{BiCl}_3$  and thiourea easily dissolve in polar solvents to form a yellow solution, which indicates the formation of Bi-Tu complexes.

The results confirmed that the polar solvents are more favorable for the formation of  $\text{Bi}_2\text{S}_3$  NWs. The difference in the width and length of the  $\text{Bi}_2\text{S}_3$  NWs may be related to the different physicochemical properties of the solvents. Solvent physicochemical properties such as polarity, viscosity, and softness will strongly influence the solubility and transport behavior of the precursors [366]. It has been reported that dielectric constants and dipole moments have been used in the quantitative characterization of solvent polarity [366]. These parameters are generally used to describe the overall solvation ability of a solvent. From Table 3, one can see that the dielectric constants are in the order  $\text{H}_2\text{O} > \text{EG} > \text{DMF} > \text{eth} > \text{en} > \text{py} > \text{THF}$ , whereas the dielectric constants for DEE, benzene, and toluene are much smaller than those polar solvents. The Bi-Tu complexes are more easily formed in polar solvents than in apolar solvents. It is believed that the difference in particle sizes (width and length) could be attributed to the influence of the solvents on the solubility of Bi-Tu complexes and the decomposition reaction rate of the Bi-Tu complexes.

**Table 3.** Effect of solvents on the synthesis of  $\text{Bi}_2\text{S}_3$  and physical properties of solvents [403].

Solvent	Dielectric <sup>403</sup> constant	Boiling point <sup>403</sup> (°C)	Temperature (°C)	Time (h)	Product	Particle sizes

<sup>a</sup> The  $\text{Bi}_2\text{S}_3$  powders were obtained by the hydrothermal treatment in [316].

The structural analysis shows that the infinite linear chains within the  $\text{M}_2\text{S}_3$  ( $\text{M} = \text{Sb, Bi}$ ) crystal structure will play a crucial role in the anisotropic growth characteristics as shown in Scheme 6. In fact, the one-dimensional growth of nanocrystals is actually the outside embodiment of inside crystal structures. However, the autogenous pressure in the solvothermal/hydrothermal process was found to play a key role in the orientation growth of the nanocrystals.

The reaction was conducted in a closed solution system, which may be similar to the sealed-tube pyrolysis reaction of  $\text{Bi}(\text{Sbn})_3$  ( $\text{Bn} = \text{CH}_2\text{C}_6\text{H}_5$ ) [398]. The solid-liquid interactions between the formed Bi-Tu complexes and the solvent and the decomposition of the complexes under sealed conditions could be responsible for the formation of the  $\text{Bi}_2\text{S}_3$  NWs. In addition, the solvent acts as both reaction medium and dispersion medium so that it will prevent the aggregation of the particles and favor the production of uniform  $\text{Bi}_2\text{S}_3$  powder with good dispersivity in the SDP.

**Scheme 6.** The  $XY$  projection of the structural view of  $\text{M}_2\text{S}_3$  ( $\text{M} = \text{Bi, Sb}$ ), showing the infinite chain structure. The modeling was done with the Cerius<sup>2</sup> software (Accelrys).

The  $\text{Bi}_2\text{S}_3$  NWs prepared by SDP are much longer than those obtained by the hydrothermal treatment of an alkaline sol ( $\text{pH} = 8.0\text{--}10.0$ ) from  $\text{BiCl}_3$  and  $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ , with EDTA as a complexing agent, as shown in Figure 21. The direct mixing of  $\text{Bi}^{3+}$  with free  $\text{S}^{2-}$  with EDTA as complex in aqueous solution will result in spontaneous nucleation and produce a large number of nuclei. Then the nucleation is more accelerated than the growth. Therefore, only smaller particles can be produced. In contrast, the decomposition of the Bi-Tu complexes in the SDP will proceed slowly and produce a smaller number of nuclei in the solution than the direct ion-exchange reaction due to the position-resistance effect of the formed Bi-Tu complexes and its relatively stable property, which would be favorable for the oriented growth of the NWs. Therefore, the growth stage is more accelerated than the nucleation stage, since the system can finish the nucleation stage with a smaller number of nuclei.

$\text{Sb}_2\text{S}_3$  NRs can also be easily produced with high yield by the same procedure [315]. When anhydrous  $\text{SbCl}_3$  was added to the methanol solution of thiourea, the solution immediately turned yellow, which implies that the  $\text{Sb}^{3+}$ -thiourea complex is formed in the solution. The formation of such a complex was confirmed by the IR spectrum, UV-vis spectrum, and  $^1\text{H}$  NMR spectrum.

In the IR spectrum of the  $\text{Sb}^{3+}$ -thiourea complex (Fig. 22a), three characteristic absorption peaks at  $3370\text{ cm}^{-1}$ ,  $3290\text{ cm}^{-1}$ , and  $3184\text{ cm}^{-1}$  can undoubtedly be assigned to the  $\text{-NH}_2$  stretching vibration. The  $\text{-NH}_2$  bands did not shift to lower frequencies with regard to pure thiourea (Fig. 22b), which indicates that a bond from the nitrogen to the metal is not present [404]. Meanwhile, the frequency of the C-N stretching vibration of the complex blue shifted from  $1474\text{ cm}^{-1}$  in pure thiourea to  $1511\text{ cm}^{-1}$ , which approaches the value for a double bond. The blue shift of the C-N stretching vibration implies that thiourea uses the sulfur atom to coordinate with the metal ion in the complex [405]. The C=S stretching vibration of the complex at  $1413\text{ cm}^{-1}$  was split into two peaks because of the

**Figure 22.** IR spectra of the as-prepared complex (a) and pure thiourea (b). Reprinted with permission from [323], J. Yang et al., *Chem. Mater.* 12, 2924 (2000). © 2000, American Chemical Society.

formation of a metal-sulfur bond [405]. Another very apparent difference in the IR spectrum between pure thiourea and the  $\text{Sb}^{3+}$ -thiourea complex appeared at approximately  $1100\text{ cm}^{-1}$ . The strong absorption peak of pure thiourea at  $1084\text{ cm}^{-1}$  was extremely weakened in the complex. In addition, another band associated with a  $\text{C}=\text{S}$  vibration of the complex was red shifted from  $729\text{ cm}^{-1}$  in pure thiourea to  $709\text{ cm}^{-1}$ . The red shift can be attributed to the reduced double-bond character of the  $\text{C}=\text{S}$  bond due to the sulfur bonding with the metal.  $^1\text{H}$  NMR spectrum presents one broad unresolved peak at 6.96 ppm that is shifted to the high field with regard to pure thiourea. It seems that the increase in electron density around the hydrogen atom is caused by the coordination of the ligand with the metal ion.

The crystallization process of the  $\text{Sb}_2\text{S}_3$  NRs from the complex was followed by the XRD technique. The results show that the crystallinity of stibnite has been improved greatly with the prolonged reaction time. Figure 23a shows that no diffraction peaks corresponding to the starting

**Figure 23.** XRD patterns of the products obtained by solvothermal decomposition at different times at  $120\text{ }^\circ\text{C}$ . (a) The precursor. (b) 2 h. (c) 3 h. (d) 6 h. (e) The standard. Reprinted with permission from [323], J. Yang et al., *Chem. Mater.* 12, 2924 (2000). © 2000, American Chemical Society.

materials were observed. When the precursor was treated in an autoclave for 2 h at  $120\text{ }^\circ\text{C}$ , amorphous stibnite was obtained, as shown in Figure 23b. When the treatment time was prolonged to 3 h, the violet-red stibnite obtained was poorly crystallized, as shown in Figure 23c. Until the treatment time reached 6 h, the black-gray stibnite obtained was not well crystallized. The crystalline products (Fig. 23d) were identified as orthorhombic stibnite with cell constants  $a = 11.228\text{ \AA}$ ,  $b = 11.329\text{ \AA}$ ,  $c = 3.844\text{ \AA}$ , which are close to the values in the literature (JCPDS file no. 6-0474).

The time-dependent shape evolution of the nanocrystals during the crystallization was followed. When the reaction lasted for 2 h at  $120\text{ }^\circ\text{C}$ , the  $\text{Sb}_2\text{S}_3$  powders obtained were composed of amorphous nanoparticles with irregular shape and an average size of about 65 nm. When the reaction time was prolonged to 3 h, some NRs appeared in the poorly crystallized  $\text{Sb}_2\text{S}_3$  powders. After 6 h all of the initial irregular particles transformed into well-crystallized NRs with an average diameter of 60 nm that is close to the size of the initial amorphous nanoparticles. In this transformation process, many neck-like connections were observed among the adjacent nanoparticles. Meanwhile, in the head or edge of the NRs just formed, there were many obvious bulges formed by different nanoparticles. The results suggest that probably the initial adjacent nanoparticles self-assemble together to form the final  $\text{Sb}_2\text{S}_3$  NRs with the crystallinity improved.

The transformation from amorphous nanoparticles to crystallized NRs is much faster in a closed system than that in an open system. When the same solution was refluxed for 6 h in an oil bath, the products obtained were still irregular nanoparticles, as shown in Figure 24a. When the reflux time was prolonged to 10 h, some NRs did appear in the products, although the majority of the latter remained as irregular particles (Fig. 24b). When the initial amorphous nanoparticles were taken out and were washed to remove the adsorbed reactants and by-products, they were still transformed into NRs from the initial irregular nanoparticles as shown in Figure 24c, when they were treated in a closed autoclave for 10 h at  $120\text{ }^\circ\text{C}$ . With increasing reaction temperature, large  $\text{Sb}_2\text{S}_3$  single crystalline NRs with lengths of  $5\text{ }\mu\text{m}$  and 100 nm in diameter can be synthesized in

**Figure 24.** TEM photographs of the products obtained by (a) refluxing the methanol solution of the precursor for 6 h at  $120\text{ }^\circ\text{C}$  in a flask; (b) refluxing the methanol solution of the initial nanoparticles for 10 h in a flask at  $120\text{ }^\circ\text{C}$ ; (c) maintaining the methanol solution of the initial nanoparticles at  $120\text{ }^\circ\text{C}$  for 10 h in an autoclave. methanol at 180 °C for 12 h. The Bi<sub>2</sub>S<sub>3</sub> and Sb<sub>2</sub>S<sub>3</sub> NWs/NRs with high aspect ratios may be useful for important applications. The time dependence of the shape evolution of the nanocrystals during the crystallization controlled by pressure can be illustrated as in Scheme 7.

The above solvothermal process can be rapidly extended for the synthesis of other chalcogenide nanomaterials through the choice of suitable reaction conditions and precursors. A recent report shows that Sb<sub>2</sub>Se<sub>3</sub> NWs with a diameter of 30 nm and lengths as long as 8 μm can be synthesized in diethylene (DEG) media at 120–140 °C by the solvothermal reaction, with SbCl<sub>3</sub>, ammonia, NaSO<sub>3</sub>, and Se as reactants [325]. The further optimization of the solvothermal reaction will make it possible to readily synthesize well-defined 1D III–IV nano-building blocks, which could be very useful for the synthesis of other 1D semiconductors based on sulfo salts of bismuth and related compounds and sulfoantimonates of antimony and related compounds.

### 2.5.3. Growth of Other Metal Chalcogenide Crystals

Both solvents and temperatures play important roles in the formation of different phases, their phase transformation, and morphologies of the products. It is possible to selectively synthesize metal chalcogenide nanostructured materials and grow large single crystals with perfect shapes and preferred sizes by choosing the suitable conditions. These materials with different phases and unusual shapes may have interesting catalytic, semiconducting, and magnetic properties. In this section, the influence of solvents on phase, shapes, and reactivity will be discussed with specific examples.

Various metal chalcogenide materials can be synthesized under mild conditions by the following solvothermal reaction [318, 372, 373]:

Table 4 lists experimental conditions for the synthesis of various metal chalcogenide materials and the characterization of the powders. As shown in Table 4, the solvothermal reactions in en proceed more completely than in other solvents such as py and THF, suggesting that the higher reactivity in en can be achieved compared with other solvents. Both solvent and temperature play key roles in the reaction, shapes, sizes, and phases. Solvent in particular has a significant effect on the morphology of the particles as shown in Table 4. The reaction of bismuth oxalate with selenium and tellurium proceeded in a manner similar to that of lead

**Scheme 7.** Pressure-controlled formation process of the Bi<sub>2</sub>S<sub>3</sub> and Sb<sub>2</sub>S<sub>3</sub> NRs.

oxalate. Bi<sub>2</sub>Se<sub>3</sub> particles with flake-like morphology are single crystal [318].

The influence of solvents on the phase transformation during the solvothermal reaction was well demonstrated by a Ni-S system [377]. A detailed study of the synthesis of various phases of nickel sulfide materials such as NiS, Ni<sub>3</sub>S<sub>2</sub>, NiS<sub>1.03</sub>, NiS<sub>2</sub>, metastable Ni<sub>3</sub>S<sub>4</sub>, and their phase transformation and the phase transformation under solvothermal conditions was recently reported to be studied with a liquid-solid interfacial reaction between nickel substrate and sulfur, and the reaction Ni<sup>2+</sup> ion with sulfur in different solvents such as en, water, ethanol, toluene, and py at lower temperatures (≤200 °C) [377]. When the nickel salt was used instead of metal Ni, the reaction proceeded more easily. The main results of the reaction between Ni<sup>2+</sup> and S in en at different temperatures are summarized in Scheme 8.

Through control of the reaction time, the phase transformation process from NiS (M) to NiS<sub>2</sub> (cubic) can be nicely captured. The SEM image in Figure 25a shows that NiS (M) whiskers, with diameters ranging from 1 μm and lengths up to several micrometers, and spherical NiS<sub>2</sub> particles with a size of 1.2 μm were found to coexist in the product obtained at 200 °C for 12 h. EDX analysis confirmed that the spherical particles and whiskers in Figure 25 are composed of exact compositions of NiS<sub>2</sub> and NiS (M) phases, respectively. The tips of the NiS whiskers tend to bend, “melt,” or dissolve further as shown in Figure 25b, indicating that the formation of the NiS<sub>2</sub> phase was at the expense of NiS (M) whiskers, and the transformation process from the NiS (M) phase to NiS<sub>2</sub> indeed exists during the reaction with the prolonging of the reaction time, which corresponds to the XRD results. Pure NiS<sub>2</sub> single crystals with well-defined dodecahedron crystals and uniform sizes of about 1.5–2.7 μm can be obtained by further prolonging the reaction time to 18 h at 200 °C as shown in Figure 25c. Figure 25d shows a typical NiS<sub>2</sub> single crystal with a well-developed dodecahedron {101} unit polytype shape and a size of 1.8 μm. Cubic NiSe<sub>2</sub> single crystals with a perfect octahedral shape and a size of 15 μm were obtained by a reaction of NiC<sub>2</sub>O<sub>4</sub> · 2H<sub>2</sub>O with Se in en [373]. FeSe<sub>2</sub>, CoSe<sub>2</sub> crystals can be synthesized by a modified solvothermal process [374].

Various ternary metal chalcogenide NRs such as CdIn<sub>2</sub>S<sub>4</sub> [346], CuInS<sub>2</sub>, AgInS<sub>2</sub> [347], AgBiS<sub>2</sub> [348], Ag<sub>3</sub>CuS<sub>2</sub> [349], Cu<sub>3</sub>SnS<sub>4</sub> [350], and PbSnS<sub>3</sub> [351] have been synthesized by solvothermal/hydrothermal approaches under mild conditions. Even though the mechanism of the reaction and the formation of 1D NRs are still not clear, solvothermal/hydrothermal processes have already shown powerful versatilities and capabilities in the controlled solution synthesis of nonoxide 1D nanocrystals, in contrast to previous high-temperature approaches.

### 2.5.4. Controlled Growth of 1D Chalcogen Nanocrystals with More Complexity

Chalcogens are a group of important elements with unique combinations of many interesting and useful properties [406], which are also important reactant sources for the generation of metal chalcogenides, such as for the synthesis of semiconductor materials.

**Table 4.** Summary of various metal chalcogenides synthesized by a solvothermal process, including experimental conditions such as reactants and mole ratio (M/E) (M = metal source, E = S, Se, Te), solvent, temperature, and time; the phases were detected by X-ray powder diffraction, symmetry, and the particle shape.

Trigonal selenium NWs with well-defined sizes and aspect ratios have been synthesized by a solution-phase approach [233, 234]. The first step of this approach involved the formation of amorphous  $\alpha$ -Se in an aqueous solution through the reduction of selenious acid with excess hydrazine by refluxing this reaction mixture at 100 °C:

When this solution was cooled to room temperature, the small amount of selenium dissolved in the solution precipitated out as nanocrystallites of trigonal *t*-Se. Cooling the solution to room temperature will produce a small amount of trigonal Se in the solution, which will act as seeds for the formation of a large amount of trigonal Se NWs during further aging of the solution in a dark place [233]. The 1D

morphology of the final product was determined by the linearity of infinite, helical chains of Se atoms contained in the trigonal phase.

A recent report by Xia et al. shows that single crystalline NWs of  $\text{Ag}_2\text{Se}$  can be synthesized by templating against the trigonal Se NWs [328, 329] at room temperature as shown in Figure 26.

In addition, trigonal tellurium NBs, NTs, and nanohelices can be synthesized [235, 236]. The tellurium NTs were synthesized by refluxing a solution of orthotelluric acid in ethylene glycol at  $\sim 197$  °C [235] as shown in Figure 27. The early stage shows that tubular structures grew from the cylindrical seeds as shown in Figure 27a.

A very simple controlled hydrothermal route has been developed for the synthesis of tellurium NBs, NTs, and nanohelices by reaction of sodium tellurite ( $\text{Na}_2\text{TeO}_3$ ) in aqueous ammonia solution at 180 °C [236]. The NBs have thicknesses of about 8 nm with widths of 30–500 nm and lengths up to several hundred micrometers, as shown in Figure 28a. The NBs tend to twist and form helices as shown in Figure 28b. When the NBs were further

twisted and rolled, NTs formed. In addition, an interesting nanostructure, a “coaxed nanobelt within a nanotube,” was observed, as shown in Figure 28c. The template-roll-growth mechanism and template-twist-joint-growth mechanism were proposed to explain the formation of such special nanostructures [236]. However, the detailed mechanism still needs to be investigated further.

The above novel chalcogen nanostructures can be rapidly used as templates for the synthesis of other, more specialized and more complex 1D and 2D metal chalcogenide nanostructures, which could find interesting applications.

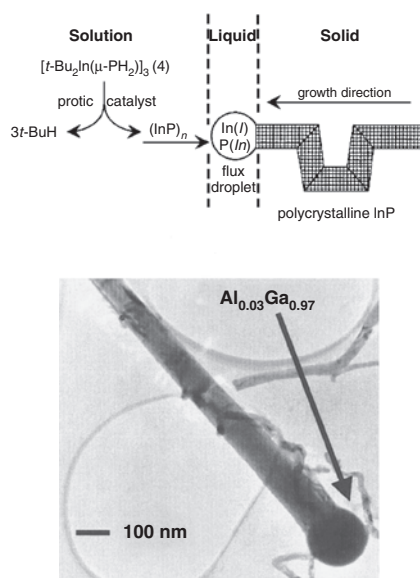

## 2.6. Solution-Liquid-Solid Mechanism

The solution-liquid-solid (SLS) growth mechanism, which is analogous to the well-known VLS mechanism, was first discovered by Buhro et al. [66]. This route is mainly for growing group III–V nanofibers (InP, InAs, GaAs,  $\text{Al}_x\text{Ga}_{1-x}\text{As}$ , InN) in hydrocarbon solvents at relatively low temperatures (less than or equal to 203 °C) [66–69]. More features about this route have been summarized in [67], as shown in Figure 29. The synthesis involved the methanolysis of  $\{t\text{-Bu}_2\text{In}[\mu\text{-P}(\text{SiMe}_3)_2]\}_2$  in aromatic solvents to produce polycrystalline InP fibers (dimensions 10–100 nm  $\times$  50–1000 nm) at 111–203 °C [68]. The chemical pathway consists of a molecular component, in which precursor substituents are eliminated, and a nonmolecular component, in which the InP crystal lattices are assembled. The two components working in concert comprise the SLS mechanism. The molecular component proceeds through a sequence of isolated and

J. Trentler et al., *J. Am. Chem. Soc.* 119, 2172 (1997), and [69], P. D. Markowitz et al., *J. Am. Chem. Soc.* 123, 4502 (2001). © 1997, 2001, American Chemical Society.

fully characterized intermediates to form the  $[\text{t-Bu}_2\text{In}(\mu\text{-PH}_2)_3]$  complex. The complex, which is alternatively prepared from  $\text{t-Bu}_3\text{In}$  and  $\text{PH}_3$ , undergoes alkane elimination catalyzed by the protic reagent  $\text{MeOH}$ ,  $\text{PhSH}$ ,  $\text{Et}_2\text{NH}$ , or  $\text{PhCO}_2\text{H}$ . In the subsequent nonmolecular component of the pathway, the resulting  $(\text{InP})_n$  fragments dissolve into a dispersion of molten In droplets and recrystallize as InP fibers [68].

This approach has been extended for the synthesis of InN NWs by solution-state thermolysis of the dialkyl(azido)indane precursor [259].

Group IV Si and Ge crystals can be generated by a supercritical fluid solution-phase approach [70]. Recently, Korgel et al. reported a supercritical fluid solution-phase self-assembly approach with a similar SLS mechanism for growing bulk quantities of defect-free Si NWs with diameters of about 4–5 nm and aspect ratios greater than 1000 by using alkanethiol-coated gold nanocrystals as uniform seeds to direct one-dimensional Si crystallization in supercritical hexane [71]. In this process, the sterically stabilized Au nanoparticles were dispersed in supercritical hexane together with diphenylsilane, which underwent decomposition at 500 °C and 270 bar. The phase diagram for Si and Au indicated that at temperatures above 363 °C, Si and Au will form an alloy in equilibrium with pure solid Si when the Si concentration with respect to Au is greater than 18.6%. Under this condition, the Si atoms dissolve into the sterically stabilized Au nanocrystals until the supersaturation is reached, at which point they are expelled from the particles as a thin nanometer-scale wire. The supercritical fluid medium with high temperature promotes Si crystallization. The Au nanocrystals will be maintained to seed NW growth under supercritical conditions.

## 2.7. Capping Agent/Surfactant-Assisted Synthesis

### 2.7.1. Self-Assembly under Hot Conditions

Capping agent/surfactant-assisted synthesis has been widely explored for the fabrication of NRs, NTs, and more complex structures. Recently, Alivisato's group synthesized the elongated CdSe nanocrystallites by injecting a solution of dimethylcadmium and selenium in tributylphosphine into a mixture of hexylphosphonic acid (HPA) and trioctylphosphine oxide (TOPO) at 340–360 °C [11, 72].

The surfactant molecules adsorb and desorb rapidly from the nanocrystal surface at the growth temperature, permitting the addition and removal of atoms from the crystallites, while aggregation is suppressed by the presence of (on average) one monolayer of surfactant at the crystallite surface. It is well known that the solubility of crystals increases as the size of the crystals decreases, according to the Gibbs-Thompson law. This law plays an important role in determining the growth kinetics of the nanocrystals. Peng et al. observed that if the monomer concentration in the solution is higher than the solubility of all existing nanocrystals, all nanocrystals in the solution grow and the size distribution narrows. The so-called focusing of size distribution can be exploited for the spontaneous formation of close to monodisperse colloidal nanocrystals and can form a three-dimensional orientation. The CdSe NRs with variable aspect ratios can be well achieved by kinetic control growth of the nanoparticles (Fig. 30).

The diverse range of observed shapes can be understood as arising from three basic effects: the nanocrystals will eventually tend toward nearly spherical shapes at slow growth rates; rods form at high growth rates by unidirectional growth of one face; and HPA accentuates the differences in the growth rates among various faces. A large injection

volume or a very high monomer concentration favors rod growth.

Recently, Peng et al. proposed a diffusion-controlled crystal growth model based on their careful observation of the shape evolution of CdSe NRs as shown in Scheme 9 [407]. They believed that a typical temporal shape evolution of CdSe quantum rods occurs in three distinguishable stages. When the Cd monomer concentration in the solution was between 1.4% and 2% of cadmium element by mass, all of the nanocrystals grew almost exclusively along their long axis, and both the aspect ratio and the volume of the crystals increased rapidly. This stage is called the “1D-growth stage.” The second stage, the “3D-growth stage,” occurred when the Cd monomer concentration dropped to between 0.5% and 1.4%. In this stage, crystals grew simultaneously in three dimensions [Fig. 31]. The aspect ratio remained constant, but the crystal volume increased. It should be mentioned that this stage was not observed before [11], probably because of the higher growth rates. The final stage, called “1D-to-2D ripening,” was identified when the Cd concentration was constant at 0.5%. The aspect ratio of the rods dropped noticeably, because the dimension of the crystals increased along the short axis and decreased along the long axis. Nanocrystal volumes and number remained constant, and there was no noticeable net growth or net dissolution of nanocrystals. This indicates that the monomers very likely moved on the surface of a crystal from one dimension ( $c$  axis) to the other two dimensions in an intraparticle manner.

The 1D-growth stage was confirmed by a reaction whose monomer concentration was maintained in the corresponding 1D-growth range for a longer time through the addition of more monomers to the reaction system at certain time intervals. The long axis of the quantum rods can be further extended from about 35 nm to over 100 nm by the secondary injections, but the short axis remained almost constant, at about 3–4 nm.

In this model, each crystal is surrounded by a diffusion sphere as shown in Scheme 9 [407]. The monomer concentration gradient between the bulk solution and the stagnant solution, as well as the diffusion coefficient of the monomers, determines the direction (out of or into the diffusion sphere) and the diffusion flux. The monomer concentration in the stagnant solution maintains the solubility of a given facet by the rapid growth onto or dissolution from the facet.

**Scheme 9.** A schematic diagram for the proposed mechanisms of the three stages of the shape evolution. The circle in each stage is the interface between the bulk solution and the diffusion sphere. Arrows indicate the diffusion directions of the monomers. The double-headed arrows represent the diffusion equilibrium in the 1D-to-2D ripening stage. Reprinted with permission from [407], Z. A. **Figure 31.** HRTEM image (a) of a typical tetrapod-shaped CdSe nanocrystal, looking down the  $[001]$  direction of one arm. Lattice spacings confirm that all four arms are of the wurtzite structure. In image (b), we see a tetrapod that has branches growing out of each arm. There are zinc blende layers near the ends of the original arms, and the branches are wurtzite with some stacking faults. Reprinted with permission from [72], L. Manna et al., *J. Am. Chem. Soc.* 122, 12700 (2000). © 2000, American Chemical Society.

The wurtzite structural characteristics are shown in Scheme 10, showing that all of the atoms on both facets perpendicular to the  $c$  axis (unique facets) have only one dangling bond without surface reconstruction [407]. The facets terminated by negatively charged Se atoms and positively charged Cd atoms are the  $(00\bar{1})$  facet and  $(001)$  facet, respectively. The negatively charged  $(00\bar{1})$  facet is more or less uncoated, because the ligands in the solution are all electron-donating ligands and should bind exclusively to cationic species. Additionally, without surface reconstructions, any surface Cd atom grown on the  $(00\bar{1})$  facet has to possess three dangling bonds, even if the surface Cd atoms reach a full monolayer. These unique structural features of the  $(00\bar{1})$  facet and the dipole moment along the  $c$  axis significantly increase the chemical potential of the unique facets, especially the  $(00\bar{1})$  facet, compared with the others [407].

The above surfactant-driven shape-controlled synthesis strategy was further extended for the synthesis of group III–VI semiconductor NRs for the first time by Cheon’s group

**Scheme 10.** Schematic structure of CdSe quantum rods in growth. The most stable form of a rod is shown on the left; its  $(00\bar{1})$  facet terminated by Se atoms does not have any ligands. After growing a monolayer of Cd atoms on the  $(00\bar{1})$  (right), this facet is still relatively active compared with the other facets, because the surface Cd atoms on this facet have three dangling bonds. See text for more details. Reprinted with permission from [407], Z. A. Peng and X. G. Peng, *J. Am. Chem. Soc.* 123, 1389 (2001). © 2001, American Chemical Society.

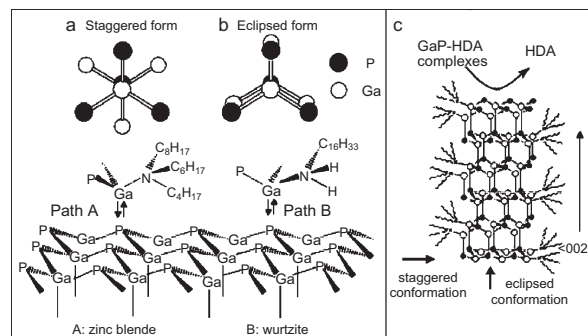

[254]. Gallium phosphide semiconductor nanocrystals can be synthesized by using thermal decomposition of a single molecular precursor, tris(di-*tert*-butylphosphino)gallane ( $\text{Ga}(\text{PtBu}_2)_3$ ), in a hot mixture of amine stabilizers. As in the case of CdSe, the shape of GaP nanocrystals can also be varied from nanospheres to rods with highly monodispersed size distributions by controlling the type and amount of stabilizing surfactants.

When only trioctylamine (TOA) was used as a stabilizer, spherical GaP nanoparticles with zinc blende structure were formed. Increasing the stabilizer ratio of HAD to TOA leads to the formation of NRs [254]. The addition of HDA to TOA leads to changes in the shape and crystalline phase of the GaP nanocrystals. Figure 32 shows that wurtzite GaP NRs with a diameter of 8 nm and a length of 45 nm were grown by thermal decomposition of the precursor in TOA solution, which was injected into a mixture of TOA and hexadecylamine (HDA) at 330 °C. A low HDA-to-TOA ratio seems to favor the formation of zinc blende nanospheres, but a high concentration of HDA leads to the formation of the wurtzite phase and induces anisotropic growth of the nanocrystals [254].

The steric effects of the stabilizers during crystal growth are illustrated in Scheme 11 [254]. The thermodynamically stable GaP zinc blende structure is a staggered conformation with  $\langle 111 \rangle$  directions, and the kinetically stable wurtzite structure is an eclipsed conformation with  $\langle 002 \rangle$  directions (Scheme 11). Kinetic stability of the wurtzite structure is induced by strong dipole interaction of incoming GaP monomers with surface GaP lattice atoms. The conformation of crystal structures is highly affected by changes in the stabilizer, since stabilizers can dynamically bind to the crystal surfaces during the GaP crystal growth. When the highly bulky tertiary amines (e.g., TOA) are used as stabilizers, a staggered conformation is favored, minimizing steric hindrance between these ligands and GaP lattices (Scheme 11, path A), and zinc blende GaP is preferred over wurtzite. In contrast, when an excess amount of less sterically hindered HDA is added to TOA, the rotational barrier between GaP-HDA complexes and GaP lattices is reduced. Therefore, the formation of the kinetically stable wurtzite GaP is now facilitated (Scheme 11, path B) under the kinetic growth regime induced by a high monomer concentration [254].

**Figure 32.** Large-area TEM image (a) and a HRTEM image (b) of GaP nanorods. Reprinted with permission from [254], Y.-H. Kim et al., *J. Am. Chem. Soc.* 124, 13656 (2002). © 2002, American Chemical Society.

**Scheme 11.** Proposed mechanism for surfactant-driven steric effects on the crystalline phases (a, b) and rod growth (c) of GaP nanocrystals. Reprinted with permission from [254], Y.-H. Kim et al., *J. Am. Chem. Soc.* 124, 13656 (2002). © 2002, American Chemical Society.

The steric difference between these two stabilizers seems to induce the anisotropic growth of the wurtzite GaP. It is likely that, when wurtzite seeds are formed, sterically bulky TOA selectively binds to the other faces (e.g., 100 and 110 faces) with staggered conformation rather than to 002 faces and blocks growth on these faces. On the other hand, GaP-HDA complexes continuously supply monomers on the 002 faces with high surface energy and therefore promote growth along the *c* axis (Scheme 11c). In addition, the thermolysis of a monomeric precursor  $[\text{Zn}(\text{TePh})_2][\text{TMEDA}]$  prepared from  $\text{Zn}(\text{TePh})_2$  and donor ligand TMEDA in a mixed surfactant trioctylamine-dimethylhexylamine produced ZnTe NRs [312], which could be templated from the rod-like micelles formed in the mixed-solvent system.

Currently, this approach has been successfully applied to the synthesis of transition metal NRs such as Co [205], Fe [208], and Ni [210], as well as perovskite  $\text{BaTiO}_3$ ,  $\text{SrTiO}_3$  NRs [104].

### 2.7.2. Self-Assembly under Natural/Mild Conditions

In contrast to the above capping agent/surfactant-driven synthesis of semiconductor NRs in hot solvent, self-assembly of nanofiber bundles, NTs, NWs, and their structure modulation under natural/mild conditions have emerged recently [25, 72–79]. The reverse micelle reaction medium usually consists of either the anionic surfactant AOT (sodium bis(2-ethylhexyl)sulfosuccinate) or nonionic surfactants. Various kinds of 1D inorganic NRs/NWs such as  $\text{BaCrO}_4$ , [25, 75],  $\text{BaSO}_4$  [74, 75],  $\text{BaCO}_3$  [77], and  $\text{BaWO}_4$  [78],  $\text{CaSO}_4$  [107],  $\text{CaCO}_3$  [408], CdS [292, 409], and Cu [410] have been synthesized in reverse micelle media or microemulsions. Other novel nanostructures, such as Ag nanodisc [192], flat CdS triangles [291], and CdS, CdSe NTs/NWs [76], can also be synthesized by this approach.

The strong binding interactions between surfactants and inorganic nuclei effectively inhibit the crystal growth and put the spontaneous structure reconstruction and self-organization of the primary nanoparticles under control. Micrometer-long twisted bundles of  $\text{BaSO}_4$  and  $\text{BaCrO}_4$  nanofilaments in water-in-oil microemulsions were prepared from the anionic surfactant AOT [25]. The reaction occurs at

room temperature in unstirred isoctane containing a mixture of  $\text{Ba}(\text{AOT})_2$  reverse micelles and  $\text{NaAOT}$  microemulsions with encapsulated sulfate (or chromate) anions. The reverse micelles are about 2 nm in diameter and consist of a spherical cluster of about 10  $\text{Ba}^{2+}$  ions strongly associated with the sulfonic acid headgroups of the surfactant, along with the water of hydration [25]. In contrast, the microemulsions are larger (4.5 nm across) because they contain bulk water (aqueous  $\text{Na}_2\text{SO}_4$  or  $\text{Na}_2\text{CrO}_4$ ) at a water-to-surfactant molar ratio of  $w = 10$ . When mixed together, the two reaction fields interact so that the constituents are slowly exchanged and  $\text{BaSO}_4$  or  $\text{BaCrO}_4$  nanoparticles nucleate and grow within the delineated space. With time, other filaments are formed parallel to the original thread to produce a small bundle of coaligned inorganic nanofilaments held together by surfactant bilayers. The locking in of new filaments by surfactant interdigitation generates a bending force in the nonattached segment of the longer primary thread. This results in the coiling of the bundle into a characteristic spiral-shaped structure several hundred nanometers in size that becomes self-terminating at one end because further addition of the primary nanoparticles is prevented by spatial closure.

The construction of higher-order structures from inorganic nanoparticle building blocks was successfully demonstrated by achieving sufficient informational content in the preformed inorganic surfaces to control long-range ordering through interactive self-assembly [25]. The NRs have flat surfaces with low curvature so that the hydrophobic driving force for assembly can be strengthened through intermolecular interaction, resulting in the formation of a bilayer between adjacent particles by the interdigitation of surfactant chains attached to nanoparticle surfaces. When the  $[\text{Ba}^{2+}]:[\text{SO}_4^{2-}]$  (or  $[\text{Ba}^{2+}]:[\text{CrO}_4^{2-}]$ ) molar ratio is equal to 1.0, remarkable linear chains of individual  $\text{BaSO}_4$  or  $\text{BaCrO}_4$  NRs are formed as shown in Figure 33.

**Figure 33.** TEM image showing ordered chains of prismatic  $\text{BaSO}_4$  nanoparticles prepared in AOT microemulsions at  $[\text{Ba}^{2+}]:[\text{SO}_4^{2-}]$  molar ratio = 1 and  $w = 10$ . Scale bar = 50 nm. Reprinted with permission from [25], M. Li et al., *Nature* 402, 393 (1999). © 1999, Macmillan Magazines Ltd.

Semiconductor NTs and NWs have recently been obtained with the use of nonionic surfactants such as *t*-octyl- $(\text{OCH}_2\text{CH}_2)_x\text{OH}$ ,  $x = 9, 10$  (Triton-X) and anionic surfactant AOT [76]. NWs of sulfides and selenides of Cu, Zn, and Cd with high aspect ratios can be prepared with Triton 100-X. The results show that it is possible to obtain both NTs and NWs of CdSe and CdS by this surfactant-assisted synthesis. For the synthesis of CdSe NTs, a suspension of cadmium oxide (10 mmol) was prepared in 20 ml of Triton 100-X (~24 mmol). A solution of  $\text{NaHSe}$  ( $\text{NaBH}_4/\text{Se}$  in 40 ml of water) was added dropwise under constant stirring to the suspension at 40 °C in an argon atmosphere. The resulting mixture was refluxed for 12 h and left overnight. The NTs are generally long, with lengths up to 5  $\mu\text{m}$ , as shown in Figure 34. The outer diameter of the NTs is in the 15–20-nm range, and the diameter of the central tubule is in the 10–15-nm range. The wall thickness is therefore around 5 nm. The formation mechanism of the NTs in the presence of surfactant is still not clear.

It should be pointed out that the poor crystallinity of the nanostructures obtained by this approach as well as the use of large excess surfactants could restrict the applicability of this approach.

## 2.8. Bio-Inspired Approach for Complex Superstructures

### 2.8.1. Polymer-Controlled Crystallization

Bio-inspired approaches to the synthesis of inorganic minerals have been a hot research subject [73, 80, 81]. Recently it was shown that so-called double-hydrophilic block copolymers (DHBCs) [81–94] can exert a strong influence on the external morphology and/or crystalline structure of inorganic particles such as calcium carbonate [82–85], calcium phosphate [86], barium sulfate [87, 88], barium chromate [89–91], cadmium tungstate [92], and zinc oxide [93].

Elegant nested calcium phosphate nanofibers were mineralized in the presence of DHBC poly(ethylene oxide)-*b*-alkylated poly(methacrylic acid) (PEO-*b*-PMAA- $\text{C}_{12}$ ), which was synthesized from PEO-*b*-PMAA by partial alkylation with dodecylamine [411]. Through the control of the pH of the  $\text{Ca}^{2+}$ -loaded polymer solution, delicate mesoskeletons of interconnected calcium phosphate nanofibers with star-like, neuron-like, and more complex nested forms can be obtained, as shown in Figure 35 [86].

**Figure 34.** TEM image of CdSe nanotubes obtained with Triton 100-X as the surfactant. Reprinted with permission from [76], C. N. N. Rao et al., *Appl. Phys. Lett.* 78, 1853 (2001). © 2001, American Institute of Physics.

Very long  $\text{BaSO}_4$  and  $\text{BaCrO}_4$  nanofibers and fiber bundles with remarkable similarity have been successfully fabricated by a polymer-controlled crystallization process at room temperature [88–90]. More complex morphologies of hashemite can be formed in the presence of partially phosphonated block copolymer poly(ethylene glycol)-*block*-poly(methacrylic acid) (PEG-*b*-PMAA- $\text{PO}_3\text{H}_2$ , PEG =  $3000 \text{ g mol}^{-1}$ , 68 monomer units; PMAA =  $700 \text{ g mol}^{-1}$ , 6 monomer units) [84]. Figure 36a and b shows SEM images of fibrous superstructures with sharp edges composed of densely packed, highly ordered, parallel nanofibers of  $\text{BaCrO}_4$ . The TEM micrograph with higher resolution in Figure 35c shows the self-organized nature of the superstructure. Whereas the majority of the fibers appear to be aligned in a parallel fashion, gaps between the single fibers can form but are also closed again. An electronic diffraction pattern taken from such an oriented planar bundle as shown in Figure 36d (right) confirmed that the whole structure

**Figure 36.** SEM and TEM images of highly ordered  $\text{BaCrO}_4$  nanofiber bundles obtained in the presence of PEG-*b*-PMAA- $\text{PO}_3\text{H}_2$  (21%, phosphonation degree) ( $1 \text{ g liter}^{-1}$ ) ( $[\text{BaCrO}_4] = 2 \text{ mM}$ ), pH 5. (a) Two fiber bundles with cone-like shape and length about  $150 \mu\text{m}$ . (b) Very thin fiber bundles. (c) TEM image of the thin part of the fiber bundles, inserted electronic diffraction pattern taken along the  $\langle 001 \rangle$  zone, showing the fiber bundles are well-crystallized single crystals and elongated along  $[210]$ . scatters as a well-crystallized single crystal where scattering is along the  $[001]$  direction and the fibers are elongated along  $[210]$ .

The initially formed nanoparticles stabilized by polymers are amorphous with sizes of up to 20 nm, which can aggregate to larger clusters. Evidently, this state of matter is the typical starting point for all types of highly inhibited reactions. The very low solubility product of barium chromate ( $K_{\text{sp}} = 1.17 \times 10^{-10}$ ) shows that the superstructures do not really grow from a supersaturated ion solution but by aggregation/transformation of the primary clusters formed [89].

All structures always grow from a single starting point, implying that the fibers grow against the glass wall or other substrates such as TEM grids, which obviously provide the necessary heterogeneous nucleation sites. The growth front of the fiber bundles is always very smooth, suggesting the homogeneous joint growth of all single nanofilaments with the ability to cure occurring defects, in line with the earlier findings for  $\text{BaSO}_4$  [88]. The opening angle of the cones is always rather similar, which seems to depend on temperature, degree of phosphonation of the polymer, and polymer concentration [89]. The control experiments show that the higher the temperature, the more linear the structures become. The superstructure developed more clearly, and to a much larger size, when the mineralization temperature was lowered to  $4^\circ\text{C}$ , as shown in Figure 37a. A rather lower phosphonation degree ( $\sim 1\%$ ) of a PEG-*b*-PMAA is already powerful enough to induce the formation of the fiber bundles and the superstructures, as shown in Figure 37b.

Interestingly, secondary cones can nucleate from either the rim or defects onto the cone, thus resulting in a tree-like structures (Fig. 37a). The fact that a cone stops growing once a second cone has nucleated at one spot on the rim shows that the growth presumably is slowing down with time, favoring the growth of the secondary cone. The cone-like superstructures tend to grow farther into a self-similar, multi-cone “tree” structure, which was observed before for barite mineralized in the presence of polyacrylates, but only under very limited experimental conditions [88]. From a structural viewpoint, the hashemite/barite crystals have a mirror plane perpendicular to the  $c$  axis, implying that a homogeneous nucleation will always result in crystals with identical charges of the opposite faces, and no dipole crystals can be formed. However, a dipole crystal may be favored

**Figure 37.** (a) A typical cone-like superstructure contains densely packed  $\text{BaCrO}_4$  nanofiber bundles in the presence of PEG-*b*-PMAA- $\text{PO}_3\text{H}_2$  (21%, phosphonation degree) ( $1 \text{ g liter}^{-1}$ ) ( $[\text{BaCrO}_4] = 2 \text{ mM}$ , pH 5), 2 days,  $4^\circ\text{C}$ ; (b) multi-funnel-like superstructures with remarkable self-similarity in the presence of PEG-*b*-PMAA- $\text{PO}_3\text{H}_2$  (1%, phosphonation degree) ( $1 \text{ g liter}^{-1}$ ) ( $[\text{BaCrO}_4] = 2 \text{ mM}$ , pH 5). Reprinted with permission from [89], S. H. Yu et al., *Chem. Eur. J.* 8, 2937 (2002). © 2002, Wiley-VCH.

for a heterogeneous nucleation as one end of the crystal is determined by the heterogeneous surface, the other by the solution/dispersion. The crystal has a dipole moment  $\mu = Q \cdot l$  ( $Q$  = charge and  $l$  = length of the crystal), which increases while the crystal is growing. This implies self-limiting growth so that a new heterogeneous nucleation event on the rim should become favorable after the dipole moment has reached a critical value due to energy minimization [89].

Based on the foregoing experimental observation and understanding, a self-limiting growth mechanism was proposed to explain the remarkable similarity of the superstructures [89] as shown in Scheme 12: (i) At the beginning, amorphous nanoparticles are formed, which are stabilized by the DHBCs (stage 1). (ii) Heterogeneous nucleation of fibers occurs on glass substrates, and the fibers grow under the control of a functional polymer, presumably by multipole field-directed aggregation of amorphous nanoparticles as proposed in [88]. (iii) The growth is continuously slowed down until secondary nucleation or overgrowth becomes more probable than the continuation of the primary growth. The secondary cone will grow as the first ones have done. (iv) The secondary heterogeneous nucleation event taking place on the rim can occur repeatedly, depending on the mass capacity of amorphous nanoparticles in the system.

A very recent observation shows that low-molecular-weight polyacrylic acid sodium salt serves as a very simple structure-directing agent for the room-temperature, large-scale synthesis of highly ordered cone-like crystals or very long, extended nanofibers made of  $\text{BaCrO}_4$  or  $\text{BaSO}_4$  with hierarchical and repetitive growth patterns as shown in Figure 38, where temperature and concentration variation permit control of the finer details of the architecture, namely length, axial ratio, opening angle, and mutual packing [90]. The formation of interesting hierarchical and repetitive superstructures is worth exploring further for other mineral systems.

Interestingly, single uniform  $\text{BaCrO}_4$  nanofibers can also be synthesized by a combination of polymer-controlled crystallization process and controlled nucleation by colloidal species producing locally a high supersaturation of both DHBCs and  $\text{Ba}^{2+}$ . The addition of a minor amount of a cationic colloidal structure such as PSS/PAH polyelectrolyte capsule (PSS/PAH: poly(styrene sulfonate, sodium salt)/polyallylamine hydrochloride) in the same reaction system can promote the independent growth of a number of

**Scheme 12.** Proposed mechanism for the formation of  $\text{BaCrO}_4$  complexity superstructure with self-similarity by polymer-controlled crystallization. Reprinted with permission from [89], S. H. Yu et al., *Chem. Eur. J.* 8, 2937 (2002). © 2002, Wiley-VCH.

**Figure 38.** Complex forms of  $\text{BaSO}_4$  bundles and superstructures produced in the presence of 0.11 mM sodium polyacrylate ( $M_n = 5100$ ), at room temperature,  $[\text{BaSO}_4] = 2$  mM, pH = 5.3, 4 days. fibers, thus leading to the dynamic discrimination of side nucleation and the resulting altered superstructures.

In addition to the formation of the mentioned superstructures under the control of block copolymers, DHBCs can also be used to fine-tune the nanostructural details of other inorganic crystals. Very thin 1D and 2D  $\text{CdWO}_4$  nanocrystals with controlled aspect ratios were conveniently fabricated at ambient temperature or by hydrothermal ripening under the control of DHBC [92]. The TEM image in Figure 40a shows very thin, uniform  $\text{CdWO}_4$  NRs/NBs with lengths in the range of 1 to 2  $\mu\text{m}$  and a uniform width of 70 nm along their entire length (aspect ratio of about 30). The thickness of the NBs is  $\sim 6\text{--}7$  nm. The slow and controlled reactant addition by the double-jet technique under stirring maintains the formation of intermediate amorphous nanoparticles at the jets [84] so that nanoparticles are the precursors for further particle growth rather than ionic species. Successive hydrothermal ripening after the double-jet reaction leads to a rearrangement of the rods into 2D lens-shaped, raft-like superstructures with a resulting lower aspect ratio, as shown in Figure 40b. In contrast, very thin and uniform nanofibers with a diameter of 2.5 nm, a length of 100–210 nm, and an aspect ratio of 40–85 as shown in Figure 40c

**Figure 39.** TEM images and electron diffraction pattern of the separated and very long  $\text{BaCrO}_4$  nanofibers with high aspect ratio obtained in the presence of a small amount of PSS/PAH capsules ( $20 \mu\text{l}$ ), PEG-*b*-PMAA- $\text{PO}_3\text{H}_2$ ,  $1 \text{ g liter}^{-1}$ ,  $[\text{BaCrO}_4] = 2$  mM, pH 5,  $25^\circ\text{C}$ . **Figure 40.** TEM images of the samples obtained under different conditions. (a) and (b) No additives: (a) pH = 5.3, double jet,  $[\text{Cd}^{2+}]:[\text{WO}_4^{2-}] = 8.3 \times 10^{-3}$  M (final solution), at room temperature; (b) pH = 5.3, double jet,  $[\text{Cd}^{2+}]:[\text{WO}_4^{2-}] = 8.3 \times 10^{-3}$  M (final solution), then hydrothermal crystallization: 80 °C, 6 h. (c) pH = 5.3, in the presence of PEG-*b*-PMAA (1 g liter<sup>-1</sup>), 20 ml, double jet,  $[\text{Cd}^{2+}]:[\text{WO}_4^{2-}] = 8.3 \times 10^{-3}$  M (final solution), then hydrothermal crystallization: 80 °C, 6 h. (d) Direct hydrothermal treatment of 20-ml solution containing equal molar  $[\text{Cd}^{2+}]:[\text{WO}_4^{2-}] = 8.3 \times 10^{-2}$  M, pH = 5.3, at 130 °C, 6 h, in the presence of 1 g liter<sup>-1</sup> PEG-*b*-PMAA-PO<sub>3</sub>H<sub>2</sub> (21%). Reprinted with permission from [92], S. H. Yu et al., *Angew. Chem. Int. Ed.* 41, 2356 (2002). © 2002, Wiley-VCH.

can readily be obtained when the DHBC PEG-*b*-PMAA is added to the solvent reservoir before the double-jet crystallization process, and the mixture is then hydrothermally ripened at 80 °C. When the partly phosphonated hydrophilic block copolymer PEG-*b*-PMAA-PO<sub>3</sub>H<sub>2</sub> (21%) (1 g liter<sup>-1</sup>) is added at an elevated temperature of 130 °C, even without the use of the double jets but at higher concentrations and coupled supersaturation, very thin platelet-like particles with a width of 17–28 nm, a length of 55–110 nm, and an aspect ratio of 2–4 are obtained by a direct hydrothermal process, as shown in Figure 40d. The nanoparticles display an interesting shape-dependent evolution of the luminescent properties, which may be of interest for applications.

Polymer-controlled crystallization in water at ambient temperature provides an alternative and promising tool for the morphogenesis of inorganic nanocrystals and superstructures that could be extended to various systems.

### 2.8.2. Supramolecular Self-Assembly

Supramolecular directed self-assembly of inorganic and inorganic/organic hybrid nanostructures has been emerging as an active area of recent research. The recent advance shows the remarkable feasibility of mimicking a natural mineralization system by a designed artificial organic template.

The supramolecular functional polymer can be directly employed for mineralization template of novel inorganic nanoarchitectures. CdS helices were successfully templated from supramolecular nanoribbons [94]. This novel inorganic nanostructure has a coiled morphology with a pitch of 40–60 nm, which can be rationalized in terms of the period of the twisted organic ribbons. A triblock architecture termed “dendron rodcoils” (DRC) can hydrogen bond in head-to-head fashion through dendron segments and self-assemble into nanoribbons [94]. The mineralization of the helical structures was done in both 2-ethylhexyl methacrylate (EHMA) and ethyl methacrylate (EMA). Figure 41 shows a typical CdS helix with a zigzag pattern and a pitch of 40–50 nm, which was isolated from a 1 wt% gel of the DRC in EHMA, to which a solution of cadmium nitrate in THF had been added prior to exposure to hydrogen sulfide gas [94]. HRTEM studies revealed that the polycrystalline zinc blende CdS is made up of small domains with grain sizes of about 4–8 nm. The results suggest that it is possible to achieve good control over the morphology of the templated product by using extremely uniform, stable, nonaggregated supramolecular objects as templates.

A peptide-amphiphile (PA) molecule was designed for the mineralization of PA nanofibers and hydroxyapatite (HAp) nanofibers [412]. This amphiphile molecule can assemble in water into cylindrical micelles because of the amphiphile’s overall conical shape, resulting in alkyl tails packed in the center of the micelle while the peptide segments are exposed to the aqueous environment [412]. The PA molecules were found to self-assemble at acidic pH but disassemble at neutral and basic pH. After self-assembly into nanofibers, the nanofibers were cross-linked by the oxidation of the cysteine thiol groups through treatment with 0.01 M I<sub>2</sub>. The cross-linked PA fibers contained intermolecular disulfide bonds, and intact fiber structures were still kept. These cross-linked fibers with negative charged surfaces are able to direct mineralization of HAp to form a composite material in which the crystallographic *c* axes of HAp are coaligned with the long axes of the fibers. The alignment of HAp nanofibers resembles the lowest level of hierarchical organization of bone [413].

In addition, supramolecular self-assembly using organogelators as template to transcribe inorganic nanostructures has been intensively studied. Organogelators are low-molecular-weight compounds that can gelate organic fluids at low

**Figure 41.** TEM micrograph of a typical CdS helix with a pitch of 40–50 nm precipitated in gels of the DRC in EHMA. Reprinted with permission from [94], E. D. Sone et al., *Angew. Chem. Int. Ed.* 41, 1705 (2002). © 2002, Wiley-VCH.

concentrations [414–419]. The gelators can gelate in organic solvents to form unique superstructures, which can transcribe inorganic nanostructures [420–429].

A helically structured silica has been successfully templated by a sol–gel transcription in chiral organogel systems [420–426]. The results show that certain cholesterol derivatives can gelate even tetraethoxysilane (TEOS), which can be used to produce silica by sol–gel polymerization [420]. Sol–gel polymerization of gelled TEOS solutions produces silica with a novel hollow fiber structure due to the template effect of the organogel fibers [420–426]. The formation of a three-dimensional network based on fibrous aggregates in organic fluids could be responsible for the formation of the gelling phenomenon.

This approach can be extended to the production of other metal oxide nanofibers or NTs with chiral structures.  $\text{TiO}_2$  fibers were fabricated with the use of an amphiphilic compound, *trans*-(1*R*,2*R*)-1,2-cyclohexanedi(11-aminocarbonylundecylpyridinium) hexafluorophosphate as template [427]. The amphiphilic compound containing cationic charge moieties is expected to electrostatically interact with anionic titania species under basic conditions in the sol–gel polymerization process of  $\text{Ti}[\text{OCH}(\text{CH}_3)_2]_4$ . Transition-metal (Ti, Ta, V) oxide fibers with chiral, helical, and nanotubular structures can be prepared by the sol–gel polymerization of metal alkoxides, with *trans*-(1*R*,2*R*)- or *trans*-(1*S*,2*S*)-1,2-di(undecylcarbonylamino)cyclohexane as structure-directing agents [428]. A recent report describes well-defined  $\text{TiO}_2$  helical ribbons and NTs obtained through sol–gel polymerization of titanium tetraisopropoxide  $[\text{Ti}(\text{O}_i\text{Pr})_4]$  in gels of a neutral dibenzo-30-crown-10-appended cholesterol gelator [429]. These chiral helical tubes could have various applications in electronics, optics, and photocatalysts.

### 2.8.3. Small Molecular Organic Species-Mediated Crystallization

In contrast to the previously mentioned polymer-controlled crystallization and supramolecular template synthesis, some small molecular organic species can also exert significant influence on crystal orientation growth.

A very recent report by Liu et al. describes unusually oriented and extended helical ZnO nanostructures grown from a synthetic ceramic method, which is surprisingly very similar to the growth morphology of nacreous calcium carbonate [95]. The helical ZnO nanostructures were grown on a glass substrate containing oriented ZnO NR arrays [430], which was placed in a solution containing  $\text{Zn}(\text{NO}_3)_2$ , hexamethylenetetramine, and sodium citrate and was reacted at 95 °C for 1 day. Figure 42 shows the similarity of SEM images of the helical ZnO nanocolumns (Fig. 42a and b) and the growth tip of a young abalone shell containing oriented columns of aragonite nanoplates (Fig. 42c). In the secondary growth on the helical NRs, aligned and well-defined nanoplates are formed, as in nacre. The side-width growth of the ZnO nanoplates leads to hexagonal ZnO plates that begin to overlap with one another.

**Figure 42.** Comparison of ZnO helical structures with nacre. (a) and (b) High-magnification image of oriented ZnO helical columns. (c) Nacreous calcium carbonate columns and layers near the growth tip of a young abalone. Reprinted with permission from [95], Z. R. Tian et al., *J. Am. Chem. Soc.* 124, 12954 (2002). © 2002, American Chemical Society.

The organic species were reported to act as simple physical compartments or to control nucleation or to terminate crystal growth by surface poisoning in the biomineralization of nacre [431, 432]. The similarity of the biomimetic structures of helical ZnO rods to nacreous  $\text{CaCO}_3$  indicated that helical growth might play some role in the formation of organized nacreous calcium carbonate. However, the organic species citrate ion still plays critical roles in the formation of such structures since the citrate ion has a large tendency to inhibit the growth of the (002) surfaces, possibly through selective surface adsorption.

The discussed polymer controlled mineralization and small molecular organic species-mediated mineralization could shed new light on the morphology and orientation control of inorganic crystals.

### 2.9. Oriented Attachment Growth Mechanism

Traditionally, crystal growth can be described as an Ostwald ripening process. The formation of tiny crystalline nuclei in a supersaturated medium occurred first and then was followed by crystal growth. The larger particles will grow at the cost of the small ones because of the difference between large particles and the smaller particles of a higher solubility. Penn and Banfield [96–98] confirmed that both anatase and iron oxide nanoparticles with sizes of a few nanometers can coalesce under hydrothermal conditions in a way called “oriented attachment” (Fig. 43). The crystal lattice planes may be almost perfectly aligned, or dislocations at the contact areas between the adjacent particles lead to defects in the finally formed bulk crystals. The so-called oriented attachment was also proposed by other authors for the crystal growth of  $\text{TiO}_2$  [99] and for micrometer-sized ZnO particles during the formation of rod-like ZnO microcrystals [100]. However, until now, no direct evidence has been reported.

**Figure 43.** TEM micrograph of a single crystal of anatase that was hydrothermally coarsened in 0.001 M HCl, showing that the primary particles align, dock, and fuse to form oriented chain structures. Reprinted with permission from [98], R. L. Penn and J. F. Banfield, *Geochim. Cosmochim. Acta* 63, 1549 (1999). © 1999, Elsevier Science.

A very recent report by Weller et al. provided some strong evidence that ZnO NRs can be conveniently self-assembled from small ZnO quasi-spherical nanoparticles based on the oriented attachment mechanism by the evaporation and reflux of a solution containing 3–5-nm smaller nanoparticles [102]. Previously, self-assembly of nanoparticles capped by ligands was mainly driven by the interactions of the organic ligands rather than by the interaction of the particle cores.

ZnO sol with an average particle size of approximately 3 nm as shown in Figure 44a was easily prepared by adding dropwise a 0.03 M solution of KOH (65 ml) in methanol to a solution of zinc acetate dihydrate (0.01 M) in methanol (125 ml) under vigorous stirring at about 60 °C. Refluxing of the concentrated solution leads to the formation of rod-like nanoparticles. Prolonging the heating time mainly leads to an increase in the elongation of the particle along the *c* axis. After refluxing for 1 day, single crystalline NRs with average lengths of 100 nm and widths of approximately 15 nm were formed, as shown in Figure 44b. The authors argued that oxide nanoparticles are very favorable for oriented attachment for two reasons: first, organic ligands, which prevent intimate contact of crystal planes, are usually not needed for stabilization; and second, crystalline fusion of correctly attached particles leads to a gain not only in lattice-free energy but also in the free energy of polycondensation [102].

The spontaneous aggregation and self-assembly of the small nanoparticles into very elongated NRs/NWs was again observed in the case of CdTe when the protective shell of organic stabilizer on the surface of the initial CdTe nanoparticles was removed [103]. The presence of “pearl-necklace” agglomerates as intermediates of the

**Figure 44.** TEM images of ZnO. (A) Starting sol. (B) After 1 day of reflux of the concentrated sol. The insets show high-resolution TEM images of individual nanoparticles. Reprinted with permission from [102], C. Pacholski et al., *Angew. Chem. Int. Ed.* 41, 1188 (2002). © 2002, Wiley-VCH.

nanoparticle-NW transition suggested that the growth mechanism could be related to a special interaction/attraction between the nanoparticles. A dipole-dipole interaction was believed to be the driving force for such self-organization of the nanoparticles [103]. This approach provides a new pathway to high-quality luminescent CdTe NWs, even though the yield is still low.

Although there have been only few reports on the self-organization of nanoparticles, this new growth mechanism could offer an additional tool for the design of advanced materials with anisotropic material properties and could be used for the synthesis of more complex crystalline three-dimensional structures in which the branching sites could be added as individual nanoparticles, and could even lead to nearly perfect crystals [101, 102].

### 3. SUMMARY

In this chapter, the state of art of the synthesis of low-dimensional nanocrystals and more complex superstructures through the different approaches has been overviewed. The current advances in synthetic methodologies demonstrated that it is possible to rationally design 1D, 2D, and even more complex superstructures.

The “hard” approaches, such as template-directed growth method, the VLS mechanism, the VS mechanism, and oxide-assisted NW growth routes, have shown their powerful and straightforward pathways to the target 1D nanomaterials and their superstructures with high crystallinity, although they usually require either a carefully and costly predesigned template or rather strict reaction conditions.

The “soft” approaches show very promising alternative pathways for the synthesis of 1D nanocrystals. In addition to the strategies of solvent-mediated shape and structure modulation, the soft-hard interface between polymers/surfactants (or organic species) and inorganic crystals is also an area of great interest at present. The current progress indubitably emphasizes that all crystals will probably be amenable to morphosynthetic control by use of the appropriate templating molecules. The emerging new solution routes to 1D NRs/NWs and more complex superstructures, such as the solvothermal process, the SLS mechanism, capping agent/surfactant-assisted synthesis, bio-inspired approaches, and the oriented attachment growth mechanism, open alternative doorways to low-dimensional nanocrystals and more complex superstructures. Among these solution strategies, the solvothermal process shows possibilities and versatility for selective synthesis of various semiconductor nanocrystals with controllable shape, size, phase, and dimensionalities under mild conditions. The successful synthesis of various semiconductor NRs/NWs with the use of a suitable ligand solvent as a “shape controller” indicates that the solvothermal process is indicative of a fruitful and promising route to 1D and 2D semiconductor nanocrystals in the future.

The further understanding on the nucleation, crystallization, self-assembly, and growth mechanism of the nanocrystals in these solution strategies should open new rational pathways to prepare various kinds of highly crystalline nanowires/nanorods, nanotubes with well-defined monodispersed, sizes, and aspect ratios, and highly ordered/oriented

complex superstructures. Furthermore, it is no doubt needed to investigate the relationship between the structural specialties (shape, sizes, phases, dimensionality, and complexity etc.) of the low dimensional nanocrystals and their properties, which could shed light on their novel applications and fundamental properties as building blocks in nanoscience and nanotechnology.

## 1. INTRODUCTION

Microscopic particles such as small pollen grains bounce erratically when immersed in water. The discovery of this phenomenon, systematically investigated by Brown [1] but observed long before, was the starting point in the study of fluctuations and noise. Almost eight decades were necessary for the scientists to understand that brownian motion is one of the most subtle macroscopic manifestation of the microscopic world. Fluctuations or noise proved to be very fine tools to access the microscopic world for they allowed the determination of the Avogadro number [2], Boltzmann constant [3, 4], the electron charge [5, 6], and, more recently, the fractional Laughlin charge,  $e/3$ , where  $e$  is the elementary charge [7].

Since Schottky's magistral work on the vacuum diode [8], it became clear that the performances of the electronic devices processing the signals are fundamentally limited by their intrinsic noise. Soon after Schottky's discovery, Johnson found that the brownian motion of the charged carriers generates thermal noise [3]. Both shot noise and thermal noise are unavoidable and act as fundamental limits,

especially in the high-frequency domain. During his experiments on thermal and shot noise, Johnson also found that at low frequency the noise spectrum in the vacuum diodes changes inversely to the frequency ( $1/f$  noise). For almost 80 years,  $1/f$  noise—as it is called today—proved to be a universal and one of the most difficult to explain phenomena.

Besides thermal, shot, and  $1/f$  noise, two other kinds of noise were found in semiconductors and the new solid-state devices: generation–recombination noise and a kind of noise which consists of random switching between two (or more) distinct levels. In large devices, it was called burst or popcorn noise, while in small dimensional structures it is known as random telegraph signal (RTS) noise. The unabated scaling of the device dimensions is systematically approaching the microscopic roots of these low-frequency noise phenomena. This inexorable trend requires the reduction of power supply voltages, which “amounts to reduction in the signal noise level” [9]. The top down approach in the contemporary nanotechnology will encounter some given thresholds where “the noise is the signal,” to quote Rolf Landauer [10] who used this syntagm in a different context, however. In nanoscaled solid-state devices, the signal to noise ratio is close to 1, thus leading us to the vicinity of the fundamental limits. As a consequence, finding where the noise comes from could be a *sine qua non* condition for the further evolution in the field. It is very interesting that the noise in nanostructures brings back to light some very old and unsolved problems regarding the controversial physical mechanisms of  $1/f$  noise.

In this context, the purpose of this contribution is twofold. On one hand, we will briefly review the status of the low-frequency noise research in nanomaterials and some nanostructures/nanodevices. On the other hand, we shall investigate whether the nanoscience could answer old, perennial questions, in the field of low-frequency noise. The very old yet hot problematics of the  $1/f$  noise will be discussed in the light of some new achievements in the nanoscience. It is shown that the very old question regarding the topology of the noise sources (surface or bulk origin) of this phenomenon is clarified, while its microscopic origin

cannot be unambiguously answered. Although present even in the quantum dots, the RTS noise as a fundamental component of the  $1/f$  spectrum seems to be a nonsequitur. The enhanced phonon density of states in nanomaterials seems to be a source of higher noise levels, while the surface anharmonicity is proposed as a possible ingredient in the generation of  $1/f$  noise in carbon nanotubes. The low-frequency noise appears to be a powerful tool to characterize nanomaterials and nanodevices.

## 2. SMALL IS BEAUTIFUL BUT NOISY

### 2.1. Infrared Catastrophe: From Vacuum Diode to Nanotriode and Carbon Nanotube

At high enough frequency, the noise of a vacuum diode is dominated by shot noise [8]. Below a given frequency, Johnson [3] observed that noise intensity starts to increase above shot noise. The noise continuously increases while the frequency decreases ( $1/f$ ). No tendency to roll off was found to date. Since its discovery, the phenomenon was found in an astonishing number of physical systems. In solid and solid-state devices,  $1/f$  noise is omnipresent. By analogy with the ultraviolet catastrophe in the theory of blackbody radiation,  $1/f$  noise was called infrared catastrophe.

Soon after its discovery,  $1/f$  and burst noise were found to dominate the low-frequency noise of bipolar transistors. In comparison with a vacuum triode, the bipolar transistor was very noisy [11], its performances being much worse than those of a vacuum diode. However, it was not due to the reduced dimensions of the new device but rather to the undeveloped technology. This is not the case for some microelectromechanical systems manufactured by advanced modern technology. For instance,  $1/f$  noise is the dominating noise mechanism in small piezoresistive ultrathin cantilevers [12]. Although a 100 nm thin cantilever features superior performances, its  $1/f$  noise is higher than in a 1  $\mu\text{m}$  thick cantilever [11]. Moreover, for the 100 nm thin cantilevers, the noise intensity increases while the volume decreases. The tendency for the noise is to decrease with the total number of the carriers in the cantilever, which is in agreement with the Hooge phenomenological formula [13],

$$\frac{S_V}{V^2} = \frac{\gamma}{Nf} \quad (1)$$

where  $S_V$  is noise spectral density, at a given frequency ( $f$ ), of a fluctuating voltage ( $V$ ) which develops across the terminals of a resistor when a current is injected in it;  $N$  is the total number of either electrons or atoms in the investigated sample (still in dispute). This fact clearly points out that the performances of reduced-dimensionality systems can be limited by noise. An illustrating example in this respect can also be the nanometer-scale electrometer whose ultimate performance at higher frequency is limited by thermal noise [14], whereas for frequencies lower than  $10^3$  Hz, the limits are imposed by  $1/f$  noise.

In fact, by reducing the dimensions we come closer to the limit imposed by the noise phenomena. Vacuum nanodiodes and nanotriodes have been recently fabricated and their

noise performances evaluated by Driskill-Smith et al. [15]. Nanopillars of 1 nm diameter or less and having heights up to 15 nm are formed on the cathode surface by a natural lithographic technique. In contrast to the classical vacuum diode, the electrons are emitted from the metallic cathode by the Fowler–Nordheim effect. The emission takes place at nanopillars, in a gas for nanodiodes and in vacuum in the case of the encapsulated nanotriodes. For both nanodiode and nanotriode, the turn-on voltage is about 8 V and does not depend on temperature. A fine structure in the field-emitted current (anode current) vs. gate voltage was observed from room temperature to 20 K. In the nanotriode, this structure does not depend on the time it has been registered or temperature, which suggests that it is an inherent property of the device. It is reminiscent of the universal conductance fluctuations observed in solid-state devices and is the fingerprint of the electron interference between cathode and anode.

As can be seen from Figure 1a, when a constant voltage is applied, the emission current shows time fluctuations. Bistable (burst or RTS) noise pulses were observed at room temperature, while at 20 K they disappeared. This behavior is in contrast to what happens in some other physical system such as, for instance, MOS transistors where the burst (RTS) noise becomes dominant at low temperature. When Fourier transformed, the  $1/f^\beta$  noise was found to dominate

**Figure 1.** (a) Current stability of the nanotriode at 300, 77, and 20 K. RTS noise is observed at room temperature. (b)  $1/f$ -like noise spectrum in a nanotriode operating at 6 nA and at 300 K, in the frequency ranges 0.03–10 Hz and 10 Hz–4 kHz. Reprinted with permission from [15], A. G. Driskill-Smith et al., *J. Vac. Sci. Technol. B* 18, 3481 (2000). © 2000, American Vacuum Society.

the noise performance of the nanotriode below about  $10^4$  Hz (Fig. 1b). The frequency exponent  $\beta$  is about 1.3, but a closer look at the spectrum indicates that this is somehow larger, namely, 1.43. This is mainly due to the presence of the bistable noise at room temperature. The  $1/f$  spectrum crosses the shot noise floor at a corner frequency of about  $10^5$  Hz [15], while from the Johnson's data (from 1925!) [3] for classical triodes, most of the corner frequencies are far less than  $10^5$  Hz. Apparently, the nanotriode is much noisier than the classical triode.

However, one can compare quantitatively the noise performance of the two devices. For instance, in a vacuum triode (see Fig. 7 from Ref. [3]), at a frequency of about 1000 Hz, "the ratio of the apparent to the actual charge of the electron," in the terminology used by Johnson himself [3], is about 10. This is nothing but the ratio between  $1/f$  noise intensity and shot noise,  $2eI$ , where  $e$  is the electron charge and  $I = 5$  mA is the average current through the triode. With these data, one obtains  $S_{\text{shot}} = 2eI = 1.6 \times 10^{-21}$  A<sup>2</sup>/Hz and  $S_{1/f} = 10 \times S_{\text{shot}} = 1.6 \times 10^{-20}$  A<sup>2</sup>/Hz. From the noise data for nanotriode [15], we have  $S_{1/f} \approx 10^{-24}$  A<sup>2</sup>/Hz, at a frequency of 1000 Hz, for a current  $I = 6 \times 10^{-9}$  A. Assuming that noise intensity depends quadratically on current for both devices, one obtains the normalized noise intensity  $S_{1/f}/I^2 = 6.4 \times 10^{-16}$  Hz<sup>-1</sup> for the classical triode and  $S_{1/f}/I^2 = 2.7 \times 10^{-7}$  Hz<sup>-1</sup> for the nanotriode. Hence, in terms of normalized values, the nanotriode is apparently much noisier (eight orders of magnitude!) than the vacuum triode. However, this difference could be much smaller if the comparison is made between the  $1/f$  noise parameters,  $\gamma$ , because it depends on the total number of carrier ( $N$ ) in the sample. The simplest way out is to compare, as Johnson did [3], the Fano numbers, which is the ratio between the actual  $1/f$  noise and the shot noise intensity:  $S_{1/f}/S_{\text{shot}}$ . In this case, at the same frequency (1000 Hz),  $S_{1/f}/S_{\text{shot}} = 10$  for the vacuum triode and  $S_{1/f}/S_{\text{shot}} \approx 10^3$  for the nanotriode. Consequently, the very small nanotriode is two orders of magnitude noisier than its classical counterpart.

In the same line of argumentation, it came as a big surprise when, recently, Collins and co-workers [47] reported very high  $1/f$  noise levels in single-walled carbon nanotubes. The noise intensity was 4 to 10 orders of magnitude higher than in conventional systems. By conventional systems they meant carbon resistors which are well known for their very high noise levels. Usually, the recommendations are that for low-frequency noise circuitry these resistors should be avoided. In this context, the applicability of the carbon nanotubes for low-frequency noise applications is of great concern: "Unless the excess noise can be somehow suppressed, this certainly calls into question the applicability of SWNTs [single-walled carbon nanotubes] for many low-noise electronic applications," to cite Collins and co-workers [47]. Although the contacts are suspected to play a role in the noise measurement on carbon nanotube, there are some other groups that reported similar results.

Besides increased noise levels, in small dimensional structures unusual noise spectra can occur. If properly interpreted, they could be invaluable in the understanding of the noise mechanisms, some of them still in dispute.

## 2.2. "Forgotten" Spectra: The Case of the MOS Transistor

The case of MOS transistor is of particular interest not because this device is very noisy but merely for the fact that it is the most important constituent of the present and future ultralarge scale integrated circuits. In a sense, it can be considered as a paradigmatic example for the evolution of an electron device from microscopic scale to the nanoscale dimensions [16]. Its high noisiness is due to the specific surface conduction mechanism in the channel. McWhorter number fluctuation mechanism [17] due to the tunneling into interface/oxide states was for quite a long time used to explain the occurrence of  $1/f$  noise in this device. Tunneling into a single state generates a Debye-Lorentz spectrum. If the states are uniformly distributed in the oxide and the distribution of their relaxation time ( $\tau$ ) is proportional to  $1/\tau$ , a  $1/f$  spectrum is obtained by Lorentzian superposition.

The noise intensity scales inversely with the channel length ( $L$ ) [18, 19]. For channel length  $L < 0.6$   $\mu\text{m}$ , the McWhorter theory fails to explain experimental data [18]. However, a Lorentzian superposition is still used to generate the  $1/f$  noise spectrum. This approach is based on the observation that in small MOSFETs, the RTS is the dominant noise source. This is due to a carrier capture into a single trap located around the Fermi level. Experiments performed on very small devices [20–23], usually in the mesoscopic region, revealed that only Lorentzian spectra corresponding to RTS noise are present. The quite general belief is that  $1/f$  noise decomposes into its fundamental components, so in reducing the dimensions what we are seeing is the contribution of each fluctuator [20–24]. Ghibaudo et al. [25] observed that the noise intensity in MOS structures increases by orders of magnitude when the scaling factor increases. Of great concern is also the fact that the noise sample-to-sample dispersion strongly increases (three orders wide) with the scaling factor. At the same time, "a strong evolution of the noise spectra from  $1/f$  to Lorentzian like for devices with the channel lengths from 1 to 0.1  $\mu\text{m}$ " [24] was calculated.

Nevertheless, the observation of Lorentz spectra in very small devices does not have a unique interpretation. An alternative explanation would be that the mechanism generating  $1/f$  noise does not exist anymore or it is so weak that the RTS noise is dominant. Some examples given in this chapter seem to support this statement. In a very small MOSFET there is a good chance of having no trap in the channel. A related question would be: does  $1/f$  noise disappear when there is no trap in the channel? A partial answer to this question already exists, since the experiments performed by the Grenoble school [25] showed that the residual signal after the subtraction of the RTS noise exhibits a  $1/f$  spectrum. Similar results were obtained long ago by Strasilla and Strutt [26].

In some small MOSFETs,  $1/f$  noise is somewhat hidden. For instance, recently Bu et al. [27] performed noise measurements on nanometric MOSFETs with 100 nm channel length and 25 nm channel width. Although RTS noise was present in the time trace, Figure 2 shows that neither  $1/f$  nor Lorentzian spectra were observed but a  $1/f^3$  spectrum was found. Such spectra were long searched by van der Ziel's

**Figure 2.**  $1/f^3$  input-referred noise spectra observed in a MOSFET with an ultranarrow channel at different gate voltages and  $T = 100$  K. Note that at frequencies lower than 100 Hz, the slope of the spectra is even higher. An RTS spectrum is presented for comparison. Reprinted with permission from [27], H. M. Bu et al., *Appl. Phys. Lett.* 76, 3250 (2000). © 2000, American Physical Society.

Minnesota school [28, 29] who predicted that such a spectrum could be described by the formula

$$S_I = \frac{A + B/f}{1 + (2\pi f)^2} \quad (2)$$

In this case,  $1/f$  noise and RTS noise go hand-in-hand, in the sense that one modulates the other. A spectrum of this form can be obtained only in the situation in which both phenomena have a common source. Such “forgotten” spectra are rarely discussed although they are not such a very *rara avis*. For, instance, a  $1/f^3$  spectrum was observed in a germanium filament by Mapple et al. [30] in 1955 and used by McWhorter himself in his famous paper (see Fig. 1 of Ref. [17]) to exemplify the existence of  $1/f$  noise. Apparently, these results do not support the RTS noise as the fundamental component of  $1/f$  noise. On the other hand, the fact that such a spectrum occurs in nanometer MOSFETs could be a chance to give an answer to this longstanding question.

Also, some experiments performed recently at Bell Labs [31] on deep submicron MOS transistors with 100 nm gate length and 40 nm gate oxide revealed that, in comparison with a  $0.5 \mu\text{m}$  gate length MOSFET, the  $1/f$  noise intensity increases by about two orders of magnitude and the spectrum spans over seven decades of frequency, with a corner frequency of about  $10^7$  Hz. To explain such an extension in the frequency, one needs more Lorentzians, therefore more traps. In direct connection with these results, one can come up with some questions such as: does the number of traps increases by decreasing the channel dimensions? This question has to be answered if credence is to be given to the idea that Lorentzian superposition is the source of the  $1/f$  noise. A possible answer to all these questions would be to look for other noise mechanisms in MOSFETs [32]. In essence, the new approach reveals the role of both surface and bulk phonons in the  $1/f$  noise generation in MOSFETs. Tunneling is not excluded but the noise is associated merely with the phonons which inelastically assist the carriers tunneling into surface states. The idea has also been

coined for some time in connection with the contribution of the RTS noise to the  $1/f$  noise [20, 33]. Recently, to check the role of the surface states, Kramer and Pease [34] proposed noise measurements on cylindrical surrounding-gate nanoscale MOS transistors. The dimension of the channel (few nanometers) could allow single or, possibly, “zero trap” behavior; hence, one can discriminate between different mechanisms of noise in MOSFETs. To date, we are not aware whether these measurements have been performed or not.

### 3. THERE IS MUCH NOISE AT THE BOTTOM [35]

#### 3.1. Low-Frequency Noise in Nanocrystalline and Nanoparticle Films

In the last half century, noise measurements have been performed on granular structures and discontinuous metal films. It is now well established that granularity and discontinuity are an important source of excess noise in these materials. In fact, it is considered that diffusion of the atoms at the grain boundaries or the tunneling between the metallic islands are the mechanisms responsible for the  $1/f$  noise generation in such systems. If in the case of some classical materials the granular structure was more or less accidental, this particular feature is a desired, intrinsic property of nanomaterials. The study of noise in granular, discontinuous, or grain-boundary-containing materials heralded what is going to happen in nanomaterials.

Specific to nanomaterials is the presence of the grain boundaries in a high concentration. Naturally, they strongly contribute to the scattering of conduction electrons, so they could be a source of excess noise. Performing noise measurements on gold nanocrystalline films, with grain diameters between 10 and 60 nm, Ochs et al. [36] found a  $1/f$  noise spectrum. Indeed, the noise intensity was about 5 times larger than in polycrystalline gold films. To our knowledge, this is the first noise measurement on a nanocrystalline film. Also, the grain boundary area per unit volume was found to be 5 times larger in nanomaterials than in the polycrystalline film. Consequently, the authors attributed the increased noise level to the presence of grain boundaries which “occupy a large volume fraction” [36] and, as such, large  $1/f$  noise is to be expected. According to Ochs et al. [36], noise measurement could be a novel tool to investigate the atomic motion at the grain boundaries between nanocrystallites.

Another way to understand why in nanocrystalline materials the  $1/f$  noise level is high would be to resort to the microscopic interpretation of the  $1/f$  noise parameter. As is well known, from Hooge’s [13] heuristic formula, the noisiness of a linear physical system can be evaluated by calculating the so-called  $1/f$  noise parameter,  $\gamma$ . Understanding the physical significance of this parameter has been a longstanding goal for the last three decades. In this respect, it has been recently proposed [37] that a connection between the  $1/f$  noise parameter ( $\gamma$ ) and the Eliashberg function,  $\alpha^2 F(\omega)$ , could exist,

$$\gamma \propto \alpha^2 F(\omega) \quad (3)$$

where  $F(\omega)$  is the phonon density of states,  $\alpha^2$  is the electron–phonon matrix element, and  $\omega$  is the atomic vibration frequency. The above equation predicts increased noise levels in systems with increased phonon density of states. Apparently, this is in contradiction with the role of the grain boundaries in generating excess  $1/f$  noise. However, recent results demonstrating that the atoms located at the grain boundaries are at the origin of enhanced phonon density of states in nanomaterials show that relation (3) is not incompatible with the role of the grain boundaries. For instance, it has been shown both theoretically [38, 39] and experimentally [40, 41] that in nanomaterials, at both low and high energy sides of the phonon spectrum, there is an enhancement in the phonon density of states. This enhancement is mainly “caused by the high number of grain-boundary atoms” [39], while the “atoms within grains do not noticeably contribute to the additional low-frequency modes” [41]. Moreover, the phonon density of states depends on the size and shape of the grains [41, 42]; namely,  $F(\omega)$  increases by decreasing grain size. This can explain, at least qualitatively, why in some physical systems the noise intensity increases with the particle size. All of these arguments support the idea that the increased noise levels observed by Ochs et al. [36] in nanocrystalline gold could be associated with an enhanced phonon density of states at grain boundaries.

Noise measurements have been used by Otten et al. [43] in order to investigate monocrystalline PbS nanoparticle films. The main goal was to look for an explanation of the “charge transport mechanisms in these structures” [43]. The samples were prepared by statistical deposition of 20 nm diameter PbS nanoparticles “until a nonhomogeneous film with a mean thickness of one monolayer is reached” [43]. As for the substrates, either GaAs or GaAs topped with a  $\text{SiN}_x$  layer for insulation was used. Prior to nanoparticle deposition, white noise has been detected on the  $\text{SiN}_x$  substrate. On GaAs samples, diffusion noise spectra have been found,  $1/f^\beta$ , with the slope  $\beta = 1/2$  and  $3/2$ . A problem here would be to explain where the factor  $1/2$  comes from, because it is specific to one-dimensional diffusion [44]. The weighted noise spectra exhibit maxima at frequencies which shift with the applied voltage. Assuming that the PbS nanoparticles create areas with different conductivity between the electrodes, it results that these areas “modulate the charge transport due to the interparticle potential barrier and the particle–substrate interface” [43]. The thermal agitation of the carrier between nanoparticles is influenced by the applied voltage through the interparticle potential. From the shift of the characteristic frequency, which is due to the different applied voltage [45], the diffusion coefficient can be calculated. Since the GaAs samples are three orders of magnitude more conductive than the  $\text{SiN}_x$ -type ones, the authors conclude “that the main charge transport takes place in the substrate and in the surface” [43]. Hence, the charge carriers located at the PbS nanoparticles randomly move between these and their movement is influenced by applied voltage through the interparticle potential. As is apparent from these results, the conduction phenomena in nanoparticle films could be quite complicated and the noise measurement offers a very fine tool to reveal as well as characterize them. This could prove very useful for device applications.

Tungsten trioxide ( $\text{WO}_3$ ) nanoparticle films have also been investigated by noise measurements by Hoel et al. [46]. The particles were deposited onto an indium tin oxide-coated glass substrate. Aluminum contacts were deposited on the nanoparticle film to create a capacitor. The authors found that thermal noise calculated from the ac impedance measurements is in very good agreement with the measured value, so the fluctuation–dissipation theorem is valid for this dielectric material.  $1/f$  noise has also been found, especially in the thinnest samples. It has been attributed to the penetrating columns of aluminum in the structure of the nanoparticles. All these results show “that noise measurements can be used for quality assessment of nanocrystalline insulating films” [46].

### 3.2. Low-Frequency Noise in Carbon Nanotubes: The End of an Old Controversy

The noise properties of carbon nanotubes are of great interest because they are perceived as the future building blocks for nanoelectronics and molecular electronics. The first noise measurements on carbon nanotubes have been performed by Collins et al. [47]. Excess  $1/f$  noise has been found in different configurations of SWNTs such as isolated individual tubes, two-dimensional (2D) films, and 3D materials. In a single SWNT, the noise power ( $S_V$ ) was found to depend quadratically on the dc biasing current. Therefore, as in many other solid-state physical systems,  $1/f$  noise in carbon nanotubes is due to genuine resistance fluctuations. A Hooge-type formula was used to characterize the absolute intensity of the voltage noise power for all 1D, 2D, or 3D morphologies:  $S_V = AV^2/f^\beta$ . Collins et al. found that the parameter  $A$  is a function of the sample resistance:  $A = 1.0 \times 10^{-11}R$ . For a sample with a resistance  $R = 100 \Omega$ , the noise amplitude is  $A = 10^{-9}$ . When compared with the conventional systems, such as high quality metal films or metal film containing grain boundaries, or damaged by electromigration or ion bombardment, carbon fibers or very noisy carbon composite resistors, the  $1/f$  noise in carbon nanotubes was found to be four to ten orders of magnitude larger! Carbon resistors are well known for their very high noise levels and usually, it is recommended to avoid their use for low-frequency noise circuitry. If so, the high noise level could strongly hinder the applicability of the carbon nanotubes in low-noise nanoelectronics.

When compared with the Hooge formula,  $A$  is simply connected with the  $1/f$  noise parameter ( $\gamma$ ) by the relation  $A = \gamma/N$ , where  $N$  is the total number of the carrier/atoms in the sample. For a SWNT with  $N = 10^4$  atoms  $\gamma \approx 0.2$ , which is two orders of magnitude larger than the value 0.002 postulated by Hooge [13]. The authors do not exclude the possible contact contribution to such large noise, although the measurements on 2D and 3D systems were done in a four-probe configuration. The authors suppose that the source of noise could be the electrical barriers at nanotube–nanotube junctions but this is not valid for single SWNTs. However, in this last case, the measurement was done in a two-probe configuration.

Recently, Roumiantsev et al. [48] have investigated noise on partially iron-filled, multiwalled carbon nanotubes

(MWNTs). Contacting the nanotube is a fundamental problem, in general, and in the noise measurements especially. In this experiment, the nanotubes were sprayed onto a SiO<sub>2</sub> surface and the individual nanotube, with optimal shape and most strategically placed in rapport to the previously deposited Cr/Au contacts, was contacted by focused ion beam (FIB) method. The noise measurements were done in the ohmic region of the  $I$ - $V$  characteristic. As in the case of Collins et al. [47],  $1/f^\beta$ -like noise spectra were found, with  $\beta$  close to unity. In contrast to the Collins et al. [47] results, Roumiantsev et al. [48] observed that the noise intensity is much smaller. Also, the current dependence of the  $1/f$  noise intensity was very different from the quadratic dependence found by Collins et al. [47]. In this case, the noise spectral density depends sublinearly on the injected current:  $S_V \sim I^\alpha$ , with  $\alpha$  between 1 and 1.5 for different samples. According to Roumiantsev and co-workers, “the noise could be generated by a small nonlinear contact resistance at the points of the contacts of FIB metal to the nanotube.” [48]. When measured in a simple FIB stripe, the noise showed a quadratic dependence on the current,  $S_I \sim I^2$ ; therefore the role of the contact is decisive in the noise measurements. It would be of interest to mention here that nonlinear effects in the  $1/f$  noise of a 2D electron gas have also been reported although the noise measurements were performed in the ohmic region of the  $I$ - $V$  characteristics [49]. The local deviations from the quadratic law have been attributed to the specific electron-phonon interaction in a 2D electron gas. Since the carbon nanotube is a quantum wire, one can expect nonlinear effects in its  $1/f$  noise even when the contact is perfect and this is due to the specific scattering mechanisms in a 1D electron gas. In addition, it is worth noting that the noise measurements of Collins et al. [47] were done at very small voltages (mV), while Roumiantsev et al. [48] measured at much higher voltages (volts). At these voltages, nonlinear effects can be very important.

$1/f$  noise has been very recently reported by Postma et al. [50] in individual metallic SWNTs. In equilibrium at room temperature, the thermal noise floor measured by Postma in a nanotube with a resistance  $R = 12.6$  k $\Omega$  was in excellent agreement with theory:  $S_V = 4k_B TR = 2.1 \times 10^{-16}$  V<sup>2</sup>/Hz, where the terms have their usual meaning. Under nonequilibrium conditions, when current is injected into the nanotube terminals, the noise spectrum of the voltage fluctuations is  $1/f$  and its intensity depends quadratically on voltage. For the resistance of 12.6 k $\Omega$ , a parameter  $A = \gamma/N = 1.8 \times 10^{-6}$  was found to fit the noise data. For a nanotube with a diameter of about 1.4 nm and a 0.5  $\mu$ m length [51], containing approximately 2000 conduction electrons, the  $1/f$  noise parameter is about  $\gamma = 3.6 \times 10^{-3}$ , very close to the value postulated by Hooge ( $2 \times 10^{-3}$ ). This value is at odds with the value calculated by Collins et al. [47], who found a two order of magnitude larger value. However, if it is to compare the noise data of Postma et al., for the nanotube with the resistance  $R = 12.6$  k $\Omega$ , with those of Collins et al., from the fitting relation  $A = 1.0 \times 10^{-11} R$  of Collins et al. [47], one finds  $A = 1.26 \times 10^{-7}$ , an order of magnitude smaller than the value obtained by Postma. In fact, the experimental values determined by Collins et al. (Fig. 3 from Ref. [47]) are of the order  $10^{-6}$ ; hence there is no discrepancy between the Postma et al. data and those

of Collins et al. in terms of parameter  $A$ . The discrepancies in the  $\gamma$  values come from the fact that Collins considers  $N = 10^4$  to be the total number of the atoms in the sample, while Postma considers  $N = 2000$  the total number of the conduction electrons in the sample.

Postma et al. also stated that “carbon nanotubes provide the right ingredients to study the origin of  $1/f$  noise in detail” [50]. Indeed, the temperature dependence of the  $1/f$  noise in carbon nanotube seems to be relevant for the physical mechanism of the  $1/f$  noise. It has been recently shown that the frequency exponent ( $\beta$ ) could be affected by the lattice anharmonicity (nonlinearity) [37]. The anharmonicity participation in the  $1/f$  noise can also be inferred from some simple analogies between the temperature dependence of  $1/f$  noise and the thermal conductivity of carbon nanotubes. In the first measurement on the temperature dependence of  $1/f$  noise in a SWNT, Postma et al. [50] reported that in a temperature range from 8 to 300 K, the  $1/f$  noise intensity ( $A$ ) increases by three orders of magnitude. In a temperature interval ranging from 4.2 to 290 K, Templeton and McDonald [52] found that  $1/f$  noise in conventional carbon resistors did not vary by more than an order of magnitude. The same situation was reported by Fleetwood et al. [53] between 77 and about 400 K.

The results of Postma et al. [50] are shown in Figure 3. Similar results were obtained on several samples, the sample-to-sample variation being roughly within one order of magnitude [51]. From Figure 3 one can speculate that there is a tendency in the noise to show a plateau or a maximum around 300 K. In the same temperature range, it has been experimentally demonstrated that the thermal conductivity of multiwalled carbon nanotubes increases by three orders of magnitude and exhibits a maximum at 320 K [54]. Also, Osman and Srivastava [55] calculated that the thermal conductivity of a nanotube with a diameter of 5 nm shows a maximum located at 300 K. It does not depend on chirality but on the diameter. This peak has been attributed to the participation of the phonon-phonon interaction, namely, to the Umklapp processes [54, 55]. If any, a maximum or a plateau in noise close to the temperature where the thermal conductivity is dominated by Umklapp processes would

**Figure 3.** Temperature dependence of the parameter  $A = \gamma/N = fS_V/V^2$  for a single-wall carbon nanotube. The inset shows the temperature dependence of the nanotube resistance. The lines are guides to the eye. Reprinted with permission from [50], H. W. Ch. Postma et al., in “Electronic Correlations: From Meso- to Nanophysics” (T. Martin, G. Montanboux, and J. Trần Thanh Vân, Eds.) EDP Sciences, 2001, France. © 2001, EDP Sciences.

suggest that also Umklapp phonons are involved in the noise generation. Even more interesting, since the nanotube is nothing but a rolled surface, we are dealing with the surface anharmonicity which is stronger than bulk anharmonicity. However, it would be quite unusual for the surface anharmonicity to explain such a huge noise, 4 to 10 orders of magnitude more than in carbon resistors, as observed by Collins et al. [47].

Individual and two crossing multiwalled carbon nanotubes were investigated by noise measurements by Ouacha et al. [56]. The nanotube diameter was about 10 nm and the length from 1.5 to 3  $\mu\text{m}$ . At frequencies below  $10^3$  Hz, the noise intensity ( $S_V$ ) exceeded the thermal noise limit. In the individual nanotube, the spectrum is  $1/f^{1.02}$ , while in the crossed nanotubes the noise intensity is higher and the spectrum is  $1/f^{1.56}$ . A frequency exponent close to  $3/2$  would indicate a 1D diffusion noise in nanotube [44]. Such an exponent was never observed before in a carbon nanotube and, according to the authors, it “indicates a current dependent coupling mechanism to the measured voltage noise” [56]. In the individual nanotube, the noise intensity depends quadratically on the current,  $S_I \sim I^{1.98}$ , while a superlinear dependence has been observed in the crossed nanotubes. The authors consider that this unusual dependence can be assigned to the presence of a small resistance at the junction between the two nanotubes, or, possibly, to the metal–nanotube contacts. On the other hand, the quadratic dependence found in individual nanotubes is a clear indication that  $1/f$  noise comes from conductivity fluctuation. The ratio between the current noise ( $S_I$ ) and the shot noise ( $2eI$ ) was calculated, at a frequency  $f = 10^4$  Hz, and found to be about 2.47 for voltages higher than 50 mV. It shows that the noise intensity is quite close to shot noise “which suggests the presence of an electrical barrier at the nanotube–nanotube junction” [56].

In spite of some disputable problems regarding the noise measurement in such a very difficult to access physical system, the experiments on single wall carbon nanotubes are a beautiful demonstration of how nanoscience can clarify some very old disputes in the field of  $1/f$  noise. For instance, in the case of SWNT there is no bulk atom. “Every atom that constitutes the SWNT is a surface atom” [47]. Hence,  $1/f$  noise in a SWNT is a pure surface effect, a statement which is in glaring contradiction with Hooge’s idea that “ $1/f$  noise is no surface effect” [13]. It was the  $1/N$  dependence, where  $N$  is the total number of the carriers in the sample, which caused Hooge to state that  $1/f$  noise is a volume effect. It is also a matter of evidence that in carbon nanotubes McWhorter’s [17] number fluctuation model does not work at all. In this context, the surface atomic motion as a microscopic source of  $1/f$  noise comes to the fore, as experimentally demonstrated in very thin (8 nm) discontinuous platinum films [57, 58]. In this case, the role of the surface atomic motion proved to be fundamental. Excess phonon densities of states were found in carbon nanotubes in comparison with graphite [59]. According to the relation (3) between the  $1/f$  noise parameter and the phonon density of states, this could be a cause for the excess noise in nanotubes, although it is difficult to invoke for a quantitative justification. However, it turned out recently that lattice anharmonicity affects the frequency exponent [37]; thus one

could extend this observation and suppose that anharmonicity is involved in the  $1/f$  noise of carbon nanotubes, too. If this holds true, the role of the anharmonicity can be much more important in SWNT than in MWNT because the surface atoms feature stronger anharmonicity than bulk atoms. It can explain, at least in principle, the different noise levels between SWNT and MWNT. In this context, we propose surface lattice anharmonicity as a possible ingredient in the generation of  $1/f$  noise. This can be the result of some non-linear excitations in nanotubes.

#### 4. WHEN THE ELECTRON IS THE SIGNAL: LOW-FREQUENCY NOISE IN SINGLE ELECTRON TRANSISTORS

The single electron transistor (SET) or the Coulomb blockade electrometer [60] is considered to be the most probable candidate to replace the MOS transistor although it is very likely that the MOSFET will also be scaled down to the nanometer range [16]. However, as recently pointed out by Ahmed [61], if it is to work with 10 electrons in the channel, due to fluctuations in the number of electrons it would be impossible to distinguish between the two classical 0 and 1 levels. In this context, the advantage of working with a single electron becomes evident. The major obstacle in application of the SET transistor in the “single electronics” is the excess  $1/f$  noise observed in the fluctuating charge of the island. If these noise sources could be eliminated, what remains is the shot noise, which is due to the intrinsic conduction mechanism in SET.

Measurements performed by Zimmerli et al. [62] revealed that the shot-noise energy sensitivity of a SET “could approach  $\hbar$  (Planck constant) if the source of  $1/f$  noise were eliminated.” The energy sensitivity ( $E_N$ ) is defined as the ratio  $Q_N^2/2C_S$ , where  $Q_N$  is the charge noise and  $C_S$  is the island capacitance. According to Zimmerli et al. [62],  $1/f$  noise in SETs would be “probably associated with the presence of charge traps in the dielectric surrounding the island electrode.”

Using a multilayer fabrication process, Vissher et al. [63] obtained SET structures with better noise performance. Although they used amorphous SiO as dielectric layer, well known for its high density of traps and defects, the charge noise  $Q_N$  was found to be  $4 \times 10^{-4} e/\sqrt{\text{Hz}}$ , an order of magnitude lower than the result of Zimmerli et al. [62]. Verbrugh et al. [64] observed that charge noise intensity increases with the island size. They have also revealed that  $I$ – $V$  characteristics of different SET structures are well fitted by a model where the heat flow from the device is limited by the electron–phonon coupling in the island.

As for the origin of the  $1/f$  noise in SETs, it is still unclear but experiments performed to date [65, 66] indicate that this is due to fluctuating traps “distributed either in thin dielectric layers (including the barriers) adjacent to the island or, alternatively but more likely, in a volume of the substrate” [65]. According to Zimmerman et al. [66], a “significant modulation of the transistor island charge” could be induced by some noisy defects located outside the tunnel barriers. However, in aluminum single electron tunneling transistors, Tavkhelidze and Mygind [67] have observed the same noise

spectrum for fixed bias on both slopes of  $V(V_g)$ , where  $V$  is the dc voltage across the device terminals and  $V_g$  is the gate voltage. This is a hint that noise could be brought about by the trapping near or inside the junction which limits the tunnel current through the device.

Altogether, these results indicate that the substrate whereupon the island is placed is strongly contributing to the noise of the SET. Employing a stacked design which eliminates the effect of the substrate, Krupenin et al. [68] effectively reduced the substrate contribution to the background noise of metallic SET structures. They have also found evidence of a noise source due to the barrier conductance fluctuations but the mechanism producing these fluctuations remained obscure. Besides a gain dependent noise, excess noise has been reported in both Nb and Al SETs [69] but the noise intensity did not follow a quadratic dependence on the voltage; it excludes the association of this noise with the resistance fluctuations. This excess noise was tentatively attributed to the current which heats the SET. The influence of the temperature on the excess noise in SETs is crucial for the high-temperature applications. Kenyon et al. [70] investigated the temperature dependence of noise in metallic SETs between 85 mK and 4 K. They have found that above 1 K, the noise intensity increases quadratically with the temperature. An effect yet to be explained is that below about 0.5 K, the noise intensity does not tend to zero but saturates.

Single electron transistors have also been fabricated in crossed [71], freestanding [72], and buckled nanotubes [73]. The Coulomb blockade effect was observed in devices made from both SWNTs [71] and MWNTs. Ahlskog et al. [71] obtained a single electron transistor by crossing two MWNTs of 15 nm diameter. At low temperature, the lower tube is metallic while the upper one, playing the role of gate, is semiconducting. The Coulomb blockade in this device developed only at sub-Kelvin temperatures (150 mK). The authors investigated the transport and noise properties of the lower nanotube. The noise was measured over one period of the gate modulation curve. "The noise measured at the output of the SET had approximately a  $1/f$  power spectrum" [71] and the noise intensity featured an irregular dependence on the gate voltage ( $V_g$ ). When compared to the gain variation, it has been revealed that the noise intensity corresponding to the zero-gain point at a maximum of the current is rather shallow. This indicates the presence of some other noise sources in the nanotube SET, in addition to the charge fluctuations amplified by the SET. This could be a current dependent noise source for the noise measurement done outside the Coulomb blockade (room temperature) revealed that the noise power in MWNT is roughly equal to the high noise level observed by Collins et al. [47] in SWNTs. The input equivalent charge noise sensitivity at 10 Hz is about  $6 \times 10^{-4} e/\sqrt{\text{Hz}}$ , which compares very well with the typical values for metallic SETs.

Trapping centers of charge close to the island or in the tunneling barrier cause the  $1/f^\beta$  ( $\beta \sim 1 - 2$ ) in SET structures. To reduce noise intensity in SETs one has to avoid contact of the central island with the dielectric material. This solution has been selected by Roschier et al. [72] to realize an ultrasensitive electrometer using a freestanding carbon nanotube as island. A MWNT with a diameter of 14 nm

was manipulated by atomic force microscopy to move on top of two gold electrodes. A side gate was used to modulate the current. Noise measurement on this structure evidenced  $1/f^2$  spectra at both minimum and maximum gain. The charge noise of this freestanding carbon nanotube SET strongly improved. At a frequency of 45 Hz, a value of  $6 \times 10^{-6} e/\sqrt{\text{Hz}}$  has been found, which is comparable with the best metallic SETs.

Using the atomic force microscope, Postma et al. [73] created two buckles in a metallic nanotube. The nanotube segment between the two buckles featured Coulomb blockade effects when the nanotube potential was varied by a nearby gate [73]. When measured as a function of gate voltage, at a frequency of 10 Hz and a temperature of 60 K, the noise intensity clearly shaped the peaked  $I_{\text{DS}}$  vs. gate voltage characteristic, where  $I_{\text{DS}}$  is the drain-source current. The optimum value of the input equivalent charge noise is  $q = 2 \times 10^{-3} e/\sqrt{\text{Hz}}$ , which reasonably compares with the values for the conventional SET at very low temperature (mK).

## 5. NOISE ENGINEERING IN SEMICONDUCTOR QUANTUM WIRES

A quantum wire (QWR) has one unconfined direction and therefore it is a 1D conductor. As a consequence, the electronic density of states is highly localized and peaked [74], allowing for high electron mobility. This property is extremely useful to realize different nanostructures such as QWR field effect transistors, to give only an example. Progress in this field was somewhat hindered by the photolithographic accuracy. However, this disadvantage has been recently removed by the realization of a self-organized QWR structure, a technique successfully applied to obtain  $\text{In}_{0.15}\text{Ga}_{0.85}\text{As}/\text{GaAs}$  quantum-wire field effect transistors with very good performances [75]. To date, the noise performances of the semiconductor QWR-based nanodevices have not been evaluated. Also, the noise data for the quantum wire itself are scarce. However, Sugiyama et al. [76] measured noise in both V-groove and ridge  $\text{InGaAs}$  QWRs of 10 nm thickness, 100 nm width, and 2  $\mu\text{m}$  length. For both QWRs the noise spectrum was  $1/f$ -like. In the V-groove QWR, a bulge in the spectrum was found at around 10 kHz. The estimated  $1/f$  noise parameter at 1 Hz was  $2.1 \times 10^{-3}$  for the V-groove QWR, while for the ridge one calculations led to a value of  $6.4 \times 10^{-4}$ . The differences between the  $1/f$  noise parameter have been put down to different factors such as surface scattering, interface roughness scattering, and strain.

Due to the one-dimensional phonon confinement and the singular density of electronic states, the quantum wire is a system of particular interest to investigate the  $1/f$  noise mechanisms. The first theory of the  $1/f$  noise in semiconductor QWR has been introduced and elaborated by Balandin and co-workers [77]. Other contributions are due to Bandyopadhyay, Svizhenko, and others [78]. The theory naturally adopts the hypothesis of mobility fluctuation because the trapping–detrapping in such one-dimensional systems is very improbable. Momentum relaxation contributes significantly to mobility fluctuation  $1/f$  noise because it modifies the change in the velocity ( $\Delta v$ ) of an electron in the collision process. In such a 1D system, an electron can be scattered

directly forward or directly backward; thus no sideways scattering is possible. The first process does not considerably change  $\Delta v$ , so it contributes weakly to  $1/f$  noise. On the contrary, backscattering, which typically turns the electron around, consistently modifies  $\Delta v$ , so its contribution to  $1/f$  noise is important.

Quantitatively, the general idea of the theory is to calculate the change in the velocity,  $\Delta v$ , of an electron due to a collision process.  $(\Delta v)^2$  is then averaged in the wavevector space ( $k$ -space) over all final scattering states weighted by the scattering rate. The result,  $(\Delta v)^2(k)$ , is then averaged to obtain  $\langle(\Delta v)^2\rangle$  by ensemble averaging over the initial states assuming, in the case of Balandin et al. [77], that their occupation is described by a drifted Maxwellian distribution.  $\langle(\Delta v)^2\rangle$  can also be obtained directly by Monte Carlo simulation, as was done by Bandyopadhyay and Svizhenko [78]. Once  $\langle(\Delta v)^2\rangle$  is known, the  $1/f$  noise parameter can be calculated [79] from  $\gamma = 4\alpha/3\pi[\langle(\Delta v)^2\rangle/c^2]$ , where  $\alpha$  is the fine structure constant ( $\alpha = 1/137$ ) and  $c$  is the speed of light. The effect of the magnetic field on the  $1/f$  noise parameter was also taken into consideration. Balandin et al. [77] found that the theory gives  $\gamma$  values which are “less than or comparable to that found in three-dimensional mesoscopic samples” [77].

From the above considerations, it follows that to control the noise in a quantum wire one has to relax the energy without relaxing momentum. In the case of a bulk sample, if high energy phonons would be involved in the energy relaxation, the momentum would be relaxed too. This is due to the fact that such phonons have a high wavevector; therefore backward scattering is favored and naturally the momentum strongly relaxes. Hence, one has to look for phonons of high energy but small wavevector ( $k$ ), because they can relax energy without strongly affecting the momentum. In a quantum wire, phonon folding due to quantum confinement allows for the energy relaxation without relaxing the carrier momentum [74]. Consequently, although phonon folding increases the scattering rate, the  $1/f$  noise intensity goes down. It results that  $1/f$  noise suppression in QWR is possible and that phonon folding can be exploited in order to make quieter devices. To this purpose, bulk devices could be replaced with parallel arrays of QWR [78].

At the same time, in the presence of a magnetic field, the noise is strongly reduced especially at lower temperature and low electric field [78]. The explanation for  $1/f$  noise quenching is that magnetic field “suppresses the acoustic phonon mediated backscattering by spatially separating the wavefunctions of oppositely traveling states in a quantum wire” [77]. A disadvantage of the acoustic phonon confinement in a QWR is that it also degrades the mobility and, therefore, affects other parameters of the nanodevices. A solution could be the presence of a magnetic field. In appropriately designed QWRs or quantum wire-based nanodevices, high magnetic fields can be locally produced by inserting magnetic quantum dots of Fe, Ni, or Co [78].

## 6. NOISE IN POINT CONTACTS AND METALLIC NANOBRIDGES

Historically, the first noise measurement in mechanical point contacts (PC) was done by Hooge and Hoppenbrouwers [80, 81]. By using shear deformation in liquid helium,

Yanson et al. [82] later fabricated noble metal point contacts with the diameter ( $d$ ) smaller than the electron mean free path ( $\lambda$ ). These are much better than the “needle-anvil” pressure-type contact. Since  $d < \lambda$ , the contacts are satisfying the condition of ballistic transport regime for electrons. From the  $I$ - $V$  curve nonlinearities, the second derivatives  $d^2V/dI^2$  have been determined which, according to Yanson’s [83] point contact spectroscopy method, are the image of the Eliashberg function (phonon spectrum),  $\alpha^2F(\omega)$ . The noise spectra observed in all contacts were  $1/f$ -like. In the case of silver, no similarity was found between the Eliashberg function and the energy dependence of the noise intensity, while for copper there are some similarities but only for energies larger than the optical phonon energy (approx. 30 meV). However, in the case of the gold point contact, there is a good connection between the noise structure and the Eliashberg function, especially for longitudinal phonon peaks (see Fig. 1 of Ref. [82]).

The most interesting result found by Yanson and co-workers [82] is an oscillatory structure in the noise which is “approximately periodic in eV and independent of d.c. voltage polarity.” At higher temperature the oscillations are slightly smeared out, indicative of their spectroscopic origin. The authors assigned the structure to the coherent phonon emission, but it was also suggested that Umklapp processes, among others, could be important.

The role of Umklapp phonons was later clarified in a paper by Akimenko et al. [84]. To this purpose they have measured noise, at and below 4.2 K, in point contacts of metals with different Fermi surfaces. Point contacts with diameters between 10 and 30 nm have been prepared from Na, Cu, and Sn. For sodium contacts, the point contact phonon spectrum and the noise intensity were determined as a function of energy (eV) in all possible regimes: ballistic regime (both momentum and energy mean free path are much larger than the diameter), diffusion regime (the electrons are elastically scattered by impurities or defects), and the thermal regime (the PC properties are bulklike material). A very clear phonon spectrum was observed in the ballistic regime. At the same time, the noise featured a very well defined fine structure composed of maxima and minima. In the diffusion regime, the phonon spectrum is not essentially modified, while the noise structure is strongly smeared out. Both the phonon spectrum and the noise structure practically disappear in the thermal regime. The phonon spectrum is determined by the energy distribution function, which is the same in both ballistic and diffusion regimes. This feature explains why no differences occur between the phonon spectra in the two regimes. What is essentially different between the two regimes is the momentum distribution function. This is the reason behind the fact that strong differences exist between the noise structure in the two regimes. Therefore, the noise spectra in PC is determined “by the momentum distribution function of electrons and thus are more intimately connected with the electron-phonon scattering dynamics” [84].

By far, the most interesting phenomenon observed in the ballistic regime is the structure of minima and maxima in the noise vs.  $eV$ . No correlation between this structure and the differential resistance ( $dV/dI$ ) in all PCs has been determined; therefore the structure cannot be associated

with the resistance change. As before, the noise minima have been correlated with the phonons having wavevectors close to the Brillouin zone boundaries for the correlated emission can explain the deep noise. For sodium and copper, the noise maxima correlate well with the Umklapp phonons which assist the transitions between the Fermi surfaces in the adjacent Brillouin zones.

The noise measurements in nanometric point contacts evolved as a very fine tool to investigate the transport properties in materials. Moreover, the results of Akimenko et al. [84] show that the noise spectra are more sensitive to the crystallographic anisotropy than the PC phonon spectra because of the strong anisotropy of the nonequilibrium phonon distribution. This property can be exploited to properly design low noise nanostructures and nanodevices.

By the means of electron beam lithography and reactive ion etching, Ralls et al. [85–87] and Holweg et al. [88, 89] patterned a nanohole in a silicon nitride membrane. Evaporating metal onto both sides of the membrane, a nanobridge is formed between the two massive electrodes. A sketch of the nanobridge is presented in the inset of Figure 4. The metallic nanobridge is the microfabricated equivalent of the mechanical point contact but its mechanical and electrical stability is much better. At low temperature, the electron mean free path ( $\lambda$ ) is much larger than the diameter of the nanobridge, thus leading to ballistic transport. This is the situation that was probed by both groups of authors who found high quality point-contact phonon spectra (Eliashberg function) in investigated nanobridges. For a constriction with the radius  $a$ , the resistance  $R$  can be approximated with the relation [86]

$$R = \rho/2a + 4\rho\lambda/3\pi a^2 \quad (4)$$

where  $\rho$  is the resistivity. The first term (Maxwell) dominates the resistance in the diffusive regime, while the second one (Knudsen) is dominant in the ballistic regime ( $\lambda \geq a$ ).

**Figure 4.** Eliashberg function (phonon spectrum) of a 15  $\Omega$  copper nanobridge, obtained by point-contact spectroscopy at 4.2 K. The spectrum is of high quality for the background signal is almost absent. The inset shows the schematic of the nanobridge, where  $a$  is the diameter of the nanoconstriction. Reprinted with permission from [85], K. S. Ralls and R. A. Buhrman, *Phys. Rev. Lett.* 60, 2434 (1988). © 1988, American Physical Society.

The last term depends only on the geometry of the constriction because  $\rho \sim 1/\lambda$ . According to the point-contact spectroscopy method [83], the derivative of  $R$  vs. applied voltage signal gives the phonon spectrum  $dR/dV \sim \alpha^2 F(\omega)$ , where the terms have their usual meaning. The phonon spectrum of a copper nanobridge, as determined by Ralls et al. [86], is shown in Figure 4. One observes that the background signal is very small and this is the proof that the nanoconstriction is of good quality.

Ralls et al. [86–88] performed detailed noise investigations on metallic nanobridges of copper, aluminum, and palladium with resistance ranging from 1 to 100  $\Omega$ , corresponding to the constriction diameter of (1.7–17) nm. The temperature dependence of the noise intensity differs from metal to metal. For instance, at temperatures below 150 K, sharp peaks in the noise were detected for copper and aluminum. They were assigned to “strategically placed defects” which give Lorentzian noise spectra. Below about 100 K, extremely rare two-level fluctuators (TLF) were observed in the Al nanobridge; therefore the noise was very small, impossible to measure. However, at about 100 K, the noise increases very sharply, one order of magnitude in about 20 K. In Pd, the metal with the highest melting point, the noise is almost temperature independent, although a close look at the data indicates some broad peaks in the noise, too. The different behavior of noise in the three metals is attributed to the “strong differences in the distribution of defect activation energies” [87]. Searching for the constituents, sometimes called fluctuators [90], of the  $1/f$  noise in metals, Ralls and Buhrman observed time trace noise signals in very small copper nanobridges at  $T < 150$  K. Usually, excess noise over the thermal noise was found only at some temperatures. The authors found that this excess noise is produced by resistance switching between two discrete levels. The amplitude of this random signal is independent of temperature and depends linearly on the applied bias, which points to the genuine resistance fluctuations. The average time ( $\tau$ ) spent in the low or high resistance state is thermally activated:  $\tau = \tau_0 \exp(E_0/kT)$ , where  $\tau_0$  is the so-called attempt time and  $E_0$  is the activation energy. For different fluctuators, the values of  $\tau_0$  were between  $10^{-11}$  and  $10^{-15}$  s, clustering around  $10^{-13}$  s, while the activation energies ranged from 30 to 300 meV. The attempt time value of  $10^{-13}$  s is characteristic for the atomic vibration in solid. From the amplitude of the resistance fluctuation  $\Delta R$ , the change in the cross section  $\Delta\sigma \sim \pi d^2(\Delta R/R)$ , where  $d$  is the constriction diameter, ranged from 0.28 to 3.6  $\text{\AA}^2$ , values of the order of atomic dimensions. Together with the values of the attempt time, the atomic dimensions of the cross scattering section point to “the individual atomic motion as the origin of this noise” [87]. Consequently, in the model elaborated by Ralls et al. TLF is generated by “reversible motion of a single defect in the constriction region between two metastable states” [87]. The above considerations show that low-frequency noise in nanobridges is not due to defect diffusion in nanoconstriction.

TLFs were also observed by Holweg et al. [89] in gold nanobridges. In both copper [86] and gold nanobridges [89], TLFs manifest at lower temperature and low bias voltages. At high voltages, many fluctuators are active and, at even higher voltages, net atomic motion (electromigration) occurs

in the sample. A consequence of the electromigration is that the average resistance changes. Different TLFs were observed in the time trace after such an event [86, 89]. The overall sample heating is excluded as a source of resistance fluctuation because of the small background signal observed in the phonon spectrum. Another reason is the asymmetry in the fluctuation rate as a function of the voltage polarity, an effect evidenced in both copper [86] and gold [89] nanobridges. A defect jumping back and forth in a double-well potential can be a source of two-level discrete resistance switching. Under the effect of the bias, the activation energy ( $E$ ) of the defect is modified,

$$E = E_0 - \zeta V \quad (5)$$

where  $\zeta$  is the electromigration parameter and  $V$  is the voltage. It was proved experimentally that for both bias polarities, the defect fluctuation rate increases, supposedly due to the fact that the temperature of the defect ( $T_d$ ) is higher than the lattice temperature ( $T$ ). Thus, one has to replace  $T$  with  $T_d$  in the expression of  $\tau$ :

$$\tau = \tau_0 [\exp(E_0 - \zeta V)/kT_d] \quad (6)$$

According to Holweg et al. [89], the local heating of the defect above lattice temperature is due to the inelastic scattering with the electrons. Under this assumption, a model, not presented here, was developed by Holweg et al. [89] which allowed for the calculation of  $T_d$ . With this expression, it was found that the relation (6) fits well the experimental dependence of the fluctuation rate in a gold nanobridge [89] in both lower and higher states of the resistance.

Ralls et al. [86] followed another way. First, from the experimental values of  $\tau_0$ ,  $E_0$ , and  $\zeta$  at low voltages  $V$ , the measured fluctuation time ( $\tau$ ) in an aluminum nanobridge was converted into an effective temperature of the defect ( $T_d$ ). Then, a model was elaborated which took into consideration the fact that the defect not only gains energy from the electrons but it can also lose energy to the lattice. They have found that the experimental data are well fitted by the theory for both bias polarities.

The effect of the lattice on the TLFs behavior in nanobridges, at large biases, was also investigated by Kozub and Rudin [91]. In this approach, the TLF is described with the help of the soft double-well potential model. Hence, the TLF behavior was investigated in terms of the interaction between the potential and the nonequilibrium phonons emitted by the ballistic (nonequilibrium) electrons. Calculating the probability for interlevel transition induced by both phonons ( $W_{ph}$ ) and the electrons ( $W_{el}$ ), they arrived at  $W_{ph} \geq W_{el}$ , which strongly supports the starting hypothesis. The analytical expression for the temperature of the defect (TLF) was finally found to fit well the bias dependence of the TLF relaxation time for aluminum, gold, and copper nanobridges. An important feature of the model is that it can explain the asymmetry of the TLF relaxation rate on bias polarity by the current flow direction-induced asymmetry in the spatial distribution of the nonequilibrium phonons. This asymmetry can be very different for normal phonons, in comparison with the Umklapp phonons.

In the theory of Kozub and Rudin [91], the role of nonequilibrium phonons is essential because they are

responsible for the activation of TLFs in nanobridges, hence for noise. Some other observations seem to further support this hypothesis. For instance, in a silver nanobridge, Holweg et al. [88] reported that the rms amplitude of the conductance starts to decrease at a bias voltage of 10 mV, which corresponds to the transverse-acoustic phonon peak in the point-contact phonon spectrum. This decreasing behavior was attributed to the phonon emission by electrons with excess energy  $eV$ . Another possible example is taken from Ralls and Buhrman [87]. They observed that noise in small resistance nanobridges—that is, “large” devices—is the same as in the bulk films deposited in the same manner. Large deviations occur for nanobridges of high resistance (small samples). To explain this, it was assumed that more active fluctuators exist in smaller samples and the cause could be the surface tension produced by the extremely small radius of curvature of the nanoconstriction. But a smaller radius can also lower the melting temperature and the activation energies for atomic motion in the nanobridge. As a consequence, they assumed that in small copper nanobridges one could get a maximum in the  $1/f$  noise intensity at a lower temperature than the one found (500 K) by Eberhard and Horn [92] for a bulk copper film. Indeed, as Figure 5 shows, for a  $7 \Omega$  ( $c \sim 6.4$  nm) nanobridge, a maximum exists at 350 K. Speculating about the origin of this peak, and in connection with the possible relationship (3) between the noise intensity and the Eliashberg function, we have tried to connect the maximum in noise with some specific phonon energies in copper [93]. In Figure 5, curve 1 represents the Eliashberg function for longitudinal phonons obtained by deconvolution of the point contact spectrum of Ralls and Buhrman (Fig. 1 from Ref. [87]) for a  $15 \Omega$  nanobridge. Its maximum at about 325 K is rather close to the noise maximum. In a better fit with the noise maximum is an Eliashberg function (curve 2 in Fig. 5) obtained by Yanson [83]

**Figure 5.** Comparison between the temperature dependence of the  $1/f$  noise spectral density ( $S_V$ ) in a  $7 \Omega$  copper nanobridge and the different Eliashberg functions: 1—from Ralls and Buhrman [85]; 2—from Yanson [83]. Curve 3 is the bulk phonon spectrum for copper calculated by Kurpick and Rahman [94]. Reprinted with permission from [93], M. Mihaila, in “Quantum  $1/f$  Noise and Other Low-Frequency Fluctuations in Electronic Devices” (P. H. Handel and A. L. Chung, Eds.), Am. Inst. Phys. Conf. Proc. Vol. 466, p. 48, American Institute of Physics, New York, 1999. © 1999, American Physical Society.

at 1.8 K for a Cu point contact of  $4 \Omega$ . It has a maximum at about 350 K, the better fit most probably due to the fact that the point-contact resistance is closer to the nanobridge resistance. Also shown in Figure 5 is the bulk phonon spectrum of Cu calculated in Ref. [94]. The highest peak, corresponding to the longitudinal phonons (30 meV), is located at the noise maximum.

As for the type of defect causing two-level resistance fluctuations, Ralls and Buhrman [87] did not get a definite answer. In any case, a single point defect is ruled out because there is no reason why interstitials, vacancies, or impurity atoms would jump between only two metastable positions. Complex time traces were found and analyzed by Ralls and Buhrman [85–87] in terms of the interactions between defects. In fact, they found that defect interaction dominates the fluctuation dynamics and it is the reason the system samples all times, which is essential for  $1/f$  noise. They conclude that there is actually no “independent defect even in crystalline films with elastic-scattering length of 200 nm” [87]. In this context, Ralls and Buhrman introduced the concept of “defect glass” as an entity composed of the defects involved, by their strong interaction, in the generation of  $1/f$  noise.

At room temperature, in both copper [87] and gold [89] nanobridges the resistance still switches but the noise spectrum changes from a Lorentzian, as it is at low temperature, to a  $1/f$ -like spectrum. Since the gold constriction is in the diffusion regime, Holweg et al. [89] calculated, from an estimation of the diffusive resistance, the  $1/f$  noise parameter ( $\gamma$ ). They obtained  $\gamma = 5.6 \times 10^{-3}$ , which is well within the domain found for other physical systems. The authors consider that this is an additional argument that  $1/f$  noise is due to the Lorentzian superposition. However, the frequency exponent of their spectrum is about 1.4, a value slightly outside the usual domain of the  $1/f$ -like frequency exponent ( $0.7 < \beta < 1.3$ ) and rather close to the specific diffusion noise exponent (3/2). A similar situation was presented by Ralls and Buhrman [87] for a copper nanobridge. In this case, the spectrum was also  $1/f$ -like, with  $\beta \approx 1.3$ . It seems that in the presence of TLFs at room temperature, the frequency exponent is always larger than 1 whereas, at low temperature, a pure TLF noise signal features a Lorentzian spectrum, as demonstrated by Holweg et al. [89]. This transition from a Lorentz spectrum to a  $1/f$ -like one is associated with the activation of many fluctuators. However, for the same physical system, the frequency exponent vs. temperature can be larger or smaller than 1, within the widely accepted values:  $0.7 \leq \beta \leq 1.3$ . At higher temperature, in the presence of TLFs, the frequency exponent tends to 1 but is consistently larger than 1. It would be interesting to see whether, in the presence of TLFs, the frequency exponent could be slightly lower than 1.

The first noise measurement in a quantum point contact (QPC) was done by Li et al. [95]. A 2D electron gas confined at the GaAs/AlGaAs heterointerface was constricted with two point-type gates (see the insert in Fig. 6). Figure 6 shows that the channel resistance ( $R$ ) has plateaus which are close (within 10%) to the theoretical quantized values ( $h/2eN$ , with  $N = 2, 3, 4$ , and 5). Below 1 kHz, the current noise spectrum  $S_I(f)$  has a  $1/f$  dependence and is described by the relation  $S_I(f) = A/f + S_{I0}$ , where  $S_{I0}$  is a white

**Figure 6.** Dependence of the point contact resistance  $R$  vs.  $V_g$  and of the parameter  $A_0$  vs.  $V_g$ . The values of  $A_0$  were obtained at three currents ( $I = 0.4, 0.5$ , and  $0.6 \mu\text{A}$ ) from the fitting relation  $S_I(f) = A_0 I^2 / f + S_{I0}$ . The approximate plateaus in  $R$  are assigned to the quantized resistance  $h/2e^2 N$ , where  $N = 2, 3, 4$ , and 5. Device geometry is shown in the inset. Reprinted with permission from [95], Y. P. Li et al., *Appl. Phys. Lett.* 57, 774 (1990). © 1990, American Physical Society.

noise background. In general, when the gate voltage ( $V_g$ ) is fixed, the coefficient  $A \sim I^\alpha$ , with  $\alpha = 2 \pm 0.4$  for  $-2.4 \text{ V} < V_g < -1.4 \text{ V}$  and current  $I < 0.6 \mu\text{A}$ . A new coefficient  $A_0 = A/I^2$  was defined and represented in Figure 6 vs.  $V_g$ , for  $I = 0.4, 0.5$ , and  $0.6 \mu\text{A}$ . With some exceptions,  $A_0$  is independent of current, increases as the channel width goes down (by decreasing  $V_g$ ), and features peaks between the  $R$  plateaus. In this case, the  $1/f$  noise is correlated with the resistance quantization. The authors consider that  $1/f$  noise in the quantum point contact “may result from some processes which are related to the 1D density of states in the channel” [95]. The white noise component  $S_{I0}$  was attributed to the trapping and detrapping of the conduction electrons at the GaAs/AlGaAs interface, its intensity being, quite unexpectedly, below the full shot noise.

Low-frequency noise spectroscopy has been used to investigate the kinetics of charge transport in quantum point contacts [96, 97]. Dekker et al. [96] observed that low-frequency noise characteristics of quantum point contacts vary from device to device. For instance, in a QPC the noise spectrum was a Lorentzian, while in another one the spectrum was  $1/f$ -like and “weaker by many orders of magnitude” [96]. Although the spectra are very different, in both QPCs the normalized spectral density ( $S_V/V^2$ ), at low temperature (1.4 K), exhibits strong universal quantum size effects. Figure 7 shows that  $S_V/V^2$  vs.  $G$ , where  $G$  is the conductance in units of  $2e^2/h$ , features sharp minima at the quantized conductance plateaus, where the Fermi energy  $\epsilon_F$  is between the bottom energies  $E_n$  of two 1D subbands. The maxima in noise occur between the plateaus in  $G$ , where  $\epsilon_F = E_{n+1}$ . Attributing the quantum size effects in noise “to fluctuations in the transmission probability for the subband which is closest to cutoff,” Dekker and co-workers [97] found that  $S_V/V^2 = 1/G^2 [\partial G / \partial \epsilon_F]^2 S_{EF}$ , where  $S_{EF}$  is the spectral density of the fluctuations of Fermi energy.

The factor  $[\partial G / \partial \epsilon_F]^2 / G^2$  vs.  $G$  is shown at the bottom of Figure 7. It is evident that the universality of the

**Figure 7.** Relative noise spectral density  $S_V/V^2$  vs. conductance ( $G$ ), at 1.4 K, for two quantum point contacts: QPC1 with  $1/f$  noise spectrum (values measured at 100 Hz) and QPC2 with Lorentzian spectrum (values measured on the Lorentzian plateau). Arrows denote upper bounds. Bottom figure: calculated factor  $[\partial G/\partial \varepsilon_F]^2/G^2$  vs.  $G$ . Reprinted with permission from [96], C. Dekker et al., *Phys. Rev. Lett.* 66, 2148 (1991). © 1991, American Physical Society.

quantum size effect in noise comes from the dependence of  $S_V/V^2$  on the  $1/G^2[\partial G/\partial \varepsilon_F]^2$ . The difference between the two noise spectra resides in the fact that the discrete resistance switching (RTS noise) was observed in the QPC featuring a Lorentz noise spectrum. At high temperature ( $T > 15$  K), the RTS signal disappears and the noise spectrum changes its shape from a Lorentzian to a  $1/f$ -like one. Dekker et al. [96] explained the occurrence of the RTS noise by the presence of a single electron trap in the immediate vicinity of the point contact. Random filling and emptying of the trap modulate the electrostatic confining potential and thus the conductance of the QPC. In the presence of a strong external magnetic field, not only did the existing noise minima sharpen but additional minima were found [97]. It is an indication that a residual backscattering exists in the constriction. As in the case of QWRs, the magnetic field could be a possibility to engineer noise in QPC. The observation of Dekker et al. [96] that the disappearance of the RTS noise is accompanied by a transition from a Lorentz spectrum to a less intense  $1/f$ -like spectrum casts some doubt on the idea that RTS noise is the fundamental component of the  $1/f$  noise. The suppression of the RTS noise at the conductance plateaus has also been investigated by Timp et al. [98] and Cobden et al. [99, 100] in a one-dimensional wire (channel) using the same split-gate technique to constrict a highly conductive 2DEG. They found that the transition between two adjacent plateaus in the quantized conductance is accompanied by RTS noise. There is no RTS noise on the plateaus which signifies that “RTS is inhibited whenever an integral number of 1D subbands

are occupied” [98]. The absence of the noise on the conductance plateaus is due to the lack of scattering and this is the expression “of the insensitivity of the quantized resistance to the exact microscopic device parameters” [99]. Hence the quantum constriction “feels” the potential fluctuations induced by the presence of a defects only when the gate voltage value is between two consecutive plateaus. The defect can be located by modifying the gate voltage as done in Refs. [98, 100], but its nature is still not clear. Finally, we mention that some of the issues briefly reviewed here have also been discussed by Kogan [101].

## 7. BLINKING QUANTUM DOTS

Quantum dots (QDs) are the analogue of the real atoms because they have atomiclike energy levels. Often called “artificial atoms,” they stand as very attractive candidates for optical memories and high performance zero-dimensional devices such as optical switches, lasers, etc. At the same time the silicon single-electron quantum dot transistor operating at room temperature looks very promising for single-electron memory [102], while a quantum dot-based sensor was proposed to measure the magnetic fields at micron scale [103], to give just a few examples.

However, some of these possible applications could be affected by the fact that the luminescence of the quantum dots randomly switches between discrete levels. These are the so-called blinking quantum dots. The effect is the photoluminescence analog of the electrical RTS noise. This blinking phenomenon manifests in a variety of QDs realized from different materials [103–107]. To fully illustrate how a QD blinks, Figure 8 shows the time trace of the photoluminescence of an InP quantum dot as registered by Pistol et al. [113]. The photoluminescence switching between two or more states was attributed by Nirmal et al. [104] to QD photoionization.

Zhang et al. [106] reported the emission intermittences from II–IV ZnCdSe QDs with a diameter of about 120 Å, embedded in a ZnSe matrix. The intensity of the emission lines of the photoluminescence spectra, registered at 40 K and different time, featured sudden increases and decreases from run to run. These fluctuations qualified as “on” and,

**Figure 8.** Discrete levels in the photoluminescence of an InP blinking quantum dot observed by Pistol et al. [112]. Reprinted with permission from [112], M.-E. Pistol et al., *Phys. Rev. B* 59, 10725 (1999). © 1999, American Physical Society.

respectively, “off” states “reflect the ionization and neutralization of the QDs” [106]. By decreasing the temperature the emission time became very long. This observation suggests an explanation in terms of the thermal ionization of QDs. Ionization, corresponding to the off state, can be produced either by thermal ionization or Auger scattering. In a thermal ionization process, the carriers in QDs are thermally excited over the confinement barrier into the matrix, while in an Auger process, the recombination energy of an electron–hole pair is transferred to a third particle which is ejected to the matrix. The reverse processes correspond to the “on” state. In the model proposed by Efros and Rosen [109], in the “off” state the luminescence is quenched by nonradiative Auger recombination, whereas “the durations of the off periods depends on the ionization rate of the dot via thermal or Auger autoionization” [109].

Temporal instabilities in both ground and first excited state luminescence have been observed by Bertram et al. [107] in a single strain-induced quantum dot realized in a GaAs/(AlGa)As material system. The photoluminescence spectra were extracted at 6.9 K. When registered at a given time, the ground state line was dominant, while after a few seconds, the spectral line of the first excited state took over. The effect was called two color blinking (TCB). The TCB appeared “as beating of the luminescence intensity between the ground and the excited state” [107]. No physical explanation was possible for this phenomenon. Aoki et al. [108] observed that macroscopic InGaAs clusters blink even at room temperature. The lifetimes spent by the blinking signal in both on and the off states superlinearly decreased when the excitation intensity went down. This is clear evidence that RTS noise is a many-carrier effect generated by a photoassisted process, not by a thermal one. It was suggested that the off state could be caused by nonradiative centers such as dislocations located in the InAlAs cluster. Only one from 100–1000 clusters shows RTS noise. Because the estimated average density of dislocations in a cluster was one, it resulted that not all dislocations generated RTS. Another possibility would be to have more than one dislocation in a cluster. It might be of some relevance for the above considerations to mention that burst noise, the equivalent of the RTS noise in larger devices, was quantitatively correlated with the presence of the dislocation clusters in the p–n junctions [110, 111].

Detailed investigations on the photoluminescence RTS noise in InP quantum dots were performed by Pistol et al. [112, 113]. The samples were grown on a InGaP barrier, which was lattice-matched to a GaAs substrate. The QDs were fully strained for they have been capped with a 300 nm InGaP layer. The dots were excited at 7 K with the 488 nm line of an Ar<sup>+</sup> laser or the 532 line of a YAG laser [112, 113]. Under these excitations, the QDs continuously emitted light. However, in some of them the intensity switches between two discrete levels [112] (see Fig. 8). One hundred of more than 100,000 dots exhibited RTS noise in the emission intensity. Quantum dot switching between three or even four levels have been found too [113]. Since no switching was observed at zero excitation power, it was concluded that the mechanism is induced by the excitation light. In the on state, the emission intensity vs. excitation power density is linear, while the switching rates scale superlinearly with

the power density. Hence, multiple particles are involved in the switching. For power excitation of about 50 W/cm<sup>2</sup>, the RTS disappears and the dot irreversibly remains in the on state even at reduced excitation power. The switching rates increase with both excitation power and temperature.

The results of Pistol et al. [112] for the emission spectra of a quantum dot in the on state and the off state, at different excitation power densities, are shown in Figure 9. As can be seen, the spectra are similar in both on and off state and there is no line energy shift. State filling is visible in the off state. Pistol et al. [112] observed that if the carriers are generated only in the dot and not in the barrier, RTS is still active; therefore the mechanism involved seems to be the modulation of the radiative recombination instead of the modulation of the carrier capture in the dot. Another interesting observation of Pistol [113] is that in the off state the emission lines are slightly “thiny” than in the on state, which is the signature of a lower electron concentration in the dot when in the off state. The most probable candidate to explain the effect is a competing nonradiative channel associated with a native defect in the neighborhood of the dot. The ways the dot “communicates” with the defect can be different. For instance, electric-field-assisted ionization of the dot due to a nearby charged defect is excluded because, under the influence of an electric field, no Stark shift was found in the case of a switching dot. The defect involved in the RTS noise has to be mobile; otherwise switching turn off under strong illumination conditions cannot be explained. A defect activated via phonon

**Figure 9.** Photoluminescence spectra of a switching InP quantum dot registered by Pistol et al. [112] for different excitation power densities ( $P = 0.5 \text{ W/cm}^2$ ). Full lines correspond to the on state and dashed lines correspond to the off state. Reprinted with permission from [112], M.-E. Pistol et al., *Phys. Rev. B* 59, 10725 (1999). © 1999, American Physical Society.

emission (phonon-kick model) seems to fulfill this condition. Phonons could be generated by carrier relaxation in the dot [112]. Phonon-assisted recombination at the defect-induced deep levels would be another possibility [113]. Although the attempt of Pistol [113] to observe emitted infrared radiation failed, Sugisaki et al. [114] found that the blinking rate of a InP QD is sensitive to infrared radiation. In addition to a band-to-band excitation (Ar-ion laser), Sugisaki et al. [114] irradiated the dot with a near-infrared laser (Ti-sapphire) and observed that the switching rate is very sensitive to an infrared energy threshold of 1.5 eV. In addition, new blinking dots were triggered when the surface was intentionally scratched by a needle. They concluded that “deep defect levels with an excitation threshold energy of 1.5 eV” [114] are involved in the generation of InP QDs photoluminescence RTS noise. We mention that the phonon-activated defect model to explain RTS noise in QDs shows close resemblance to the model proposed by Kozub and Rudin [91] for the RTS noise in metallic nanobridges.

Also, fluorescence of 27 Å radius (ZnS overcoated) CdSe QDs fluctuates between two distinct levels [115]. Neither the quantum jump model nor the Auger ionization model are able to explain experimental facts [115]. Instead, an exponential distribution of traps within the semiconductor gap reasonably accounts for the probability distribution of the off state. However, for the on state this model fails to give an adequate answer. This is one of the reasons the “observed blinking kinetics is inconsistent with any static model and instead requires fluctuations in the QD environment” [115].

Genuine electrical RTS noise was observed by Peters et al. [116] in a silicon quantum dot of about 35 nm radius, placed in the channel of a deep submicron MOSFET. At liquid helium temperature and around the threshold, roughly equidistant peaks occurred in the conductance vs. gate voltage ( $V_g$ ) dependence. These Coulomb blockade oscillations are the signature of a quantum dot in the channel. Keeping the drain current constant and sweeping the gate voltage ( $V_g$ ), Peters et al. [116] observed that the drain voltage ( $V_D$ ) switches between two or more Coulomb oscillation curves. Maxima and minima were observed in the dependence of the amplitude of this RTS noise vs. gate voltage. The minima occur at the points where the two Coulomb curves cross each other. To provide an explanation for this result, the authors consider that the shift of the Coulomb curves is due to a single fluctuator which produces a fixed fluctuation,  $\Delta\Phi$ , of the dot potential  $\Phi$ , and, consequently, fluctuations  $\Delta G$  in the dot conductance  $G$ . Finally,  $\Delta G \sim \partial G / \partial V_G$ ; hence minima in  $\Delta G$  should occur where the conductance is zero. This is in good agreement with what has been experimentally found.

However, RTS noise manifested only in some “specific gate-voltage ranges.” Outside these voltage intervals, the noise was weaker and featured a  $1/f$ -like spectrum. In the ohmic region, it is a resistance fluctuation effect because its intensity has a quadratic dependence on drain current. The dependence of both normalized drain voltage noise  $fS_{VD}/V_D^2$  and  $V_D$  on gate voltage is shown in Figure 10a and b, respectively. The period of the noise variation is half that of the Coulomb oscillations. The noise is strongly suppressed at the conductance peaks and valleys. To explain this behavior, Peters et al. resorted again to the idea of

**Figure 10.** Coulomb oscillations in the drain voltage vs. gate voltage (a) and dependence of  $fS_{VD}/V_D^2$  vs. gate voltage (b) at two frequencies; the measurements were done at  $T = 1.9$  K and  $I_D = 6$  nA; the factor  $(1/V_D)^2(\partial V_D/\partial V_G)^2$  (times a constant) is presented with the full line. Reprinted with permission from [116], M. G. Peters et al., *J. Appl. Phys.* 86, 1523 (1999). © 1999, American Physical Society.

a “uniformly fluctuating potential created by a fixed distribution of fluctuators” [116]. Under this assumption, the drain spectrum  $S_{VD}$  is directly connected to the gate voltage fluctuation  $S_{Vg}$ :  $S_{VD} = (\partial V_D/\partial V_G)^2 S_{Vg}$ . Finally, the relative drain noise intensity  $fS_{VD}/V_D^2$  is described by the factor  $(1/V_D)^2(\partial V_D/\partial V_G)^2$ , which is determined from time-averaged characteristics (Fig. 10a). The authors concluded that if noise is considered “as a result of a complex superposition of an ensemble of fluctuators” its behavior can be described by a model which relies on time-averaged transport properties.

In summary, low-frequency noise phenomena in small dimensional systems such as nanotriodes, MOS transistors, single electron transistors, quantum wires, quantum dots, and nanomaterials such as nanocrystalline gold and carbon nanotubes were briefly presented.  $1/f$  noise and RTS noise are the dominating noise phenomena in nanodevices and nanomaterials. However, in nanostructures and nanodevices they could manifest in an unpredictable way, hence the difficulty to control. Small dimensional systems seem to be very noisy while, on the other hand, there is much information in the low-frequency noise. If properly interpreted, the noise can be an invaluable tool to investigate nanomaterials and nanoscaled solid-state devices. Low-frequency noise proves to be a noninvasive, inexpensive, very sensitive, subtle, and fundamental tool to characterize nanomaterials and nanostructures.

On the other side, some passages in this work brought some arguments that nanoscience could answer some longstanding questions in the field of low-frequency noise. Some of them such as topology of the  $1/f$  noise sources were in passing discussed in the light of the new phenomena observed in carbon nanotubes. Surface anharmonicity was proposed as a fundamental ingredient in the generation of  $1/f$  noise in carbon nanotubes. Through the noise measurements, the nanoscience and nanotechnology are already

paying a great tribute to the science from which they were born. And all these seem to be only the beginning. Much more is within reach.

## GLOSSARY

**Generation-recombination noise (g-r noise)** Fluctuations originating from the processes of generation and recombination in semiconductors.

**Noise spectrum** Frequency distribution function of a random signal.

**1/f noise** Fluctuations with a spectrum inversely proportional to the frequency ( $f$ ).

**Random telegraph signal (RTS) noise** Fluctuation mimicking telegraph signal and consisting of random transitions between two or more discrete levels.

**Shot noise** Fluctuations originating from the granular structure of the electrical charge.

**Thermal noise** Fluctuations originating from the random discontinuities in the motion (Brownian, m.n.) of the carriers due to their collisions with the atoms (R. E. Burgess, *British J. Appl. Phys.* 6, 185 (1955)).

## ACKNOWLEDGMENTS

The author is very grateful to Dr. Henk W. Ch. Postma for communicating some details about his noise measurement in carbon nanotubes. Many thanks are also due to Dr. Ioan Pavelescu and to Andrei-Petru Mihaila for invaluable help in preparing the manuscript.

## 1. INTRODUCTION

Nearly half a century ago, on December 29, 1959, Richard P. Feynman gave a visionary talk at the annual meeting of the American Physical Society, entitled *There is Plenty of Room at the Bottom* [1]. It was an invitation to enter a new field of physics, the problem of manipulating and controlling things on a very small scale, the nanoscale. Feynman was not afraid to consider the final question as to whether, ultimately—in the great future—we can arrange the atoms the way we want, the very atoms, all the way down! What would happen if we could arrange the atoms one by one the way we want them. . . The principles of physics do not speak against the possibility of maneuvering things atom by atom. It is not an attempt to violate any laws, it is something, in principle, that can be done, but, in practice, it has not been done because we are too big. . .

*When we get to the very, very small world—circuits of seven atoms—we have a lot of new things that would happen that represent completely new opportunities for design. Atoms on a small scale behave like nothing on a large scale, for they satisfy the laws of quantum mechanics. So, as we go down and fiddle around with the atoms down there, we are working with different laws, and we can expect to do different things. We can manufacture in different ways. We can use, not just circuits, but some system involving the quantized energy levels, or the*

*interactions of quantized spins, etc. . . At the atomic level, we have new kinds of forces and new kinds of possibilities, new kind of effects. . .*

*But it is interesting that it would be, in principle, possible for a physicist to synthesize any chemical substance that the chemist writes down. Give the orders and the physicist synthesizes it. How? Put the atoms down where the chemist says, and so you make the substance. The problems of chemistry and biology can be greatly helped if our ability to see what we are doing, and to do things on an atomic level, is ultimately developed—a development which cannot be avoided.*

In 1981 the vision of Feynman became closer to reality with the invention of the scanning tunneling microscope (STM) by G. Binnig, H. Rohrer, Ch. Gerber, and E. Weibel [2, 3]. They describe their invention as follows [3]. *The principle of the STM is straightforward. It consists essentially in scanning a metal tip over a the surface at constant tunnel current as shown in Figure 1. The displacements of the metal tip given by the voltages applied to the piezodrives then yield a topographic picture of the surface. The very high resolution of the STM rests on the exponential dependence of the tunnel current on the distance between the two tunnel electrodes, i.e., the metal tip and the scanned surface.*

Subsequently the STM and its numerous descendents have become the natural tool for investigations on the atomic scale. This instrument has allowed us to perceive individual atoms on surfaces and it was realized that the tip of the STM is a very versatile instrument, not only for imaging, but also for manipulation of individual atoms.

The first experiment to show a stunning realization of the atom-by-atom construction of artificial, man-made nanostructures in the spirit of Feynman was performed in 1990 by D. M. Eigler and E. K. Schweizer [4]. Using a scanning tunneling microscope operated at a temperature of 4 K, they were able to position Xe atoms on a single-crystal Ni surface with atomic-scale precision. This capability allowed the authors to fabricate structures of their own design, a linear cluster of 7 Xe atoms and the letters IBM consisting of 35 Xe atoms, atom by atom.

The last sentence in their publication *The prospect of atomic scale logic circuits is a little less remote* indicated the research direction which led to the realization of an

**Figure 1.** Principle of operation of the scanning tunneling microscope. (Schematic: distances and sizes are not to scale.) The piezodrives  $P_x$  and  $P_y$  scan the metal tip  $M$  over the surface. The control unit (CU) applies the appropriate voltage  $V_p$  to the piezodrive  $P_z$  for constant tunnel current  $J_T$  at constant tunnel voltage  $V_T$ . The broken line indicates the  $z$  displacement in a  $y$  scan at (A) a surface step and (B) a contamination spot, C, with lower work function. Reprinted with permission from [3], G. Binnig et al., *Phys. Rev. Lett.* 49, 57 (1982). ©1982, American Physical Society.

atomic switch realized with the STM [5] just one year later. The authors report the operation of a bistable switch which derives its function from the motion of a single Xe atom which is moved by applying a voltage pulse of the appropriate sign reversibly between two stable positions on the STM tip and on a Ni surface. The state of the switch was identified by measuring the conductance across the leads.

Most recently, A. J. Heinrich et al. [6] made a breakthrough in realizing atomic-scale circuits: nanometer-scale computation by cascades of molecular motion. They present a scheme in which all of the devices and interconnects required for the one-time computation of an arbitrary logic function are implemented by atomically precise arrangements of CO molecules bound to a Cu(111) surface. The motion of one molecule causes a nearby molecule to hop to a new site, which in turn moves another molecule in a cascade of motion similar to a row of toppling dominoes. They used a low-temperature STM to assemble and demonstrate a three-input sorter that uses several AND gates and OR gates. The most exciting feature of these molecular cascades is their size: a three-input sorter implemented in next generation CMOS technology requires an area of  $53 \mu\text{m}^2$ , while the cascade implementation uses only  $200 \text{nm}^2$ , an area 260,000 times smaller.

Feynman's dream of *put the atoms down where the chemist says, and so you make the substance* has also been realized very recently. Hla et al. [7] write in their abstract: *All elementary steps of a chemical reaction have been successfully induced on individual molecules with an STM in a controlled step-by-step manner utilizing a variety of manipulation techniques. The reaction steps involve the separation of iodine from iodobenzene by using tunneling electrons, bringing together two resultant phenyls mechanically by lateral manipulation and, finally, their chemical association to form a biphenyl molecule mediated by excitation with tunneling electrons. The procedures presented here constitute an important step towards the assembly*

*of individual molecules out of simple building blocks in-situ on the atomic scale.*

These few prominent examples from the nanoscale research laboratory set the scene for the present chapter. We have chosen to review recent advances in low-temperature scanning tunneling spectroscopy and microscopy of atoms, molecules, supermolecules, clusters, and islands on mostly metallic surfaces which have provided new opportunities for investigating locally and individually the geometric, electronic, optical, and magnetic properties of nanostructures on surfaces, created by manipulation with the STM tip (artificial nanostructures) or by self-assembly (diffusion and growth). The emphasis is on the discovery of new phenomena characteristic for the nano- and subnanometer scale. This choice was motivated by the fascination emerging from different aspects of local spectroscopies and microscopies documented by recent research highlights, the observation of, for example, light emission from single molecules and clusters [8–12], surface electron standing wave patterns at steps, quantum corrals, islands, and impurities [13–23], the Kondo effect of single magnetic adatoms and clusters [24–26], the quantum mirage [26], the observation of the Abrikosov flux lattice and the density of states near and inside a fluxoid [27–29], the local pair-breaking effects of magnetic impurities on superconductivity [30], the effect of individual impurity atoms on the superconductivity in a high-temperature superconductor [31], self-assembly phenomena of adsorbed molecules forming supramolecular structures [32–37], the formation of surface-supported supramolecular structures whose size and aggregation patterns are controlled by tuning the non-covalent interactions between individual adsorbed molecules [38], insulators at the ultrathin limit [39], spin-resolved tunneling determining magnetic properties of nanostructures [40–43], single-molecule vibrational spectroscopy [44], single-bond formation with an STM [45], chemical reactions on the nanoscale [7], manipulation of single atoms, molecules and clusters on surfaces including lateral movement, vertical transfer, and dissociation [4, 33, 46–57], nanometer-scale computation by cascades of molecular motion [6]. The cited examples clearly demonstrate that we are now able to construct, to image, to characterize, and, to some extent, to functionalize artificial man-made nanoscale objects.

These and related achievements with other scanning probe methods, for example, the atomic force microscope (AFM) [58], made it possible to give a definition for the emerging field of nanotechnology [59]. *Nanotechnology is the creation and utilization of materials, devices, and systems through control of matter on the nanometer-length scale, that is at the level of atoms, molecules, and supramolecular structures. The essence of nanotechnology is the ability to work at these levels to generate larger structures with fundamentally new molecular organizations. These nanostructures, made with building blocks understood from first principles are the smallest human-made objects, and they exhibit novel physical, chemical, and biological properties and phenomena. The aim of nanotechnology is to learn to exploit these properties and efficiently manufacture and employ the structures.*

As STM and STS have now become mature research tools for the nanoworld, there exist already a selection of books and review articles in the literature, treating both technical aspects and scientific subjects [60–70]. Especially

the proceedings of the series of *International Conferences on Scanning Tunneling Microscopy/Spectroscopy and Related Techniques*, which were organized in Santiago de Compostela (Spain) in 1986, Oxnard (USA) in 1987, Oxford (UK) in 1988, Oarai (Japan) in 1989, Baltimore (USA) in 1990, Interlaken (Switzerland) in 1991, Beijing (China) in 1993, Snow Mass Valley (USA) in 1995, Hamburg (Germany) in 1997, Seoul (South Korea) in 1999, Vancouver (Canada) in 2001 give an excellent account on the progress made in the field. The interested reader will find a wealth of valuable information in these publications which provide a good starting point to enter the field.

The present chapter is organized as follows. In Section 2, typical state-of-the-art setups of a low-temperature STM in ultrahigh vacuum and the different modes for scanning tunneling microscopy and spectroscopy including electrons and photons as probes are outlined. Subsequently, in Section 3, results on single, supported atoms concerning the Kondo effect are presented. In Section 4, the lifetime of surface state electrons is addressed and standing wave phenomena due to the scattering of surface state electrons at islands, steps, corrals, and other quantum well structures on the (111) surfaces of noble metals are reviewed. Section 5 deals with adsorbed molecules and two-dimensional supramolecular self-assembly. Section 6 summarizes the knowledge obtained on individual molecular and metal clusters. Section 7 discusses the dielectric and magnetic properties of nanostructures, with a brief account on vortices of magnetic flux lattices in classic and high-temperature superconductors. Finally, Section 8 presents a short summary and an outlook for the field.

## 2. EXPERIMENTAL

At low temperatures, due to the reduced broadening of the Fermi level of the STM tip and the sample, an energy resolution from the meV down to the  $\mu\text{eV}$  range in scanning tunneling spectroscopy (STS) is achievable. Moreover, the absence of surface diffusion together with the spatial resolution of the STM enables detailed studies of electronic states on and near single adsorbed atoms, molecules, clusters, and other nanoscale structures [69].

Typical low-temperature ultrahigh-vacuum (UHV) STMs [4, 25, 41, 71–86] operate at a pressure of  $10^{-11}$  mbar and employ temperatures down to 4 K and 1.3 K. In some of these low-temperature STMs, magnetic fields are applied in the tip-sample region [85–87] and, in addition, luminescence measurements are carried out [87]. More recently, a few new instrumental developments towards the millikelvin range using a dilution refrigerator [88] or a  $^3\text{He}$  refrigerator [6, 89, 90] with magnetic fields up to 7 and 11 Tesla in the tunnel junction have been reported. As STM tip material, usually, electrochemically etched W, Pt, or Ir tips were prepared in UHV by heating and rare-gas ion bombardment.

Information of the local density of states (LDOS) [91] is generally obtained by measuring the differential conductance  $dI/dV$  versus the sample bias voltage  $V$  performed under open feedback loop conditions with lock-in detection; see, for example, [13]. Constant-current topographs very close to the Fermi level have been shown to correspond to the LDOS of the sample surface [13]. Moreover,

simultaneously spectroscopic ( $dI/dV$ ) and constant-current images are acquired [26]. For recording spectra on, for example, semiconductors or ultrathin insulators, over wide voltage intervals, the tip-sample separation is varied continuously during the voltage sweep in different modes, (i) by a linear ramp [92], (ii) by keeping constant either the tunnel current or (iii) the tunnel resistance. In these modes, band onsets naturally appear as peaks [93, 94].

The tip-surface region of an STM emits light when the energy of the tunneling electrons is sufficient to excite luminescent processes [95]. Photons emitted from the tunneling gap are collected by a lens [8, 10] or a parabolic mirror [9] and transmitted through a sapphire viewport. Outside the vacuum chamber these photons are refocused onto an optical fiber leading to a cooled multi-alkali photomultiplier which is operated in a pulse counting mode. The count-rate is recorded by the STM electronics quasi-simultaneously with the acquisition of constant-current topographs for each image pixel [8, 11]. For spectroscopic measurements the light is focused outside the vacuum chamber onto the slit of a UV/visible-grating spectrograph and detected with a liquid nitrogen cooled CCD camera [9, 11, 96, 97].

## 3. MAGNETIC ADATOMS

The STM has been used to perform local spectroscopy with atomic-scale resolution in a study of Fe atoms on a clean Pt(111) surface [98]. Resonances of 0.5 eV width were found in the adatom local density of states above the Fermi level. Characteristic circular standing wave patterns around single adatoms have been detected in spatially resolved spectroscopic STM images [13, 14, 16, 18, 99]. Recently the local pair-breaking effects of a single magnetic adatom on a classical superconductor have been observed with scanning tunneling spectroscopy [30]. In what follows, the effects of magnetic and nonmagnetic adatoms on the LDOS of noble metal surfaces are reviewed. In particular, a depletion of the LDOS near the Fermi energy, which occurs for magnetic adatoms only, is interpreted in terms of Kondo scattering.

The interaction of a single magnetic impurity with the conduction electrons of its nonmagnetic metallic host gives rise to unconventional phenomena in magnetism, transport properties, and the specific heat. As the temperature approaches  $T = 0$  K, the local moment is gradually screened by the conduction electrons of the metal host and a many-body nonmagnetic singlet ground state is formed close to the Fermi energy. These low-energy excitations with a characteristic width of  $\delta = kT_K$  ( $T_K$  is the Kondo temperature and  $k$  the Boltzmann constant) are known as Abrikosov–Suhl [101, 102] or Kondo resonance [103–108]. High-resolution photoelectron spectroscopy (PES) provided direct experimental evidence of such a resonance [109–111]. However, a direct observation of the Kondo effect from a single magnetic impurity on an atomic length scale was achieved only recently in STM and STS experiments [24–26].

In the first experiment, magnetic Ce adatoms on a single-crystal Ag(111) surface were chosen to represent a typical Kondo system [24, 107, 110, 111]. Isolated Ce atoms and, for comparison, isolated Ag atoms on Ag(111) were deposited by evaporation from a tungsten filament onto the Ag substrate at  $T = 5$  K. The adatoms appear as protrusions with  $\approx 0.9$  Å and  $\approx 1.2$  Å height for Ag and Ce, respectively,

with typical widths of  $\approx 15 \text{ \AA}$  in constant-current topographs taken at a tunneling resistance of a few hundred  $M\Omega$ . Figure 2b displays a  $dI/dV$  tunneling spectrum measured on top of an isolated Ce adatom. A depression is observed in  $dI/dV$  around the Fermi energy. When the tip is moved laterally, the typical spectrum of the Ag(111) surface state onset (for Au(111) and Cu(111) see [13, 113, 114]) at  $E \cong -70 \text{ meV}$  reappears (Fig. 2e) [19, 115]. At intermediate distances (Fig. 2c,d) the surface state edge broadens reflecting a decreased hot-hole lifetime due to scattering of surface state electrons at the impurity [134]. The weak spectral features above the onset of the surface state are due to standing wave patterns caused by scattering at the adatoms [15, 19, 99]. These energy-resolved Friedel oscillations [114] are also visible in space [13–16] as weak circular waves around the adatoms (see Section 4).

The tunneling spectra of a single adsorbed Ag atom (Fig. 2a) are featureless throughout the range from  $-200 \text{ mV}$  to  $200 \text{ mV}$  which is attributed to quenching of the Ag(111) surface state [19]. These data indicate that the dip near the Fermi energy  $E_F$  is indeed characteristic of the magnetic Ce adatom.

The authors of [24] offered an explanation for the existence of an antiresonance in the tunneling spectra as opposed to the resonance predicted by theory [116] and measured by photoemission for similar systems [111, 117]. The probing of a localized state immersed in a continuum by the tunneling microscope resembles the spectroscopy of a discrete autoionized state, treated by Fano [118]. When the transition matrix element for the localized state approaches zero, the autoionization spectrum shows an antiresonance as a consequence of the interference effects at the site with the localized state. At the usual tip-surface distances, the STM is known to probe  $sp$  wave functions rather than the confined

**Figure 2.**  $dI/dV$  spectra on (a) a single Ag adatom and (b)–(e) on and near a single Ce adatom at  $T = 5 \text{ K}$ . The lateral distance between the tip position and the center of the adatom is indicated. Before opening the feedback loop the tunnel parameters were  $V = 200 \text{ mV}$ ,  $I = 0.1 \text{ nA}$ . $4f$  core-levels [119]. Thus, the  $dI/dV$  spectrum should show an antiresonance instead of a  $f$ -spectral peak as observed experimentally. By approximating the Fano dip shape by the inverse non-crossing-approximation (NCA) [117, 120] resonance [24], the lineshape in Figure 3 (solid curve) is obtained, in agreement with the experimental observations (dots). The width of the Kondo antiresonance obtained from the NCA calculation for the single isolated Ce impurity on Ag(111) (Fig. 3 (solid curve)) is  $\delta = kT_K = 25(5) \text{ meV}$  yielding a Kondo temperature of  $T_K = 290(50) \text{ K}$  which is considerably lower than the value of  $1000 \text{ K}$  found for bulk  $\alpha$ -Ce [107, 111]. This result is consistent with the expected decrease in hybridization with decreasing Ce coordination.

These findings and the interpretation within the Fano picture have been corroborated by related STS observations of Co atoms on Au(111) [25, 121] (see Figs. 4 and 5) and on Cu(111) [26]. Recent experiments [122] on Co adatoms on Cu(111) and Cu(100) have detected a scaling of the Kondo temperature with the host electron density at the magnetic impurity. Furthermore, a quantitative analysis of the tunneling spectra revealed that the Kondo resonance is dominated by the volume density of states. The same group observed the scattering phase shift of isolated Co impurities at the surfaces of Ag(111) [123].

A disappearance of the Kondo resonance for atomically fabricated Co dimers (i.e., by manipulation with the STM tip) on Au(111) has been reported and was explained as the result of reduced exchange coupling between Au conduction electrons and ferromagnetic cobalt dimers [124]. Recently, this group investigated the temperature-dependent electronic structure of isolated Ti atoms on Ag(100) [125]. They find that the Kondo resonance is strongly broadened when the temperature is increased, confirming the role of electron-electron scattering as the main thermal broadening mechanism.

The interaction of magnetic impurities with electrons confined in one dimension has been studied recently by spatially resolving the local electronic density of states of small Co

**Figure 3.**  $dI/dV$  spectra of a Ce impurity on Ag(111) for an energy range around the Fermi level. clusters on metallic single-walled nanotubes. The spectroscopic measurements performed on and near these clusters exhibit a narrow peak near the Fermi level which had been identified as a Kondo resonance [126].

Evidence for an orbital Kondo resonance on a transition-metal surface has been reported recently on an atomically clean Cr(001) surface. STS revealed a narrow resonance 26 meV above the Fermi level which was attributed to the manifestation of an orbital Kondo resonance formed by two degenerate  $d_{x,z}$ ,  $d_{y,z}$  surface states [127].

A Fano lineshape has been also obtained in recent theoretical treatments of the Kondo effect of a single magnetic adatom [128–131]. A beautiful experiment of a “quantum mirage” has been performed recently, where the Kondo resonance is seen in both foci of an elliptical quantum corral while the magnetic Co adatom is placed only at one focal position [26]. Evidently, detection and spectroscopy of individual magnetic adatoms open new perspectives for probing magnetic nanostructures.

The controlled modification of the electronic structure of a single Mn adsorbate placed within a geometrical array of adatoms on Ag(111) added a new aspect to the spectroscopy of single adatoms [22]. The spectral changes result from coupling between the adsorbate level and surface electronic states of the substrate. The surface state electrons are scattered coherently within the adatom array, influencing the local electronic structure of the single adatom within the array. The dimension and geometry of the adatom array provide a degree of control over the induced changes.

## 4. SURFACE STATES

### 4.1. Lifetimes

Noble-metal surface states have been the focus of substantial experimental and theoretical attention [13–16, 18, 19, 99, 114, 132, 135–143]. Accurate values are known for their binding energies, effective masses, and Fermi wavevectors, including the temperature dependence and their response to various changes in surface conditions [144]. Overall, there is good agreement of theoretical predictions with experimental results, mainly with angle-resolved photoemission spectroscopy (ARPES). However, measured values of the ARPES linewidth  $\Gamma$  of a surface state hole [145] which is linked to its lifetime  $\tau = h/\Gamma$ , despite prolonged investigation by ARPES [115, 146–148], deviated significantly from theoretical predictions. Surface imperfections have been invoked to explain the failure in observing theoretically predicted linewidths [144, 146, 148]. In the case of Ag(111), the experimental linewidth surpassed theoretical values by  $\sim 300\%$ .

STM with its ability to characterize surface topology and to identify minute amounts of contamination is ideally suited to address this issue. Defect-free surface areas can be selected for experimentation to avoid scattering from defects. Spectroscopy of the differential tunneling conductance  $dI/dV$  versus the sample voltage  $V$ , which is related to the local density of states above the surface [91, 119], can be used to probe the surface state on Ag(111). In typical conductance spectra ( $dI/dV$ ) measured at low temperatures, the surface state gives rise to a sharp rise in the conductance near  $-70$  meV which reflects the onset of tunneling from the surface state band. In the experiments, the overall slope of the spectra varies to some extent. The variations are presumably caused by differences in tip structure

or chemical composition. In more detailed measurements the width of the onset denoted  $\Delta$  is resolved. This width reflects the lifetime of the surface state hole left behind by a tunneling electron [134].

An alternative approach to measuring lifetimes, first indicated by Hasegawa and Avouris [14], is to analyze the spatial decay of electron standing wave patterns near defects [150].

An analytical relation between the experimental width  $\Delta$  and the ARPES linewidth  $\Gamma = 2\Sigma$ , where  $\Sigma$  is the imaginary part of the electron self-energy, is obtained, using approximations which have shown to be very acceptable in the context of surface state spectroscopy [13, 16, 18, 19, 99, 132]. The surface state is modeled by a two-dimensional electron gas with effective mass  $m^*$  and binding energy  $E_S$ . Lifetime effects are included via a constant self-energy  $\Sigma$ . The density of states at the surface,  $n(E)$ , then is [151]

$$n(E) = N_B + m^*[\pi - \phi(E - E_S)]/2\pi^2 \quad (1)$$

where

$$\cos \phi(E) = E/\sqrt{E^2 + \Sigma^2} \quad (2)$$

$N_B$  represents a constant background of bulk states at the surface.

A simple expression for the tunneling current can be used if the tip is electronically featureless, the coupling between the tip and the sample is weak, and the energy and momentum dependence of the tunneling matrix elements can be neglected. This yields

$$I(V) = C \int_{-\infty}^{\infty} n(\epsilon + V) [f(\epsilon) - f(\epsilon + V)] d\epsilon \quad (3)$$

where  $C$  is a constant and  $f$  the Fermi function. From Eq. (3), the differential conductance is

$$\frac{dI}{dV} = CN_B + \frac{Cm^*}{2\pi^2} \int_{-\infty}^{\infty} \frac{\Sigma}{E^2 + \Sigma^2} f(E - V + E_S) dE \quad (4)$$

Equation (4) describes a sharp increase near  $E_S$ , with a width determined by  $\Sigma$  as observed experimentally. A Sommerfeld expansion of Eq. (4)—which is reasonable since in the experiment at 5 K thermal broadening of the Fermi edge is small compared to  $\Sigma$ —yields

$$\Delta \simeq \pi\Sigma \left[1 + O(T/\Sigma)^2\right] \quad (5)$$

Equation (5) shows that the self-energy can be directly obtained from the experimental width of the onset  $\Delta$ . Thermal broadening can safely be neglected. More detailed calculations outlined below corroborate this result although the factor  $\pi$  is slightly modified to  $\simeq 0.9\pi$  in the case of Ag(111). This smaller value results from the part of the electronic wavefunction in the tunneling barrier region where  $\Sigma = 0$ .

For more realistic calculations of the conductance, multiple-scattering techniques were employed to obtain the sample Green function [152]. Lifetime effects were taken into account via an imaginary self-energy which is constant and restricted to the sample. For a tip modelled by a single atom, using a 4-eV optical potential to give a realistic spectral density [153], conductance spectra are obtained within

the many-body tunnelling theory of Zawadowski and Appelbaum and Brinkman [154].  $\Sigma$  affects the broadening of the onset of the surface state band. In addition, one observes that  $\Sigma$  also modifies the relative contribution of the surface state to the conductance above the onset. A comparison of low-temperature STM spectra with these calculations leads to an estimated imaginary self-energy of  $\Sigma \sim 5$  meV. For this value there is, in addition, an approximate agreement of the relative contribution of the surface state to the total conductance for voltages above the onset. The surface state doubles the total conductance in both experiment and calculation.

In ARPES, after eliminating experimental factors,  $\Sigma$  causes the full width at half maximum of the Lorentzian lineshape of the peak associated with the surface state  $\Gamma = 2\Sigma$ . McDougall et al. [147] have evaluated the temperature dependence of the width of the Cu(111) surface state. They observed  $\Gamma$  varying linearly between 75 meV at 625 K and 30 meV at 30 K and compared these data to a perturbative treatment of the electron-phonon coupling [155] with the Debye model and Fermi liquid theory for the electron-electron scattering [156]. Their model provides a quantitative explanation of the observed linear temperature dependence which is attributed to a dominant phonon contribution [147]. Nevertheless, the predicted absolute value  $\Gamma \sim 14$  meV at  $T = 30$  K lies well below the observations. Surface roughness has been invoked to explain this difference [147]. In agreement with this proposal, Theilmann et al. [148] observed a correlation between the photoemission linewidth and the width of LEED spots from the same surface. However, extrapolation to perfect surface order yields  $\Gamma = 43 \pm 5$  meV at room temperature, leaving a considerable gap to the theoretical estimate of  $\Gamma = 30$  meV.

For Ag(111), the situation was comparable. Using the ARPES data of Paniago et al. [115]— $\Gamma = 20$  meV at  $T = 56$  K—and repeating the calculations of [147] with an electron-phonon mass enhancement parameter of 0.13 [155] and Debye energy of 18 meV, one finds  $\Gamma = 5$  meV at  $T = 0$  K for states at the surface state binding energy. The phonon contribution increases  $\Gamma$  at  $T = 56$  K to  $\sim 6$  meV. Again, a sizeable difference exists to the ARPES value.

The value for  $\Sigma$  ( $=\Gamma/2$ ) of 5 meV represents a significantly lower experimental estimate of  $\Sigma$  than previously available. New experimental data obtained under improved experimental conditions by Kliewer et al. [157] indicate a yet smaller value of  $\Sigma \sim 3$  meV (see Fig. 6). Along with new, similar STM results for Au(111) and Cu(111), these data are explained by calculations which go beyond previous quasi-free electron gas models and take band-structure effects into account [157]. These calculations show that the contribution of electron-hole scattering for occupied surface states has previously been underestimated and remove the remaining discrepancy between experimental and calculated self-energies of noble-metal surface states.

On the other hand, new high-resolution photoemission data [158, 159] achieved now an instrumental resolution comparable to the one of STS, of  $\Gamma = 2\Sigma$  of 6 meV and 23 meV for the surface states on Ag(111) and on Cu(111), respectively. In view of the much larger surface area seen in photoemission, this is a bit surprising. In a recent STS investigation with still improved experimental conditions a

**Figure 6.**  $dI/dV$  spectra for Ag(111), Au(111), and Cu(111). All spectra were taken at least 200 Å away from impurities and are averages of different single spectra from varying sample locations and tips. Reprinted with permission from [157], J. Kliewer et al., *Science* 288, 1399 (2000). © 2000, American Association for the Advancement of Science.

value of  $\Gamma = 4.9 \pm 0.2$  meV has been obtained on Ag(111) which is in the direction of the above argument [160].

An interesting method to determine the energy dependence of surface state lifetimes has been developed recently. This method may be termed *lifetime engineering* [22, 23], as it is based again on the atom manipulation capabilities of the STM. Both groups arranged artificial arrays of atoms in the form of rectangles (Mn on Ag(111) [22]) or triangles (Ag on Ag(111) [23]). The scattering of the surface state electrons at these adatoms results in complex interference patterns (see next section) which were observed in spectroscopic images and local  $dI/dV$  spectroscopy. From a lineshape analysis of  $dI/dV$  spectra and multiple scattering calculations, quasiparticles lifetimes near the Fermi level were derived. The experimental results indicated that the electron lifetimes deviate from a  $(E - E_F)^{-2}$  dependence and reflect the electronic band structure at the surface as well as the local influence of the adatom array.

## 4.2. Standing Wave Phenomena

On the close-packed faces of the noble metals some electrons occupy surface states, quasi-two-dimensional states localized at the metal surface and which have nearly free-electron-like dispersion [161]. In recent years there has been a renaissance of interest in the physics of these electrons, which it is argued play an important role in a variety of physical processes, including epitaxial growth [162], in determining equilibrium crystal shapes [163], in surface catalysis [164], in molecular ordering [165], and in atom sticking [166]. This attention may be largely attributed to the advent of the scanning tunneling microscope (STM), which has enabled direct imaging in real space of electrons in surface states, and their interactions with single adsorbates [13, 17], steps [14, 16], and other structures [15, 16] (see Figs. 7 and 8).

Probably the most striking observation has been of the confinement of surface state electrons within artificial nanoscale structures [15], geometrical arrays of Fe atoms positioned with atomic-scale precision using the STM (see Fig. 9), and which have also received theoretical attention [167–171]. Scattering at natural structures such as steps has also been seen to result in lateral localization [16].

Confinement is important as it raises the energies of the surface state electrons, resulting in a depopulation of the

**Figure 7.** Constant current  $13 \times 13$  nm image of a single Fe adatom on the Cu(111) surface. The concentric rings surrounding the Fe atoms are standing waves due to the scattering of surface state electrons with the Fe adatom. Reprinted with permission from [15], M. F. Crommie et al., *Science* 262, 218 (1993). © 1993, American Association for the Advancement of Science.

surface state band and a concomitant modification of surface properties associated with the surface state electrons [162–164]. However, to date there has been little attention paid to the systematics of the confinement, especially in the limit of smaller-scale structures. Can one still talk of surface state electrons supported on a structure just three or four atoms wide? These structures are the ones most likely to result in significant depopulation, and exist naturally on surfaces especially during epitaxial growth. In contrast to the corral studies of [15], a recent angle-resolved photoemission study [172] on vicinal Cu(111) surfaces with monatomic

**Figure 8.** Constant current  $50 \times 50$  nm image of the Cu(111) surface at 5 K. Standing waves in the LDOS with a periodicity of  $\sim 1.5$  nm can be seen emanating from monatomic step edges. Reprinted with permission from [13], M. F. Crommie et al., *Nature* 363, 524 (1993). © 1993, Macmillan Magazines Ltd.

**Figure 9.** Circular quantum corral built from 48 Fe atoms on the Cu(111) surface. Average diameter of ring (atom center to atom center) is 14, 26 nm. An electronic interference pattern can be seen inside of the Fe ring. Reprinted with permission from [15, 168], M. F. Crommie et al., *Science* 262, 218 (1993). © 1993, American Association for the Advancement of Science, and M. F. Crommie et al., *Surf. Rev. Lett.* 2, 127 (1995). © 1995, World Scientific Publishing Company.

steps spaced  $\sim 1.5$  nm apart has found shifts in surface state energies only a fraction of those expected on the basis of ideal confinement, suggesting the step edges only act as weak and permeable barriers. Thus the validity of confinement as a mechanism of surface state depopulation seemed to be in question.

Standing waves on an Ag island at room temperature, identified as resulting from surface state confinement, have been first observed in [16]. Li et al. [19] report on a low-temperature study of surface state electrons confined to small Ag islands on Ag(111). In contrast to adatom corrals, these are stable structures even at elevated bias voltages in the STM, enabling the observation of standing waves over a wide range of voltages. Complementary electronic structure calculations enabled the authors to extend the investigation down to the smallest island sizes, quantifying the nature of surface state confinement.

Differential conductance maps taken above individual islands exhibit strongly voltage-dependent features. Figure 10 shows a typical series of scans taken above an island. For voltages around  $-65$  mV and lower (negative voltage corresponds to tunneling from the sample), the image of the interior of the island is featureless. At higher voltages standing wave patterns of increasing complexity are observed, beginning with a single peak near the center of the island and gradually evolving to multiple rings with sixfold azimuthal modulations, which are partially distorted by deviations of the island shape from hexagonal symmetry. STM measurements of  $dI/dV$  are related to the local density of states above the surface [91], and the standing waves may be identified as originating from surface state electrons, confined by the rapidly rising potential at the edges of the island. On the clean surface the surface state disperses upwards from  $E_0 = -67$  meV, with an effective mass  $m^* = 0.42$  [18, 115].

**Figure 10.** Upper row: topographic image of an approximately hexagonal Ag island on Ag(111) (area  $\sim 94$  nm<sup>2</sup>), and a series of  $dI/dV$  maps recorded at various bias voltages (at  $T = 50$  K). Lower: geometry of a hexagonal box confining a two-dimensional electron gas, and the resulting local density of states. Experimental values have been used for the surface state onset  $E_0$ , electron effective mass  $m^*$ , and the island size. The calculations include a self-energy of  $\Gamma = 0.2(E - E_0)$ . Reprinted with permission from [19], J. Li et al., *Phys. Rev. Lett.* 80, 3332 (1998). © 1998, American Physical Society.

Positioning the STM tip above the center of a particular island and recording  $dI/dV$  spectra, a series of peaks is observed, reminiscent of those measured at the center of adatom corrals [15]. The peaks correspond to energy levels of the confined surface state electrons, broadened into resonances by single-particle scattering processes [167, 169], many-body interactions [170], and instrumental effects such as thermal broadening. Electronic structure calculations on small Ag islands on Ag(111), using the multiple-scattering approach described in [170, 173], were performed to model the experimental observations [19]. The potentials were taken from *ab initio* calculations of the clean surface, which give the binding energy and effective mass of the surface state band as  $E_0 = -72$  meV and  $m^* = 0.37$ .

Regular hexagonal islands with sizes up to 631 atoms were considered. As the island size decreases, the calculated levels rise markedly, consistent with a high degree of confinement. To quantify the nature of the confinement the energy levels were analyzed in terms of two-dimensional “particle-in-a-box” eigenstates, corresponding to electrons with effective mass  $m^*$  confined within a hexagonal domain of potential  $E_0$  by infinitely high barriers [133].

The eigenvalues scale with the inverse of the area of the hexagon,  $\Omega$ . In atomic units ( $\hbar = m_e = e^2 = 1$ )

$$E_n = E_0 + \frac{\lambda_n}{m^* \Omega} \quad n = 1, 2, 3 \dots \quad (6)$$

Only eigenstates which transform according to the  $A_1$  representation of the group  $C_6$  (6 mm) of the hexagon [175] have a nonzero amplitude at the origin, and for these the lowest few are  $\lambda_1 = 9.296$ ,  $\lambda_4 = 48.70$ , and  $\lambda_{10} = 117.0$  [133]. In comparing with the experimental  $dI/dV$  data and/or the multiple-scattering calculations, it is not clear *a priori* what the relevant size of an island is. The confinement is effected by the rapid rise in the potential beyond the edges of the island. However, a sizeable fraction of the surface state extends into the first few layers of atoms and so will not be directly influenced by the island edge. The effective location of the boundary confining the surface state electrons is uncertain, relative to either the measured topological linescan of the island or the actual positions of the edge atoms. To circumvent this difficulty a *fit* of the results from the scattering calculations with the energies from Eq. (6)

was carried out, assuming the effective boundary lies a constant distance (independent of island size) beyond the positions of the edge atoms. This distance was the only fitting parameter. The scattering calculations were then used to simulate constant-current topographs by evaluating the integrated LDOS above the surface, enabling an identification *theoretically* of the effective boundary on the topographical cross section.

The location identified as the effective boundary of the surface state electrons lies close to the midpoint of the rise in the topological linescan,  $\sim 0.5$  nm beyond the edge atoms. The precise value depends upon the potential in the vicinity of the island edge, for which only an approximate description is available, but which always coincides closely with the midpoint of the rise in the simulated topological linescan. With this definition, remarkable agreement between the energies of the surface state electrons as derived from both experimental  $dI/dV$  spectra and the theoretical LDOS was found, compared to the scaling behavior expected of two-dimensional electrons. The smallest island contains just 19 atoms, and the smallest measured island is  $\Omega \sim 16$  nm<sup>2</sup> containing  $\sim 100$  atoms. These results indicate that as far as the energy levels are concerned, it is valid to talk of surface states confined to nanoscale islands, right down to the smallest island sizes. The confinement corresponds to an infinite barrier, and the area to which the electrons are confined corresponds to a boundary lying a fixed distance beyond the outermost atoms, independent of both energy and the island size.

There are deviations from this interpretation of the electron behavior, as witnessed by the finite width of the confined energy levels. The levels should be infinitely sharp for ideal confinement. The width of each energy level stripped of instrumental contributions,  $\Delta E_n$ , implies a finite lifetime for the confined electrons,  $\Delta t_n \simeq \hbar/\Delta E_n$ , dominated by scattering into other electron states at the island edges [167, 169, 170]. While these processes do not influence the energies of the levels, one potential consequence is that depopulation of the surface state only becomes significant for island sizes smaller than those derived from a two-dimensional analysis. Even at  $T = 0$  each energy level will have a finite width, resulting in partial occupation *after* the level has risen above the Fermi energy. Assuming a Lorentzian lineshape, the state will be 1/4 full when  $E_n$  lies  $\Delta E_n$  above the Fermi level. For an estimate of the significance of this effect, the experimental spectra yield

$$\Delta E_n \simeq 0.2 (E_n - E_0) \quad (7)$$

Using this relation, the island area at which the lowest level is 3/4 depopulated is 10% smaller than that which yields complete depopulation assuming perfect confinement. Hence the influence of the finite widths is marginal. A more detailed analysis of the level widths is given in [133, 134], incorporating them into the two-dimensional description as a self-energy provides a good model of the confined states. Allowing for the clear deviations in shape of the experimental island from the ideal hexagon assumed theoretically, which (alongside the finite resolution of the STM) results in the more rounded features, there is good agreement between the theoretical and experimental images. The

largest differences arise at the island edges, when experimental  $dI/dV$  data are influenced by tip-height variations [18] and because theoretically the background of bulk states is not included.

This quantitative study of electron confinement to nanoscale Ag islands on Ag(111) using low-temperature STM and electronic structure calculations confirmed the validity of the “particle-in-a-box” model for confined surface state electrons. The energies conform to the expected scaling behavior down to the smallest of island sizes, and the width of the confined levels has only a marginal effect on the surface state depopulation. For larger island sizes the island edges have the same atomic structure as low-energy steps oriented along  $\langle 1\bar{1}0 \rangle$  directions on the (111) surface, and so these conclusions should hold also for confinement to raised terraces and to finger-like structures characteristic of the dendritic formations which occur in the low-temperature growth of Ag/Ag(111) [176]. In addition, these conclusions should also hold for confinement on Cu(111) and Au(111) surfaces, due to the similarities in the band structures of the noble metals. The failure to observe these effects in angle-resolved photoemission [172], apart from limits in the instrumental resolution, most likely results from the presence of a sizeable distribution of terrace widths within the spot area of the incident radiation.

Subsequently, confinement of Ag(111) surface state electrons had been studied in symmetric and asymmetric resonators formed by two atomically parallel step edges. The local density of states in the resonator was measured by  $dI/dV$  spectroscopy and spectroscopic imaging and was analyzed within a simple Fabry–Pérot model. The energy-dependent reflection amplitudes and scattering phase shifts of the different step edges were determined [20].

A recent investigation of the surface state depopulation on such small Ag(111) terraces showed [177] that with decreasing terrace width, the electronic density in the occupied surface state shifts monotonically towards the Fermi level, leading to a depopulation at 3.2 nm terrace width in quantitative agreement with the above Fabry–Pérot model. These observations also confirm the earlier results obtained on small silver islands [19, 133].

It was shown later that a simple “particle-in-a-box” model is already sufficient to identify all major features in the observed  $dI/dV$  maps and in constant-current topographic images of a similar quantum box [160]. These authors obtained atomically resolved constant-current images of a Ag(111) single-crystal surface at a temperature of 5 K, which simultaneously display standing wave patterns arising from electron confinement of surface state electrons to nanoscale terraces. It was shown how the energy-dependent patterns develop from the superposition of allowed wavefunctions in the quantum box. This experiment constitutes a direct verification of the Tersoff–Hamann model for arbitrarily localized tip wavefunctions [160].

It has been predicted [178] and found recently that the standing waves mediate long-range oscillatory interactions between adatoms [179–181]. In the case of Cu on Cu(111), the interaction potential was determined by evaluating the distance distribution of two adatoms from a series of STM images taken at temperatures of 9–21 K [180]. The long-range interaction had a period of half the Fermi wavelength

and decayed for larger distances as  $1/d^2$ . A comparison of three adsorbate/substrate systems, Cu/Cu(111), Co/Cu(111), and Co/Ag(111), essentially confirmed the earlier observations and demonstrated that the long-range interactions depend crucially on the Fermi wavelength of the surface state electrons [181].

The realization of two-dimensional imaging of electronic wavefunctions in metallic single-walled carbon nanotubes represents another highlight in low-temperature STS [182]. The measurements reveal spatial patterns, which can be directly understood from the electronic structure of a single graphite sheet. The authors observed also energy-dependent interference patterns in the wavefunctions and exploit these to directly measure the linear electronic dispersion relation of the nanotube.

In the context of standing wave patterns, the observation of the development of one-dimensional band structure in artificial gold chains marks the beginning of manipulation and spectroscopy of local one-dimensional structures on surfaces [183]. The authors used the ability of the STM to manipulate single atoms to build well-defined gold chains on NiAl(110). The electronic properties of the one-dimensional chains are dominated by an unoccupied electron band, gradually developing from a single atomic orbital present in a gold atom. Spatially resolved conductance measurements along a 20-atom chain provided the dispersion relation, effective mass, and density of states of the free electron-like band.

## 5. SUPRAMOLECULAR SELF-ASSEMBLY

Self-assembly of regular arrays of thermodynamically stable nanostructures from appropriately functionalized molecules is a promising approach to future mass-fabrication of nanoscale structures [184, 185]. Molecules adsorbed on surfaces are particularly appealing because their arrangement is directly observable with the scanning tunneling microscope [186–190]. Understanding supramolecular aggregation starting from the basic interactions of the constituent molecules is a prerequisite to eventually control the self-assembly process.

The aromatic molecule 1-nitronaphthalene (NN, structure Fig. 11, inset) adsorbed on the reconstructed Au(111) surface [191] was chosen in a recent experiment as structural unit for self-assembly. The confinement of NN to two dimensions introduces a chirality not present in the gas phase. On the surface both enantiomers are present in equal amounts, thus forming a racemic mixture. The Au(111) sample was held at room temperature during the deposition and below 50 K during the measurements. In order to minimize tip-induced motion of the molecules at submonolayer coverages [192, 194, 195], small tunneling currents ( $I = 10$  pA) were used.

At coverages between 0.05 and 0.15 ML self-assembled quasi-0D clusters of distinct size and structure appear at the fcc elbows of the reconstruction (Fig. 11b). At slightly higher coverage (0.2 ML) identical clusters are observed within fcc domains (Fig. 11c) and, sporadically, within hcp domains and on domain walls. All decamers appear identical in the STM images, except for a mirror symmetry (clusters 1 and 2 in Fig. 11c). They consist of an 8-molecule ring surrounding

**Figure 11.** STM images at 50 K of a reconstructed Au(111) surface with adsorbed NN; (a) 0.7 ML NN. Inset: Structural formula of NN. The dashed line encloses the “exclusion” area resulting from steric repulsion. The distance of the full line from the dashed line indicates the strength of a negative electrostatic potential computed on the dashed line. (b) 0.1 ML NN at 65 K. (c) 0.2 ML NN at 50 K. Inset: 0.2 ML NN at 10 K. Reprinted with permission from [32], M. Böhlinger et al., *Phys. Rev. Lett.* 83, 324 (1999). © 1999, American Physical Society.

a 2-molecule core. Manipulation experiments at decreased tunneling resistance show that the decamers behave like stable “supermolecules” [33]. Therefore, the structure and stability of the decamers is determined by highly specific intermolecular forces while the interaction of these “supermolecules” with the reconstructed substrate and a mutual repulsion at small distances determine their lateral spacing.

At medium coverage (0.3–0.75 ML) the growth mode changes to the formation of 1D molecular double chains (Fig. 11a at 0.7 ML) guided by the reconstruction domains or by step edges. At full monolayer coverage 1D and 2D periodic molecular structures coexist on the surface [193].

At a tunneling voltage  $V = -2.3$  V, intramolecular structure is resolved and the contrast pattern shows the expected handedness [32]. The charge density calculated for the highest occupied molecular orbital (HOMO) of the free NN molecule closely resembles the observed submolecular structure [32]. At lower bias voltage hybridization with Au-substrate states results in a nearly symmetric appearance of the molecules [196] where the long axis of the ellipsoids coincides with the long axis of the naphthalene core.

Molecular-dynamics simulations rationalize the observed supramolecular arrangements [32]. Within each single strand the molecules are arranged in a “head-to-tail” configuration via hydrogen bonds between a negatively charged oxygen atom and the “backside” hydrogen atom at a carbon atom of a neighboring NN molecule. The second strand is rotated by  $180^\circ$  and shifted by half a period such that opposite charges are close to each other. The double chains are positively

charged outside and therefore mutually repel as observed experimentally. Straight, defect-free segments of the double chains consist of exclusively one NN enantiomer and thus represent a 1D conglomerate [32]. Below a critical density of molecules quasi-0D decamers are energetically more favorable than linear double chains with unsaturated hydrogen bonds at their ends [32]. In the decamers a homochiral molecular ring along the periphery is stabilized by a core composed of two molecules with opposite chirality.

STM observations and theoretical modeling led to a detailed understanding of the stability and the internal geometry of self-assembled supramolecular structures of the 2D chiral molecule 1-nitronaphthalene on Au(111). Recently, these tools were extended to obtain an understanding of the supramolecular self-assembly and selective step decoration of these molecules on the Au(111) surface [197]. Furthermore, a coverage-driven chiral phase transition from a conglomerate to a racemate was followed in real space [34, 198, 199].

Subsequently, other supramolecular nanostructures have been built by self-assembly on surfaces taking advantage of hydrogen bonding [35–37]. These range from one-dimensional supramolecular nanogratings on Ag(111) [35] made of chains of benzoic acid to the mesoscopic correlation of supramolecular chirality in one-dimensional hydrogen-bonded assemblies [36] (see Fig. 12). The stereochemical

effects in supramolecular self-assembly on surfaces, that is, the 1D versus 2D enantiomorphic ordering of these organic molecules, were reported in [37].

In the meantime, a promising new approach towards a controlled self-assembly had been developed for substituted porphyrin molecules adsorbed on a gold surface: the formation of surface-supported supramolecular structures whose size and aggregation pattern were rationally controlled by tuning the non-covalent interactions between individual adsorbed molecules [38].

## 6. CLUSTERS

### 6.1. Electronic Properties

Whereas the electronic structure of atoms, molecules, and extended solids is quite well explored from both an experimental and a theoretical viewpoint, very little is known about the systematic development of the electronic structure as single atoms are combined to form a solid. There are fundamental questions to be answered about the onset of metallic behavior in small metal clusters or the influence of quantum size effects on the electronic structure of small particles. Therefore, it is of primordial interest to study individually, that is, locally, these objects of “embryonic” condensed matter [200].

An ideal tool for this type of investigation is again offered by scanning probe methods which have been used in three pioneering studies of nanometer-size clusters of Au on GaAs(110) [201], Fe clusters on the same surface [202], and of size-selected  $\text{Si}_{10}$  clusters on a reconstructed Au(001) surface [203], which all have been published already in 1989. In the first investigation [201] a characteristic spectrum of bandgap states was observed for the Au particles grown on GaAs. Both donor and acceptor states have been observed and they have been identified with the first and second electron states of the Au-Ga bond, respectively. In the second study, the formation of a local Schottky barrier has been realized by deposition and growth of Fe clusters (9–127 atoms per cluster) on GaAs surfaces in ultrahigh vacuum. STS revealed the onset of the metallic character of the Fe clusters above about 35 atoms per cluster by the observation of a continuum of occupied cluster-induced states at the Fermi energy in the bandgap of the semiconductor [202]. The third experiment [203] represents the first STM/STS study of supported size-selected clusters on a solid surface. The Si clusters were generated by pulsed laser vaporization of a silicon rod in a continuous flow of He buffer gas. The quadrupole mass spectrometer was set to transmit only  $\text{Si}_{10}$  clusters and after mass analysis the ions were focused into a low-energy ion beam and deposited on the sample with an energy of approximately 5 eV, well below the threshold for cluster fragmentation. After cluster deposition the sample was transferred to the STM chamber. During deposition, transfer, and measurement, the sample was maintained under UHV conditions. The cluster images were found to depend on the sample bias voltage, and from STS measurements the clusters were found to have a bandgap of about 1 eV. A wide variety of cluster images were observed even though size-selected clusters were deposited. When only Si atoms were deposited on the surface flat islands

**Figure 12.** (a) Chirality of PVBA upon confinement to two dimensions. The mirror symmetry is reflected by a dashed line. (b) STM topographs of the two possible supramolecular chiral twin chains from self-assembly of PVBA on Ag(111) (image size  $4 \times 13.5$  nm). The corresponding models for the energetically favored configurations reveal the underlying chiral resolution (hydrogen bonds indicated by dashes). Reprinted with permission from [36], J. Weckesser et al., *Phys. Rev. Lett.* 87, 096101 (2001). © 2001, American Physical Society.

were formed. Surprisingly, in spite of these first promising results, up to the present time experiments on size-selected supported clusters with local probes have been scarce.

One interesting experiment used the fact that the tip-surface region of an STM emits light when the energy of the tunneling electrons is sufficient to excite luminescent processes [95]. These processes provide access to dynamic aspects of the local electronic structure that are not directly amenable to conventional STM experiments. In order to explore the lateral resolution obtainable in the photon signal, adsorbed  $C_{60}$  molecules on a reconstructed Au(110)( $1 \times 2$ ) surface were chosen [8]. At sub-monolayer coverage  $C_{60}$  islands with monomolecular height were observed. In the STM image of Figure 13a indi-

**Figure 13.** Au(110) surface covered with an annealed monolayer of  $C_{60}$ . Topograph (a) and photon map (b) are represented as gray-scale images. Area: 6.5 nm by 6.5 nm, tip voltage  $V_t = -2.8$  V, tunneling current  $I_t = 4.4$  nA, intensity scale: 800 cps, temperature of tip and sample: 50 K. Reprinted with permission [8], R. Berndt et al., *Science* 262, 1425 (1993). © 1993, American Association for the Advancement of Science.

vidual  $C_{60}$  molecules are resolved as protrusions. They form an approximately hexagonal array with a corrugation amplitude of 0.1 nm. A comparison of this STM image with the photon emission map measured simultaneously (Fig. 13b) shows that the individual  $C_{60}$  molecules give rise to bright spots in photon emission. The photon emission is maximal when the tip, acting as an electron source, is placed above a molecule. The emitted intensity from intermolecular regions is significantly lower. The lateral extent of the emission spots (0.4 nm full width at half maximum) is smaller than that of the topographic features (0.6 nm). For a few molecules no enhanced emission is observed, indicating that the photon emission channel contains some additional information on  $C_{60}$  not apparent in the topographic image. It was suggested [8] that the molecules interact strongly with the electromagnetic modes of the cavity between tip and sample. In analogy to the case of surface-enhanced Raman scattering (SERS) from molecules in pores of Ag films [100], such a confinement effect may also affect molecular photon emission.

The above experiment [8] was the first photon emission measurement where individual molecules self-assembled in nanometer separation were clearly resolved. This technique has again been used recently to measure photon emission spectra of individual alumina-supported silver clusters obtained by evaporation and growth [9]. The light emission was attributed to the excitation and the decay of local plasmon modes (Mie-plasmon resonances) in these particles [9]. As the cluster size decreases, the resonance shifts to higher energies and the linewidth increases. In the 1.5- to 12-nm size-range of the clusters studied, intrinsic size effects are proposed to be at the origin for the observed size dependence of the Mie resonance [9]. Similar investigations were carried out on Ag clusters on Si single-crystal surfaces, where the light emission enhancement was also ascribed to the excitation of plasmon modes [11]. Moreover, coupled plasmon modes were detected in an ordered hexagonal monolayer of silver nanospheres on Au(111) [10]. A very recent finding was the observation of luminescence from metallic quantum wells, a new phenomenon in STM-induced photon emission [96] from metal surfaces. Another recent highlight in STM-induced light emission was the observation of luminescence from individual supported molecules on an ultrathin alumina film [12].

The energy gap of pristine silicon clusters supported on HOPG has been studied recently by STM and STS [204]. The clusters have been obtained by magnetron sputtering of a Si target and deposition on HOPG at room temperature; that is, they were not size-selected but have been individually addressed by the tip of the STM. Clusters with sizes between 0.25 and 4 nm were studied and the size dependence of the bandgap was determined. For clusters below 1.5 nm, gaps up to 450 meV were found, while for larger particles no gaps were recorded. The results were explained in terms of a transformation from diamond to a compact structure occurring at 1.5 nm (about 44 atoms per cluster). For clusters with diamond structure the surface dangling bond density is high, leading to electronic states filling the energy gap. On the other hand, the compact arrangement of the smaller clusters tends to eliminate dangling bonds. Therefore, finite gap values are observed for clusters with less than 44 Si atoms [204]. Interesting STS results on individual non-size-selected

Pt and Ag clusters produced by a PACIS cluster source and deposited onto HOPG have been obtained recently [205]. The observed spectral structures for Pt have been interpreted in terms of a Fano resonance and those of Ag clusters in terms of three-dimensional electron confinement in analogy to recent spectroscopic findings and interpretations for Kondo systems (Ce atoms and Ce clusters on Ag(111) [24], Co atoms on Au(111) [25], and on Cu(111) [26]), and for two-dimensional electron confinement found in quantum corrals [15, 22, 26] and on islands [16, 19]. Effects of electron confinement have also been observed recently with STS for silver-islands grown in nanopits on HOPG [206].

Recently, STS and STM have been applied to study the onset of the catalytic activity of Au particles grown on titania [207], which appeared to be correlated with the layer thickness of the particles on the surface. In this context, the recent investigations of the catalytic activity of small supported Au clusters on MgO are interesting [208] where the challenge of local investigations with the STM still remains. While inert as bulk material, nanoscale gold particles dispersed on oxide supports exhibit a remarkable catalytic activity. Temperature-programmed reaction studies of the catalyzed combustion of CO on size-selected small monodispersed  $Au_n$  ( $n \leq 20$ ) clusters supported on magnesia, and first-principles calculations, reveal the microscopic origins of the observed unusual catalytic activity, with  $Au_8$  found to be the smallest catalytically active size. Partial electron transfer from the surface to the gold cluster and oxygen-vacancy F-center defects are shown to play an essential role in the activation of nanosize gold clusters as catalysts for the combustion reaction.

The above presentation of the spectroscopic results on deposited clusters clearly shows that valuable information on these nanosystems can now be obtained by the application of an arsenal of local and nonlocal surface science analysis methods. Therefore, in the near future a much more intense employment of scanning probe techniques such as STM, STS, AFM, and others will beyond any doubt improve considerably the assembly, characterization, and functionalization of size-selected clusters on solid surfaces.

## 6.2. Geometric Structure

The microscopic structure is of primordial interest as it influences most physical and chemical properties of the cluster. The determination of the exact microscopic arrangement of the atoms in a cluster on a surface is an enormous experimental challenge. Diffraction methods, which are perfectly adapted to obtain the positions of the atoms in a material, have been applied for the study of free clusters [209–212]. Two other experimental techniques were employed so far to obtain the geometric structure of clusters on surfaces, STM and infrared spectroscopy (IRS). In principle, STM is able to reveal the exact arrangement of all atoms in a planar cluster. For three-dimensional clusters the positions of the topmost layer of surface atoms can be imaged. In favorable cases, the atomic arrangement on the lateral facets was also obtained. In both cases a minimal cluster size seems to be necessary in order to obtain atomic resolution of the individual atoms of the cluster [213].

Infrared spectroscopy can in principle give a more complete picture if all the normal modes in the cluster are obtained. An example for measuring vibrational modes of ligand molecules in a nonlocal mode is given below [214]. When used on the local scale, inelastic electron tunneling spectroscopy (IETS) is especially promising [44].

First attempts for mapping metal clusters on surfaces with atomic resolution were performed in the late 1980s, summarized in [215]. Small two-dimensional platinum and aluminum clusters were imaged on highly oriented pyrolytic graphite (HOPG) with an STM at room temperature. The interpretation of this pioneering work is, however, unconfirmed, as pinning of clusters or contaminations on defects might have influenced the images. Mo et al. [216] showed in a beautiful measurement that the Stranski–Krastanov growth of Ge on Si(001) resulted in a metastable 3D phase consisting of small well-defined hut clusters. These were imaged with atomic resolution and shown to consist of prisms or four-sided pyramids with four [103] facets (see Fig. 14).

The group of Henry achieved a complete characterization of the morphology of a 27-atom palladium cluster supported on a cleaved  $MoS_2$  single crystal [217]. The three-dimensional shape, azimuthal orientation on the substrate, and arrangement of atoms on lateral facets were determined from atomically resolved images of a palladium cluster grown in UHV on the  $MoS_2$  (0001) facet. The resulting *in-situ* STM image is shown in Figure 15. The cluster clearly consists of two monolayers. The first layer is a regular hexagon with a three-atom wide side and an additional atom attached to the left hexagon side. This layer is composed of 20 atoms. The top layer has a regular hexagonal shape and the sides are composed of two atoms, resulting in a top layer of 7 atoms. This  $Pd_{27}$  cluster is schematically shown also in Figure 15. The observed atomic arrangement is identical to the structure of bulk palladium with a (111) basal plane. From this atomically resolved STM image, in particular from the two-dimensional representation, the relative orientation between cluster and the substrate is obtained in real space, showing that the azimuthal orientation of the particle dense-Pd-atom rows are parallel to the rows of sulfur atoms of the  $MoS_2$  surface. So far, this is the only experiment where the number of atoms is directly obtained from the STM image and it seems that the system was well chosen, as for

**Figure 14.** STM image of a single Ge hut cluster. Perspective plot: scan area  $40 \times 40$  nm. The height of the hut is 2.8 nm. Reprint with permission from [216], Y.-W. Mo et al., *Phys. Rev. Lett.* 65, 1020 (1990). © 1990, American Physical Society.

**Figure 15.** (a) STM image of an isolated Pd cluster of small size ( $\sim 1.5$  nm) supported on the (0001) surface of  $\text{MoS}_2$ . A single atom and a trimer are seen on the top and on the bottom of the figure, respectively. (b) Schematic representation of the cluster containing 27 atoms. Reprinted with permission from [217], A. Piednoir et al., *Surf. Sci.* 391, 19 (1997). © 1997, Elsevier Science B. V.

other systems atomic resolution of such small clusters was not obtained.

Imaging large particles on oxide surfaces with atomic resolution is less system-restricted. Hojrup Hansen et al. [213] reported atomic resolution on Pd particles hundreds to thousands of atoms large. The authors believe that obtaining atomic resolution is also possible for other systems as long as the particle diameter is larger than  $\sim 4$  nm and higher than about four layers ( $\geq 500$  atoms/particle). The Pd particles were grown on a 0.5-nm-thick  $\text{Al}_2\text{O}_3$  film. Figure 16 shows STM images of a Pd particle with atomic resolution. It reveals a (111) layer for the top facet. The measured nearest-neighbor distance is  $2.76 \pm 0.07$  Å, indicating the absence of any strain in the cluster ( $d = 2.75$  Å; for

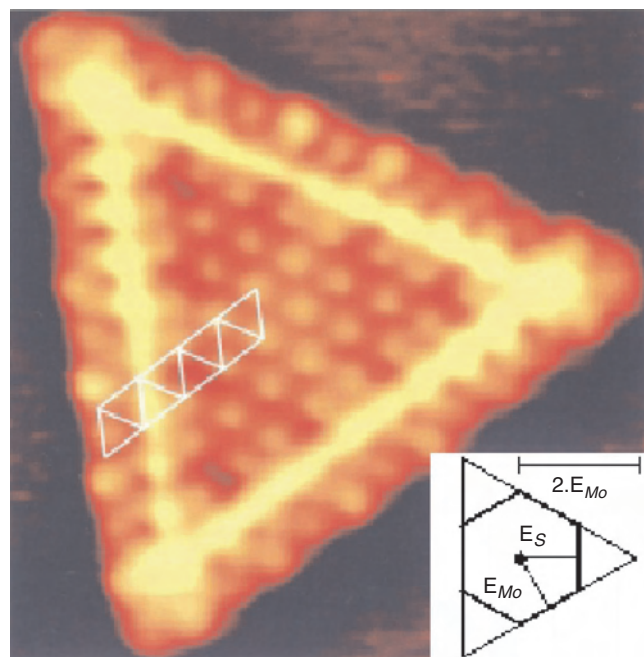

**Figure 16.** Atomic-resolution images of crystalline nanosize Pd clusters. (a)  $9.5 \times 9.5$  nm image size. The resolution is kept a few layers down the sides, allowing identification of the side facets. The dots in (b) indicate the atomic positions consistent with a (111) facet. Pd(111)). In addition, these results show that for such large particles supported on oxide surfaces it is possible to obtain atomic resolution across the entire cluster surface, although the tunneling conditions at the edge of the cluster change. As the tip-apex moves away from the top layer of the particle when approaching the edge, tunneling occurs between the top layer of the particle and the atoms on the side of the tip. In some cases the authors even report atomic resolution on the largest side facets of the particles and observed a (111) crystallographic orientation. In addition, the particle morphology was characterized by three parameters, which are the height of the particles, the width of the top facets, and the ratio between the side lengths of the top facets.

The smallest observed particle with a crystalline structure had a top facet of 2–3 nm widths and a height of 0.5–1 nm, corresponding to a thickness of 2–4 layers. Furthermore, these measurements revealed quantitative information on the work of adhesion. The observed shapes of the particles were compared with the ones resulting from a Wulff construction based on calculated surface energies. For Pd on  $\text{Al}_2\text{O}_3$  a value of  $W_{\text{adh}} = 2.8 \pm 0.2 \text{ J/m}^2$  was reported.

In another example [218] the same group synthesized on a Au(111) template single-layer  $\text{MoS}_2$  nanocrystals with a width of  $\sim 3 \text{ nm}$ . The  $\text{MoS}_2$  nanocrystals were obtained by first growing  $\sim 3\text{-nm}$ -wide Mo particles on the Au(111) template and by subsequent sulfidation in an  $\text{H}_2\text{S}$  atmosphere. Atom-resolved STM images reveal that the small nanocrystals exhibit triangular morphology in contrast to bulk  $\text{MoS}_2$ . Figure 17 depicts an atomically resolved STM image of such a triangular nanocrystal. The observed protrusions are arranged with hexagonal symmetry and an average interatomic spacing of  $3.15 \pm 0.05 \text{ \AA}$ . This is consistent with the interatomic spacing of S atoms in the (0001) basal plane of  $\text{MoS}_2$ . From the apparent height of only  $2.0 \pm 0.3 \text{ \AA}$  the authors conclude that the  $\text{MoS}_2$  nanocrystals are present as single layers on the Au surface. The triangular shape of the monolayer crystals is in contrast to the expected hexagonal morphology of multilayer  $\text{MoS}_2$ . This implies that one of the edge terminations is considerably more stable. To answer which edge structure is more stable, high-spatial-resolution images of the edge structures of the triangles were taken. These atomic-resolution images showed that the S atoms at

**Figure 17.** An atom-resolved STM image ( $4.1 \times 4.1 \text{ nm}$ ) of a  $\text{MoS}_2$  nanocrystal. The grids show the registry of the edge atoms relative to those in the basal plane of the  $\text{MoS}_2$  triangle. The yellow triangle is the manifestation of a one-dimensional electronic edge state. The inset shows a Wulff construction of the  $\text{MoS}_2$  crystal. Reprinted with permission from [218], S. Helveg et al., *Phys. Rev. Lett.* 84, 951 (2000). © 2000, American Physical Society.

the edges are out of registry with the S atoms in the hexagonal lattice of the basal plane and that they are shifted by half a lattice constant along the edge. A comparison with DFT calculations revealed that the observed edge structure is only obtained when the stoichiometry on the edges is changed; for example, only one S atom is bound to a Mo edge atom. Thus these atomic-resolution STM images provided insights into the morphology (shape) and edge structure of the  $\text{MoS}_2$  nanocrystals.

The same group observed directly by STM that a single layer of these  $\text{MoS}_2$  nanoparticles supports one-dimensional electronic edge states (see Fig. 17), which were viewed as one-dimensional conducting wires [219].

For small metal clusters composed of up to a few tens of atoms and supported on metal surfaces, no atomically resolved STM images exist; different cluster sizes can often be distinguished only by small variations in their heights and not by different contrasts in the measured electron density. An interesting method was introduced by Schaub et al. [220] where size-selected  $\text{Ag}_{19}$  clusters on a Pt(111) surface were decorated with rare-gas atoms. This leads to a pronounced corrugation in the rare-gas necklace around the cluster, making the rare-gas atoms a sensitive probe to determine cluster size. Figure 18 shows a high-resolution STM image and a linescan across the cluster of a gas phase deposited  $\text{Ag}_{19}$  cluster on Pt(111) surrounded by 12 Kr atoms. This situation can easily be obtained as the binding energy of Kr to step edges and around the cluster is enhanced. From the observed number of Kr atoms around the silver cluster and the shape of the ring, the cluster size is deduced. By assuming a silver atom diameter of  $2.77 \text{ \AA}$ , and knowing the Pt(111) lattice constant, and by determining the height of the cluster to be of only one monolayer, the authors showed that a regular hexagon containing 19 atoms fits perfectly the topographic image seen in

**Figure 18.**  $\text{Ag}_{19}$  cluster on Pd(111) surrounded by 12 Kr atoms. (a) The image has been filtered to increase the contrast. (b) Linescan across the cluster. (c) Model superimposed to the image. (d) Model. Reprinted with permission from [220], R. Schaub et al., *Phys. Rev. Lett.* 86, 3590 (2001). © 2001, American Physical Society.

Figure 18c. Figure 18d shows that the Kr necklace is sensitive to the form of the cluster and the exact number of silver atoms in the cluster. This is the first experiment where after cluster deposition a one-to-one correspondence between the cluster size in the beam and on the surface was obtained.

## 7. SPECIFIC NANOSTRUCTURES

### 7.1. Insulators

Metal oxides play a crucial role as insulators in many electronic and magnetic devices. As these devices become ever smaller, it becomes more and more important to understand the behavior of ultrathin insulating layers. Recently, the growth of ultrathin insulating NaCl layers on Al(111) [221] and of CoO and NiO layers on Ag(001) [222] has been studied by STM and atomic resolution has been obtained. From the change in image contrast a maximum thickness of three layers for successful imaging was inferred [221]. Based on image contrast as well as on tunneling current versus voltage curves taken on both NiO islands and Ag substrate, the existence of a bandgap has been deduced [222]. For nanostructures of CaF<sub>1</sub> and CaF<sub>2</sub> on Si(111), chemical imaging of insulators has been demonstrated using STS in combination with a simple model for tunneling across two barriers, the vacuum gap and the insulating film [94]. However, no atomic resolution has been obtained in this case and, for CaF<sub>2</sub>, it was only assumed that the full gap is already formed for the first CaF layer on Si(111) [94].

As model system for a metal oxide, Schintke et al. [39] have chosen MgO on silver. The films were grown on a Ag(001) substrate at 500 K by evaporating Mg in an O<sub>2</sub> partial pressure of  $1 \cdot 10^{-6}$  mbar [223]. After deposition of 0.3 ML MgO (Fig. 19a), two-dimensional square islands of 10–15 nm size have nucleated homogeneously on the Ag(001) surface. Some islands are embedded in the silver layer of the upper terrace, due to Ag adatom diffusion [224]. Two different island contrasts (i, ii) near a terrace step (Fig. 19a) are indicative of the position and orientation of the terrace step prior to nucleation. After deposition of about 2 ML MgO (Fig. 19d), the Ag surface is completely covered with MgO, forming terraces of typically 50 nm width and 3D pyramidal islands.

Figure 20a shows representative  $dI/dU$  spectra measured with the tip positioned above a 1-ML-thick MgO island. At negative sample bias (occupied sample states), the LDOS increases at  $-4$  V, whereas at positive sample bias (unoccupied states), two structures are detected around 1.7 V and 2.5 V. Between  $-4$  V and  $+1.7$  V, the tunnel current remains finite and the  $dI/dU$  spectrum is essentially flat. The intensity of the LDOS peak around 1.7 V observed in STS for 1 ML MgO diminishes for 2 ML and is no more detectable for a MgO film of 3 ML (Fig. 20b). This feature is attributed to MgO-Ag interface states [225]. In contrast, the high local density of unoccupied states around 2.5 eV does not decrease with film thickness and is identified with MgO states [226, 227]. Consequently the onset of the 2.5-eV peak observed in STS (Fig. 20a,b) corresponds to the onset of the MgO(001) empty surface state band [228–231].

Combining the local  $dI/dU$  observations of the occupied and unoccupied LDOS on the ultrathin MgO films (Fig. 20)

**Figure 19.** Morphology of MgO thin films: STM images at 50 K. (a) 0.3 ML MgO/Ag(001),  $U = 5.0$  V,  $I = 1.0$  nA; (b) Ag(001) atomic resolution through an MgO island,  $U = 30$  mV,  $I = 2$  pA (left bottom corner: bare Ag substrate); (c) atomic resolution of the MgO layer (one type of ion is resolved),  $U = 2.5$  V,  $I = 50$  pA; (d) 2.0 ML MgO/Ag(001),  $U = 3.0$  V,  $I = 1.0$  nA. Reprinted with permission from [39], S. Schintke et al., *Phys. Rev. Lett.* 87, 276801 (2001). © 2001, American Physical Society.

with the conventional surface science measurements on thick MgO films [232], implies that the electronic structure of a MgO(001) single-crystal surface develops already within the first three monolayers.

First-principles calculations based on DFT yielded the layer-resolved LDOS as a function of the number  $n$  of adsorbed MgO layers ( $0 \leq n \leq 3$ ) [39]. The states at  $\Gamma$  determine the minimum gap width, in agreement with the electronic structure of MgO [226, 231, 233]. In the gap, the average surface LDOS decays exponentially with the number of adsorbed MgO layers. Increasing the MgO film thickness up to three layers produces a surface bandgap corresponding to that of the five-layer pure MgO slab, which is representative for the MgO(001) surface.

Field resonance states influence the STM image contrast [234]. Their modified energetic positions when tunneling through the oxide are used to distinguish between the oxide and the metal. For STM images taken at, for example, 5 V (Fig. 19a), which corresponds to the energetic position of the second Ag(001) field resonance state when tunneling through 1 ML MgO [39], the 1 ML MgO islands appear higher than the Ag-Ag steps. At higher coverage, the apparent MgO-MgO step heights (e.g., Fig. 19d) are found to correspond to their geometric heights when tunneling into MgO states.

At a bias voltage of 2.5 V, atomic resolution of the MgO layer is obtained. (Fig. 19c). The observed surface lattice constant has twice the value of the one of MgO; thus only

**Figure 20.** Electronic structure of ultrathin MgO/Ag(001) films as determined by STS- $dI/dU$  spectra on defect-free regions ( $U$ -sweep interval, tunneling parameters before opening the feedback loop, linear tip-sample distance variation): (a) tip placed above a 1 ML MgO island:  $-6.0$  to  $0$  V,  $U_0 = -6.0$  V,  $I_0 = 0.2$  nA,  $\frac{dz}{dU} = -0.12$  nm/V;  $3.0$  to  $0$  V,  $U_0 = 3.0$  V,  $I_0 = 0.2$  nA,  $\frac{dz}{dU} = -0.16$  nm/V; (b) film thickness dependent  $dI/dU$  spectra:  $3.0$  V to  $1.0$  V,  $U_0 = 3.0$  V,  $I_0 = 1.0$  nA,  $\frac{dz}{dU} = -0.25$  nm/V. Reprinted with permission from [39], S. Schintke et al., *Phys. Rev. Lett.* 87, 276801 (2001). © 2001, American Physical Society.

one type of ion is imaged. According to theory, the observed protrusions are due to accumulated charge density above the Mg atoms. Within the gap ( $-4$  V to  $+2.5$  V), MgO reduces exponentially the probability of tunneling into the substrate. The remaining finite density of Ag states within the gap leads to atomic resolution of the Ag(001) substrate imaged

through a 1 ML MgO island (Fig. 19b). For bias voltages outside the gap, the islands appear always with bright contrast.

Thus, within the first three atomic layers of MgO, a bandgap of about 6 eV develops corresponding to the value found for MgO(001) single crystals. These results do not just constrain the minimum usable thickness for layers of insulating MgO (and, by inference, other wide-bandgap materials). They also suggest that, by carefully controlling the number of dielectric monolayers deposited on a metal substrate, the electronic, magnetic, and chemical properties of the resulting surface could be tuned in a controlled manner. This opens new perspectives for the development of oxide heterostructure-based nanodevices [235].

## 7.2. Vortices

One of the more remarkable states of a superconductor, the Abrikosov flux lattice, is also accessible to STM. New insights into the nature of type-II superconductivity have been achieved by this local probe of the electronic density of states both inside and outside the flux cores [27–29].

The Abrikosov flux lattice was imaged in NbSe<sub>2</sub> by tunneling into the superconducting gap edge. The tunneling conductance into a single vortex core was found to be strongly peaked at the Fermi energy, suggesting the existence of core states or core excitations. Moving laterally away from the core, this peak evolves into a density of states which is consistent with a BCS superconducting gap [27]. Subsequent investigations of the same group [28] revealed a zero-bias peak in the superconducting-vortex-core spectra which splits within a coherence length of the core. Further away from the core these split peaks merge gradually with the gap edge and give a direct local measure of the superfluid velocity. Images of the vortex core states showed an anisotropy which was interpreted as a consequence of the crystalline band structure and the interaction with neighboring vortices of the Abrikosov flux lattice.

The local density of states of a superconducting vortex core has also been measured as a function of disorder in the alloy system Nb<sub>1-x</sub>Ta<sub>x</sub>Se<sub>2</sub> [29]. Here the peak observed in the zero-bias conductance at a vortex center was found to be very sensitive to disorder. The peak gradually disappeared with substitutional alloying and at  $x = 0.2$  the density in the vortex center was found to be equal to that in the normal state. It was suggested that the vortex-core spectra provide a sensitive measure of the quasi-particle scattering time.

## 7.3. Impurities and Superconductors

The competition between magnetism and superconductivity manifests itself in the dramatic reduction of the superconducting transition temperature when magnetic impurities are introduced into a superconductor [236]. Macroscopic planar tunnel junctions doped with magnetic impurities have shown sub-gap features in the density of states [237]. The first direct measurement on the structure of a magnetically induced quasi-particle excitation on the atomic length scale around a single magnetic impurity has only been achieved recently with a low-temperature STM [30].

Tunneling spectra obtained near magnetic adsorbates revealed the presence of excitations within the superconductor's energy gap which were detected over a few atomic

diameters around the impurity at the surface. The details of the local tunneling spectra were rationalized within a model calculation based on the Bogoliubov–de Gennes equations [30].

In the copper oxide high-temperature superconductors the superconductivity is believed to originate from strongly interacting electrons in the  $\text{CuO}_2$  planes. Substitution of a single impurity atom for a copper atom strongly perturbs the surrounding electronic environment and therefore was used to probe high-temperature superconductivity at the atomic scale.

In a very interesting recent experiment [31], a low-temperature STM had been employed to investigate the effects of individual zinc impurity atoms in the high-temperature superconductor  $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ . Intense quasi-particle scattering resonances [238] were found at the Zn sites, coincident with a strong suppression of superconductivity within  $\sim 15\text{\AA}$  of the scattering sites. Imaging of the spatial dependence of the quasi-particle density of states in the vicinity of the impurity atoms revealed the long-sought fourfold symmetric quasi-particle cloud aligned with the nodes of the  $d$ -wave superconducting gap which is believed to characterize superconductivity in these materials.

#### 7.4. Nanoscale Magnetism

A long-standing challenge in magnetism was to correlate the structural and electronic properties on the local scale with the magnetic properties. Two different concepts have been used to achieve spin-polarized vacuum tunneling. (i) With magnetic STM probe tips the spin-valve effect [239] is exploited, which relies on the fact that the tunneling conductance between two ferromagnetic electrodes separated by an insulating barrier depends on whether the magnetic moments are directed parallel or antiparallel. This effect has been studied before in planar tunnel junctions [240–242] and has been applied in STM to probe the topological antiferromagnetic order of a  $\text{Cr}(001)$  surface with a  $\text{CrO}_2$  tip [243]. (ii) Optically pumped GaAs tips enable spin-polarized vacuum tunneling [244], a technique which had been applied to image the magnetic domain structure of thin Co films [245]. (Most recently, electron spin resonance techniques have been combined with STM to detect radio-frequency spin signals from clusters of a few organic molecules [250].)

These experiments were limited by the need to separate topographic, electronic, and magnetic information in the case of magnetic probe tips, and to eliminate thermal or film thickness induced effects in the case of semiconducting tips. These difficulties were overcome by tunneling into the surface state of  $\text{Gd}(0001)$  [40] which is exchange-split into a filled majority and an empty minority spin-contribution [246, 247]. In analogy to the low-temperature experiments performed with ferromagnet-insulator-superconductor planar tunneling junctions [248, 249], where the quasi-particle density of states of superconducting aluminum is split by a magnetic field into spin-up and spin-down part, Bode et al. [40] used two spin-polarized electronic states with opposite polarization to probe the magnetic orientation of the sample relative to the tip. The authors demonstrated spin-polarized tunneling by measuring the asymmetry of the differential tunneling conductance with magnetically (Fe) coated W-tips

at bias voltages corresponding to the energetic positions of the two spin-contributions of the exchange-split surface state in an external magnetic field. This method enabled the separation of the electronic and magnetic structure information. By mapping the spatial variation of the asymmetry parameter, they were able to observe the nanomagnetic domain structure of  $\text{Gd}(0001)$  ultrathin films with a spatial resolution below 20 nm [40].

This group achieved atomic resolution in spin-polarized STM at 16 K by imaging a two-dimensional antiferromagnetic structure within a pseudomorphic monolayer film of chemically identical Mn atoms on  $\text{W}(110)$  [41]. They show, with the aid of first-principles calculations, that the spin-polarized tunneling electrons give rise to an image corresponding to the magnetic superstructure and not to the chemical unit cell. Subsequently, this group observed a magnetic hysteresis on a nanometer scale in an ultrathin ferromagnetic film, consisting of an array of iron nanowires grown on a stepped  $\text{W}(110)$  substrate. The microscopic sources of hysteresis, domain wall motion, domain creation, and annihilation were observed with nanometer resolution [42].

Recently, Kubetzka et al. [43] performed low-temperature spin-polarized STM of two monolayers Fe on  $\text{W}(110)$  using tungsten tips coated with different magnetic materials. With Cr as a coating material, they recorded images with an antiferromagnetic tip. The advantage of its vanishing dipole field was most apparent in external fields. This approach appears to resolve the problem of the disturbing influence of a ferromagnetic tip in the investigation of soft magnetic materials and superparamagnetic particles.

## 8. CONCLUSION

In this review STM and STS experiments at the scale of atoms, molecules, supermolecules, clusters, and other nanostructures have been presented which reveal new and exciting physical and chemical phenomena. The common link is the characterization of the structural and electronic properties of supported nanostructures at atomic-scale spatial and meV-scale spectral resolution. The opportunities of this concept in the emerging field of nanotechnology, where size matters, are evident. For example, a reduction in size often provides an increase in speed for electronic or magnetic devices. Any further advancement towards a future nanotechnology will depend crucially on the precise control, characterization, and ultimately, functionalization, of matter at the atomic and molecular level. This prospect remains an inciting scientific and technological challenge. To cite again R. P. Feynman, *there is plenty of room at the bottom . . .*

## GLOSSARY

**Adatom** An atom adsorbed at the surface.

**Catalytic activity** The capacity of a substance to take part in a chemical reaction.

**Chemical imaging** The possibility to obtain a chemical (elemental) contrast in STM images.

**Cluster** Aggregate formed by atoms.

**Confined electronic state** An electronic state which is confined in one, two or three dimensions. The confinement gives rise to quantum size effects.

**Fano resonance** Interference between two competing electronic transitions leading to the same final state.

**Field resonance state** A two-dimensional unoccupied electronic state which is localized outside the surface.

**High-temperature superconductor** Superconductor with a high critical temperature, typically a ceramic.

**Impurity** An atom (or adatom) of a species different from the one of the medium.

**Kondo effect** Screening of the magnetic moment of an impurity by the conduction electrons of the medium.

**Lifetime** Laps of time during which an excited state exists, before it decays.

**Photon emission** Inelastic process in which photons are emitted during electron tunneling between tip and sample of an STM.

**Standing waves** Stationary electronic waves, due to constructive interference between waves travelling backward and forward.

**Superconductor** Material for which the following properties are verified below the critical temperature: it is perfect diamagnet, it has no measurable DC electrical resistivity, it presents a gap centered around the Fermi level.

**Supramolecular self-assembly** Self-organization of molecule, giving rise to molecular aggregates.

**Surface diffusion** The capacity of an adatom or a molecule to diffuse at surfaces. It depends on both, the adatom and the surface, as well as on the temperature.

**Surface state** Electronic state existing only at the surface, decaying exponentially into bulk and into vacuum.

**Ultrathin insulator** Insulator film grown on a substrate with a thickness of only few atomic layers.

**Vortices** In superconductors, regions of the material that remain in the normal state, through which the lines of the magnetic field pass.

## 1. INTRODUCTION

### 1.1. Quantum Size Confinement

There has been much recent interest in low dimensional systems such as quantum wells, quantum wires, and quantum dots. The interest of this subject stems from two main desires. The first is the desire to understand the transition from molecular to bulk electronic properties, while the other is the prospect of practical application of these materials to optoelectronic devices, photocatalysts, and chemical sensors. Perhaps the most striking property of nanoscale semiconductors is the massive change in optical properties as a function of size due to quantum confinement. This is most readily manifest as a blueshift in the absorption spectra with the decrease of the particle size. The variation of the energy gap in semiconductors with size may also result in different emission wavelengths for different sizes of nanoparticles. One example is shown in Figure 1 [1] for ZnS-capped CdSe nanoparticles with different sizes which display a fluorescence rainbow of blue–green–orange–yellow–red with the emission maxima at 443, 473, 481, 500, 518, 543, 565, 587, 610, and 655 nm, respectively.

The exciton Bohr radius is a useful parameter in quantifying the quantum confinement effects in semiconductor physics. The Bohr radius ( $a_B$ ) of an exciton in semiconductors may be calculated by [2]

$$a_B = \frac{\hbar^2 \varepsilon}{e^2} \left[ \frac{1}{m_e} + \frac{1}{m_h} \right] \quad (1)$$

where  $\varepsilon$  is the dielectric constant,  $\hbar$  is the Planck constant, and  $m_e$  and  $m_h$  are the electron and hole effective mass respectively. As the particle size is reduced to approach

**Figure 1.** Ten different emission colors of different size ZnS-coated CdSe nanoparticles excited with a near-UV lamp. From left to right (blue to red), the emission maxima are 443, 473, 481, 500, 518, 543, 565, 587, 610, and 655 nm, respectively. Reprinted with permission from [1], M. Y. Han et al., *Nature Biotechnol.* 19, 631 (2001). © 2001, Macmillan Magazines Ltd.

the exciton Bohr radius, there are drastic changes in the electronic structure and physical properties. These changes include shifts of the energy levels to higher energy, the development of discrete features in the spectra, and the concentration of the oscillator strength into just a few transitions (Fig. 2) [2].

A straightforward theoretical model based on the effective-mass approximation [2] can be applied to explain most observations. This model has established two limiting regimes: the weak and the strong confinement regimes. The weak confinement regime occurs when the particle radius is larger than the exciton radius. In this regime, the exciton translational motion is confined and the size dependence of the energy of the exciton can be expressed as

$$E_{nl} = E_g - \frac{R_y^*}{n^2} + \frac{\hbar^2 \chi_{nl}^2}{2MR^2} \quad (2)$$

**Figure 2.** A schematic model for the energy structures of bulk solids, nanoparticles, and isolated molecules.

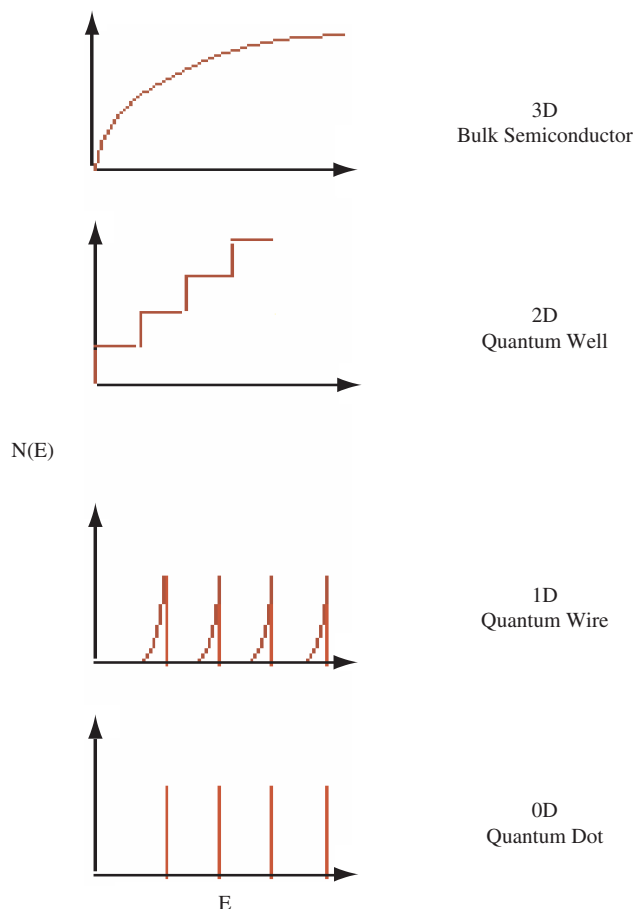

where  $E_g$  is the bulk bandgap,  $R_y^*$  is the exciton Rydberg energy,  $\hbar$  is the Planck constant,  $R$  is the particle size,  $M = m_e + m_h$ , and  $m_e$  and  $m_h$  are the effective mass of the electron and hole respectively.  $X_{nl}$  are the roots of Bessel functions describing the energy states with  $n$  being the number of the root and  $l$  being the order of the function ( $\varphi_{1S} = 3.14$ ,  $\varphi_{1P} = 4.49$ , and  $\varphi_{1D} = 5.76$ ) [2]. The strong confinement regime occurs when the particle radius is smaller than the exciton radius. In this regime, the individual motions of electrons and holes are independently quantized. In this case, the size dependence of the exciton energy can be expressed by

$$E_{nl} = E_g + \frac{\hbar^2}{2\mu R^2} \chi_{nl}^2 \quad (3)$$

where  $\mu$  is the reduced mass of the electron and hole pair,  $1/\mu = 1/m_e + 1/m_h$ .

In both regimes the main experimental effects of confinement are the appearance of a structured absorption spectrum due to the presence of discrete energy levels and the blueshift of the absorption edge, which is roughly proportional to the inverse of the square of the particle radius. However, some electronic properties such as electron–hole interactions are expected to be modified only in the strong confinement regime. This is due to the increase of the spatial overlap of the electron and hole wavefunctions with decreasing size. As a consequence, the splitting between the radiative and nonradiative exciton states is enhanced largely in the strong confinement regime.

Quantum confinement not only causes an increase of the energy gap (blueshift of the absorption edge) and the splitting of the electronic states but also changes the density of states (DOS). Many novel physical properties and potential applications of low-dimensional semiconductors and many of the differences between the electronic behavior of the bulk and of quantum-confined low-dimensional semiconductors are due to their differences in the density of states [3]. Figure 3 shows the variation of the DOS with dimensionality [3]. The dimensionality of the system describes the number of dimensions of free transport of an electron gas; thus boxes are two-dimensional structures, quantum wires are one-dimensional, and quantum dots are considered zero-dimensional because electrons are confined in all spatial dimensions. Passing from three dimensions to two dimensions the density of states  $N(E)$  changes from a continuous dependence, where  $N(E) \sim E^{1/2}$ , to a steplike dependence. Thus the optical absorption features are different for the bulk and for the quantum well structure. The optical absorption edge for a quantum well is at higher photon energy than for the bulk semiconductor and, above the absorption edge, the spectrum is stepped rather than smooth, the steps corresponding to allowed transitions between valence-band states and conduction-band states. In addition, at each step sharp peaks appear corresponding to confined electron–hole (exciton) pair states. In the case of lower dimensional systems (quantum dots, nanocrystallites, clusters, nanoparticles, colloids, etc.), the DOS becomes more discrete as the dimensionality decreases, and large optical absorption coefficients are observed [4]. The low-dimensional structure has proven to be very promising in applications to semiconductor lasers, due mainly to the quantum confinement of the

**Figure 3.** Profiles of the density of states of three-dimensional bulk semiconductors, a two-dimensional quantum well, a one-dimensional quantum wire, and zero-dimensional quantum dots. carriers and the variation of the density of states with dimensionality [5]. The changes in the DOS lead to a change in the gain profile, a reduction of threshold current density, and a reduction of the temperature dependence of the threshold current. Owing to the steplike density of states, high gain with a lower spontaneous emission rate has been realized in a GaAs/AlGaAs GRIN-SCH SQW laser [6]. Thus low-dimensional structured materials are interesting, for both basic research and practical applications.

### 1.2. Quantum Size Confinement and Quantum Efficiency of Nanoparticles

From these arguments, it is clear that nanoparticles may have tunable absorption and emission spectra. In addition, luminescent nanoparticles may have higher quantum efficiency than conventional phosphors, making it possible to design and fabricate more sensitive sensors or more efficient devices. The oscillator strength,  $f$ , is an important optical parameter that underlies the absorption cross-section,

recombination rate, luminescence efficiency, and the radiative lifetime in materials. The oscillator strength of the free exciton is given by [7]:

$$f_{\text{ex}} = \frac{2m}{\hbar} \Delta E |\mu|^2 |U(0)|^2 \quad (4)$$

where  $m$  is the electron mass,  $\Delta E$  is the transition energy,  $\mu$  is the transition dipole moment, and  $|U(0)|^2$  represents the probability of finding the electron and hole at the same site (the overlap factor). In nanostructured materials, the electron-hole overlap factor increases largely due to quantum size confinement, thus yielding an increase in the oscillator strength. The oscillator strength is also related to the electron-hole exchange interaction that plays a key role in determining the exciton recombination rate. In bulk semiconductors, due to the extreme dislocation of the electron or hole, the electron-hole exchange interaction term is very small, while in molecular-size nanoparticles, due to confinement, the exchange term should be very large. Therefore, there may be a large enhancement of the oscillator strength from bulk to nanostructured materials. The radiative decay lifetime ( $\tau$ ) is closely related to the oscillator strength of a transition by [8]

$$\tau = 4.5(\lambda_A^2/nf) \quad (5)$$

where  $n$  is the refractive index and  $\lambda_A$  is the emission wavelength. Thus, the lifetime may be shortened with decreasing size due to the increase of the oscillator strength,  $f$ . Higher efficiencies with concomitant shorter decay times thereby make nanoparticles a promising new type of luminescent material.

## 2. FLUORESCENCE OF SEMICONDUCTOR NANOPARTICLES

Typical absorption and fluorescence spectra of CdS nanoparticles are shown in Figure 4 [9]. The sizes of the two samples estimated from the absorption edge are 3.4 nm

**Figure 4.** Absorption and emission spectra of CdS nanoparticles. Sample I is 3.4 nm in size and sample II is 4.3 nm. Reprinted with permission from [9], A. Hasselbarth et al., *Phys. Lett.* 203, 271 (1993). © 1993, Elsevier Science.

(sample I) and 4.3 nm (sample II) respectively. Both of the samples exhibit a sharp excitonic fluorescence band (at 435 nm for the 3.4 nm sample and 480 nm for the 4.3 nm sample), as well as a broad fluorescence band at longer wavelengths arising from the recombination of trapped charge carriers at surface or defect states.

Optical excitation of semiconductor nanoparticles often leads to both band-edge and deep trap luminescence. The size dependence of the excitonic or band edge fluorescence has been studied extensively and can be reasonably explained by the effective-mass approximation. The fluorescence process in semiconductor nanoparticles is very complex and most nanoparticles exhibit broad and Stokes-shifted luminescence arising from the deep traps of surface states [10]. Only clusters with good surface passivation show high band-edge emission. The absence of band-edge emission has been previously attributed to the large nonradiative decay rate of the free electrons trapped in these deep-trapped states. As the particles become smaller, the surface/volume ratio and hence the number of surface states increases rapidly, reducing the excitonic emission [11]. Thus, surface states often determine the physical properties, especially the optical properties, of nanoparticles. Often, however, little is known about the physical properties of the surface states.

For particles in such a small size regime, a large percentage of the atoms are on or near the surface. Surface states near the bandgap can mix with interior levels to a substantial degree, and these effects may also influence the spacing of the energy levels. Thus, in many cases it is the surface of the particles rather than the particle size that determines the properties. It is, therefore, a major goal to characterize the surface states and to control them through chemical modification. For example, 99% of the atoms are on the surface for a 1 nm sized Si particle [3]. The existence of this vast interface between the nanoparticles and the surrounding medium can have a profound effect on the particle properties. The imperfect surface of the nanoparticles may act as electron and/or hole traps following optical excitation. Thus the presence of trapped electrons and holes can in turn modify the optical properties of the particles.

Although there are many reports on the luminescence of nanoparticles, only a small number are dedicated to the size dependence of the fluorescence from surface states. By examining the size dependence of the two main emission features (i.e., the excitonic and the trapped emissions), it is possible to determine to what extent the carriers are confined in the emitting state. If the luminescence and the absorption of the surface states are dependent on size, it indicates that not only the excitons but also the trapped carriers at the surface states are confined by the quantum size effect. If the luminescence of the surface states is not dependent on size, then the trapped carriers are not likely confined by the quantum size effect. Thus knowledge of the surface and defect states response to quantum confinement may be important when attempting to adjust the energy levels of the surface states relative to the intrinsic levels through quantum confinement.

The emission spectra of ZnS nanoparticles of different sizes are shown in Figure 5 [12]. No excitonic emission is observed in the ZnS nanoparticles. The luminescence clearly arises from trap states, indicating that the surfaces of the

**Figure 5.** Luminescence spectra of ZnS nanoparticles with average sizes of 1.24, 1.65, and 2.28 nm, respectively. The luminescence exhibits almost exclusively trap state emission, likely because of poor surface passivation. Reprinted with permission from [12], W. Chen et al., *J. Appl. Phys.* 82, 3111 (1997). © 1997, American Institute of Physics.

particles are not well passivated. The luminescence intensity increases as the size decreases, as the increase in the trapped states results in more luminescence. The trap state emission also shifts to the blue as the size decreases demonstrating that the trap states exhibit quantum confinement behavior. Similarly, the results reported by Hoheisel et al. [13] show that both the excitonic and the trap state emission peaks shift in energy as a function of size in CdSe nanoparticles (Fig. 6), demonstrating that the emission energy of the surface states in these particles is also correlated to the quantum-size effects.

### 3. LUMINESCENCE DYNAMICS

Absorption of a photon places an atom or molecule in a naturally meta-stable excited state. This meta-stable state must ultimately re-emit the energy in one or more of three possible relaxation pathways. The first is radiative, via either fluorescence or phosphorescence. The second pathway is through nonradiative processes such as internal conversion

**Figure 6.** Absorption and emission spectra of CdSe nanoparticles with average sizes of 9, 11, 13, 16, and 21 Å. Quantum confinement results in both the excitonic and trap state emissions clear blueshift with decreasing particle size. Reprinted with permission from [13], V. Hoheisel et al., *J. Chem. Phys.* 101, 8455 (1994). © 1994, American Institute of Physics.

or energy transfer. The third possibility is chemical change, such as the breaking of bonds to form a new chemical species.

In a typical experiment, a photon is absorbed taking the atom or molecule from the ground state to an excited state, where the excited state may be a rotationally and/or vibrationally excited molecule in the electronic excited state. Internal conversion is the process where ro-vibrational energy is lost to the surroundings as the molecule cascades down the ro-vibrational ladder. In solids, promotion of an electron from the valence band to the conduction band produces an excited state which may then relax by phonon relaxation to the conduction band edge. This energy is ultimately lost as heat to the surroundings. Internal conversion in excited states is very rapid relative to radiative rates and therefore the system may be assumed to radiate from the lowest energy level of the lowest excited state of like multiplicity. This is known as “Kasha’s rule” and is obeyed a majority of the time [14].

Once in the lowest excited state, there are many possible forms of relaxation, both radiative and nonradiative. The total rate of relaxation is the sum of all rates. In this chapter we will assume that there is no chemical change and that all luminescence originates from the lowest excited state (Kasha’s rule) [14]. Therefore the total relaxation rate ( $k_t$ ) out of the lowest excited state is given by

$$k_t = k_{\text{rad}} + k_{\text{non}} \quad (6)$$

where  $k_{\text{rad}}$  and  $k_{\text{non}}$  are the radiative and nonradiative rates respectively. The observed luminescence therefore decays exponentially with time,

$$I(t) = I(0) \exp(-t/\tau_{\text{obs}}) \quad (7)$$

with the observed lifetime  $\tau_{\text{obs}}$  proportional to  $1/k_t$ . Thus, in a purely radiative system such as an isolated atom, the observed lifetime is proportional to the inverse of the radiative rate. In this case, the lifetime is termed the natural radiative lifetime. The natural lifetime may be related to the absorption strength or oscillator strength  $f$  by Eq. (5). Thus, a strong transition has a large radiative rate and therefore a short natural lifetime.

Most photochemical systems are not purely radiative; therefore the influence of nonradiative transitions must be taken into account. Nonradiative transitions in general serve to deplete the excited state, thus increasing  $k_t$ . This results in a shortened observed lifetime  $t_{\text{obs}}$ , which is shorter than the natural radiative lifetime. In some cases, nonradiative energy transfer from a nearby excited molecule or atom results in promotion of a ground state atom or molecule to its excited state. If the energy transfer is fast relative to the spontaneous luminescence rate, the luminescence does not display a single exponential decay but exhibits a rise followed by a decay as the population of the excited level initially increases due to the energy transfer. The rise time of the luminescence may then be related to the energy transfer rate, while the fall time can be related to  $k_t$  in a straightforward manner.

It is important to realize that in the absence of this energy transfer, all excited state luminescence from a single species should display a single exponential decay. In practice, often

biexponential or higher order lifetime decays are observed. The existence of a biexponential decay does not, however, imply two different rate processes for a single species but rather the existence of two distinct subsets of species, each with its own unique lifetime. Higher order, multiexponential decays then represent larger numbers of distinct species and often can be modeled as a distribution of species, each with its own decay constant.

It is clear that the longer the natural lifetime, the higher the probability for nonradiative processes to deplete the excited state. Nonradiative processes also result in a shortened lifetime; however, the luminescence efficiency similarly decreases. Thus, the goal in luminescent systems is to increase the luminescence efficiency either through increasing the radiative rate (decreasing the natural lifetime) or decreasing the nonradiative rate (increasing the observed lifetime). Nanoparticles may have an increased natural radiative rate and thus enhanced quantum efficiency due to the effects of quantum confinement on the electron-phonon coupling and DOS. However, in nanoparticles, perhaps the single most important contribution to the nonradiative rate is trapping to surface states. Trapping to surface states usually occurs on the subnanosecond timescale [15]. Figure 7 shows luminescence decays from  $\text{Eu}_2\text{O}_3$  nanoparticles encapsulated in the porous host MCM-41 [16]. The existence of multiple time regimes is apparent as subnanosecond to millisecond timescale decays are represented. The subnanosecond decays shown in the inset of Figure 7 have been attributed to either species exhibiting surface state trapping of carriers or else to energy transfer to defect states within the MCM-41. Passivation of surface states is therefore a key requirement in increasing the luminescence efficiencies of nanoparticles relative to bulk materials [16].

**Figure 7.** Lifetime decay curves of the  ${}^5D_0 \rightarrow {}^7F_2$  emission following excitation at 525 nm of  $\text{Eu}_2\text{O}_3$  bulk powder, an  $\text{Eu}_2\text{O}_3/\text{MCM-41}$  mixture, and  $\text{Eu}_2\text{O}_3$  particles in MCM-41 prepared by heat treatment at 140, 600, 700, and 900 °C. The inset shows an expanded view of the short-time (<1 microsecond) time regime for the bulk powder and the sample prepared at 600 °C. Reprinted with permission from [16], W. Chen et al., *J. Phys. Chem. B* 106, 7034 (2002). © 2002, American Chemical Society.

#### 4. PHOTOLUMINESCENCE OF DOPED SEMICONDUCTOR NANOPARTICLES

Semiconductor nanoparticles may also be doped with impurities that have a strong luminescence of their own. Quantum size confinement affects not only the excitonic emission in the host but also the luminescence from the dopants. Figure 8 shows the luminescence spectra of both nanocrystalline and bulk ZnS:Eu<sup>2+</sup> at different temperatures [17, 18]. Two differences can be observed between the bulk and the nanoparticles. One is that the emission of the nanoparticles is shifted to shorter wavelengths; the second is that strong luminescence is observed from the nanoparticles, while the luminescence from bulk ZnS:Eu<sup>2+</sup> is only observed at low temperature [18]. In order to understand the emission shift, the energy structure of the ZnS:Eu<sup>2+</sup> system must be considered. The ground state of Eu<sup>2+</sup> is 2.25 eV below the edge of the conduction band, and its first excited state is ~0.35 eV above the edge of the conduction band in bulk ZnS [18]. The excited states of Eu<sup>2+</sup> are degenerate with the continuum of the conduction band (CB). Photoionization occurs very easily, and no intraion transition is observed, because the intraion excitation process requires a larger energy than that for the photoionization transition. In order to observe the intraion transition of Eu<sup>2+</sup> in the ZnS:Eu<sup>2+</sup> system, the edge of the CB needs to be raised above the first excited state of Eu<sup>2+</sup>. This may be realized via quantum size confinement. If the diameter of ZnS:Eu<sup>2+</sup> nanoparticles is smaller than 3.5 nm, the edge of the ZnS conduction band moves to higher energy than the first excited state level of Eu<sup>2+</sup> and thus enables the intraion transition of Eu<sup>2+</sup> ions (see Fig. 9) [17].

The Eu<sup>2+</sup>-bound exciton luminescence in bulk ZnS decreases rapidly with increasing temperature from 4.2 to 80 K and is barely visible at 200 K [18]. However, in ZnS:Eu<sup>2+</sup> nanoparticles, the Eu<sup>2+</sup> bound exciton luminescence is observed at room temperature. This indicates that the bound exciton in nanostructured semiconductors may be more stable with respect to multiphonon relaxation, and its luminescence efficiency is higher compared to that of the bulk. This is attributed to quantum size confinement.

**Figure 8.** The traces on the left are the emission spectra of the 3 nm sized ZnS:Eu<sup>2+</sup> nanoparticle at room temperature excited at 260, 340, and 390 nm, respectively [17], and the traces on the right are the 488 nm excited emission spectra of bulk ZnS:Eu<sup>2+</sup> at 4.2, 100, and 200 K. Reprinted with permission from [18], W. Chen et al., *Phys. Rev. B* 61, 11021 (2000). © 2000, American Physical Society.

**Figure 9.** Energy levels of bulk ZnS:Eu<sup>2+</sup> and ZnS:Eu<sup>2+</sup> nanoparticles. The energy levels of Eu<sup>2+</sup> are in black, while the energy levels of the ZnS host are in gray. In bulk ZnS:Eu<sup>2+</sup>, the lowest excited state of Eu<sup>2+</sup> is within the conduction band of ZnS; no emission is observed from the intraion transition of Eu<sup>2+</sup>. In nanoparticles, due to the increase of the energy gap of ZnS, the lowest excited state of Eu<sup>2+</sup> is moved into the energy gap, and therefore strong luminescence from the intraion transition of Eu<sup>2+</sup> is observed at room temperature. Reprinted with permission from [18], W. Chen et al., *Phys. Rev. B* 61, 11021 (2000). © 2000, American Physical Society.

Quantum confinement increases the exciton binding energy and recombination rate, due to the increase of the overlap between electron and hole wavefunctions. In doped semiconductors, the excitons are bound to impurity centers. Thus, the oscillator strength is given by [19]

$$f = f_{\text{ex}} \left| \int dx F(x) \right|^2 / \Omega_{\text{mol}} \quad (8)$$

where  $f_{\text{ex}}$  is the oscillator strength of the free exciton,  $\Omega_{\text{mol}}$  is the volume of one molecule, and  $F(X)$  is the envelope function. The oscillator strength of a bound exciton is actually given by  $f$  multiplied by the number of molecules covered by the overlap of the electron and hole wavefunctions. The absorbance and luminescence efficiency are proportional to the exciton oscillator strength; therefore, they can be enhanced via quantum size confinement. Strong evidence for this theory comes from our observations of ZnS:Mn<sup>2+</sup> [20] and EuS [21] nanoparticles, since the luminescence intensity of the 1 nm sized ZnS:Mn<sup>2+</sup> nanoparticles in zeolite-Y is much stronger than other sizes of ZnS nanoparticles [20]. More interesting is that bulk EuS at room temperature is not luminescent but strong luminescence is observed when EuS nanoparticles are formed in zeolites [21].

#### 5. ELECTROLUMINESCENCE OF NANOPARTICLE LIGHT EMITTING DIODES

Light-emitting diodes (LEDs) from organic polymers and II–VI semiconductor nanocrystals have attracted considerable attention because polymer nanoparticle composites combine key properties required for flat-panel displays (FPDs) including low weight, low power, low voltage, and compact size [22]. FPDs are gradually replacing many of the traditional cathode ray tube (CRT) displays in military applications and in civilian technologies, such as information processing. However, FPDs do have limitations that prevent their wholesale adoption. Most notably they lack the

brightness and resolution of CRTs. This restricts their overall readability, particularly in bright light. Flat-panel displays also face area limitations because the complexity increases with size.

Technology based on highly luminescent semiconductors holds the potential to overcome these shortcomings. Nanoparticle LEDs (NLEDs) can provide improved brightness and multicolor capabilities compared to many of the existing flat-panel technologies. In addition, the extremely small size of nanoparticles creates the prospect of displays with unprecedented resolution. Besides their low cost and color availability, thin-film displays made from NLEDs offer additional competitive advantages over other display technologies. Importantly, NLEDs display turn-on voltages ( $E_{on}$ ) in the range of 5–10 V [22–24] which are significantly lower than in liquid crystal FPDs. One of the most appealing advantages is that a thin film formed either by spin coating or by layer-by-layer (LBL) assembly can be laid over virtually any solid substrate and will contour to the shape of the substrate.

Formation of a LBL assembled LED may be performed as follows: For deposition of poly(*p*-phenylenevinylene) (PPV) hole transport layers, indium tin oxide (ITO) glass is immersed in a poly-acrylic acid solution (1%, pH = 8) for 15 minutes then the ITO glass is rinsed with deionized water and immersed in a *p*-PPV solution for 15 minutes and rinsed with water. This step is repeated nine times, so that 10 bilayers of PPV with a total thickness of ~70 nm are deposited on the ITO slide.

Next, the nanoparticle emitting layers of CdTe/polydiallyldimethylammonium (PDDA) are deposited on the PPV-coated ITO slide. In order to accomplish this, the PPV-coated ITO is immersed in PDDA solution (1%, pH = 8–9) for 30 minutes, rinsed with deionized water, immersed in a CdTe nanoparticle solution for 30 minutes, and then rinsed again with deionized water. These steps are repeated to obtain a desired thickness, though the immersion time for subsequent cycles may be reduced to as short as 5 minutes.

Next, a cathode (Al) of about 0.97 cm<sup>2</sup> is deposited on the nanoparticle side by a thermal evaporator and contact leads are attached to the anode (ITO) and cathode (Al) for electroluminescence and current-voltage measurements. The structure of the nanoparticle LED is schematically shown in Figure 10. By applying voltage, electroluminescence (EL) is observed from the LED. Figure 11 shows electroluminescence spectra of a CdTe/PPV nanoparticle LED at different

**Figure 10.** A schematic model for the structure of a semiconductor nanoparticle light-emitting diode.

**Figure 11.** Electroluminescence spectra of a CdTe nanoparticle light-emitting diode at different applied voltages. Reprinted with permission from [24], W. Chen et al., *J. Nanosci. Nanotechnol.* 1, 47 (2002). © 2002, American Scientific Publishers.

applied voltages [24]. The electroluminescence of the LED is visible to the naked eye. At 4 V, the electroluminescence is detectable, and its intensity increases with applied voltage up to 9.21 V. At voltages greater than 9.21 V, the EL decreases in intensity. The color (emission wavelength) also changes at different voltages. At higher voltages, the emission wavelength shifts toward the red.

Figure 12 shows the absorption, photoluminescence, and electroluminescence spectra of the LED, CdTe nanoparticles, and *p*PPP/PPV solution [24]. The absorption of the *p*PPP/PPV solution occurs between 300 and 400 nm, while the absorption of CdTe nanoparticles is at around 550 nm. The fluorescence bands of *p*PPP/PPV are at 460

**Figure 12.** Absorption (ABS) and fluorescence (FL) of a *p*PPP/PPV solution (*p*PPP/PPV), a CdTe nanoparticle solution (CdTe), and CdTe/*p*PPP layer-by-layer thin film before (LBL1) and after (LBL2) curing. and 510 nm, while the CdTe nanoparticles have emission at 600 nm. After curing, the absorption and luminescence of *p*PPV/PPV and CdTe particles both increase in intensity, and the luminescence emission of *p*PPV/PPV is stronger than that of CdTe nanoparticles. However, in the EL spectra, only the emission of CdTe nanoparticles is observed, due to the confinement of carriers (electrons and holes) in the particle layers. In addition, the EL emission spectrum is shifted to longer wavelengths compared to the PL spectra of the thin film and of the particle solution.

The redshift of EL from photoluminescence (PL) is a common phenomenon observed in nanoparticle light-emitting diodes [25]. This redshift has been attributed to the effect of reabsorption of a portion of the EL within the nanoparticle layer or to the Förster energy transfer from small to large nanoparticles [25]. However, these two processes cannot reasonably explain the redshift of the EL from PL, because reabsorption or Förster energy transfer from small to large particles occurs in both EL and PL, provided the emission of the small particles overlaps partially with the absorption of the larger particles.

This redshift may also be the result of size selection due to charge injection. For smaller nanoparticles, the carrier injection barriers are larger due to stronger quantum confinement (with larger energy gaps). Thus, at lower applied voltages, carrier injection occurs preferentially in larger particles while at higher voltages, injection occurs in both large and small particles. If this is the case, the EL should shift to the blue (shorter wavelengths) from low to high applied voltages. However, no shift has been observed in CdSe(CdS) nanoparticle LEDs reported in [25]. On the contrary, it has been observed here that the EL shifts to the red (longer wavelengths) at higher applied voltages. Thus, size selection does not reasonably explain the observed redshift of the EL from PL.

Heating and oxidation of the nanoparticles may cause a redshift of the emission energy. However, based on our observations, heating is not likely a major problem. If the device undergoes significant heating, spot lines longer than 700 nm should be observed, and the device should lose its emission quickly. The device continues working at 28 V and no spot line is detected until the device stops working, indicating little heating. On the other hand, oxidation cannot be avoided when the device operates in air. Oxidation may create some defects in the energy gap of the nanoparticles and may shift the emission to longer wavelengths [26].

In nanoparticles or clusters, most of the atoms or ions at the surface are not coordinatively saturated. Excited electrons or holes may be trapped at surface states located in the forbidden gaps. Thus in nanoparticles both excitonic and surface emissions are usually observed. It is known that the exciton luminescence from nanoparticles involves some contribution from the surface carriers, and this can shift the excitonic emission to lower energies. This may provide another explanation for the redshift of electroluminescence compared to photoluminescence. The excitation energy for electroluminescence is much less than the energy gap of the emitting materials. When the excitation energy is comparable to or higher than the barrier energy, which is 1 to 2 eV, carrier injection occurs and electroluminescence follows. Excitation at such low energies cannot produce a

transition from the ground state to the excited states as in photoluminescence; however, it can excite the surface trap states in the nanoparticles, which have energy depths of 0.5 to 2 eV [12, 27, 28, 31]. Similar ideas are used to explain the anti-Stokes luminescence of CdTe nanoparticles.

The quantum confined Stark effect (Franz-Keldysh effect) [26] is another factor that may lead to a redshift of the electroluminescence from the photoluminescence. The electric field may push electrons and holes in opposite directions making the energy separations smaller, inducing a redshift. If the redshift is induced by only the quantum confined Stark effect, the shift should be linear or monotonic to the red upon increasing applied voltage. However, this is not the case as observed in Figure 11. Therefore other factors such as the involvement of surface states must be considered in order to explain the observations.

## 6. THERMOLUMINESCENCE

Thermoluminescence (TL) is luminescence generated following excitation with heat instead of visible or near-infrared photons. Obviously the TL process is different from the PL process, as the energy of thermostimulation is not sufficiently high to excite the electrons from their ground states to their excited states. Thus, TL arises from defect or trap states within the bandgap. The energy corresponding to the peak of the TL spectrum, called a glow curve, is equal to the trap depth. In TL, trapped carriers may be formed during sample processing, because the small particles have large numbers of ions at the surface, and most ions at the surface are not coordinatively saturated. Carriers trapped at the surface states or defect sites may be released by heating to recombine to give thermoluminescence. Since trapping is a very fast process [15], spontaneous luminescence cannot effectively compete with it. Therefore, TL is a good method for studying the trapped carriers and the surface states.

Figure 13 shows the glow curves of capped ZnS nanoparticles recorded without prior irradiation. Equal amounts of sample were used for each measurement. The sizes of the particles are 1.24, 1.65, and 2.28 nm, respectively [12]. An obvious glow peak around 380 K is exhibited from the nanoparticles. All three samples show the glow peaks at almost the same position and the TL intensity increases as the particle size decreases. The intensity change of the TL is consistent with that of surface luminescence. The glow peaks in Figure 13 are caused by the trapped carriers which are produced during sample processing, because these samples had not been previously exposed to radiation. TL from semiconductor nanoparticles without any prior irradiation has been observed in CdS [30] and ZnS nanoparticles as well [12, 31]. Preexisting carriers or occupation of localized states has been proposed by Chenstnoy et al. [32] to explain the very weak dependence of the fluorescence decay lifetime upon CdS cluster size and by Klimov et al. [33] to explain the extremely fast buildup dynamics of the low-energy emission bands of CdS nanocrystals.

According to the theories of thermoluminescence [34], the TL intensity of clusters is given by

$$I = -\frac{dm}{dt} = mnA \quad (9)$$

**Figure 13.** Thermoluminescence glow curves of ZnS nanoparticles with average sizes of 1.24, 1.65, and 2.28 nm, respectively. Reprinted with permission from [12], W. Chen et al., *J. Appl. Phys.* 82, 3111 (1997). © 1997, American Institute of Physics.

where  $m$  and  $n$  represent the density of holes and electrons for recombination, and  $A$  is the carrier recombination probability. Decreases in the particle size may enhance the surface ions and states rapidly. As the content of the surface states increases, the particles may provide more accessible carriers (holes and electrons) for the TL recombination [i.e.,  $m$  and  $n$  in Eq. (9) are proportional to the surface states]. Furthermore, in nanoparticles the overlap of the electron and hole wavefunctions is stronger, which may result in the increase of their recombination probability or rate ( $A$ ). These two effects may make the TL of small particles much stronger than that of the bulk and increase the intensity of the luminescence as the size decreases.

## 7. CATHODOLUMINESCENCE

Cathodoluminescence is luminescence excited by an electron beam such as that observed in traditional cathode ray technologies. The excitation mechanism under electron beam excitation consists of electron transitions from the valence to conduction band of the lattice followed by transfer of the electron-hole (e-h) recombination energy to luminescent ions that may be doped into the phosphor. The efficiency of the process ( $\eta_{cr}$ ) can be written as [35]

$$\eta_{cr} = (1 - r_b)(h\nu_m/\varepsilon)\eta_l\eta \quad (10)$$

where  $r_b$  is the primary backscattering coefficient,  $h\nu_m$  is the mean energy of the luminescent photons,  $\varepsilon$  is the average energy required to generate one e-h pair,  $\eta_l$  is the efficiency for transfer of the e-h recombination energy to luminescent ions, and  $\eta$  is the quantum efficiency of the activator

emission. In general,  $r_b$  increases with the average atomic number of the material atoms [35].

Within the material the incident electron loses its energy either by generating e-h pairs or by creation of optical phonons. The energy required to create e-h pairs ( $\varepsilon$ ) increases with increasing bandgap. For high efficiency the bandgap must be slightly larger than the energy of the photons emitted; therefore ZnS with a bandgap of 3.8 eV is an appropriate material for emission in the visible range.  $\varepsilon$  also increases with the phonon energy; thus sulfides are more favorable than oxides regarding this characteristic because sulfides in general have lower energy phonon spectra relative to their oxide counterparts. The highest efficiency cathodoluminescence materials include ZnS:Cu, Al, ZnS:Ag, Cl, CaS:Pb, and CaS:Ce, with energy efficiencies between 15 and 20%. Other materials such as Y<sub>2</sub>O<sub>2</sub>S:Eu, Gd<sub>2</sub>O<sub>2</sub>S:Tb, and LaOBr:Tb have efficiencies between 8 and 14%, while Y<sub>2</sub>O<sub>3</sub>:Eu, Y<sub>3</sub>(Al, Ga)<sub>5</sub>O<sub>12</sub>:Tb, YVO<sub>4</sub>:Eu, Zn<sub>2</sub>SiO<sub>4</sub>:Mn, and Y<sub>2</sub>Si<sub>2</sub>O<sub>7</sub>:Ce show relatively low 4–7% efficiencies [35].

The development of flat-panel field-emitting displays requires phosphors with high cathodoluminescence efficiency at electron acceleration voltages near 1 kV, and high-definition displays require submicrometer particle sizes to maximize screen resolution and screen efficiency [36, 37]. Semiconductor nanoparticles, particularly Mn-doped ZnS nanoparticles, have been shown to have the required cathodoluminescence properties and suitable size range [37, 38].

Recent studies have shown that the cathodoluminescence spectra of annealed ZnS:Mn/ZnO nanoparticles resemble the spectra of the bulk phosphor (Fig. 14) [38]. The inorganic ZnO cap layer is essential for bright cathodoluminescence, which is 4 times brighter than MgO capped nanoparticles. The annealed nanoparticles are about 200 times brighter than the unannealed particles and 40% as

**Figure 14.** Cathodoluminescence spectra of ZnS:Mn/ZnO samples. The unannealed nanoparticles (solid curve), annealed nanoparticles (dashed curve), and the Sarnoff phosphor (dotted curve) are shown. The electron acceleration voltage was 650 V and the current was 24  $\mu$ A (120  $\mu$ A/cm<sup>2</sup>). Inset: comparison of the photoluminescence (PL) and cathodoluminescence (CL) spectra of the unannealed nanoparticles. Reprinted with permission from [38], A. D. Dinsmore et al., *J. Appl. Phys.* 88, 4985 (2000). © 2000, American Institute of Physics.

bright as the bulk material. In addition, the annealed nanoparticles exhibit 50% less saturation with increasing electron-beam current. Furthermore, the nanoparticle annealing temperature (535 °C) is much lower than the firing temperatures used in commercial bulk ZnS:Mn processes [37, 38].

In addition, the Mn doping concentration in ZnS:Mn material also affects the cathodoluminescence efficiency as for photoluminescence, and it has been found that ~2 wt% is the optimal concentration for bulk material [36] and may be similar in nanoparticles [38]. In short, small size, high quantum efficiency, reduced current saturation, and lower processing temperature make nanoparticles attractive for use in new high-resolution display technologies.

## 8. MAGNETOLUMINESCENCE

Recent advances in producing zero-dimensional semiconductor quantum well structures such as InGaAs/GaAs [39–41], InAs/GaAs [42–44], CdMnTe [45–48], CdSe/ZnSe [49, 50], and CdTe [47, 51] by use of epitaxial or other growth techniques has allowed the study of both excitonic structure and dilute magnetic systems (DMS) by using magnetoluminescence (ML). The quantum dots are prepared such that the vertical confinement is provided by the well potential and the lateral confinement is usually provided by a strain field due to lattice mismatch during growth. Thus quantum dots represent a zero-dimensional structure with few carriers within the well potential. The shallow well depth of the potential means that with magnetic fields of a few tens of Tesla, the cyclotron energy can be made larger than the binding energy, thus allowing the study of the transition from bound well states to bulklike Landau levels.

In a typical magnetoluminescence experiment in a semiconductor, the luminescence from either exciton recombination or dilute magnetic spin dopants such as  $Mn^{2+}$  is recorded as a function of an applied external magnetic field. One traditional problem with ML experiments is that the luminescence spectra from quantum dots (QDs) is often quite broad due to size and shape dispersion. The broad peaks tend to limit the shifts and splitting observed in a ML experiment. While the inhomogeneous nature of the luminescence usually results in broad lineshapes, early work on InGaAs/GaAs self-organized quantum wells was able to resolve the discrete states that exist in these unique structures [39]. Since then, most magnetoluminescence experiments have utilized various techniques to limit the luminescence viewing area to single or small numbers of QDs, in order to observe the underlying sharp excitonic structure in the inhomogeneously broadened spectra. Techniques such as near-field microscopy [52] and the use of small apertures or masks [46, 47, 49–51, 53] have allowed the observation of single or near single QDs with narrow emission linewidths.

Recently much work has been focused on the magnetoluminescence from semiconductor quantum dots, mostly using GaAs and InPGaAs structures. The magnetic length, given by  $(\hbar/eB)^{1/2}$ , of commonly used magnetic fields is on the order of 10 nm, making ML a good way to study interactions in small quantum dot systems. The application of a magnetic field has two effects on QDs. First it induces a

Zeeman splitting of the magnetic sublevels within an angular momentum state. Second, it induces a diamagnetic shift of the levels which, under high fields, resort to traditional bulklike Landau levels.

Most work has centered on excitonic luminescence in these systems. Due to the axial symmetry resulting from the strain field, the exciton in many QD systems may be characterized by a radial quantum number and an angular momentum quantum number  $m$ . In zero field, the  $m$  states are degenerate and form a single level. In an applied field, states with  $m \neq 0$  split linearly with the field strength, analogous to the Zeeman effect in molecular spectroscopy. Information about the exciton state may be obtained as  $S$ -like orbital states with  $m = 0$  do not split while  $p$ -like states split into two components and  $d$ -like orbitals split into 3. There is an additional shift of the energy levels, called the diamagnetic shift, which is proportional to the square of the applied field although it saturates to linear at high fields. Figure 15 displays the ML spectrum from QDs composed of self-organized InP islands atop an InGaAs/GaAs quantum well with the magnetic field oriented parallel (Fig. 15a) and perpendicular (Fig. 15b) to the growth direction [39]. No aperture was used to collect this spectrum so the luminescence bands are relatively broad. The dashed lines serve to connect the transitions split by the interaction with the magnetic field. The lowest energy transition clearly shows no splitting while the next higher lying transitions split into two and three states respectively (Fig. 15a).

Early ML work on InGaAs/GaAs QDs observed a splitting of the electronic levels of upper excited states due to the Zeeman effect while the ground state for which  $m = 0$  showed no Zeeman splitting and only a weak diamagnetic shift [39]. These effects were quantitatively modeled using a potential that consisted of a vertical quantum well and lateral, parabolic confinement due to strain [39]. Similar work distinguished three bound electron and hole states in 20–40 nm dots at zero magnetic field [40]. From the magnetic field dependences, the angular momentum quantum number of the states could be assigned and the states were seen to converge toward Landau levels at higher field strengths, consistent with calculations [40]. More recently, ML experiments utilizing high spatial resolution have been used to study biexcitons in CdSe/ZnSe QDs [49], to determine the effective mass of confined carriers [43, 44], and to study the effects of defects on excitonic states [53]. ML experiments on CdTe/ZnTe nanostructures have observed a doublet at zero field attributed to the splitting of excitonic states split by local asymmetries in the potential [51]. Increasing the magnetic field strength allows mixing of bright and dark exciton states and allows an estimate of the electron and hole  $g$ -factors and isotropic exchange energy [51].

While there have been ample studies of excitonic structure in zero-dimensional quantum dots using ML, there have also been numerous magnetoluminescence studies of dilute magnetic systems. II–VI semiconductor systems lend themselves to the incorporation of transition metals as dopants, particularly  $Mn^{2+}$ . The incorporation of Mn spins in the system gives rise to an  $sp$ – $d$  exchange interaction determined by the overlap of the Mn spins with the spins of charge carriers. Quantum confinement is expected to be smaller in

**Figure 15.** Magnetoluminescence spectra of InGaAs/GaAs quantum dots with the magnetic field oriented parallel (a) and perpendicular (b) to the growth axis. The dashed lines connect transitions split by the magnetic field. Reprinted with permission from [39], R. Rinaldi et al., *Phys. Rev. Lett.* 77, 342 (1996). © 1996, American Physical Society.

DMS of small sizes [54, 55] and has been confirmed experimentally [48, 55]. As carrier wavefunctions overlap more strongly with the  $Mn^{2+}$  spins, the effective g-factor becomes larger. For instance, g-factors of between 6 and 7 have been observed in II–IV magnetic quantum dots [50].

Recent experiments comparing semimagnetic  $Cd_{0.93}Mn_{0.07} \cdot Te/Cd_{0.60}Mg_{0.40}Te$  quantum dots with the nonmagnetic  $Cd_{0.93}Mg_{0.07}Te/Cd_{0.60}Mg_{0.40}Te$  counterpart show increased line broadening in the semimagnetic QDs due to this exchange interaction [46]. At higher magnetic fields, however, this broadening decreases significantly, becoming comparable to the nonmagnetic counterpart. This decrease has been explained by the suppression of magnetic fluctuations and the destruction of exciton magnetic polarons at high fields [46]. Other experiments on CdMnTe quantum dots also show increased broadening of the emission lines but the

linewidths did not decrease in width at higher fields presumably due to the relatively small size of the quantum dots used in that study [47].

## 9. UPCONVERSION LUMINESCENCE AND ANTI-STOKES LUMINESCENCE

Upconversion luminescence is a phenomenon in which the excitation energy (wavelength) is lower (longer) than the emission energy (wavelength). The mechanism responsible for upconversion is a popular issue that has attracted much attention. Sequential two-photon absorption can lead to upconversion excitation with a first photon populating an intermediate state and a second photon, which in the most general case would be of different energy, causing a transition from this intermediate state to a higher level. As an alternative, energy transfer between excited ions can result in efficient upconversion when a sufficiently large number of ions have been excited to an intermediate state [56].

A third type of efficient upconversion excitation is the photon avalanche process that involves excited state absorption of the pump light as well as interionic cross-relaxation. In addition, two-photon absorption and cooperative sensitization of luminescence [57] are two other channels for upconversion. Two-photon absorption processes via virtual states usually occur only at high excitation densities ( $\geq 10^3 \text{ W cm}^{-2}$ ) [58].

Cooperative luminescence is a special energy transfer process with energy transfer from one excited ion to another excited ion [56] resulting in one ground state ion and another “doubly excited” ion. Upconversion by cooperative energy transfer has the important advantage of requiring a single pump wavelength, obviating the problems related to beam alignment and pump efficiency that are associated with sequential two-photon absorption using two different pump lasers [56]. This is very favorable for practical applications like displays, infrared detection, optical storage, and communications.

In our recent research, we have investigated II–VI semiconductor nanoparticles doped or co-doped with transition or rare earth ions as a new type of upconversion material. The most common upconversion mechanisms for these systems are via two-photon absorption and energy transfer. For sequential two-photon absorption upconversion, the efficiency is mainly determined by the excited state absorbance and the emission efficiency, while for upconversion via energy transfer, the energy transfer rate and the intermediate state lifetime are the key parameters determining upconversion efficiency. A few basic principles serve to show how the quantum size effect can lead to improved upconversion efficiency.

First of all, quantum size confinement may enhance absorbance and luminescence efficiency and shorten decay lifetime, as discussed in Section 1.2. Second, for upconversion luminescence other than two-photon absorption, the energy transfer mechanism is very important. Many ions that demonstrate efficient sequential two-photon absorption upconversion pumping also exhibit cooperative energy transfer. In some ions the cooperative process is substantially more efficient than sequential two-photon absorption

upconversion. Thus, the enhancement of the energy transfer rate is very important.

For electric multipolar interactions the energy transfer probability [ $P_{SA}(R)$ ] can be generally written as [59]

$$P_{SA}(R) = \frac{(R_0/R)^s}{\tau_s} \quad (11)$$

where  $\tau_s$  is the actual lifetime of the donor excited state,  $R_0$  is the critical transfer distance for which excitation transfer and spontaneous deactivation of the donor have equal probability, and  $R$  is the separation between the donor and the acceptor.  $S$  is a positive integer taking the following values:

- $s = 6$  for dipole–dipole interactions
- $s = 8$  for dipole–quadrupole interactions
- $s = 6$  for quadrupole–quadrupole interactions

Equation (11) indicates that donor–acceptor separation is a key parameter in determining the energy transfer rate. The separation between ions is affected by dopant concentrations. The separation is smaller when the concentration is higher, which is favorable for energy transfer. The energy transfer rate and luminescence efficiency can also be enhanced by encapsulating nanoparticles in small cavities such as cavities in zeolite-Y [20, 21] and MCM-41 [16]; however, the enhancement mechanism is not yet clear.

The excited state luminescence may suffer quenching due to relaxation by phonons serving to decrease the upconversion yield. In bulk materials, the phonon density of states forms a continuous band that near the zone center can be described by the Debye model. Energy relaxation from high levels to low levels occurs by cascade emission of LO phonons and this process is controlled by the energy gap law [60]. The dependence of the multiphonon relaxation rate constant ( $K_{mp}$ ) across an energy gap ( $\Delta E$ ) on the phonon energy is well described by [60]

$$K_{mp} = C e^{-p\beta} \quad (12)$$

where  $C$  and  $\beta$  are positive constants characteristic of the material.  $p$  is defined as [60]

$$p = \frac{\Delta E}{\hbar\omega_{\max}} \quad (13)$$

such that  $p$  is the number of highest energy phonon quanta required to bridge the energy gap and  $\hbar\omega_{\max}$  is the highest lattice phonon energy. As a rule of thumb for multiphonon relaxation processes, the relaxation rate is smaller if  $p$  is larger. In other words, the lower the highest lattice phonon energy, the smaller the relaxation rate and the higher the upconversion efficiency. Similarly, the electron–phonon coupling determines the efficiency of energy transfer from the excited state to the phonons. The electron–phonon coupling strength in nanoparticles is determined by both the quantum confinement and the surface characteristics [61]. First, in nanocrystalline materials, the density of states is modified due to the size effect and, for an isolated nanoparticle, both the electronic energy and the phonon spectra become discrete. Thus, both the density of electron energy

and phonon energy levels decrease with decreasing size, which is likely to result in a weaker electron–phonon coupling. Similarly, the increased overlap between the electron and hole wavefunctions also decreases the electron–phonon coupling [61]. However, the overlap between the electron and hole wavefunctions may decrease due to the trapping of electrons or holes to the surface states. These factors indicate that electron–phonon interactions can be weaker in nanoparticles with good surface passivation.

Generally, it is not necessary to consider the host energy structure in order to understand multiphonon relaxation in insulating phosphors such as  $\text{BaF}_2:\text{Eu}^{3+}$  and  $\text{BaTiO}_3:\text{Er}^{3+}$  because the host energy gap is large ( $>8$  eV) [62] and the energy levels of the dopant are contained within the energy gap of the host. However, for semiconductor phosphors such as  $\text{ZnS}:\text{Tb}^{3+}$  or  $\text{CdS}:\text{Eu}^{3+}$ , the host energy structure must be considered because the host energy gap is less than 5 eV and the dopant energy levels intercept the host energy levels. Thus the energy relaxation from an excited state to a lower state of the dopant is possible via energy levels of the semiconductor host. This is particularly true for nanoparticles in which the energy levels are split. It is well known that the energy splitting between two levels increases with decreasing size [2]. According to Eq. (13),  $p$  increases with decreasing size. Therefore multiphonon relaxation from higher levels to lower levels may decrease in nanoparticles. This is actually the famous “photon bottleneck” [63]. According to the energy gap law, this is quite favorable for improving the upconversion efficiency.

Summarizing these arguments, in nanoparticles, due to size confinement, the increase of electron–hole wavefunction overlap may enhance the absorbance and luminescence efficiency as well as shorten the emitting state lifetime. Due to the decrease of both the phonon and electric state densities, the electron–phonon interaction is weaker. These are strong reasons to consider doped nanoparticles as a new type of upconversion material with good efficiency and faster response, whether the upconversion is due to energy transfer or two-photon absorption. For these reasons, upconversion luminescence of nanoparticles is becoming a topic under much investigation.

The study of nanoparticle upconversion luminescence is relatively new and not much work has been reported; yet strong upconversion luminescence of  $\text{Mn}^{2+}$  in  $\text{ZnS}:\text{Mn}^{2+}$  nanoparticles has been observed [64]. The upconversion emission band excited at 767 nm is redshifted from the photoluminescence emission excited at 300 nm (Fig. 16) [64]. In the nanoparticles, the decay lifetimes of the upconversion emission excited at 767 nm are shorter than the 300 nm excited luminescence lifetimes, while in bulk the two decays are almost identical. When the photoluminescence is obtained by excitation at 383.5 nm, which is the sum energy of two photons at 767 nm, the emission spectra and the lifetimes of the two types of luminescence are almost identical [64]. The power dependence of the photoluminescence is linear, while that of the upconversion emission is quadratic [64]. Based on these observations, two-photon excitation has been identified as the excitation mechanism responsible for the upconversion luminescence of  $\text{Mn}^{2+}$  in  $\text{ZnS}:\text{Mn}^{2+}$  nanoparticles.

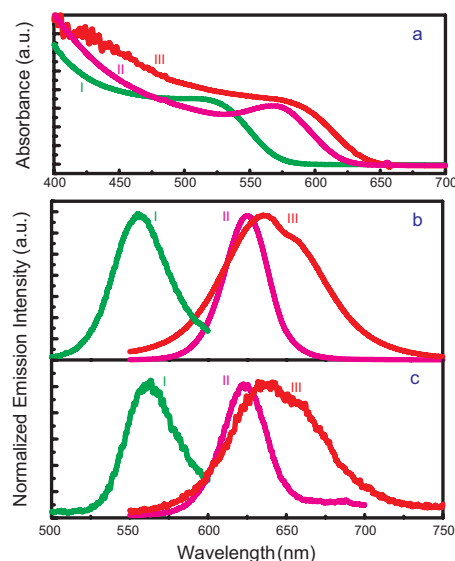

**Figure 16.** The photoluminescence spectra after excitation at 300 nm (solid), at 383.5 nm (dash), and the upconversion luminescence spectra resulting from 767 nm excitation (dot) of ZnS:Mn<sup>2+</sup> bulk and nanoparticles. Upconversion luminescence is visible to the naked eye in these systems. This reveals that upconversion luminescence of ZnS:Mn<sup>2+</sup> can be realized at relatively low power densities. Our recent tests demonstrate that an 808-nm semiconductor quantum well laser module with 40 microwatts (power density of 1 mW/cm<sup>2</sup>) can stimulate upconversion luminescence of ZnS:Mn<sup>2+</sup> nanoparticles visible to the unaided eye. Similar upconversion luminescence is observed in ZnS:Mn<sup>2+</sup>, Eu<sup>3+</sup> nanoparticles. Emissions of both Mn<sup>2+</sup> and Eu<sup>3+</sup> are observed in the upconversion emission spectra and the upconversion is due to two-photon absorption of Mn<sup>2+</sup> and the emission of Eu<sup>3+</sup> is due to energy transfer from Mn<sup>2+</sup> [65].

Upconversion luminescence has also been reported in undoped semiconductor nanoparticles such as CdS and CdTe nanoparticles [66]. The term anti-Stokes luminescence is frequently used to describe the upconversion luminescence in undoped semiconductor nanoparticles. In general, any luminescence that occurs at frequencies larger than that of the excitation frequency is called anti-Stokes luminescence. Therefore, in this case, upconversion is just one variety of anti-Stokes luminescence. Figure 17a displays the optical absorption spectra of three CdTe nanoparticle samples [67]. The absorption edges of these nanoparticles are blueshifted from the 827 nm bulk CdTe bandgap as

**Figure 17.** The absorption spectra (a), the photoluminescence emission spectra (b, excited at 350 nm), and the anti-Stokes luminescence spectra (c, excited at 750 nm) of CdTe nanoparticles with average sizes of 3 (I), 5 (II), and 6 nm (III), respectively [67].

a consequence of quantum size confinement. According to the shift and based on the effective-mass approximation [2], the estimated particle sizes are around 3, 5, and 6 nm, respectively. Their photoluminescence spectra are shown in Figure 17b. The nanoparticles show a pronounced excitonic luminescence band, which shifts to higher energies for smaller sizes. Strong anti-Stokes luminescence is observed from these nanoparticles as shown in Figure 17c with excitation at 750 nm. As in the photoluminescence, the anti-Stokes luminescence is also size dependent, shifting to higher energies for smaller nanoparticles. These results may be reasonably explained by a two-step absorption process via surface states [24, 67], which is actually upconversion luminescence through a two-step absorption.

## 10. PHOTOSTIMULATED LUMINESCENCE AND MEDICAL IMAGING OF NANOPARTICLES

Photostimulated luminescence (PSL) describes the phenomenon in which phosphors release trapped charge carriers when stimulated by infrared or visible light [68]. The trapped carriers recombine with luminescent centers to generate the PSL. Thus, in photostimulated luminescence the stimulation (excitation) wavelength is longer than the emission wavelength in contrast to photoluminescence. Because photostimulable phosphors have the ability to store energy, they are also called storage phosphors. X-ray storage phosphors such as BaFBr:Eu<sup>2+</sup> have been widely discussed [68]. The PSL mechanism of BaFBr:Eu<sup>2+</sup> involving X-ray irradiation proposed by Takahashi et al. [69] assumes that during X-ray irradiation, the Eu<sup>2+</sup> ions are partly ionized into their trivalent charge state (Eu<sup>3+</sup>) and the liberated electrons drift via the conduction band to form F centers. Upon subsequent photostimulation, the electrons are released from the

F centers into the conduction band and they recombine with  $\text{Eu}^{3+}$  ions to produce the photostimulated luminescence of  $\text{Eu}^{2+}$  at 390 nm (Fig. 18) [69]. Other recent results indicate that tunneling may be the mechanism of recombination in  $\text{BaFBr:Eu}^{2+}$  phosphors [70].

In nanoparticles, the energy scheme can be modified via quantum size confinement. This offers a new way of designing PSL phosphors. When electrons and holes are produced in nanoparticles by photoexcitation, the electrons and holes may de-excite or relax to the lowest excited states and recombine to give luminescence. They also may be trapped by electron or hole traps at the surfaces, interfaces, and/or in a surrounding host. The electrons or holes at traps are in a metastable state. When stimulated by light or by heat, some may be released and recombine to give luminescence (i.e., photostimulated luminescence or thermoluminescence).

Controlled charge separation and trapping in nanoparticles are key to the processes of erasable optical storage, sensors, and digital imaging. The PSL of nanoparticles requires not only charge separation and trapping but also the return of the carriers to the nanoparticles. Evidence for charge separation, trapping, and subsequent return has been obtained from pump-probe measurements and photon-gated hole burning (PHB) of nanoparticles [71]. For example, in  $\text{BaFCl:Sm}^{2+}$ , the hole-burning process can be described as the photoionization reaction

If the electrons release from the traps and return to the  $\text{Sm}^{2+}$ , the hole will be erased, a process termed hole filling [72]. The hole burning corresponds to the photoionization process in PSL and the hole filling is similar to the photostimulation. Thus, the occurrence of PHB in a system is an indication of PSL, and vice versa.

In most systems, hole burning is only observable and stable at low temperatures. Only in a few materials is hole burning at room temperature possible. However, PSL is not as dependent on temperature. For example, in a

**Figure 18.** A schematic model for excitation and photostimulated luminescence processes in a  $\text{BaFBr:Eu}^{2+}$  phosphor. Reprinted with permission from [69], K. Takahashi et al., *J. Lumin.* 31–32, 266 (1984). © 1984, Elsevier Science.

$\text{BaFCl}_x\text{Br}_{1-x}:\text{Sm}^{2+}$  system, low temperature is necessary to observe PHB, while strong PSL is observed at room temperature [72]. The hole-burning efficiency or the storage density increases by a factor of  $\Gamma_I/\Gamma_H$ , where  $\Gamma_I$  is the inhomogeneous linewidth and  $\Gamma_H$  is the homogeneous linewidth. This ratio is highly temperature dependent. Phonon-broadening causes  $\Gamma_H$  to increase with temperature and makes hole burning difficult at high temperature. Phonon broadening has little effect in the PSL process; thus it is unnecessary to work at low temperature. This is one of the advantages of PSL and forms the basic premise for the construction of a doped nanoparticle that exhibits PSL for use in storage devices, sensors, and optical image display systems.

Two new and intriguing upconversion materials are Ag and AgI nanoclusters encapsulated in zeolite-Y (Ag/Y and AgI/Y). AgI nanoclusters encapsulated in zeolite-Y show strong luminescence and photostimulated luminescence at room temperature. Figure 19a shows the PL spectra of AgI/Y following excitation at 305 nm [73]. The broad emission band actually consists of two subbands. The first band results from AgI nanoparticle emission peaking at 474 nm and appears as a small but discernible shoulder on the blue energy edge of the broad emission peak in Figure 19a. The second band results from Ag nanocluster emission centered at 510 nm. Ag is known to coexist with AgI nanoparticles and efficient energy transfer is known to occur among them. The luminescence decreases in intensity when the sample is irradiated by ultraviolet light at 254 nm (Figure 19b). This decrease can be partially recovered by exposing the sample to visible light (Figure 19c).

After ultraviolet (UV) irradiation for a few minutes, strong PSL can be detected from AgI nanoparticles in zeolite-Y as shown in Figure 20 [73]. PSL excitation is easily stimulated using near-infrared wavelengths. Figure 20 shows that the emission consists almost exclusively of Ag nanoclusters resulting in a narrower band than the PL emission band [48]. Similarly, Ag nanoclusters in zeolite-Y (Ag/Y) are photosensitive and exhibit strong photostimulated luminescence. Similar to AgI/Y, Ag/Y particles show a marked decrease in PL after UV irradiation. This decrease

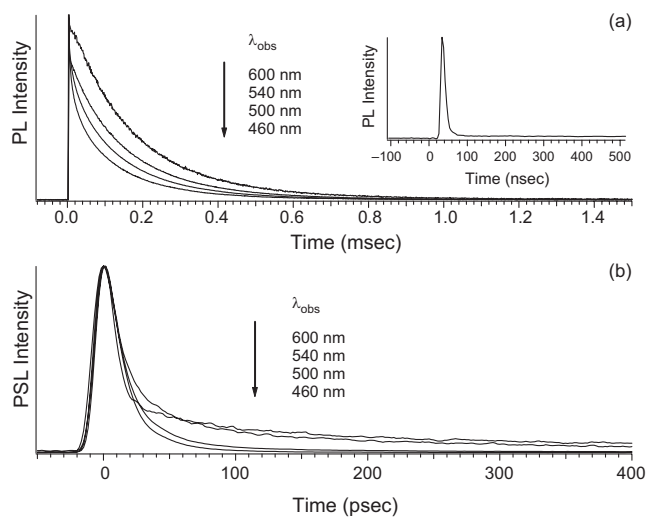

**Figure 19.** Photoluminescence spectra of AgI/Y before (a) and after (b) UV irradiation at 254 nm for 5 minutes. After exposure to a visible lamp for 5 minutes (c). Reprinted with permission from [73], W. Chen et al., *Phys. Rev. B* 65, 24554041 (2002). © 2002, American Physical Society.

**Figure 20.** Photostimulated luminescence spectrum of AgI/Y after UV irradiation at 254 nm for 10 minutes. Excited at 840 nm. Reprinted with permission from [73], W. Chen et al., *Phys. Rev. B* 65, 24554041 (2002). © 2002, American Physical Society.

is almost completely reversible following irradiation by photons between 650 and 900 nm. Thus both materials may be considered for use as reusable image or digital storage media.

Figure 21a displays the PL lifetime decays at 500 nm from AgI/Y following excitation at 305 nm [73]. The inset shows the existence of a short (<15 nanosecond) component present in addition to the microsecond decays. The longest PL lifetime of Ag/Y particles at 500 nm is about 65 microseconds compared to AgI/Y particles which show about a 185 microsecond decay. In contrast to the PL decays, PSL measurements show only the fast (<15 nanosecond) component. Figure 21b shows PSL lifetime decays from both samples on a picosecond timescale following excitation at 800 nm. At 500 nm, the PSL decay from AgI/Y particles is 125 ps, which

**Figure 21.** Lifetime decays of (a) photoluminescence (excitation at 305 nm) and (b) photostimulated luminescence (excitation at 800 nm) in AgI/Y nanoparticles. The inset in (a) displays the PL lifetime at higher time resolution showing the fast (<15 ns) time component. Reprinted with permission from [73], W. Chen et al., *Phys. Rev. B* 65, 24554041 (2002). © 2002, American Physical Society.

is almost a factor of 3 faster than the PSL decay from Ag/Y particles [73]. Even though in both cases the PSL derives from the silver particles, there is a noticeable difference in the PL and PSL lifetimes. This may reflect the differences in energetics between the two samples, given that Ag is metallic while AgI is a direct bandgap semiconductor.

In either sample, excitation by UV photons likely ionizes Ag to  $\text{Ag}^+$  leading to both a luminescent center,  $\text{Ag}^+$ , and a source of electrons. The electrons are then trapped in the zeolite framework, most likely at regions with a missing oxygen link, which serve as Lewis acid sites. Upon near-infrared (IR) excitation, this trapped electron is released and transfers to the nearby  $\text{Ag}^+$  site which is on the surface of the nanoparticles and at the zeolite–nanoparticle interface. This results in the characteristic emission of Ag as

where  $e$  represents an electron released from the color center,  $\text{Ag}^{0*}$  is the excited state of Ag, and  $\text{Ag}^0$  is the ground electronic state after emitting a photon,  $h\nu$ . This model explains the decrease in PL intensity following UV irradiation as the  $\text{Ag}^0$  is ionized and the electron becomes trapped in the zeolite. Following near-IR excitation, the electron is transferred to the nearby  $\text{Ag}^+$ . Therefore, the PSL is dominated by interfacial Ag clusters leading to exclusively Ag luminescence. The interfacial nature allows access to trap sites both at the surface and in the zeolite framework leading to extremely short lifetimes. The short lifetimes and strong PSL make these materials good candidates for new phosphor screens or digital storage applications.

The photostimulable phosphor used in commercial X-ray imaging system is  $\text{BaFBr:Eu}^{2+}$ ; yet the  $\text{BaFBr:Eu}^{2+}$  system suffers from poor resolution due to the long decay lifetime of  $\text{Eu}^{2+}$  emission (0.8  $\mu\text{s}$ ) as well as scattering of the stimulating laser light from the platelike polycrystals. In addition, the hygroscopic nature of this phosphor limits the stability of the system. Thus, a new type of PSL phosphor with improved characteristics is desirable and the subject of extensive investigation.

Most light detection systems suffer from low resolution due to the scattering of both the reading laser light and the emission light. The light scattering is due to the phosphor grain size, shape, and the grain boundary, as well as surface roughness [74]. Raleigh's approximation describing the interaction of light with matter indicates that for particles that are isotropic, the intensity of scattered light is approximately equal to the particle diameter to the sixth power [75]. Therefore, a 50-nm particle will scatter one million times more light than a 5-nm particle. Therefore, compared to the scattering in traditional micrometer-sized phosphors, the scattering of light in nanoparticles is negligible. This suggests that much higher resolution is possible using upconversion in nanoparticles and nanothin films for infrared detection and imaging.

Quantum size confinement of nanoparticles overcomes some of these problems. The higher luminescence efficiency, faster decay, and lower light-scattering for smaller particles results in higher spatial resolution and faster response. Nanosized  $\text{BaFBr:Eu}^{2+}$  phosphors show strong PSL [76]. The PSL from  $\text{BaFBr:Eu}^{2+}$  nanoparticles decays with a lifetime of 390 ns and provides a good example demonstrating

that the PSL imaging performance and temporal resolution may be improved via quantum size confinement.

Figure 22 shows the emission spectra of BaFBr:Eu<sup>2+</sup> nanoparticles having an average size of ~40 nm, as measured by X-ray diffraction [76]. The emission band is due to the  $4f^6 5d^1 (t_{2g}) \rightarrow 4f^7$  transition of Eu<sup>2+</sup>. In BaFBr:Eu<sup>2+</sup> nanoparticles, the emission band of Eu<sup>2+</sup> is at 407 nm, which is ~17 nm redshifted compared to that in bulk BaFBr:Eu<sup>2+</sup> at 390 nm. This is due to the change in crystal field or site symmetry of the nanoparticles.

The fluorescence of BaFBr:Eu<sup>2+</sup> nanoparticles is very sensitive to light. Under UV irradiation, the luminescence of Eu<sup>2+</sup> decreases in intensity. The luminescence is recovered by exposure to red light at approximately 600 nm (Fig. 22). Strong PSL is observed following stimulation at 600 nm, which is shown in Figure 23 [76]. The PSL spectrum is consistent with the PL spectrum. This indicates that the PSL is from the recombination of electrons with Eu<sup>2+</sup> centers as in bulk BaFBr:Eu<sup>2+</sup> phosphors.

Figure 24 shows the PL and PSL decays of BaFBr:Eu<sup>2+</sup> nanoparticles [76]. The results demonstrate that the PL decay lifetime of BaFBr:Eu<sup>2+</sup> nanoparticles is almost the same as that of bulk BaFBr:Eu<sup>2+</sup>, around 800 ns. However, the PSL decay lifetime of BaFBr:Eu<sup>2+</sup> nanoparticles is much shorter than that of bulk BaFBr:Eu<sup>2+</sup>. The PSL decay of BaFBr:Eu<sup>2+</sup> nanoparticles has two components. One is

**Figure 22.** Emission spectra of BaFBr:Eu<sup>2+</sup> nanoparticles before (blue) and after UV irradiation at 254 nm for 5 min (orange), and then photostimulation at 560 nm for 5 min (magenta), respectively (excitation at 304 nm) [76].

**Figure 23.** Photostimulated luminescence spectra (excited at 600 nm) of BaFBr:Eu<sup>2+</sup> nanoparticles and bulk after UV irradiation for 10 minutes.

shorter than 20 ns; the other is 340 ns. The short decay of less than 20 ns is likely due to surface states and the shortened decay of 340 ns is likely due to quantum confinement. The difference in the PSL decay behavior of the nanoparticles and the bulk material indicates that the PSL energetics in the bulk and the nanoparticles are different. The faster decay in the nanoparticles demonstrates that it is possible to improve the storage and imaging performance by the size effect.

Biological and biomedical applications of nanoparticles represent a new direction in nanoscience and nanotechnology [1, 77, 78]. This includes biological labeling, biomedical imaging, and diagnostics. The nanoparticle photostimulable phosphors described may be used in medical imaging devices such as a computerized radiography system.

One of the most important parts of the computerized radiography system is the imaging plate (IP) with its layer

**Figure 24.** Photoluminescence (PL) and photostimulated luminescence (PSL) lifetime decays of BaFBr:Eu<sup>2+</sup> nanoparticles.

of photostimulable phosphor. During X-ray exposure, part of the energy of the absorbed X-rays is stored in the phosphors as trapped electrons and holes. The stored energy is released by a focused He–Ne laser which empties the traps by optical stimulation to give luminescence due to electron–hole recombination [68, 69]. The photostimulated luminescence intensity, which is proportional to the X-ray dose, is measured for each spot on the imaging plate, using a photomultiplier tube, and stored in a computer. It has been demonstrated in the laboratory that using this PSL system the X-ray dosage can be reduced to one-tenth of the conventional screen-film method while the radiograph remains of the same quality. This indicates that the photostimulable phosphor IP is an excellent detector for digital radiography, which may replace some of the conventional screen-film methods. When the IP is placed in a cassette, it can be used with conventional machines, and the digital imaging radiographs can be shared among hospitals through the Internet. In addition, large area IPs are conveniently produced, are reusable, have linear response over a wide range of X-ray dosage, and are erased simply by exposure to a uniform stimulating light or by thermal clearance. Thus, as compared to the conventional radiation image sensors, the IP method not only visualizes the latent radiation image with a high sensitivity through the digital process of conventional radiation image sensors but also makes it possible to quantify the position and intensity of the radiation image [68, 69].

Nanoparticles exhibit strong photostimulated luminescence, and therefore nanoparticle thin films display excellent potential for medical imaging applications. The advantages of using nanoparticle thin films for medical imaging may be summarized as follows:

- (1) high emission quantum efficiency resulting in higher sensitivity
- (2) low scattering resulting in better resolution
- (3) shortened decay lifetime leading to faster response
- (4) particles with desired size and shape
- (5) thin films with desired uniformity, area, thickness, and flexibility

These advantages may make nanoparticles a potentially more cost effective alternative to traditional medical imaging technologies.

## 11. X-RAY EXCITED OPTICAL LUMINESCENCE

X-ray excited optical luminescence (XEOL) refers to the measurement of the optical luminescence spectrum following excitation with X-ray photons. XEOL involves energy transfer from the initially absorbed X-ray photons and may be represented as the sequence of the following steps [79]:

- (1) absorption of the ionizing radiation (X-ray photons) and creation of primary electrons and holes
- (2) relaxation of primary electrons and holes which may produce secondary electrons, holes, photons, plasmons, and other electronic excitations
- (3) thermalization of the low-energy secondary electrons (holes) resulting in a number of electron–hole pairs (excitons) with energy roughly equal to the bandgap energy  $E_g$

- (4) energy transfer from the electron–hole pairs to the luminescence centers thereby inducing their excitation
- (5) emission from the luminescence centers

XEOL uses tunable soft X-ray sources such as synchrotron radiation and therefore can achieve state and site selective excitation [80], and thus XEOL is closely related to X-ray absorption near edge structures (XANES). XANES may be measured in terms of total electron yield (TEY), fluorescence yield (FLY), and photoluminescence yield (PLY) [80–82]. Generally, there is no obvious distinction made between “fluorescence” and “photoluminescence” yields. However, here the distinction is made that photoluminescence yield refers to the emission of optical photons and fluorescence yield typically refers to the emission of X-ray fluorescence photons. Thus, PLY typically deals with emission photons of the order of a few eV whereas FLY deals with emission photons that could be as much as several keV. The TEY measurement is sensitive to the surface and near-surface regions of the sample, while FLY is more sensitive to the bulk, and PLY is sensitive only to the sites where the photoluminescence originates [80–82]. By tuning the excitation photon to energies of a specific absorption band (valence region) or edge (core levels) of an element or its compounds, one can achieve some degree of site selectivity [80]. Table 1 lists the attenuation length of the incident photons for the four regions of interest for both silicon and SiO<sub>2</sub> [80]. Table 1 demonstrates that the incoming photons are completely absorbed within a couple of micrometers from the surface with the photons below the Si *K*-edge as an exception. Thus, tuning the photon energy from just below to just above the edge allows for a sudden increase of the absorption of the incident photons (energy) into a select excitation channel [80]. By using a combination of XEOL, TEY, FLY, and PLY information on the emitting states, the chemical environment, sites, coordination number, chemical bond length, and the sampling depth may be obtained. Recently, XEOL technology has successfully been applied to investigate the luminescence mechanism of porous silicon [83] and CdS nanoparticles [84].

**Table 1.** Attenuation length (one absorption) of incident photons in Si and SiO<sub>2</sub> below and above the relevant edge.

	Photon energy (eV)	Attenuation length ( $\mu\text{m}$ )	
		Si	SiO <sub>2</sub>
Inner valence	20–40	0.23–0.26	0.020–0.026
Si <i>L</i> <sub>3,2</sub> -edge	below 100 (Si), 105 (SiO <sub>2</sub> ) above 100 (Si), 105 (SiO <sub>2</sub> )	0.122	0.113
O <i>K</i> -edge	below 538 above 538	0.51	1.04
Si <i>K</i> -edge	below 1840 (Si), 1847 (SiO <sub>2</sub> ) above 1840 (Si), 1847 (SiO <sub>2</sub> )	14	7.4
		1.26	2.2

The discovery of luminescence from nanostructured porous silicon in 1990 is a breakthrough event in silicon optoelectronics [85]. However, there has been some debate as to the origin of the luminescence. Different models have been proposed to explain the luminescence from porous silicon, such as the quantum size confinement model [85], formation of siloxene [86], and the production of hydrogenated amorphous silicon [87]. Using XEOL, Sham et al. [83] have shown that porous silicon is essentially crystalline silicon locally, the surface silicon oxide components are not responsible for the luminescence, and, more importantly, the luminescence does not originate from siloxene. This result strongly supports the model of quantum size confinement [85].

The argument and controversy over the luminescence mechanism from porous silicon are due to the fact that porous silicon is very complex. Silicon oxides, siloxene, oxygen- and hydrogen-related defects, and surface states may exist in porous silicon produced by HF chemical etching [85]. In most cases, porous silicon is covered with a layer of amorphous SiO<sub>2</sub> which may contain defects that also exhibit luminescence. To distinguish these two luminescence mechanisms, the XEOL excited at and above the L<sub>3,2</sub> edge of Si and SiO<sub>2</sub>, respectively, are shown in Figure 25. The attenuation length of photons at the Si L<sub>3,2</sub> edge (~100 eV) is ~60 nm, which is significantly less than the thickness of porous silicon. An intense peak at around 650 nm and two satellites at 480 and 380 nm are observed in the XEOL spectrum [81]. The 650 nm peak is the most intense at 100 eV excitation; however, upon excitation into the SiO<sub>2</sub> absorption edge, the intensity decreases greatly while the two satellites increase in intensity. In addition, the two satellite peaks disappear upon HF treatment (a' in Figure 25) which removes the SiO<sub>2</sub> overlayer. These results strongly

**Figure 25.** XEOL spectra excited at (a) 100 and (b) 110 eV from an as-prepared porous silicon sample. Luminescence of the HF treated sample excited at 100 eV is shown as (a'). XANES of the HF refreshed sample in TEY and PLY and of the Si(100) in TEY are shown in the inset. Reprinted with permission from [81], Y. F. Hu et al., *Rev. Sci. Instr.* 73, 1379 (2002). © 2002, American Institute of Physics.

imply that the emission at 650 nm is from the nanocrystalline silicon and that the two satellite peaks are from the surface oxide [80–82].

The particle size and porosity in porous silicon are determined by the preparation conditions which include the wafer resistance, HF concentration, current density, and etching time [4, 88]. Therefore, the luminescence energy (wavelength) and efficiency are determined by the preparation conditions [82]. One example is shown in Figure 26 for the XEOL of porous silicon samples prepared from *c*-Si wafers with two different resistances, 10 (a, b) and 16–20 Ω cm (A, B), at different current densities but the same HF concentration [88]. Figure 27 displays the XANES, recorded in TEY and PLY modes at the Si K edge of a typical porous silicon sample before (top) and after HF treatment [88]. The XANES spectra recorded by TEY and PLY for an aged sample (top) are very different in the region just above the edge, while they are nearly identical for the fresh sample (bottom). The peak at 1847 eV present in the TEY spectrum of the aged sample is a consequence of Si–O bonding due to the presence of SiO<sub>2</sub> on the surface. Because the TEY spectrum is surface sensitive, this peak is greatly enhanced relative to the PLY spectrum. This peak disappears after HF treatment

**Figure 26.** X-ray excited optical luminescence of a porous silicon fresh sample with wafer resistance of 10 (top) and 16–20 Ω m (bottom) at different current densities (A—28, B—65, a—40, b—90 mA/cm<sup>2</sup>) but the same HF concentration. Reprinted with permission from [88], G. Dalba et al., *J. Non-Crystal. Solids* 232–234, 370 (1998). © 1998, Elsevier Science.

**Figure 27.** XANES spectra recorded in TEY and PLY modes at the Si  $K$  edge of a typical porous silicon sample before (top) and after HF treatment (bottom). Reprinted with permission from [88], G. Dalba et al., *J. Non-Crystal. Solids* 232–234, 370 (1998). © 1998, Elsevier Science.

as the  $\text{SiO}_2$  layer is etched away and the spectrum resembles the PLY spectrum. Therefore, the PLY signal does not depend on the Si–O bonds but is related only to the Si nanoclusters. These results further confirm that the luminescence does not originate from silicon oxide regions consistent with the results by Sham et al. [83].

Due to the availability of synchrotron radiation, XEOL is getting more and more popular. XEOL is being applied to investigate scintillation materials [79], organic thin films [89], and luminescent nanoparticles [84]. Figure 28 shows the XEOL spectra of 2 nm sized CdS nanoparticles stabilized in a dendrimer [81]. Spectra (a), (b), and (c) were excited with selected photon energies across the S  $K$  edge marked with vertical bars in the XANES (Fig. 28, inset), collected in both TEY and PLY. The PLY spectrum shows one strong resonance at 2474 eV due to the S ( $1S$ ) transition to the unoccupied orbitals in CdS. The TEY spectrum shows an additional peak at 2480 eV due to the S( $1S$ ) to  $\text{SO}_4^{2-}$  transition present because the surface of the dendrimers are oxidized to sulfate groups. The luminescence intensity increases greatly from (a), below the S  $K$  edge to (b), at the CdS S  $K$  edge. The luminescence decreases when excited at (c), corresponding to the surface sulfate groups and the strongest peak in the TEY spectrum. Since comparison of the CdS nanoparticle PLY XANES with the TEY of bulk CdS shows that they are identical, the luminescence originates mainly from CdS nanoparticles and not from the surface sulfate groups [81, 84].

**Figure 28.** XEOL spectra of 2 nm sized CdS nanoparticles stabilized in dendrimer with various X-ray energies across the S  $K$  edge. The inset shows the XANES in TEY and PLY and the corresponding excitation photon energies (vertical bars) for (a), (b), and (c). Reprinted with permission from [81], Y. F. Hu et al., *Rev. Sci. ## 12. BIOLOGICAL LABELS AND MARKERS

Over the past 20 years, organic chemistry has developed a wide array of molecular probes, usually organic dyes, for a variety of applications in cellular imaging, biomolecular analysis, sensing, and biophysics. However, the current selection of organic dyes leaves much to be desired. Broad spectral overlap, photobleaching, difficult conjugation chemistry, poor water solubility, and expense are frequently cited as limitations of commercially available organic and organometallic probes. Recent research into the physical and chemical properties of nanoparticles suggests that the photophysical behavior of these tiny particles may be more finely tunable than that of dyes and, thus, may offer a promising way to solve some vexing problems with biological labeling. The crucial development in the application of nanoparticles to biological assays and imaging has been the creation of simple, reliable synthetic routes for a variety of nanostructures. The chemical synthesis of nanoparticles is typically achieved with just one reaction, involving a

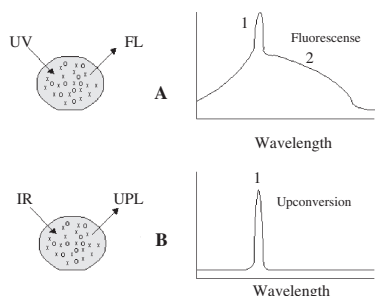

chemical transformation of a precursor source of inorganic material followed by a nanocrystallization process in the same vessel. Desired and novel properties of nanoparticles can be obtained by fine control over the synthetic conditions to determine size, size distribution, emission wavelength, and surface characteristics. Thus, nanoparticle biological probes are easier to make and are potentially less expensive than organic dyes. More importantly, the specific photochemical reactions that cause organic dyes to photobleach or to cross-link nonspecifically with biological samples are far less common for inorganic nanoparticles. In comparison with conjugates formed with organic dyes such as rhodamine, this new class of luminescent probes is 20 times as bright, 100 times as stable against photobleaching, and 1/3 as wide in spectral linewidth [90]. Therefore, inorganic nanoparticle probes may have tremendous applications in biomedicine and biology even though there are still some problems that need to be solved, such as the blinking emission of some nanoparticles, the possible toxicity, and the biocompatibility with inorganic nanoparticles. However, these limitations may be overcome by the purposeful design and fabrication of nanostructures.

Another important advantage of luminescence nanoparticles for biological labeling is the recent discovery of upconversion (anti-Stokes) luminescence [64, 65]. Since the excitation wavelength is longer than the emission wavelength, there is very little background noise, which drastically reduces the detection limit. In regular Stokes fluorescence detection, the noise is primarily associated with the autofluorescence of biological tissues, which is nearly eliminated in the case of anti-Stokes emission (Fig. 29). In addition to the improvement of resolution and sensitivity, anti-Stokes luminescence allows the use of IR/NIR light sources, which are preferred for biological labeling and long-term sensing over UV light sources because the photoinduced damage done by IR quanta to biolabels and organisms is much lower. However, species with pronounced anti-Stokes luminescence are quite rare, and there are only a few phosphors that afford labeling and observation of the targets with anti-Stokes luminescence [91]. They are based exclusively on rare-earth metals and the biolabeling is achieved with fairly large particles of about 1 micrometer in diameter [92]. The large size of these micrometer-sized colloids,

strong scattering associated with it, and lower penetration ability are the major limiting factors for many applications. With transition to nanoscale materials, parasitic scattering is drastically reduced, and the diffusion rate increases, and therefore, the response time of the sensors is also enhanced. In addition, it is possible to significantly increase the quantum yield of upconversion by proper surface modification of the nanoparticles.

The broad range selection of the shell (stabilizer) structure of semiconductor nanoparticles makes biological labeling possible in many ways, from exchange reactions with stronger binding ligands to covalent conjugation with different linking reactions [93], as well as noncovalent labeling techniques such as electrostatic attractions to labeling proteins [77]. It has been demonstrated that nanoparticle bioconjugates selectively bind to cell components, DNA, or blood proteins and can be detected by strong luminescence tunable by the particle size [1, 78]. By using narrow band tunable color or luminescence nanoparticles, polymeric microbeads (1.2  $\mu\text{m}$ ) have been tagged by different colored nanoparticles to create multiplexed coding [1]. By controlling both the size and number of nanoparticles attached to the microbeads, 5–6 colors and 6 intensity levels yield 10,000 to 40,000 distinguishable codes under excitation with a single wavelength excitation source. These tagged microbeads can be used to label DNA and protein sequences and therefore have enormous potential in genomics and proteomics research areas.

The most commonly used covalent coupling method to conjugate nanoparticles to proteins is the sulfo-NHS (*N*-hydroxysulfo-succinimide) and EDC [1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride] reaction (Scheme 1). NHS-conjugated proteins have the highest bioactivity among other conjugates as established by several comparative studies [78, 93]. The carboxylic acid group of thioglycolic acid stabilized nanoparticles can form amide bonds with the primary amine groups of the protein, or the carboxylic acid groups of the protein can form amide bonds with the primary amine groups of cysteine stabilized nanoparticles. When using this method, the pH, concentration of reagents, and reaction time vary for each particular reaction. Possible aggregation due to multiple conjugations can be avoided by carefully choosing the reaction conditions.

**Figure 29.** A schematic illustration for using fluorescence (top) and upconversion luminescence (bottom) in biological probing. Under ultraviolet excitation in the case of fluorescence, strong autofluorescence is observed along with the fluorescence. In upconversion luminescence, this autofluorescence can be avoided because the excitation energy is in the infrared. Thus, better resolution is possible using upconversion luminescence.

### 13. FLUORESCENCE ENERGY TRANSFER AND BIOLOGICAL/CHEMICAL SENSORS

Fluorescence resonance energy transfer (FRET) refers to transfer of the excited-state energy between two different luminescent molecules (or nanoparticles), from the initially excited donor (D) to an acceptor (A). FRET can occur when the donor molecules emit at wavelengths that overlap with

**Scheme 1.** Reprinted with permission from [93], S. Wang et al., *Nano Lett.* 2, 817 (2002). © 2002, American Chemical Society.

the absorption spectrum of the acceptor. Energy transfer occurs without the appearance of a photon and is the result of long-range dipole–dipole interactions between the donor and acceptor. An important characteristic of FRET is that the transfer rate is highly dependent on the distance between the donor and receptor. The distance at which FRET is 50% efficient, called the Förster distance, is typically 20–60 Å [59]. The relationship between the transfer efficiency  $E$  and the donor-to-acceptor (DA) distance  $r$  is given by

$$E = \frac{R_0^6}{R_0^6 + r^6} \quad (16)$$

where  $R_0$  is the Förster distance. This equation shows that the transfer efficiency is strongly dependent on distance when the DA distance is near  $R_0$ . FRET is widely used as a sensing mechanism for molecular level distance and binding event detection [94]. The detection limits of analytical processes based on FRET can be as low as 10 ppt with a linear dynamic range from 0.1 to 1000 ppb, while the utilization of antibodies enables the selective detection of substrates which may differ by only a few atoms. Luminescent semiconductor nanoparticles open new possibilities in this field of applications. The stability of nanoparticles under UV and visible light makes possible not only high-contrast multiplexed imaging but also a long-term monitoring of the environment, for instance for biological warfare agents or natural pathogenic organisms such as cholera and *E. coli*, which represent a critical problem for countries with limited water treatment capabilities. This task implies that no sample labeling/staining should be involved, which can be accomplished by taking advantage of the competitive inhibition of FRET in antigen–antibody immunocomplexes, as demonstrated in a recent report [93] founded on a FRET based immunological sensor using luminescent CdTe nanoparticles.

In this study, two different thioglycolic-acid-stabilized CdTe nanoparticles were used, one with a luminescence peak at 555 nm and the other one with the peak at 611 nm. Nanoparticle-conjugated BSA (bovine serum albumin) and anti-BSA IgG (immunoglobulin G) were prepared by the sulfo-NHS and EDC reaction (Scheme 1). The conjugations were purified with centrifuge and/or dialysis. The formation of conjugation was verified with electrophoresis, luminescence spectra, and high pressure liquid chromatography (HPLC). A one-to-one conjugation between nanoparticle and protein was confirmed by HPLC results. The biological structure and activity of the conjugates were retained as verified by circular dichroism spectra and ELISA (enzyme-linked immunosorbent assay).

When nanoparticle-IgG (anti-BSA) with green luminescence is combined with nanoparticle-labeled BSA with red luminescence, the nanoparticle-IgG/BSA-nanoparticle immunocomplex formed. As expected, a significant enhancement of the nanoparticle-BSA red emission at 611 nm and the corresponding quenching of the green emission of nanoparticle-IgG at 555 nm are observed after the self-assembly of the labeled biospecific ligands in the immunocomplex (Fig. 30, trace 2) [93]. The mutual affinity of the antigen and antibody brings the nanoparticles close

**Figure 30.** Fluorescence resonance energy transfer based detection of BSA in solution. (1) CdTe nanoparticle-1-BSA; (2) CdTe nanoparticle-BSA + CdTe-nanoparticle-2-IgG; (3) BSA + nanoparticle-1-BSA + nanoparticle-2-IgG. Concentrations: nanoparticle-BSA  $5 \times 10^{-7}$  M, nanoparticle-IgG  $5 \times 10^{-7}$  M, BSA  $2 \times 10^{-6}$  M. Reprinted with permission from [93], S. Wang et al., *Nano Lett.* 2, 817 (2002). © 2002, American Chemical Society.

enough together to allow the resonance dipole–dipole coupling required for FRET to occur. Thus, the energy of the excitonic state in the green-emitting nanoparticles is transferred to the similar state of the red-emitting nanoparticles. FRET efficiency is particularly high for green/red nanoparticle pairs because of the strong overlap of their emission and absorption spectra. Importantly, when unlabeled BSA is added to the immunocomplex, it competitively binds to nanoparticle-IgG, thereby replacing it in the immunocomplex with nanoparticle-BSA and inhibiting the FRET process. Therefore, the green emission peak of nanoparticle-IgG at 555 nm can be observed again, while the red emission peak at 610 nm shows decreased intensity (Fig. 30, trace 3). Alternatively, adding a high concentration of egg albumin, which does not bind to anti-BSA IgG, shows no influence on FRET efficiency between nanoparticle-IgG and nanoparticle-BSA. Unlike ELISA, the described detection process does not require multiple binding and washing steps. Following this approach, a detection limit of  $10^{-8}$  M BSA has been reported [93].

## 14. LUMINESCENCE TEMPERATURE DEPENDENCE AND TEMPERATURE SENSORS

Variation of temperature and pressure has proven to be a powerful probe for understanding electronic and optical phenomena in condensed phases [95]. Variations in temperature change the highest energy phonon population as well as the interatomic spacing. Thus, temperature dependences of luminescence may provide useful information on the electronic states of emitters, crystal field strength, energy transfer, electron–phonon coupling, and the interactions between the luminescence centers and their hosts [95]. One system under study is  $\text{Mn}^{2+}$  doped ZnS nanoparticles. Following excitation of the ZnS host, ZnS: $\text{Mn}^{2+}$  nanoparticles display both  $\text{Mn}^{2+}$  emission as well as a blue, defect-related emission. The  $\text{Mn}^{2+}$  emission is the result of energy transfer from the ZnS exciton to the  $\text{Mn}^{2+}$  impurity center. The temperature dependence of both the  $\text{Mn}^{2+}$  emission and defect-related blue emission in ZnS: $\text{Mn}^{2+}$  nanoparticles has been investigated [96–98].

The temperature dependences of both the  $\text{Mn}^{2+}$  emission and the blue donor–acceptor emission following excitation at 300 nm are displayed in Figure 31 [99]. The intensity of  $\text{Mn}^{2+}$  emission is weakly dependent on temperature (Fig. 31b). The blue DA emission intensity, however, shows a much more pronounced decrease with decreasing temperature. Figure 31c shows the changes in emission energy as a

**Figure 31.** Temperature dependence of emission spectra (a), emission intensity (b), wavelength (c), and bandwidth (d) of the defect-related blue (DA) and  $\text{Mn}^{2+}$  emissions in ZnS:Mn nanoparticles. function of temperature. As the temperature decreases, the  $\text{Mn}^{2+}$  emission shifts to longer wavelengths. On the contrary, the blue DA emission shifts to shorter wavelengths with decreasing temperature. Figure 31d displays the changes in the full-width at half-maximum bandwidth of both emissions as a function of temperature. The bandwidths of both emissions show weak temperature dependences with slight decreases as the temperature is lowered.

In order to explain the temperature results, the nature of both the orange and blue luminescence from ZnS: $\text{Mn}^{2+}$  nanoparticles must be considered. The orange luminescence arises from the  ${}^4T_1-{}^6A_1$  transition of  $\text{Mn}^{2+}$ . The blue defect-related emission in ZnS has been investigated in detail by Oda and Kukimoto [100] and is considered to be a radiative recombination of a delocalized charge carrier (electron) with a trapped charge carrier (hole) at a sulfur vacancy. Oda and Kukimoto point out that the defect-related emission is a transition within the self-activated (SA) luminescence center with an appreciable Stokes shift [100]. The SA emission in ZnS is from the donor (isolated coactivator)–acceptor pair transition.

Based on the theory of thermal quenching, the temperature dependence of the emission intensity,  $I(T)$ , can be described by [101]

$$I(T) = \frac{I_0}{1 + ae^{-E_b/KT}} \quad (17)$$

where  $E_b$  is the activation energy (thermal quenching energy),  $K$  is the Boltzmann constant,  $a$  is a constant related to the ratio of the nonradiative rate to the radiative rate, and  $I_0$  is the emission intensity at 0 K. The solid lines in Figure 31b represent a simulation of the intensities using this theory. The parameters used to obtain these simulations are shown in Table 2 along with the data of bulk ZnS: $\text{Mn}^{2+}$  for comparison. Excellent agreement between theory and experiment suggests that the intensity decrease of the two emissions is mainly due to thermal quenching.

The  $a$  value for the DA pairs is larger than that for  $\text{Mn}^{2+}$ , indicating the nonradiative rate for DA pairs is greater than that for  $\text{Mn}^{2+}$ . It is generally accepted that the major non-radiative or energy relaxation channel in semiconductors is due to phonon quenching [102]. If the phonon coupling is stronger, the nonradiative rate is higher and the luminescence is more sensitive to temperature change [102]. Therefore, the simulated results show that the phonon coupling for the DA pairs is stronger than that for  $\text{Mn}^{2+}$  emitters. It is noted that the value of the  $a$  parameter from  $\text{Mn}^{2+}$  emission in nanoparticles (9.83) is smaller than in bulk (Tab. 2) [99]. This indicates that the radiative rate of  $\text{Mn}^{2+}$  in ZnS: $\text{Mn}^{2+}$  nanoparticles is larger than in bulk, providing for a higher luminescence efficiency.

The thermal quenching energy is related to the bound exciton binding energy [97]. For bulk ZnS: $\text{Mn}^{2+}$  the exciton binding energy is about 60 meV [97]. This value is very close to the thermal quenching energy (57 meV) as estimated from the temperature dependence of  $\text{Mn}^{2+}$  luminescence in bulk ZnS: $\text{Mn}^{2+}$  [97]. In the nanoparticles, the value for the quenching energy is  $\sim 70$  meV, which is larger than the exciton binding energy in the bulk (Tab. 2) [99]. This increase in exciton binding energy is likely due to the increase in the

**Table 2.** Simulated parameters for the temperature dependence of DA and Mn<sup>2+</sup> emissions in bulk and ZnS:Mn<sup>2+</sup> nanoparticles.

	Nanoparticle		Bulk	Bulk
Emitter	Mn <sup>2+</sup>	DA	Mn <sup>2+</sup>	Mn <sup>2+</sup>
$I_0$ (a.u.)	$(4.34 \pm 0.03) \times 10^3$	$(1.19 \pm 0.01) \times 10^6$	$(1.19 \pm 0.02) \times 10^8$	$(1.30 \pm 0.02) \times 10^8$
$a$ (a.u.)	$9.83 \pm 2$	$180 \pm 50$	$20 \pm 5$	$17 \pm 7$
$E$ (meV)	$70 \pm 6$	$93 \pm 6$	$23 \pm 2$	$45 \pm 7$

overlap of the electron and hole wavefunctions as a result of quantum size confinement. The thermal quenching energy for the DA pairs is larger than that for Mn<sup>2+</sup> indicating that excitons bind more strongly to the DA centers compared to Mn<sup>2+</sup> ions.

As in bulk ZnS:Mn<sup>2+</sup>, the emission energy shifts of the Mn<sup>2+</sup> emission with temperature can be described by crystal field theory. The blueshift of the Mn<sup>2+</sup> emission wavelength with decreasing temperature is due to the enhancement of the crystal field strength at lower temperatures resulting from crystal lattice contraction. As a consequence, the emitting state, <sup>4</sup>T<sub>1</sub>(G) of Mn<sup>2+</sup>, shifts to lower energies with decreasing temperature, shifting the emission to longer wavelengths.

It is reasonable to treat the blue DA emission as a result of donor–acceptor recombination in which the donor is a trapped electron and the acceptor is a trapped hole. The emission energy may then be described by [99]

$$h\nu = E_{\text{gap}} - (E_A + E_D) + e^2/\varepsilon R \quad (18)$$

where  $E_{\text{gap}}$  is the energy gap of the host,  $E_A$  and  $E_D$  are ionization energies of the acceptor and the donor, while  $\varepsilon$  is the optical dielectric constant, and  $R$  is the distance between the donor and acceptor. Based on Eq. (18) the temperature dependence of the DA emission intensity can be explained. As temperature decreases the energy gap increases and the distance between the donor and the acceptor decreases due to crystal lattice contraction. As a consequence, the DA emission shifts to higher energy, as is observed experimentally.

From Figure 31d, it is clear that the bandwidth of both the DA and Mn<sup>2+</sup> emission decreases with temperature. Electron–phonon coupling is usually considered to be the major contribution for the variation of the emission bandwidth with temperature [101, 102]. Both emission bandwidths decrease slowly with decreasing temperature indicating that the electron–phonon coupling is only weakly dependent on temperature. The Huang–Rhys factor is a useful parameter for evaluation of the electron–phonon coupling strength [103, 104]. The emission bandwidth ( $W$ ) at half intensity can be related to the Huang–Rhys factor ( $S$ ) by [102]

$$W = 4(\ln 2)^{1/2}(KT S \hbar \omega_{\text{LO}})^{1/2} \quad (19)$$

where  $K$  is the Boltzmann constant,  $\omega_{\text{LO}}$  is the LO-phonon frequency,  $T$  is the temperature, and  $\hbar$  is Planck's constant. For bulk ZnS:Mn,  $\hbar \omega_{\text{LO}} = 350 \text{ cm}^{-1}$  [103], and for 3.6 nm nanoparticles,  $\hbar \omega_{\text{LO}} = 423 \text{ cm}^{-1}$  [96]. Using Eq. (19), the average Huang–Rhys factor for the DA emission center ( $\sim 8.4$ ) is larger than that for Mn<sup>2+</sup> ( $\sim 4.2$ ) indicating

that the electron–phonon coupling between the DA center and the lattice is stronger than that between the Mn<sup>2+</sup> ion and the lattice. This is consistent with the results from the intensity variation with temperature. The average  $S$  value for Mn<sup>2+</sup> obtained from the emission bandwidths is larger than that obtained from the Stokes shift of Mn<sup>2+</sup> nanoparticle emission from the lowest excited state ( $\sim 2.88$ ) [104] and larger than the  $S$  value ( $\sim 3.0$ ) of bulk ZnS:Mn<sup>2+</sup> obtained by measuring the zero phonon line at low temperature [105]. This is possibly a result of other broadening mechanisms in addition to the electron–phonon interaction. This additional broadening may result from either a distribution of particle sizes or a distribution of Mn<sup>2+</sup> environments [20].

The principle of luminescence temperature dependence at temperatures above room temperature is the same as described previously. Based on the temperature dependences of semiconductor nanoparticle luminescence properties, a new concept of using luminescent nanoparticles for thermometry applications has been recently described [106]. Temperature is a fundamental property of matter, and its measurement is often required for both scientific research and industrial applications. For industrial manufacturing, real-time temperature monitoring can be used to optimize processing, minimizing waste production and energy consumption. Spatially resolved temperature monitoring can establish regions of an integrated circuit in which heat builds up and suggest improvements in design of the circuit or its cooling system. Monitoring the temperature of high-speed moving parts, such as turbine blades, can identify changes that signify a weakness in the part.

In bioengineering and biochemistry, temperature changes of even a few degrees can mean the difference between life and death for a cell. Real-time, precise *in vivo* monitoring of temperature is of paramount importance in many biomedical diagnostic and treatment processes. Traditional methods of temperature measurement can be divided into two categories: contact methods, including thermocouples, thermistors, and resistance temperature detectors (RTDs), and noncontact methods such as measurement of emitted infrared light.

Fluorescence thermometry, using the fluorescence from luminescent materials to determine temperature, is a non-contact thermometry that has many advantages over other thermometry methods [107]. As the temperature of the phosphor changes, the intensity of the fluorescence, the decay lifetime of the fluorescence, the excitation spectra of the fluorescence, and the wavelength (energy) of the fluorescence may all change. Because the fluorescence can be both excited and measured optically, fluorescence-based temperature sensors are advantageous compared to contact temperature sensors (such as thermocouples, thermistors, and

RTDs) in applications where electromagnetic noise is strong or it is physically difficult to connect a wire (such as for spinning centrifuges or turbines or in wind tunnels). Emissivity does not affect the fluorescence signal, and wavelengths for fluorescence can be found for which glass and water are relatively transparent.

Conventional phosphors are made from crystalline semiconductor materials and typically have grain sizes of micrometers [107]. For noncontact thermometry, these grains are generally mixed with a binder material and coated on the surface of a part whose temperature is to be measured. The grain size limits resolution by scattering both the excitation light and emitted light. It also imposes a minimum thickness phosphor coating of several micrometers on the sample. Thick coatings are disadvantageous because the phosphor coating may act as an insulating layer on the part's surface, giving results for temperature that cannot be applied to similar uncoated parts. However, these problems can be solved by using much smaller nanoparticles [106].

As mentioned in Section 10, the light scattering is due to the phosphor grain size, the shape and the grain boundary, as well as surface roughness. According to Rayleigh's approximation [75], a 100-nm particle will scatter one million times more light than a 10-nm particle. This suggests that much higher spatial resolution is possible by using nanoparticles for fluorescence thermometry or thermal imaging. Thin films of nanoparticles could be coated or sprayed on samples. Small size and ultrathin films should enable a faster equilibration time with an underlying sample and high sensitivity, accuracy, and spatial resolution. Nanoparticles are also suited for incorporation into coatings that may already be applied to a part, such as corrosion protection, making a "smart" material. In addition, high efficiency with short decay times makes nanoparticles very good candidates for luminescence-based temperature sensors for high speed monitoring.

Another important application area of nanoparticle thermometry is in biological or biomedical applications for localized *in vivo* temperature probing, such as temperature monitoring during hyperthermia treatment. The small size, bioconjugation capability, and resistance to photobleaching make nanoparticle thermometry appealing compared to other methods.

To demonstrate the concepts of luminescent nanoparticle thermometry, the temperature response of several luminescent nanoparticle samples has been measured at temperatures above room temperature. The fluorescence peak intensity of CdTe nanoparticles is linearly and reversibly proportional to the temperature in the 30–60 °C range (Fig. 32), with a large response slope of 1.1% per °C. The signal-to-noise ratio of the fluorescence spectrometer is approximately 5000:1. Therefore, the resolution could be as good as 0.02 °C in principle. Both CdTe and ZnS:Mn<sup>2+</sup> nanoparticles could be suitable candidates for biomedical applications (*in vivo* and *in vitro* thermometry) due to their large and linear intensity shift over the physiological and hyperthermia temperature range. The –COOH group of the thioglycolic acid stabilized CdTe nanoparticle can be used to easily conjugate to the amine group of biological molecules (e.g., antibodies), such as by the widely used EDC/NHS reaction [93].

**Figure 32.** Fluorescence spectra of CdTe nanoparticles at different temperatures, from top to bottom: 30–60 °C with excitation wavelength at 350 nm (left). At right is the fluorescence peak intensity (518 nm) of CdTe nanoparticles as a function of temperature. Reprinted with permission from [106], S. Wang et al., *J. Phys. Chem. B* 106, 11203 (2002). © 2002, American Chemical Society.

Double-doped nanoparticles of ZnS:Mn<sup>2+</sup>,Eu<sup>3+</sup> show a different temperature response for each dopant; the ratio of their intensities provides a robust temperature measurement approach [106].

Other fluorescence characteristics such as the fluorescence lifetime should also respond to temperature change, as for conventional fluorophores. It may also be possible to synthesize structures in which fluorescence resonance energy transfer occurs between two different dopants in a nanoparticle or between two nanoparticles of different sizes or compositions. The FRET rate is inversely dependent on the distance between the donor and emitter to the sixth power. Therefore, if the distance between the dopants or nanoparticles is changed slightly due to thermal expansion of the

material, the energy transfer rate will be changed greatly. This may provide a useful method for temperature or pressure sensing [106].

Another potential approach to nanoparticle fluorescence thermometry is the use of upconversion luminescence in which the excitation wavelength is longer than the emission wavelength. The upconversion luminescence intensity of ZnS:Mn<sup>2+</sup> nanoparticles is highly temperature dependent [64, 65]. A close-to-linear temperature dependence of the upconversion intensity has been observed in ZnS:Mn<sup>2+</sup> nanoparticles formed in zeolite-Y [98]. One advantage of upconversion for temperature sensing or imaging, compared with fluorescence, is that the emission background from the surroundings that occurs with fluorescence can be avoided in upconversion. This is particularly interesting in biological or biomedical applications, because many biological components such as cells and tissues have strong autofluorescence upon excitation with UV light.

## 15. LUMINESCENCE PRESSURE DEPENDENCE

Similar to temperature behavior, variation of pressure has been used to understand electronic and optical phenomena in condensed phases. Increases in pressure decrease the interatomic distance and therefore increase the overlap among adjacent electronic orbitals. While pressure studies of luminescence properties in bulk materials are fairly common, there are fewer such investigations in nanoparticles. Recently Meulenberg and Strouse have measured optical properties of CdSe quantum dots in the low pressure regime [108]. These results show a size dependence roughly corresponding to the strong and weak confinement regimes for the exciton in CdSe [108]. Other results from Chen et al. on ZnS:Mn<sup>2+</sup> nanoparticles display a slightly increased pressure coefficient relative to the bulk value [109]. The increase has been attributed to an enhancement in the electron-phonon interaction in nanoparticles relative to their bulk counterparts.

Figure 33 displays the emission spectra under different pressures at room temperature (Fig. 33a) and the pressure dependences of the emission energies (Fig. 33b) of the Mn<sup>2+</sup> and the DA luminescence in ZnS:Mn<sup>2+</sup> nanoparticles [99]. The Mn<sup>2+</sup> emission shifts to lower energies with increasing pressure, while the blue emission peak changes little with pressure. The solid line in Figure 33b represents the result of the least-squares fit to the experimental data using a linear relation. The obtained pressure coefficient for Mn<sup>2+</sup> luminescence in ZnS:Mn<sup>2+</sup> nanoparticles is approximately -34.3 meV/GPa. The pressure coefficient of Mn<sup>2+</sup> emission in bulk ZnS:Mn<sup>2+</sup> is -31 meV/GPa [110]. Comparing these results, the pressure coefficient for the Mn<sup>2+</sup> luminescence in the 3.5 nm ZnS:Mn<sup>2+</sup> nanoparticles is about 10% larger than that of the bulk value, and the result from the 3.5 nm particles is also slightly larger than that for 4.5 nm particles (-33.3 meV/GPa) measured previously [109].

The pressure dependence of the luminescence energy reflects the interactions between the relevant electronic states of the center and its surrounding lattice ions. The absolute value of the pressure coefficient is related to the

**Figure 33.** Pressure dependence of the emission spectra (a) and emission energy (b), of the blue (DA) and Mn<sup>2+</sup> emissions in ZnS:Mn<sup>2+</sup> nanoparticles. Reprinted with permission from [99], W. Chen et al., *J. Appl. Phys.* 92, 1950 (2002). © 2002, American Institute of Physics.

strength of the interaction between the emitter and the host or the strength of the crystal field on the emitter [111]. A large pressure coefficient normally indicates a stronger interaction between the emitter and the host.

The pressure dependence of Mn<sup>2+</sup> emission in ZnS:Mn<sup>2+</sup> can be calculated by using crystal field theory. The pressure induced change in the energy ( $E$ ) of the Mn<sup>2+</sup> emission band of ZnS:Mn<sup>2+</sup> is a function of the crystal field strength  $D_q$  and the Racah parameter  $B$  only, assuming that the Racah parameter ratio  $C/B$  is independent of pressure [112]

$$\frac{dE}{dP} = \delta \frac{d(D_q)}{dP} + (E - D_q \delta) \frac{1}{B} \frac{dB}{dP} \quad (20)$$

where  $\delta = d(E/B)/d(D_q/B)$ . For the  $\text{Mn}^{2+}$  ion,  $\delta$  is  $-10$ .  $D_q$ ,  $B$ , and  $C$  are the crystal field parameters. For the 3.5 nm  $\text{ZnS:Mn}^{2+}$  nanoparticles,  $B$ ,  $C$ , and  $D_q$  are 490, 3357, and  $586 \text{ cm}^{-1}$ , respectively [104]. For bulk  $\text{ZnS:Mn}$ ,  $dB/dP$  and  $d(D_q)/dP$  are  $-3.48$  and  $18.2 \text{ cm}^{-1}/\text{GPa}$ , respectively [113]. From Eq. (20),  $dE/dP \approx -34.6 \text{ meV/GPa}$ , which is in excellent agreement with the experimental value ( $-34.3 \text{ GPa}$ ). The fact that bulk values used for  $dB/dP$  and  $d(D_q)/dP$  accurately reproduce the data suggests that these parameters are not significantly different in nanoparticles relative to bulk  $\text{ZnS:Mn}^{2+}$  [109].

The pressure coefficient for the blue emission is  $-3.2 \text{ meV/GPa}$ . The pressure coefficients of the blue emission reported for bulk  $\text{ZnS}$  are  $+90$  [114] and  $+125 \text{ meV/GPa}$  [115]. In comparison, the pressure coefficient value in nanoparticles is much smaller and the pressure change of the emission energy is in the opposite direction.

This surprising value for the pressure coefficient of the DA emission may be explained by considering the increased binding energies and the effects of surface states in nanoparticles. In bulk  $\text{ZnS:Mn}^{2+}$ , the DA emission shifts to higher energy with increasing pressure due to a combination of effects. The bandgap increases with pressure while the dielectric constant and distance between donor and acceptor decrease. From Eq. (18) we would expect a rapid change in the emission energy with increasing pressure. However, House and Drickamer [114] have observed that the DA emission shift in the bulk material is not as dramatic as that expected from the increase in the bandgap. This is due to the fact that the binding energies of both the donor and acceptor also increase with pressure. This serves to offset the changes due to the bandgap, distance, and dielectric coefficients.

In nanoparticles, both the energy gap and binding energy increase with decreasing size. In the small nanoparticles under investigation, increases in the bandgap and Coulomb term [ $e^2/\epsilon R$  in Eq. (18)] with pressure are apparently offset with the changes in the ionization energies with pressure. The carrier binding energy of the donor or the acceptor is increased relative to bulk due to size confinement. This increase in the binding energy leads to the increase in  $E_D$  and  $E_A$  in Eq. (18). This serves to mitigate the effects of the other parameters leading to the overall weak pressure dependence.

In addition to the increases in binding energies, the influence of surface states must be considered. Due to the size effect, defects in nanoparticles often are localized at the surface sites [116]. Once the donor-acceptor pairs are localized at the surface states, the electron wavefunctions are more atomlike, less sensitive to their nearest neighbor bond lengths [117], and thereby not as sensitive to pressure increases compared to the bulk.

## 16. LUMINESCENT NANOPARTICLES FOR OPTICAL STORAGE

In recent years, a demand for improved data storage has accompanied the dramatic advances in computing and communication technology. The requirement for high capacity optical memory has led to much research in optical materials, medium structures, and system concepts. Using nanoparticles or QDs as a storage medium offers tremendous

potential. Enhanced, cost-effective storage of information requires ultrahigh packing densities as well as inexpensive self-assembling techniques and fast methods for writing and retrieving the information. Semiconductor quantum dots, which involve a few thousand atoms, may offer an attractive path toward achieving these goals. Single-electron storage has been suggested as a possibility with quantum dots [118]. Charge storage devices based on the resistivity change of a two-dimensional electron gas located near a layer of self-assembled QDs have been demonstrated at low temperature [119]. A memory cell based on field-effect tunable lateral potential modulation in the plane of a semiconductor quantum well [120] and acoustically driven storage in a quantum well [6] have been proposed and demonstrated. The shortcoming of these approaches is that they are limited to short durations (several hundred microseconds to several seconds) and function only at low temperature.

The fluorescence of  $\text{Eu}^{3+}$ -doped nanoparticles is very sensitive to light. The emission of  $\text{Eu}^{3+}$  can be quenched by UV irradiation, and this quenching can be recovered by visible light stimulation. This is a reversible optical process that can be potentially applied for optical storage. The emission spectra following excitation at 395 nm of  $\text{BaFBr:Eu}^{3+}$  are displayed in Figure 34 [121]. The three emission bands are from the transitions of  ${}^5D_0 \rightarrow {}^7F_0$ ,  ${}^5D_0 \rightarrow {}^7F_1$ ,  ${}^5D_0 \rightarrow {}^7F_2$ , and  ${}^5D_0 \rightarrow {}^7F_3$  of  $\text{Eu}^{3+}$ . Figure 34 shows that under UV irradiation at 225 nm the  $\text{Eu}^{3+}$  emission decreases in intensity. This luminescence quenching can be recovered slightly by exposure to a red light at 600 nm, and it can be recovered very quickly by exposure to a visible light (500 to 800 nm). Similar results have also been observed in  $\text{Eu}_2\text{O}_3$  nanoparticles encapsulated in zeolite-Y,  $\text{Eu}^{3+}$  nanoclusters in zeolite, and  $\text{Eu}^{3+}$ -doped  $\text{Y}_2\text{O}_3$  nanoparticles [121]. One example is shown in Figure 35 for  $\text{Eu}^{3+}$  clusters in zeolite-Y. Under UV irradiation at 254 nm, the emission of  $\text{Eu}^{3+}$

**Figure 34.** The emission spectra of  $\text{BaFBr:Eu}^{3+}$  nanoparticles before (1) and after UV irradiation at 225 nm for 10 (2) and 15 min (3) and then exposed to a visible lamp for 15 min (4), respectively [121].

**Figure 35.** The emission spectra of  $\text{Eu}^{3+}$ -zeolite-Y before (1) and after (2) UV irradiation at 254 nm for 5 min, then photostimulation at 840 nm for 5 min (3), and then to a visible lamp for 10 min (4), respectively [121].

decreases. Under stimulation at 840 nm, very little recovery is observed. However, after stimulation from a visible lamp (500 to 800 nm), the fluorescence is recovered to almost 100% of its original value.

The emission spectral patterns of  $\text{Eu}^{3+}$  in  $\text{BaFBr}:\text{Eu}^{3+}$  and  $\text{Eu}^{3+}$ -zeolite-Y are noticeably different. In  $\text{BaFBr}:\text{Eu}^{3+}$ , the  ${}^5D_0 \rightarrow {}^7F_1$  emission band is more intense than the  ${}^5D_0 \rightarrow {}^7F_2$  emission band while in  $\text{Eu}^{3+}$ -zeolite-Y, the  ${}^5D_0 \rightarrow {}^7F_2$  band is much stronger than the  ${}^5D_0 \rightarrow {}^7F_1$  emission. This is due to the surrounding environments of  $\text{Eu}^{3+}$  which in the two materials are different. The  ${}^5D_0 \rightarrow {}^7F_1$  and  ${}^5D_0 \rightarrow {}^7F_2$  transitions are termed hypersensitive luminescence [16] because the luminescence is highly sensitive to

structure change and environmental effects. As a result, the intensity ratio of the  ${}^5D_0 \rightarrow {}^7F_1$  transition to the  ${}^5D_0 \rightarrow {}^7F_2$  transition can give much information about the site symmetry and structure of the materials.

The physical mechanism for the optical reversible process in  $\text{Eu}^{3+}$  doped nanoparticles is not yet clear. The most likely process is the reversible charge transfer between  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  ions. Charge transfer between  $\text{Eu}^{3+}$  and  $\text{Eu}^{2+}$  has been reported in several systems [122]. It has been reported that under high energy radiation, rare earth (RE) ions can be oxidized or reduced [122]. This is determined by the oxidation or reduction potentials of the ions. Nugent [123] has investigated extensively the oxidation states of RE ions. According to this investigation, the oxidation of  $\text{RE}^{3+}$  to  $\text{RE}^{4+}$  ions is possible if the optical electronegativity [ $\chi(\text{RE}^{4+})$ ] is less than or equal to 3.03, and the standard reduction potential [ $E_{\text{RE}}^0(\text{RE}^{4+} \rightarrow \text{RE}^{3+})$ ] is less than or equal to 5.2 V. For example,  $\chi(\text{Tb}^{4+})$  is 2.55 V and the  $E_{\text{RE}}^0(\text{Tb}^{4+} \rightarrow \text{Tb}^{3+})$  is 3.30 V [123], favoring the appearance of  $\text{Tb}^{4+}$  ions. For  $\text{Eu}^{3+}$  ions, oxidation to  $\text{Eu}^{4+}$  is unlikely because the  $\chi(\text{Eu}^{4+})$  (3.40) is larger than 3.03 and the  $E_{\text{RE}}^0(\text{Eu}^{4+} \rightarrow \text{Eu}^{3+})$  (6.4 V) is larger than 5.2 V [123]. This indicates the reduction of  $\text{Eu}^{3+}$  to  $\text{Eu}^{2+}$  is more favorable. In addition,  $\text{Eu}^{2+}$  is a half-filled configuration of  $4f^7$ ; thus energetically,  $\text{Eu}^{2+}$  is more stable than  $\text{Eu}^{3+}$ . Therefore, under UV irradiation at 254 nm, electrons and holes may be produced in the nanoparticles, and some  $\text{Eu}^{3+}$  ions are reduced to  $\text{Eu}^{2+}$  ions by recombination with electrons:

The UV generated holes may be trapped in the surface states of the nanoparticles or in the defects of the host materials like zeolites to form hole centers. Under visible or IR stimulation, holes can be released from their traps and recombine with  $\text{Eu}^{2+}$  to form  $\text{Eu}^{3+}$ ,

**Table 3.** A summary of the luminescence characteristics of some popular semiconductor nanoparticles.

Particles	FL	EL	TL	CL	ML	UPL	PSL	XEOL	Ref.

*Note:* This table is meant only as an overview of the many different types of luminescence from semiconductor nanoparticles. As new materials are made and new experiments performed, there will be countless additions to this rich field.

FL—fluorescence, EL—electroluminescence, TL—thermoluminescence, CL—cathodoluminescence, ML—magnetoluminescence, UPL—upconversion luminescence, PSL—photostimulated luminescence, XEOL—X-ray excited optical luminescence.

resulting in near complete recovery of the  $\text{Eu}^{3+}$  luminescence following visible or IR stimulation.

## 17. SUMMARY

Luminescent devices may benefit greatly from increased luminescence efficiencies, reduced size, and tunable wavelength selection. In this chapter, we have reviewed the luminescence of semiconductor nanoparticles which may serve to fill these needs. Quantum size confinement and the large surface-to-volume ratios of nanoparticles have profound influences on the luminescence efficiency and emission wavelength. Usually, semiconductor nanoparticles exhibit two kinds of emissions from the band-band (exciton) and surface states, respectively, and both emissions can be modified by size and surface modification. Thus, emission colors of nanoparticles can be easily adjustable by size, while the emission efficiency is highly determined by surface characteristics. Doped nanoparticles represent a new type of phosphor with promising potential applications. Their luminescence processes, decay dynamics, and temperature and pressure dependences make them ideal for many applications, such as light-emitting diodes based on electroluminescence, and temperature and pressure sensors based on the temperature and pressure dependences of nanoparticle luminescence. In addition, medical imaging, optical storage, radiation detection, and dosimetry based on photostimulated luminescence, thermoluminescence, and a newly reported reversible optical process in  $\text{Eu}^{3+}$  nanoparticles doped in zeolite-Y may benefit from nanosized materials. Sensors based on the energy transfer process have tremendous applications in chemical or biological sensors, temperature or pressure measurements, radiation detection and dosage control, medical imaging, diagnostics, and optical storage and communications.

## GLOSSARY

**Cathodoluminescence** Type of luminescence following excitation by an electron beam such as that observed in traditional cathode ray technologies.

**Electroluminescence** The emission of light from nonincandescent materials following direct (non-thermal) excitation by an electric current.

**Fluorescence** The emission of light from an excited state of like multiplicity as the lower state (usually a singlet state) and the lifetimes are typically nanoseconds or less.

**Fluorescence resonance energy transfer** A nonradiative transfer of excitation energy from one fluorescent molecule to another. Energy transfer quenches the fluorescence of the originally excited molecule and elicits the fluorescence of the absorbing molecule.

**Luminescence** The emission of light by a substance immediately after the absorption of energy from light of usually higher energy. It is formally divided into two categories, fluorescence and phosphorescence, depending on the nature of the excited state and the decay lifetime.

**Magnetoluminescence** Refers to luminescence observed under magnetic fields. Magnetoluminescence is used to study both excitonic structure and dilute magnetic systems.

**Nanoparticle** Refers to a particle with a size less than 100 nm. Also called nanocrystal, particle, nanocluster, or quantum dot.

**Phosphorescence** The emission of light from an excited state of different multiplicity and the lifetimes are usually in the millisecond to second range.

**Photostimulated luminescence** The phenomenon in which phosphors release trapped charge carriers when stimulated by infrared or visible light. The trapped carriers recombine with luminescent centers to generate the photostimulated luminescence. Thus in contrast to photoluminescence, in photostimulated luminescence the stimulation (excitation) wavelength is longer than the emission wavelength.

**Quantum size confinement** Refers to the changes in the electronic structure and physical properties as the particle size is reduced to approach the exciton Bohr radius. These changes include an increase of the energy gap, shifts of the absorption edge and emission peaks to higher energies with decreasing size, development of discrete features in the spectra, and concentration of the oscillator strength into just a few transitions.

**Semiconductor** A material with an electrical resistivity in the range of  $10^{-2}$ – $10^9$   $\Omega\text{cm}$ , or a material whose energy gap lies between zero and about 4 eV.

**Thermoluminescence** Luminescence generated following excitation with heat instead of visible or near-infrared photons.

**Upconversion luminescence** A phenomenon in which the excitation energy (wavelength) is lower (longer) than the emission energy (wavelength).

**X-ray excited optical luminescence** The measurement of the optical luminescence spectrum following excitation with X-ray photons.

## ACKNOWLEDGMENTS

The authors thank Nomadics, Inc., the National Science Foundation (NSF), the National Institute of Health (NIH), and the Oklahoma Center for Advanced Science and Technology (OCAST) for financial support of our research projects. The reviewed work here was partially supported by the President Foundation of the Chinese Academy of Sciences and the National Natural Science Foundation of China. Part of the research described in this chapter was performed at the W. R. Wiley Environmental Molecular Sciences Laboratory, a national scientific user facility sponsored by the Department of Energy's Office of Biological and Environmental Research and located at the Pacific Northwest National Laboratory (PNNL). PNNL is operated by Battelle for the U.S. Department of Energy under contract DE-AC06-76RLO1830. We thank Kim Falk at Nomadics, Inc. for her help in the reprinting of the literature figures.

## 1. INTRODUCTION

The concept of “hybrid organic–inorganic” materials emerged only very recently with the birth of “soft” inorganic chemistry processes (“chimie douce”) [1–6]. The unique low-temperature processing characteristics of the sol–gel process allow the chemical design of organic–inorganic hybrid materials through the incorporation of low-molecular-weight organic molecules with appropriate functionalities into inorganic moieties at temperatures for which the organics are not destroyed [1–39]. These materials are generally produced using various methodologies of “soft” inorganic chemistry in liquid or sol–gel media, and combine the most important properties of their constituents, such as low processing temperatures (polymer-like), high transparency, and sufficient thermal stability (glass-like). The characteristics of the sol–gel process, such as, for instance, the unique

availability of the respective precursors (commercially available metal alkoxides and organoalkoxysilanes, as well as nanoparticles), low processing temperatures, and the processing versatility of the colloidal state allow the combination of organic and inorganic components at the nanometric dimension, in virtually any ratio, leading to the so-called hybrid organic–inorganic nanocomposites [1–44]. The hybrid concept has made accessible an immense new area of materials science with extraordinary implications for the development of multifunctional materials. The combination of the appropriate processing conditions with the adequate choice of the organic and inorganic components dictates the morphology, molecular structure, and properties of the hybrids. Moreover, frequently, the combination of components provides an additional dimension to their properties in becoming part of the hybrid compound. Promising applications are therefore expected in many fields, including optics, electronics, optoelectronics, ionics, mechanics, membranes, protective coatings, catalysis, sensors, biology, and others [1–50].

Although no commercial products are available yet, there is widespread agreement within the sol–gel scientific community that active optical applications of multifunctional nanoscale organic–inorganic frameworks with tunable design and suitable features might present one of the most attractive fields to realize applications for the 21st century. We can refer to, for instance, optical switching and data storage hybrid devices [17, 51, 52]; photoelectrochemical cells and coatings for solar energy conversion [53–55]; and hybrid materials having excellent laser efficiencies and good photostability [56], fast photochromic responses [57], high and stable second-order nonlinear optical responses [58–62], or which can be used as fiber-optic sensors [63–65], photopattern waveguiding structures for integrated optics [66–74], and electroluminescent diodes [75, 76]. Further details concerning the photonic applications of siloxane-based organic–inorganic hybrid and nanocomposites throughout

the past decade may be found in various recent reviews [15, 17, 33, 36, 38, 40, 46–50].

The outgrowth of new full-color displays cheaper and less aggressive to the global environment is one of the main challenging tasks for the next generation of flat panel display systems and lighting technology. Different applications require different demands on emitted light; in some cases, pure colors are needed, whereas in other cases, a bright white light source is necessary, especially for backlight applications in large panel liquid-crystal displays. Efficient organic white light-emitting diodes (OLEDs) are currently considered as low-cost alternatives for applications in flat panel display systems and lighting technology due to the variety of attainable emission colors, the easiness of their production, and the high achievable electroluminescence quantum efficiency at relatively low operating voltages ( $\approx 4\%$ ) [77–82]. Since the first consideration of organic electroluminescent (EL) devices more than 30 years ago [83], OLEDs have been widely pursued, and near-commercial dot-matrix displays have recently been demonstrated [84]. Luminous efficiencies in excess of 30 lm/W and operating voltages as low as 4 V have been reported [85, 86]. To obtain white-light emission from OLEDs excitation, more than one molecular species is necessary since the luminescence of a single organic molecule typically does not span the entire visible spectrum. Several approaches have been established in recent years, allowing the achievement of white-light emission from OLEDs. We can emphasize, for instance, the use of multilayers in which the recombination zones are spatially controlled by the application of hole-blocking layers [87, 88], the spectral filtering of a large broad emission [89], the superposition of red, green, and blue OLEDs [90], the use of homogeneous polymer blends [80], the concept of exciplex emission [81], and the combination in a unique structure of InGaN and conjugated polymers [82]. However, obtaining pure emission colors (red, green, and blue) from conjugated polymers or small organic molecules is difficult because their emission spectra are broad, typically with full width at half maximum (FWHM) of 50–200 nm [91]. Moreover, mixing of red, green, and blue OLEDs in a single system brings forth difficulties in the integration of individual materials and electrical requirements [92]. These technical issues in the fabrication and manufacturing of light-emitting diodes (LEDs) also remain to be resolved, even if we consider the integration of different inorganic semiconductors, such as GaN, InGaN, AlInGaP, and InGaAlN [93]. In contrast to organic and semiconductor-based LEDs, very sharp emissions (FWHM  $< 4$  nm [94]) can be obtained using LEDs incorporating rare-earth (RE) ions. Moreover, the proper selection of red ( $\text{Eu}^{3+}$ ,  $\text{Pr}^{3+}$ ,  $\text{Sm}^{3+}$ ), green ( $\text{Tb}^{3+}$ ,  $\text{Er}^{3+}$ ), and blue ( $\text{Tm}^{3+}$ ,  $\text{Ce}^{3+}$ ) emitting RE ions as dopants in a common host material could simplify the LED structure, and hence, the fabrication processes, reducing the cost and resolving some of the critical integration problems. This is the case of the RE-based GaN LEDs reported recently [95–102]. On the other hand, due to the spectral sensitivity of the human eye, pure red-emitting LEDs based on  $\text{Eu}^{3+}$  are easily processed and more efficient than the corresponding ones based on polymers or organic chromophores. In fact, the main  $\text{Eu}^{3+}$  emission (610–620 nm) is still red, and appears brighter than red emission at longer wavelengths

[91, 96]. Pure red emission has been achieved recently in OLEDs by transferring energy from blue-emitting conjugated polymers to  $\text{Eu}^{3+}$ - $\beta$ -diketonate complexes [91]. Furthermore, RE-doped materials are of great interest for a wide range of other photonic applications such as tunable lasers (both in the ultraviolet (UV) and visible (Vis) ranges), low-energy scintillators, amplifiers for optical communications, and optical storage [94].

Despite the very efficient light emission under UV excitation characteristic of RE complexes of  $\beta$ -diketonates (some of them exhibit laser action in solution [103–105]), aromatic carboxylic acids, and heterocyclic ligands, such as 2,2'-bipyridine (bpy) and 1,10-phenanthroline (Phen), they have been excluded so far from practical use as tunable solid-state lasers or phosphor devices due essentially to their poor thermal stability and mechanical properties. Another drawback that derives from the use of RE  $\beta$ -diketonates lies in the difficulty in obtaining them in the anhydrous form. In general, the  $\beta$ -diketonate chelates are produced as hydrates in which two or three water molecules are attached to the central ion. The presence of water molecules in the RE first coordination shell quenches the emission, due to the activation of nonradiative decay paths. The substitution of the water molecules by other chemical species, such as heterocyclic ligands (e.g., bpy and Phen), substituted sulphoxides and phosphine oxides, aromatic carboxylic acids, among many others, has been extensively employed in order to improve the light-emission properties of RE  $\beta$ -diketonate chelates [106]. Crystalline mixed compounds, in the powder form and displaying unusually high emission quantum efficiencies (70–80%), have resulted from this concept [103–108]. Moreover, the RE  $\beta$ -diketonates are undoubtedly extremely promising for efficient light conversion molecular devices (LCMDs). Recently, these LCMDs have found a series of important applications, such as luminescent labels in fluoroimmunoassays, light concentrators for photovoltaic devices, antennas in photosensitive bioinorganic compounds, and high-technology optics [106]. One of the strategies adopted in the last few years to simultaneously improve the thermal stability, the mechanical properties, and the light-emission properties of RE complexes is to incorporate them into polymeric matrices [109–129]. However, low photostability and poor thermal stability still limit their applicability.

Taking into account the processing advantages of sol-gel matrices, such as low-temperature processing and shaping, high sample homogeneity and purity, availability of innumerable precursors, and the opportunity to prepare nanocomposites, much research has been focused recently on the possibility of using RE-based hybrid frameworks as matrices for RE photoluminescence (PL) [15, 17, 33, 36, 38, 46–50]. The luminescence efficiency of RE ions in conventional sol-gel-derived matrices is currently limited by hydroxyl quenching [130–132] originating from residual water, silanol groups, and dopant clustering [133–135]. To circumvent these drawbacks, various strategies of synthesis and chemical design of innovative sol-gel-derived hybrids have been developed recently [17, 36, 38]. A significant part of this research involves the encapsulation of RE organic complexes with  $\beta$ -diketonates, aromatic carboxylic acids, and heterocyclic ligands in sol-gel-derived matrices (in

particular, siloxane-based ones) through the simple embedding of the complexes within the sol–gel matrix [53, 55, 136–152], or through the use of complexing ligands covalently grafted to the framework [153–161]. In general, the embedding of the complexes within the sol–gel matrix gives rise to Class I nanocomposite hybrid materials [11], that is, hybrid systems where one of the components is entrapped within a network of the other component. In this case, weak interactions (van der Waals contacts, hydrogen bonding, or electrostatic interactions) between the host network and the entrapped species will be established. The sol–gel synthesis of hybrid nanostructural RE complexes *in-situ* leads instead to Class II hybrid materials [11], in which at least a proportion of the organic and inorganic components are typically grafted together by means of strong chemical interactions (covalent or ionocovalent bonds). All of these sol–gel-derived organic–inorganic hybrid photonic materials exhibit notably improved luminescence properties with respect to the simple incorporation of metal ions in silica. Indeed, such organic complexes increase the concentration of lanthanide salts in the inorganic matrix, the ligands protect the central RE ions from silanol groups present in the silica matrix, thus diminishing nonradiative decay pathways of the RE ions, and finally, RE ions encapsulated by absorbing ligands can give rise to intramolecular energy transfer from the coordinating ligands to the central lanthanide ions, which in turn undergo the corresponding radiative emitting process (the so-called “antenna effect”).

The hybrid concept has also been employed recently to synthesize stable and efficient Class II RE-doped amine or amide functionalized hybrids [153–190]. Among these functionalized nanohybrids reported, mention must be made of those which comprise polyether-based chains of variable length grafted to both ends to a siliceous backbone through urea or urethane cross linkages, termed *di-ureasils* and *di-urethanesils*, respectively [162–187]. Small-angle X-ray scattering (SAXS) data of the undoped hybrid matrices showed the presence of a well-defined peak attributed to the existence of a liquid-like spatial correlation of siloxane-rich domains embedded in the polymer matrix and located at the ends of the organic segments [178–183]. For the undoped di-ureasils, the siloxane particle radius and the average interparticle distance increase from 5 to 7 Å (error within 10%) and from  $25 \pm 2$  to  $40 \pm 2$  Å, respectively, as the average polymer molecular weight increases from 600 to 2000 g·mol<sup>-1</sup> [181]. Values slightly smaller, 3 and 15 Å (error within 10%), respectively, were found for undoped di-urethanesils with an average polymer molecular weight of 300 g·mol<sup>-1</sup> [183]. The incorporation of RE ions (particularly Eu<sup>3+</sup>) into the di-ureasil and di-urethanesils nanohybrid hosts promotes the formation of a two-level structure in which the primary level is composed of rather close-packed siloxane nanoparticles with radius between 3–10 Å (errors within 5%), depending on the matrix and on the Eu<sup>3+</sup> concentration. Clusters of these particles form the second level [181, 183].

Moreover, these diurea and diurethane cross-linked xerogels, which are easily produced as thin, elastomeric, and highly transparent monoliths, may withstand the presence of large amounts of guest dopant compound. The di-ureasils, for instance, when doped with Nd<sup>3+</sup>, Eu<sup>3+</sup>, Tb<sup>3+</sup>, Er<sup>3+</sup>,

and Tm<sup>3+</sup> ions, display remarkable emission properties. Besides a broad long-lived emission associated with the hybrid host [191–196], the di-ureasils exhibit the typical intra-4f monochromatic emission in the green (Tb<sup>3+</sup>) [172, 185], red (Eu<sup>3+</sup>) [162–164, 166, 168, 170–172, 177, 180, 184, 186, 187], and even in the infrared (Nd<sup>3+</sup> [169, 173, 174, 176], Er<sup>3+</sup> [173, 174], and Tm<sup>3+</sup> [172]), thus opening challenging new prospects for their applications. In addition, the color emitted by the Eu<sup>3+</sup>-doped di-ureasils may be readily tuned across the CIE (Commission Internationale d'Éclairage) chromaticity diagram by varying either the salt concentration or the excitation wavelength [166, 168, 170, 171]. In spite of these properties, energy transfer from the hybrid's emitting centers (the NH groups of the urea linkages and the siliceous nanodomains [191–196]) to the Eu<sup>3+</sup> ions is quite inefficient, and high multiphonon decay rates are observed for the Eu<sup>3+</sup>-excited states. Calculated quantum efficiencies around 8% are obtained for emission from the Eu<sup>3+</sup> <sup>5</sup>D<sub>0</sub> excited state within the entire range of compositions studied up to now [170]. Moreover, the activation of the energy transfer mechanism depends noticeably on the ion local coordination. For the high-molecular-weight di-ureasils, energy transfer occurs as the Eu<sup>3+</sup> coordination involves the carbonyl-type oxygen atoms of the urea bridges, which are located near the hybrid's host emitting centers. On the contrary, in the low-molecular polyether-based di-ureasils, the Eu<sup>3+</sup> ions are coordinated to the polymer chains, and therefore, the distance between the hybrids emitting centers and the metal ions is large enough to allow efficient energy transfer mechanisms [170].

This review attempts to cover the most recent advances of photoluminescent Class II siloxane-based organic–inorganic hybrids incorporating RE complexes. Emphasis is essentially given to sol–gel-derived hybrids in which: (1) an organic molecule—which is part of the hybrid framework itself—is able to complex RE ions, and (2) RE salts or complexes are encapsulated within cross-linked Class II matrices. The synthesis, the PL features, and a description of the recombination mechanisms of photoluminescent Class II siloxane-based organic–inorganic hybrids lacking activating centers are reviewed. Furthermore, some results of Class I siloxane-based photoluminescent hybrid materials incorporating RE ions are also included. This review does not, therefore, focus on Class I hybrids incorporating RE ions derived from non-siloxane precursors. The reader will be invited to travel from the description of the materials synthesis and structure features to the photoluminescent results that stress the potential application of these materials as innovative photonic hybrids. Particular attention will be given to the determination of the emission color coordinates and absolute emission quantum yields, and to the description of the host-to-metal ion energy transfer mechanisms intrinsically associated with the ion local coordination. We have tried to make this review as comprehensive as possible, and we apologize in the event that we were not successful in this regard.

## 2. SYNTHESIS OF RARE-EARTH-DOPED NANOHYBRIDS

The sol–gel process is a chemical synthetic procedure known for many years, which is based on inorganic polymerization reactions that lead to the production of dispersed

inorganic materials in solvents, through the growth of metal-oxo polymers [6]. Because of their high reactivity with water, metal alkoxides, in particular tetraethoxyortosilane [TEOS,  $\text{Si}(\text{OCH}_2\text{CH}_3)_4$ ], are the most widely used precursors in the sol–gel method. Upon *hydrolysis*, hydroxyl groups become attached to the metal ion of such compounds, and an alcohol is formed concomitantly. Depending on the amount of water and catalyst added, the hydrolysis may yield to partially hydrolyzed species,  $\text{M}(\text{OR})_{4-n}(\text{OH})_n$  (where M and R represent the metal atom and an alkyl group, respectively) [Eq. (1)] or go to completion [Eq. (2)]

Through a *condensation* reaction, two partially hydrolyzed molecules (or one partially hydrolyzed molecule and a non-reacted one) bond to each other, and a small molecule, such as water [Eq. (3)] (or alcohol [Eq. (4)]), is produced:

These reactions proceed, giving rise to large metal-based molecules, respectively. The substance will be called a *gel* when the molecule reaches macroscopic dimensions and extends throughout the solution. The *gel point* is the time at which the last bond is formed that completes this giant molecule. *Gelation* may occur after the sol (or colloidal suspension of solid particles in a liquid) is cast into a mold, allowing objects of a required shape to be made.

Bond formation does not stop at the gel point. *Aging* is the process of change in structure and properties that takes place after gelation. Aging may involve further condensation, dissolution, and reprecipitation of monomers and oligomers, or phase transformations within the solid and liquid phases [6]. *Drying* under normal conditions is accompanied by shrinkage of the gel network. The resulting dried gel, usually called *xerogel*, is reduced in volume by a factor of 5–10 compared to the original wet gel. This shrinkage process involves deformation of the network and the transport of the liquid through the pores. If the wet gel is dried under supercritical conditions, the shrinkage will be minimum, and the resulting product will be called *aerogel*. When the smallest dimension of the gel is greater than a few millimeters, the material is usually classified as a *monolith*. If, however, gelation occurs through rapid evaporation of the solvent, films and fibers are obtained.

The wide range of structures, microstructures, and compositions that can be achieved by the sol–gel method through a careful control of the several process parameters, such as the  $\text{H}_2\text{O}/\text{M}$  ratio, the nature and concentration of the catalyst, and the type of solvent, open many possibilities for practical applications.

In the remainder of this section, we will describe some particular aspects of the synthetic procedure of the most cited sol–gel-derived hybrids discussed in the present review.

It is well known that the structure, degree of order, and general features of these nanosized systems depend not only

on the chemical features of the organic and inorganic components, but also on the interactions which are established between them. Thus, the most important factors that govern the design of hybrid materials are the nature, extent, and accessibility of the inner interfaces [11, 15, 40]. On the basis of the type of interactions occurring between both components, it is possible to divide the large class of hybrid materials into two distinct subclasses, usually designated as Class I and Class II [11].

Class I includes all of those hybrid systems in which both components are linked only through weak interactions, such as van der Waals contacts, hydrogen bonding, or electrostatic forces. In contrast, in Class II, at least a proportion of the organic and inorganic components of the hybrids are grafted together by means of strong chemical bonds (covalent, ionocovalent, or acid-base bonds). Thus, the synthesis of Class II hybrids strongly depends on the relative chemical stability of the chemical bonds that associate the various components. It implies the use of precursor molecules with at least two different functionalities: alkoxy groups, which undergo hydrolysis–condensation reactions in the presence of water and yield the oxo-polymer framework, and metal-carbon bonds, which are stable with respect to hydrolysis.

## 2.1. Class I Hybrids

A significant number of promising Class I organic–inorganic frameworks based on silica ( $\text{SiO}_2$ ) alumina ( $\text{Al}_2\text{O}_3$ ) or mixtures of  $\text{SiO}_2$  and titania ( $\text{SiO}_2/\text{TiO}_2$ ) or  $\text{SiO}_2$  and zirconia ( $\text{SiO}_2/\text{ZrO}_2$ ) have been proposed in the last few years as adequate host structures for luminescent dopants, in particular RE salts and complexes [53, 55, 135–152].

Although the description of the synthetic procedure of all of the Class I systems investigated to date is beyond the scope of the present review, it is of interest to briefly mention some of the most recent works reported in this domain, and to stress the great diversity of systems proposed by the numerous researchers devoted to the investigation of the Class I hybrids.

Li et al. [148] developed attractive  $\text{Eu}^{3+}$ - and  $\text{Tb}^{3+}$ -doped complexes composed of  $\text{SiO}_2$ -based matrices. The preparation of such composites involved the addition of a metal alkoxide  $\text{M}(\text{OR})_2$  (where  $\text{M} = \text{Zr}$  and  $\text{Ta}$ ) to a mixture of TEOS, water ( $\text{H}_2\text{O}$ ), and ethanol ( $\text{CH}_3\text{CH}_2\text{OH}$ ) (molar ratio 1:10:1) and a few drops of diluted hydrochloric acid ( $\text{HCl}$ ) solution, which acted as a catalyst. The emitting centers (bis-1,10-phenanthroline europium(III) chloride ( $[\text{Eu}(\text{phen})_2]\text{Cl}_3$ ) and terbium bis-2,2'-bipyridine terbium(III) chloride ( $[\text{Tb}(\text{bpy})_2]\text{Cl}_3$ ) were dissolved in  $\text{H}_2\text{O}$  and  $\text{N,N}$ -dimethylformamide (DMF), and added to the precursor solution (molar ratio of  $(\text{Si} + \text{M})$ :complex:  $\text{H}_2\text{O}$ :DMF = 1:y:4:1, where  $y = 0.01$ –0.2). Solid composite samples were obtained after stirring and casting the above mixture and aging it at moderate temperature for several days.

The light yellow monoliths obtained by Ji et al. [145] were produced by first dissolving  $\text{Eu}(\text{TTA})_3\text{phen}$  (where TTA is trifluorothenoxyacetate) or  $\text{Tb}(\text{Sal})_3$  (where Sal represents salicylate), hydroethyl methacrylate (HEMA), and benzoyl peroxide (BPO) in DMF and then mixing them with TEOS. The latter compound was hydrolyzed and polycondensed

under acidic conditions at 40–45 °C. When the reaction reached the gel point, the container was placed in a desiccator for removal of H<sub>2</sub>O and solvents. A heat treatment at 70–100 °C was necessary for two days to initiate the polymerization of HEMA.

It is also worth referring to the Class I hybrids developed by Li et al. [146], which were synthesized in a slightly different manner. TEOS and vinyltrimethoxysilane (VTMOS) were first mixed with HCl in H<sub>2</sub>O (molar ratio TEOS:VTMOS:H<sub>2</sub>O = 1:1:4). Appropriate amounts of the Eu(TTA)<sub>3</sub>phen complex were dissolved in DMF, and this solution was added to the above one. The final mixture was stirred, and methylmethacrylate (MMA) monomer was added (molar ratio VTMOS:MMA = 1:1). BPO (10 wt% of MMA) was used as the initiator of the polymerization reaction. The sol was transferred into cuvettes, and thermal curing was performed at 70 °C until the sample solidified.

In some hybrid Class I frameworks, the organic component is a polymer segment instead of a complex. The Eu<sup>3+</sup>-containing siloxane/poly(ethylene glycol) (PEG) composites prepared by Molina et al. [150] represent a good example of this particular architecture. These authors mixed TEOS and a dilute aqueous solution of HCl under ultrasound. PEG600 (where 600 is the average molecular weight of PEG) was then added to this silica sol under ultrasound. The Eu<sup>3+</sup> ions, introduced as europium perchlorate (Eu(ClO<sub>4</sub>)<sub>3</sub>), were added to the previous solution after dissolving the salt in CH<sub>3</sub>CH<sub>2</sub>OH. Gels were obtained by pH increasing with the addition of ammonium hydroxide (NH<sub>4</sub>OH). Xerogels were obtained by submitting the casted sols to heat treatment at 50 °C for 24 h.

Cordoncillo et al. [152] synthesized two nanocomposite matrices. One was obtained through hydrolysis/condensation of the diethoxymethylsilane (MDES) and methyltriethoxysilane (MTEOS) precursors in the presence of a europium(III) salt and zirconium tetrapropoxide (ZrP). MDES and MTEOS were first hydrolyzed with neutral H<sub>2</sub>O in CH<sub>3</sub>CH<sub>2</sub>OH. The molar ratio MDES:MTEOS:H<sub>2</sub>O:CH<sub>3</sub>CH<sub>2</sub>OH was 1:1:2:2. An ethanolic solution of ZrP and europium trichloride (EuCl<sub>3</sub>) in the presence of acetylacetone was then added to the siloxane-based sol. The final molar ratio Zr:Eu:Si was 1:0.01:9. The other sol–gel-derived matrix was prepared by first cohydrolyzing EuCl<sub>3</sub> with MDES and triethoxysilane (TREOS) (molar ratio MDES:TREOS:Eu:H<sub>2</sub>O:CH<sub>3</sub>CH<sub>2</sub>OH = 1.4:0.6:0.02:2:1). This siloxane-based sol was then added to a solution of ZrP in propanol (molar ratio Zr:Si = 2:10). In both systems, the mixing of the ZrP solution and the siloxane sol leads to the evolution of hydrogen gas, which was used as a reducing agent to decrease the valence of the europium cations from III to II. The resulting clear sols were magnetically stirred for 30 min in an argon atmosphere, and then poured into plastic cuvettes or deposited onto previously cleaned glass sheets. Transparent monolithic gels and coating a few microns thin were thus obtained.

## 2.2. Class II Hybrids

In this section, we will discuss in detail the synthesis process of several examples of the two types of Class II hybrid structures that have been mentioned for the complexation

of RE emitting centers, for examples (1) hybrid frameworks in which an organic molecule—which is part of the hybrid structure itself—is able to complex RE ions, and (2) cross-linked hybrid matrices in which RE salts or complexes are encapsulated.

### 2.2.1. Complexation via an Organic Molecule

The first stage of the synthesis of the RE-activated organic–inorganic hybrid materials proposed by Franville et al. [153] involves two major types of amidation coupling reactions.

1. Reaction of the acid chloride functions of a dicarboxylic acid chloride [2,6-pyridinedicarboxylic acid chloride (A1), 4-phenyl-2,6-pyridinedicarboxylic acid chloride (A2), 4-(phenylethynyl)-2,6-pyridine acid chloride (A3), or 2,6-bis-(3-carboxy-1-pyrazolyl)pyridine acid chloride (A4)] with the primary amine group of 3-aminopropyltriethoxysilane (APTES) (B1) (Schemes 1 and 2) [155].
2. Reaction of the acid chloride functions of the dicarboxylic acid chloride A1 with the primary or secondary amine group of an aminoalkylalkoxysilane [B1], [3-(methylamino)propyl]trimethoxysilane (B2), bis[3-(triethoxysilyl)propyl]amine (B3), or N-[3-(triethoxysilyl)propyl]aniline (B4)] (Schemes 1 and 3) [153, 154].

The reactions were carried out in diethyl ether and in the presence of pyridine. The resulting solutions were stirred under argon at room temperature (RT) to prevent hydrolysis of the alkoxy groups. The nonhydrolyzed hybrid precursors were recovered by filtration of the precipitated pyridinium chloride, followed by removal of the solvents, and were then dried on a vacuum line.

The sol–gel reaction was performed in an ethanolic or methanolic medium. The RE ions (Eu<sup>3+</sup> and gadolinium, Gd<sup>3+</sup>) were introduced as hexahydrate nitrate salts (Eu(NO<sub>3</sub>)<sub>3</sub> · 6H<sub>2</sub>O and Gd(NO<sub>3</sub>)<sub>3</sub> · 6H<sub>2</sub>O, respectively). A negligible amount of HCl, used as an acid catalyst, was incorporated. The H<sub>2</sub>O/Si and Ln<sup>3+</sup>/(nonhydrolyzed hybrid precursor) molar ratios were, respectively, 1:1 and 1:3. In a typical sol–gel preparation, the hybrid precursor was dissolved in absolute alcohol, and appropriate amounts of the RE salt were then added. Water was added only in the case of the synthetic procedure involving the use of B3, to ensure that the H<sub>2</sub>O/Si molar ratio was 1:1. The mixture was vigorously stirred for about 1 h before introducing HCl to foster the hydrolysis (pH = 2). The solution was stirred for 30 additional min, and the resulting sol was aged in covered Teflon beakers at RT until the onset of gelation, which occurred within four–seven days (reaction (1) [154]) or eight–ten days (reaction (2) [153]). The gels were obtained as monolithic bulks.

Dong et al. [156] developed two series of novel transparent and crack-free nanostructured hybrid Eu<sup>3+</sup>- and Tb<sup>3+</sup>-based complex films. The precursor material, classified as TAT, was synthesized from trimellitic anhydride and APTES (Scheme 4). In a typical procedure for the preparation of the hybrid films, a Eu<sup>3+</sup> solution of DMF and deionized H<sub>2</sub>O (acidified with HCl) was added to a TAT solution of DMF.

**Scheme 1.** Adapted with permission from [154], A.-C. Franville et al., *Chem. Mater.* 12, 428 (2000), Scheme 1. © 2000, American Chemical Society.

The mixture was stirred, immediately forming a homogeneous solution. After being kept in air at room temperature for two days, the solution was spin coated onto a quartz substrate to yield a wet gel film. After aging the wet gel at 60 °C during a week, a transparent film was obtained. The molar ratio of H<sub>2</sub>O:TAT was 1.5:1. It was concluded that the lanthanide ion concentration did not exert any effect on the transparency of the films. After the complete removal of the solvent, crack-free films were obtained.

Embert et al. [157] prepared a series of highly luminescent europium(III)-containing nanostructured hybrids. These materials were obtained through the hydrolysis and condensation via the sol–gel method of isolated Eu complex monomers. The authors described in detail in their paper the synthesis of five different phosphine oxides, five phosphine oxide–europium salt complexes, and one phosphine oxide–gadolinium salt complex (Schemes 5 and 6). All of the europium salts were dehydrated by a chemical reaction between the hydrated salt and ethyl orthoformate. The europium-based complexes 6–10 (Scheme 6) were obtained in the following way: a boiling ethanolic solution of europium salt (50 mmol/L) was treated with 3 equiv of

**Scheme 2.** Adapted with permission from [154], A.-C. Franville et al., *Chem. Mater.* 12, 428 (2000), Scheme 2, Ref. [49b]. © 2000, American Chemical Society.

phosphine oxide in boiling ethanol (solution 0.2 M). The formation of a white precipitate occurred immediately. The preparation of the representative compound X<sub>A</sub>10a (where X indicates the xerogel and A specifies that 10% of HCl was used as a gelification catalyst) will be described as follows as an example. A solution of complex 10a (1.50 g) (Scheme 7)

in tetrahydrofuran (THF) (1.45 mL) was placed in a Pyrex test tube. A 0.96 mL sample of a THF solution, 4.5 M in H<sub>2</sub>O and 0.1 M HCl (10 mol%), was added dropwise at RT with a syringe. After 3 min of stirring, the solution was placed in a thermostated water bath at 30 °C without stirring. After 20 h, a gel was formed. The wet white opaque gel was allowed to age for five days at 30 °C. After this period, it was powdered and washed with acetonitrile and ether. The gel was then repowdered and dried under vacuum for 13 h at 120 °C, yielding 1.05 g of a white powder.

The hybrid proposed by Li et al. [158] consists of a europium 1,10-phenanthroline complex covalently attached to a silica-based network denoted as Phen-Si (Scheme 7). This hybrid precursor was prepared according to the synthetic procedure indicated in Scheme 7, using 5-amino-1,10-phenanthroline (Phen-NH<sub>2</sub>) as the starting reagent. Phen-NH<sub>2</sub> was dissolved in 20 mL of chloroform (CHCl<sub>3</sub>) in a round bottom flask. This solution was stirred as 2 mL of 3-isocyanatopropyltriethoxysilane (ICPTES) was added

**Scheme 5.** Adapted with permission from [157], F. Embert et al., *Chem. Mater.* 13, 4542 (2001), Scheme 2. © 2001, American Chemical Society.

dropwise. CHCl<sub>3</sub> was evaporated at atmospheric pressure, and the resulting mixture was heated at 80 °C in a covered flask for 12 h. Cold hexane was then added to precipitate the white powder. The latter powder was collected by filtration, purified in methanol, and dried in vacuum.

The sol-gel-derived lanthanide-doped Hybrid I was prepared through the dissolution of Phen-Si in methanol and the subsequent addition of TEOS and H<sub>2</sub>O (pH = 2) under stirring. An appropriate amount of EuCl<sub>3</sub> mixed with 2 mL of DMF was added to the resulting solution. This mixture was agitated magnetically to achieve a single phase, and then transferred into a cuvette. Thermal curing was carried out at 60 °C, and continued until the sample became a solid. The molar ratio of Phen-Si:TEOS:H<sub>2</sub>O:Eu<sup>3+</sup> was 1:1:4:0.5.

**Scheme 7.** Adapted with permission from [158], H. R. Li et al., *Chem. Mater.* 14, 3651 (2002), Scheme 1. © 2002, American Chemical Society.

Liu et al. [160] developed a series of sol–gel-derived luminescent films composed of terbium-complex-bridged polysilsesquioxanes using the dip-coating process. In these materials, the new bridging organic component of the silica precursor used (DPS) includes the ligand that complexes the  $Tb^{3+}$  species. DPS was obtained by reacting 10 mmol of ICPTES with 5 mmol of 2,6-diaminopyridine previously dissolved in 10 mL of dry  $CHCl_3$ . The resulting solution was refluxed for 5 h. A volume of petroleum ether (60 mL) was then added to this solution, and the white precipitate formed was filtered off and washed with petroleum ether. In a typical procedure of a doped hybrid film, a solution of  $Tb^{3+}$  in DMF and deionized  $H_2O$  acidified to 0.2 M HCl were added to a solution of DPS in DMF (molar ratio DPS:  $Tb^{3+}$  = 1). The mixture was vigorously stirred at room temperature for 8 h, and then allowed to stand for four days. The solution was dip coated onto freshly cleaned quartz substrate at 10 cm/min to give a wet film. A transparent film was obtained after the wet gel was kept at 55 °C for one week.

With the goal of developing materials well adapted for photonics, Liu et al. [161] introduced a series of Class II  $Tb^{3+}$ - and  $Gd^{3+}$ -activated hybrid thin films where: (1) the leaching of the dopants is prevented, (2) the dopant concentration limit does not exist, and (3) the aggregation of the active species is avoided. The preparation of these xerogels involved the synthesis of a urea cross-linked sol–gel precursor, classified as PABI (N-(4-benzoic acid-yl),N'-(propyltriethoxysilyl)urea) (Scheme 8).

In a typical experiment, 5 mmol of p-aminobenzoic acid were dissolved in 15 mL of dry THF. To this solution, 7.5 mmol of ICPTES were added. The resulting solution was stirred for 8 h. The white precipitate produced was filtered off and washed with 50 mL of petroleum ether to remove the

**Scheme 8.** Adapted with permission from [161], F. Liu et al., *Thin Solid Films* 419, 178 (2002), Scheme 1. © 2002, Elsevier Science.

excess of ICPTES. The precipitate was finally dried on a vacuum line to get 1.8 g of PABI at 95% yield. The  $Tb^{3+}$ -doped samples were obtained through the addition of a DMF solution of terbium oxide,  $Tb_4O_7$ , and deionized  $H_2O$  (acidified to 0.2 M HCl) to a solution of PABI in DMF (Scheme 8). This mixture was vigorously stirred at RT for 12 h, and then allowed to stand for three days. The solution was then dip coated onto quartz substrates at 5 cm/min to give a wet gel film. A transparent, crack-free film 2.5  $\mu m$  thick was obtained after aging the gel at 50 °C for two weeks. Molar ratios  $Tb^{3+}$ /PABI of 1.5, 1:20, 1:50, 1:100, and 1:200 were employed, whereas the molar ratio  $H_2O$ /PABI was 1.5:1 in all of the cases. The  $Gd^{3+}$ -based compounds were prepared by adding under stirring a solution of 1 mmol of gadolinium chloride,  $GdCl_3$ , in  $CH_3CH_2OH$  to a THF solution containing 3 mmol of PABI. The white precipitate produced was filtered off, washed with  $CH_3CH_2OH$  and THF, and dried on a vacuum line.

## 2.2.2. Complexation via the Cross Linkages

The preparation of the *di-ureasils* and of the *di-urethanesils* proposed by our group [162–176, 181–183] can be summarized in two main steps (Schemes 9 and 10). Step 1 corresponds to the formation in THF of urea linkages between the terminal amine groups of double functional diamines (chemically  $\alpha,\omega$ -diaminepoly(oxyethylene-co-oxypropylene) or O,O'-bis(2-aminopropyl)polyethylene glycol) and the isocyanate group of an alkoxy silane precursor (ICPTES) (Scheme 9). The reaction of ICPTES with the terminal hydroxyl groups of PEG induces the formation of urethane bridges (Scheme 10). The two diamines used are commercially designated as Jeffamine ED-2001® (with  $a + c = 2.5$  and  $b = 40.5$ ) (Jeffamine ED-900® (with  $a + c = 2.5$  and  $b = 15.5$ ), and Jeffamine ED-600® (with  $a + c = 2.5$  and  $b = 8.5$ ), and have average molecular weights of 2000 and 600  $mol \cdot g^{-1}$ , respectively (Scheme 9). The PEG used has an average molecular weight of 300  $mol \cdot g^{-1}$  (Scheme 10). The grafting step leads to a urea and a urethane cross-linked organic–inorganic nonhydrolyzed hybrid precursor—so-called ureapropyltriethoxysilane (d-UPTES(Y), where Y = 2000, 900, and 600 are related to the Jeffamine molecular weight, and correspond to 40.5, 15.5, and 8.5 polymer repeat units, respectively) and urethanepropyltriethoxysilane [d-UtPTES(Y'), where Y' = 2000 and 300 represents the average molecular weight of the PEG, and corresponds to approximately 45 and 6 oxyethylene repeat units]. In the second stage of the synthesis, the addition of a mixture of  $H_2O$

**Scheme 9.** Molecular structure of the di-ureasils.

**Scheme 10.** Molecular structure of the di-urethanesils.

and  $\text{CH}_3\text{CH}_2\text{OH}$  to the d-UPTES and d-UtPTES solutions (Schemes 9 and 10) promotes the hydrolysis and condensation reactions transforming the precursor into the final xerogels. Europium, gadolinium, neodymium, and erbium trifluoromethanesulphonates ( $\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $\text{Gd}(\text{CF}_3\text{SO}_3)_3$ ,  $\text{Nd}(\text{CF}_3\text{SO}_3)_3$ , and  $\text{Er}(\text{CF}_3\text{SO}_3)_3$ , respectively) were incorporated in this step, by dissolving them in the  $\text{H}_2\text{O}$  and  $\text{CH}_3\text{CH}_2\text{OH}$  mixture (molar ratio  $\text{ICPTES}:\text{CH}_3\text{CH}_2\text{OH}:\text{H}_2\text{O} = 1:4:1.5$ ). The nanohybrids were identified by the designation d-U( $Y$ ) $_n\text{Ln}(\text{CF}_3\text{SO}_3)_3$ —di-ureasils—and d-Ut( $Y'$ ) $_n\text{Ln}(\text{CF}_3\text{SO}_3)_3$ —di-urethanesils, where U and Ut denote the urea and urethane groups, Ln stands for Eu, Gd, Nd, or Er, and  $Y' = 300$  and  $2000 \text{ g}\cdot\text{mol}^{-1}$ , corresponding to 45 and 6  $\text{OCH}_2\text{CH}_2$  repeat units) and  $n = [\text{O}]/[\text{Eu}]$ , so-called composition, represents the number of ether-type oxygen atoms of poly(oxyethylene) (POE) per  $\text{Ln}^{3+}$  cation.  $\text{U}(600)_n\text{Ln}(\text{CF}_3\text{SO}_3)_3$  and  $\text{U}(2000)_n\text{Ln}(\text{CF}_3\text{SO}_3)_3$  ( $\text{Ln} = \text{Eu}, \text{Nd}, \text{Er}$ ) were synthesized with compositions  $20 \leq n \leq 400$ , which correspond to a variation of the  $\text{Ln}^{3+}$  content versus the total mass between 4.96 and 0.58%. Two  $\text{U}(Y)_{80}\text{Gd}(\text{CF}_3\text{SO}_3)_3$ ,  $Y = 2000$  and  $600$ , di-ureasils were also prepared.

Ribeiro et al. [177] proposed a slightly different synthetic procedure to obtain the di-ureasils. These authors prepared the molecular precursor through the stoichiometric reaction of ICPTES and O,O'-bis(2-aminopropyl)polyethylene glycol with an average molecular weight of approximately  $800 \text{ g}\cdot\text{mol}^{-1}$ . THF was used as a solvent, and the reaction was carried out under reflux at  $80^\circ\text{C}$  for 6 h. The hybrid precursor was isolated after evaporation of the THF, and ammonium fluoride ( $\text{NH}_4\text{F}$ ) dissolved in  $\text{CH}_3\text{CH}_2\text{OH}$  was added, to work as catalyst for the hydrolysis reaction of the precursor (molar ratio  $\text{NH}_4\text{F}/\text{Si} = 0.005$ ). A volume of 0.2 mL of an aqueous solution of  $\text{Eu}(\text{ClO}_4)_3$  was then added by stirring, allowing the formation of a clear monolithic wet gel in 4 h.  $\text{CH}_3\text{CH}_2\text{OH}$  and  $\text{H}_2\text{O}$  were removed at  $50^\circ\text{C}$  to yield a rubbery and good optical quality transparent body. Samples with  $n = 4, 8, 15, 100$ , and  $355$  were prepared.

The first stage of the preparation of the  $\text{Tb}^{3+}$ -doped urea cross-linked xerogels proposed by Bekiari et al. [185] involved mixing stoichiometric amounts of ICPTES and O,O'-bis(2-aminopropyl)polyethylene glycol with an average molecular weight of approximately  $800 \text{ g}\cdot\text{mol}^{-1}$ . The solution was stirred in refluxing THF for 6 h. The THF was evaporated to yield the hybrid precursor. The second stage

of the synthesis of the polyether-based xerogels implied the addition of  $\text{H}_2\text{O}$  and a catalyst ( $\text{NH}_4\text{F}$ ) (molar ratio  $\text{H}_2\text{O}:\text{NH}_4\text{F}:\text{Si} = 5:0.01:1$ ). The condensation of the silicon atoms led to the formation of a rubbery material within 8 h. The incorporation of the  $\text{Tb}^{3+}$  ions was achieved through the introduction of the latter material in a 20 mM  $\text{CH}_3\text{CH}_2\text{OH}$  solution of terbium nitrate,  $\text{Tb}(\text{NO}_3)_3$ . This procedure lasted a week. The terbium-enriched sample was then immersed in a  $\text{CH}_3\text{CH}_2\text{OH}$  solution of 0.1 M bpy for two days.

In another work, Bekiari et al. [186] synthesized a series of POE- and poly(oxypropylene) (POP)-based hybrid materials, and doped them with europium, terbium, neodymium, and cerium nitrates. The precursors were obtained by reacting the O,O'-bis(2-aminopropyl)polypropylene glycol (molecular weights, MW, equal to 4000, 2000, and 230) and O,O'-bis(2-aminopropyl)polyethylene glycol (MW = 1900, 800, and 500) with ICPTES in THF under reflux ( $64^\circ\text{C}$ ) for 6 h. Urea-connecting groups were thus formed. After evaporation of the THF under vacuum, a viscous hybrid precursor resulted. The chemical structure of the POE- and POP-containing precursors is illustrated in Scheme 9. The sol-gel stage involved dissolution of 4.5 g of the hybrid precursor in 15 mL of  $\text{CH}_3\text{OH}$ . The solution was stirred for 5 mn, and 0.5 mL HCl was then added. An additional stirring period of 30 mn followed. In the case of the weak-base catalyzed hydrolysis, 0.04 M  $\text{NH}_4\text{F}$  was used instead of HCl. After stirring, the sols were poured into uncovered PMMA cuvettes, and were allowed to dry in air for one week. The dopant salts were introduced by previous solubilization in  $\text{CH}_3\text{OH}$ .

Moleski et al. [187] synthesized a series of sol-gel-derived hybrid matrices incorporating organolanthanide complexes. The hybrid frameworks were obtained by mixing O,O'-bis(2-aminopropyl)polypropylene glycol (MW = 4000) in ICPTES (molar ratio 1:2) in THF under reflux ( $64^\circ\text{C}$ ) for 6 h. The reaction that took place involved the isocyanate groups of the organoalkoxysilane and the amino groups of the diamine producing urea-connecting groups between the polymer units and the inorganic part. After evaporation of the THF under vacuum, a viscous precursor, which was stable for several months, was obtained (Scheme 9). The sol-gel step was performed using the acetic acid solvolysis method that is carried out in the absence of  $\text{H}_2\text{O}$ . 0.5 g of the nonhydrolyzed hybrid precursor was first dissolved in 2 mL of  $\text{CH}_3\text{CH}_2\text{OH}$ . Acetic acid (0.4 mL) was then added to this solution under stirring. After 1/2 h, the latter solution became a gel. In the case of the synthesis of the doped materials, 20 mM of europium nitrate, 60 mM of TTA, and 20 mM of bpy were added in this order to the precursor ethanolic solution. The films were obtained by spin coating the sol on glass slides at 4000 rpm.

The  $\text{Eu}^{3+}$ -based hybrids proposed by Li et al. [188] were prepared by first synthesizing pure, crystalline  $[\text{Eu}(\text{phen})_2]\text{Cl}_3$ . An appropriate amount of this complex was dissolved in DMF and added to a mixed solution of  $\text{H}_2\text{O}$ ,  $\text{CH}_3\text{CH}_2\text{OH}$ , TEOS, and 3-(trimethoxysilyl)propyl methacrylate, TMSPM (molar ratio  $[\text{Eu}(\text{phen})_2]\text{Cl}_3:\text{H}_2\text{O}:\text{CH}_3\text{CH}_2\text{OH}:\text{TMSPM} = 12:12:3:1$ ). Dilute HCl at pH = 1 was then added to this mixture. The solution was stirred for two days, and then coated on the substrate by means of the

spin-coating process. The substrate was placed on a spin-coating machine and spun at 1000–3000 rev/min. The coated film was treated at different temperatures. The resulting dried xerogel was kept in a Petri dish at room temperature.

The synthesis of hybrid composite phosphors doped with terbium carboxyl complexes *in-situ* by the sol–gel route was reported by Li et al. [189]. Carboxyl was first dissolved in a mixture of absolute  $\text{CH}_3\text{CH}_2\text{OH}$  and DMF under stirring. TEOS, TMPSPM, and a certain amount of  $\text{Tb}(\text{NO}_3)_3$ . Carboxyl acids [benzoic acid (BA), *o*-aminobenzoic acid (*o*-ABA), *m*-aminobenzoic acid (*m*-ABA), and *p*-aminobenzoic acid (*p*-ABA)] (molar ratio 1:3) were added to the above mixture. HCl-acidified  $\text{H}_2\text{O}$  (pH = 2) was also added to the resulting solution to foster the hydrolysis and condensation reactions of the TEOS and TMPSPM precursors. The molar ratio TEOS:TMPSPM: $\text{CH}_3\text{CH}_2\text{OH}$ : $\text{H}_2\text{O}$  was 3:1:12:12. The solution was stirred at room temperature for several hours, and the resulting transparent sols were subsequently cast into plastic cups and cured at 50 °C for a month to accomplish their gelation. Additional heat treatments were carried out at various temperatures (100–200 °C) in air.

### 3. LOCAL STRUCTURE

The local structure of RE-based organic–inorganic hybrids has been intensively analyzed using different techniques, such as X-ray diffraction (XRD), SAXS, extended X-ray absorption fine structure (EXAFS),  $^{29}\text{Si}$  and  $^{13}\text{C}$  magic-angle spinning nuclear magnetic resonance ( $^{29}\text{Si}$  and  $^{13}\text{C}$  MAS NMR), and Fourier transform infrared (FTIR) measurements.

To illustrate the work performed for the characterization of the local structure of lanthanide-based Class I hybrids, we will refer to SAXS results of the  $\text{Eu}^{3+}$ -containing siloxane/PEG composites prepared by Molina et al. [150]. These data show that the nanocomposites with a low  $\text{Eu}^{3+}$  content consist of a mixture of siloxane aggregates with a fractal structure embedded in a nearly homogeneous PEG matrix. Increasing the amount of incorporated  $\text{Eu}^{3+}$  leads to a decrease in the interparticle repulsion interactions and the subsequent formation of larger aggregates. An additional aggregation process promoting the formation of very large secondary aggregates is observed for highly concentrated hybrids. The structural changes deduced from SAXS are in accordance with the observed increase in mechanical strength and glass transition temperature for increasing  $\text{Eu}^{3+}$  content [150].

In the case of the Class II materials reviewed here in which an organic molecule that complexes RE ions is anchored in the hybrid framework [153–159], a very small fraction of work was devoted to the detailed characterization of their local structure. In the next paragraphs, we will briefly refer to some structural results concerning this class of hybrids.

Apart from the typical bands due to the organic component, the FTIR spectra of the RE-activated organic–inorganic hybrid precursors prepared by Franville et al. [153–155] exhibit the characteristic absorption bands of the trialkoxysilyl groups, that is, those arising from the stretching vibration of the Si–C, Si–OEt (or Si–OMe)

groups. The sharp band situated at 1680–1640  $\text{cm}^{-1}$  confirmed the formation of the amide groups. The absence of the bands due to carboxylic acid chloride and carboxylic functions in the 1760–1720  $\text{cm}^{-1}$  range was considered as clear evidence of the completion of the reaction. The FTIR spectra of the corresponding hybrid xerogels were characterized by a band located between 1193 and 1188  $\text{cm}^{-1}$  due to the Si–C stretching vibration, a proof that the Si–C bonds remained intact during the hydrolysis/condensation reactions. The formation of the siloxane bonds was confirmed by the occurrence of a broad band around 1120–1000  $\text{cm}^{-1}$ . The presence of residual silanol groups was indicated by the band found at about 900  $\text{cm}^{-1}$ , demonstrating that the condensation process had not been complete. The complexation of the metal ions by the oxygen atoms of the carbonyl groups was accompanied by a shift of the C=O stretching band to lower wavenumbers. Some of these hybrids [155] were examined by means of  $^{13}\text{C}$  and  $^{29}\text{Si}$  CPMAS NMR spectroscopies. The  $^{13}\text{C}$  CPMAS NMR spectra displayed peaks located near 43, 23, and 11 ppm, which were associated with the  $\text{CH}_2$  aliphatic chains. The signal due to the C=O groups was clearly evidenced at 164 ppm, whereas the remaining signals in the spectra were ascribed to the aromatic carbons. The absence of new signals in the  $^{13}\text{C}$  CPMAS NMR spectra with respect to those of the hybrid precursor was considered as a solid piece of evidence that proves that the organic component was not modified under the conditions used for the sol–gel process. The broad signal found between –80 and –40 ppm in the  $^{29}\text{Si}$  CPMAS NMR spectra was attributed to trifunctional– $\text{CSiO}_3$  groups [155]. No indications of the presence of tetrafunctional groups were found, proving that the organic moieties remained covalently attached to the siloxane network via Si–C bonds. The silicon sites are labeled according to the conventional  $T_n$  notation, where  $n$  ( $n = 1, 2, 3$ ) is the number of Si-bridging oxygen atoms. Peaks due to  $T_1$ ,  $T_2$ , and  $T_3$  sites could be distinguished. The relative proportions of the different silicon species and the condensation rates were calculated. These data supported that the main species were the  $T_2$  ones, and that the condensation rates ranged from 75 to 80%.

Infrared spectroscopy allowed Dong et al. [156] to conclude that the bands occurring at 1774, 1718, 1370, and 730  $\text{cm}^{-1}$  in the spectrum of the TAT hybrid precursor (Scheme 4) could be assigned to the symmetric carbonyl stretching, asymmetric carbonyl stretching, C–N stretching, and ring carbonyl deformation vibrations, respectively. It was noted that the spectrum of the lanthanide-doped xerogel was different, as the characteristic carboxylic band around 2700–2300  $\text{cm}^{-1}$  disappeared, whereas several new features appeared at 1652 and 1385  $\text{cm}^{-1}$ , assigned to the asymmetric and symmetric stretching vibrations of the  $\text{COO}^-$  group, respectively. According to the authors, the latter findings indicate the formation of coordinated bonds between the carboxylic groups and the lanthanide ion. The proposed local structure is depicted in Scheme 4.

The phosphine oxide-based complexes proposed by Embert et al. [157] were characterized by  $^{13}\text{C}$  and  $^{29}\text{Si}$  and  $^{31}\text{P}$  CPMAS NMR spectroscopy. The resulting data allowed these authors to conclude the following.

1. While about 81% of the P=O groups remained complexed in the hybrids originating from ligands 3 and 4,

in the case of the xerogels obtained from the more flexible ligand 5, approximately 91% of the P=O moieties were found to be complexed.

2. The absence of signals in the  $^{29}\text{Si}$  CPMAS NMR spectra between  $-90$  and  $-110$  ppm was interpreted as an indication that the Si–C bonds were not cleaved during the sol–gel process.
3. No evidences of the presence of remaining ethoxy or isopropoxy groups were detected in the  $^{13}\text{C}$  CPMAS NMR spectra, suggesting the complete hydrolysis of the compounds.

The Raman spectra of the materials incorporating europium nitrate provided conclusive evidence that the contact ion pairs  $\text{Eu}^{3+}\text{NO}_3^-$  observed in the salt, which gave rise to the band situated at  $1037.5\text{ cm}^{-1}$ , persisted in the xerogels. The absence of the  $1047.4\text{ cm}^{-1}$  feature was correlated with the absence of hydrogen bonding between the nitrate ions and either water molecules or OH vibrators. The presence in the infrared spectra of the sol–gel-derived compounds of the  $741$  and  $815\text{ cm}^{-1}$  events were considered as additional proofs of the formation of contact ion pairs and the absence of hydrogen bonding around the anions.

Li et al. [158] used infrared spectroscopy to monitor the grafting reaction that yielded the Phen–Si compound. The growth of the bands located at  $1653$  and  $1645\text{ cm}^{-1}$  was attributed to the formation of the  $-\text{CONH}-$  amide group. Other spectral changes observed in the spectrum of the Hybrid I material were correlated with the hydrolysis/condensation of TEOS and Phen–Si, and with the formation of a complex between the latter compound and the  $\text{Eu}^{3+}$  ions. The presence of the organic groups in Hybrid I was further confirmed by means of  $^{13}\text{C}$  CPMAS NMR spectroscopy [158]. Peaks detected at  $43$ ,  $26$ , and  $13$  ppm were ascribed to the  $(\text{CH}_2)$ -based chains, whereas the signals seen between  $110$  and  $150$  ppm were ascribed to aromatic carbons, and the characteristic peak of the carbonyl group was found at  $161$  ppm [158]. The local structure of Hybrid I was also investigated by photoluminescence spectroscopy. The details of such a study will be reviewed in Section 4.1.

The local structure of RE-doped di-ureasils and di-urethanesils was described using XRD [162, 163, 165], SAXS [178, 179, 181–183], EXAFS [166, 180, 184], and FTIR [164, 165, 171, 181] results. The SAXS technique is particularly adequate for studying the structure of hybrid materials because of their disordered nature and the contrast of electronic densities between the organic and inorganic phases [178, 179, 181–183, 197]. The XRD patterns of the di-ureasils and di-urethanesils present a broad band, Gaussian in shape, centered around  $20$ – $22^\circ$ , and associated with the amorphous siliceous domains [165]. The polymer chains are, essentially, in a disordered regime for all of the hybrids, except in the RE-based high-molecular-weight di-ureasils and di-urethanesils (i.e.,  $\text{U}(2000)$  and  $\text{Ut}(2000)$ , respectively). In the latter case, the XRD diffractograms revealed the presence of well-defined Bragg peaks associated with the diffraction of crystalline oxyethylene units,  $\text{OCH}_2\text{CH}_2$  [163, 165]. In low-salt concentration hybrids (e.g.,  $80 \leq n \leq 400$ ), the two main peaks characteristic of the crystalline polyether chains are clearly observed at  $19.15$ – $19.3^\circ$  and  $23.45$ – $23.50^\circ$  [165]. This indicates that the incorporation of the europium

salt does not destroy the crystalline order of the polyether chains. Moreover, it strongly suggests that the  $\text{Eu}^{3+}$  ions are not coordinated to the ether oxygens of the short polyether chains present in the materials, contradicting what has been observed for analogous POE-based electrolytes. This is consistent with the thermal analysis, particularly with the differential scanning calorimetry (DSC) results discussed elsewhere [165], and is explicitly confirmed by SAXS, FTIR, and PL results [181]. For the high-molecular-weight di-ureasils and di-urethanesils, the oxyethylene moieties merely play the role of plastifying agents.

The SAXS data of  $\text{Eu}^{3+}$ -doped di-ureasils and di-urethanesils were modeled with an isotropic structure model consisting of a dense set of spherical colloidal particles of approximately the same size with short-range spatial correlation—the siloxane domains—embedded in a homogeneous matrix—the polymer chains [181–183]. A similar multiple-scale structure model based on identical spherical particles embedded in a homogeneous matrix has been successfully applied by Beaucage et al. to experimental SAXS data of similar siloxane–polymer nanocomposites [197]. The results indicate the formation of a two-level hierarchical local structure in which the primary level is constituted by strongly spatially correlated siloxane nanodomains of radius between  $3$  and  $10\text{ \AA}$ , and errors within  $5\%$ . Large clusters of these regions, with a radius between  $80$  and  $100\text{ \AA}$  (errors within  $10\%$ ), form the second level [181].

The nature of the  $\text{Eu}^{3+}$ -first coordination shell varies with the salt concentration and with the polymer molecular weight. In di-ureasils containing long organic segments,  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  ( $40 \leq n \leq 400$ ), the  $\text{Eu}^{3+}$  ions interact mainly with the carbonyl-type oxygens of the urea cross links located at the organic–inorganic interface. On the contrary, in  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  ( $n \geq 60$ ), as the  $\text{Eu}^{3+}$  ions are unable to disrupt the strong and ordered hydrogen-bonded urea–urea structures [198], the preferential coordination sites are the ether-type oxygens of the polymer chains. However, for high-salt concentration hybrids,  $n \leq 40$ , besides the coordination to the polymer ether oxygens, a distinct cation local site environment involving the interaction with the urea carbonyl oxygens atoms at the siloxane–POE interface is detected. At  $n = 10$ , the hydrogen-bonded urea–urea structures of the  $\text{U}(600)$  network are probably destroyed by the larger amount of salt present, and therefore, the carbonyl oxygens of the urea cross links are the only active coordinating groups. We must stress that, in these hybrids, only at compositions lower than approximately  $4$ , there is one urea group per each incorporated  $\text{Eu}^{3+}$  ion. This ability to tune the  $\text{Eu}^{3+}$  coordination between the carbonyl oxygens of the urea groups and the ether oxygen atoms of the poly(oxyethylene) chains—controlling both the salt concentration and the polymer molecular weight—illustrates one of the most interesting features of these materials, and opens new prospects into their potential fields of application.

The first  $\text{Eu}^{3+}$  coordination shell was further characterized by fitting filtered EXAFS spectra, using phase and amplitude functions obtained from the standard  $\text{Eu}_2\text{O}_3$  spectrum [166]. Good fits were obtained for all samples. The EXAFS results suggested a decrease in the coordination number with the increase in the relative  $\text{Eu}^{3+}$  concentration, from  $13 \pm 1$  ( $n = 200$ ) to  $10 \pm 1$  ( $n = 40$ ). The average Eu–O

distance remains constant, 2.48 Å, in the salt concentration range investigated, and the decrease of the Debye–Waller disorder factor in that range indicates the tendency of the dispersion of the Eu–O distances to decrease [166].

The FTIR spectra of the Eu<sup>3+</sup>-doped di-ureasils with  $n \geq 5$  were examined in detail to determine the nature of the species involved in the coordination of the lanthanide ions [165]. Several features observed in the spectrum of the U(2000)<sub>5</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub> compound clearly demonstrated the coordination between the ether oxygens of the polyether segments of the hybrid matrix and the lanthanide ions, and substantiated the formation of a crystalline complex. One of the most significant spectral evidences of this complexation effect was the absence of the strong band attributed to the CO stretching vibration of noncoordinated polyether chains from the spectrum of U(2000)<sub>5</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>. This band, found at 1110 cm<sup>-1</sup> in the spectrum of U(2000)<sub>20</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>, was replaced by a strong band at 1056 cm<sup>-1</sup> and a shoulder at 1069 cm<sup>-1</sup>. The downshift observed was associated with a change in the environment of the ether oxygens, probably produced by the coordination to metal ions. No evidences of changes in the environment of the ether oxygens, which would result from the dissolution of Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>, were, however, found in the spectra of a series of doped di-ureasils with  $n \geq 20$  [164, 165]. These findings were interpreted as clear proof that all of the ether oxygens were coordinated to the Eu<sup>3+</sup> ions at  $n = 5$ . The spectra of the di-ureasils also exhibited dramatic differences in the 1000–800 cm<sup>-1</sup> spectral region, which includes absorption bands produced by a mixture of skeletal stretching and CH<sub>2</sub> rocking vibrational modes, and is known to be extremely sensitive to coordination effects arising from interactions between ether oxygens of the polyether chains and metal cations. While the dominating features in the spectrum of U(2000)<sub>20</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub> were a medium intensity band located at 954 cm<sup>-1</sup>, due to the coupled vibration of CC stretching and CH<sub>2</sub> rocking modes, and a weak band found at 846 cm<sup>-1</sup>, attributed to the coupled vibration of CO stretching and CH<sub>2</sub> rocking modes, in the spectrum of U(2000)<sub>5</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>, the strongest band detected was a weak new absorption situated at 937 cm<sup>-1</sup>. Another new band, also weak, was observed at 892 cm<sup>-1</sup> in the latter spectrum. This pair of bands was associated with the presence of a crystalline complex. Another relevant result was retrieved from the analysis of the spectral region due to the symmetric deformation of the CF<sub>3</sub> group [ $\delta_s(\text{CF}_3)$ ], which allows us to evaluate the extent of ionic association in systems doped with triflate salts. In the spectrum of U(2000)<sub>20</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>, a very weak band at 755 cm<sup>-1</sup> and an even weaker shoulder at about 763 cm<sup>-1</sup> were observed in this range of wavenumbers, whereas that of U(2000)<sub>5</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub> displayed three bands: (1) the shoulder at 763 cm<sup>-1</sup> grew in intensity, and became the dominating feature of this spectral region; (2) the intensity of the absorption at 755 cm<sup>-1</sup> was drastically reduced, and the band was transformed into an almost insignificant shoulder located at 757 cm<sup>-1</sup>; (3) an additional shoulder, stronger than the latter one, appeared at 774 cm<sup>-1</sup>. The band at 764 cm<sup>-1</sup> and the shoulder at 774 cm<sup>-1</sup> were assigned to the presence of the crystalline complex. The ordered local structure of U(2000)<sub>5</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub> was further confirmed

by the breadth of its characteristic absorption bands which were markedly narrower than those of the spectrum of U(2000)<sub>5</sub>Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>, a fact that confirmed the crystalline character of the di-ureasil with  $n = 5$ .

The local structure of the di-ureasils doped with Eu(ClO<sub>4</sub>)<sub>3</sub> reported by Ribeiro et al. has been described in detail combining SAXS, EXAFS, thermomechanical analysis (TMA), and PL [177, 180]. The experimental SAXS curves show a single peak attributed to an interference effect in the X-ray scattering amplitude produced by the existence of a spatial correlation between siloxane clusters to which polymer chain ends are grafted [180]. The average radius of the siloxane nanodomains and the average distance between them, 4–5 and 25–27 Å, respectively, are similar to the values found for the di-ureasils doped with Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>. The slight decrease in the siloxane intercluster spacing for increasing Eu<sup>3+</sup> content is interpreted as a contraction of the polymer structure due to the increase in the number of O–Eu<sup>3+</sup>–O cross linkages between polymeric chains induced by the Eu<sup>3+</sup> coordination to the PEO ether-type oxygens. This interpretation was confirmed by TMA measurements [180] and FTIR results [171]. The glass transition temperature of the samples increases for increasing europium doping level, in accordance with the already mentioned interaction between the Eu<sup>3+</sup> ions and the polymer ether-type oxygens [180]. The first coordination shell of Eu<sup>3+</sup> was further characterized by fitting filtered EXAFS spectra (recorded at the XAFS beamline at LNLS, Campinas, S.P., Brazil) using phase and amplitude functions obtained from a standard solution (Eu<sup>3+</sup> 0.2 M aqueous solution) [180]. The results indicate a decrease in the coordination number at increasing Eu<sup>3+</sup> concentration, from 10 ± 1 ( $n = 80$ ) to 8 ± 1 ( $n = 8$ ). Furthermore, in this salt concentration range, the Eu–O average distance and the Debye–Waller disorder factor remain approximately constant, 2.41–2.42 Å and 0.090–0.093, respectively. All of these results are in accordance with the those obtained for similar hybrids incorporating Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub> [166].

The local environment of the Eu<sup>3+</sup> ions in the luminescent sol–gel-derived materials proposed by Ribeiro et al. [177] was studied in depth by FTIR and PL spectroscopies. The combination of the information retrieved from the analysis of characteristic bands of the FTIR spectra—the perchlorate and the Amide I/Amide II features—with that obtained from the PL data demonstrated that, at compositions  $n = 232$  and 62, the anions are free, whereas the Eu<sup>3+</sup> ions were complexed by the heteroatoms of the polyether chains. At higher salt concentration, the cations are coordinated, not only to the perchlorate ions, but also to the ether oxygen atoms of the organic segments and to the carbonyl oxygen atoms of the urea linkages. The dual behavior of the hybrid matrix with respect to cation coordination was attributed to the presence in this nanohybrid of strong hydrogen-bonded urea–urea structures which, at low salt content, cannot be disrupted, thus inhibiting the formation of Eu<sup>3+</sup>⋯O=C(urea) contacts, and promoting the interaction between the lanthanide ions and the (OCH<sub>2</sub>CH<sub>2</sub>) moieties. This Eu<sup>3+</sup> local coordination is entirely in accordance with the results aforementioned for the same matrix, U(600), incorporated Eu(CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub> in a concentration  $n \geq 60$ . These studies enabled the authors to

conclude that the activation of the coordinating sites of the hybrid di-ureasil-type framework can be tuned by varying either the guest salt concentration at constant chain length or the length of the organic segments at constant salt concentration, an extremely relevant property that opens challenging new prospects into the fields of application of this class of hybrids.

Liu et al. [160] recorded the FTIR spectra of the  $\text{Tb}^{3+}$ -containing and nondoped DPS-derived films. The presence of the bands associated with the stretching modes of the Si–C and Si–OEt groups, located at 1194 and 1080  $\text{cm}^{-1}$ , respectively, in the spectrum of DPS led these authors to the conclusion that the Si–C bonds and the ethoxy (OEt) groups had not been affected by the grafting reaction performed between ICPTES and the diamine used. The features observed at 1682, 1652, and 1562  $\text{cm}^{-1}$ , produced by the urea cross links, were interpreted as a confirmation of the success of the grafting process. In the spectra of the  $\text{Tb}^{3+}$ -based hybrids, Liu et al. [160] observed a significant downshift (20  $\text{cm}^{-1}$ ) of the carbonyl stretching band upon doping.

The bands found at 1652, 1565, and 1592  $\text{cm}^{-1}$  in the FTIR spectrum of the nondoped PABI hybrid introduced by Liu et al. [161] allowed these authors to conclude that ICPTES had been successfully grafted to p-aminobenzoic acid. The feature observed at 1689  $\text{cm}^{-1}$  was assigned to the stretching mode ( $\nu\text{C}=\text{O}$ ) of the carboxylic acid function. The events discerned around 1193 and 1080  $\text{cm}^{-1}$  were attributed to the stretching vibration of the Si–C and Si– $\text{OCH}_2\text{CH}_3$  moieties, respectively. In the spectra of the corresponding  $\text{Tb}^{3+}$ -doped materials, it was observed that, while the  $\nu\text{C}=\text{O}$  mode of the carboxylic function had disappeared, new bands associated with the asymmetric and symmetric stretching modes of the  $\text{COO}^-$  species emerged at 1556 and 1417  $\text{cm}^{-1}$ , respectively. These findings were interpreted as proof of the interaction between the  $\text{Tb}^{3+}$  ion and the carboxylic group.

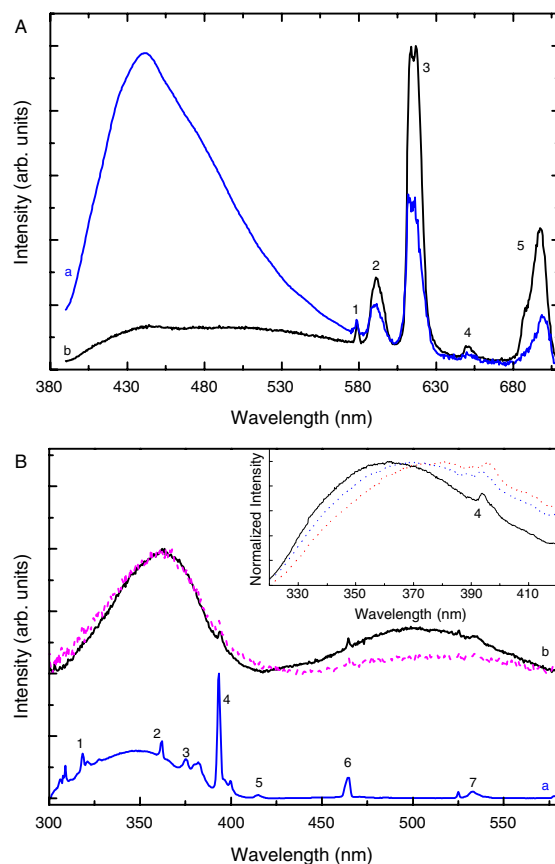

## 4. PHOTOLUMINESCENCE SPECTROSCOPY

### 4.1. Emission and Time-Resolved Spectra

Figure 1A shows the RT emission spectra obtained for the di-ureasils  $\text{U}(\text{Y})_{40}\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $\text{Y} = 600$  and 2000. Both spectra are composed of the  $\text{Eu}^{3+}$  characteristic intra- $4f^6$  transitions,  $^5\text{D}_0 \rightarrow ^7\text{F}_{0-4}$ , overlaying a large broad between 350 and 580 nm [162–164, 166, 168, 170, 171, 173, 174, 176, 177, 181]. This large broad band is red shifted toward the greenish–blue spectral region relative to that observed in the undoped di-ureasils, Section 9, and was assigned to the convolution of donor–acceptor pair recombinations occurring in the siliceous nanodomains and in the NH groups of the urea linkages [191, 193–196]. The PL spectra of the remaining di-ureasils resemble those presented in Figure 1A.

Ribeiro et al. also reported a similar result for a set of short polymer chain di-ureasil hybrids modified by  $\text{Eu}(\text{ClO}_4)_3$ , as shown in Figure 2A [177].

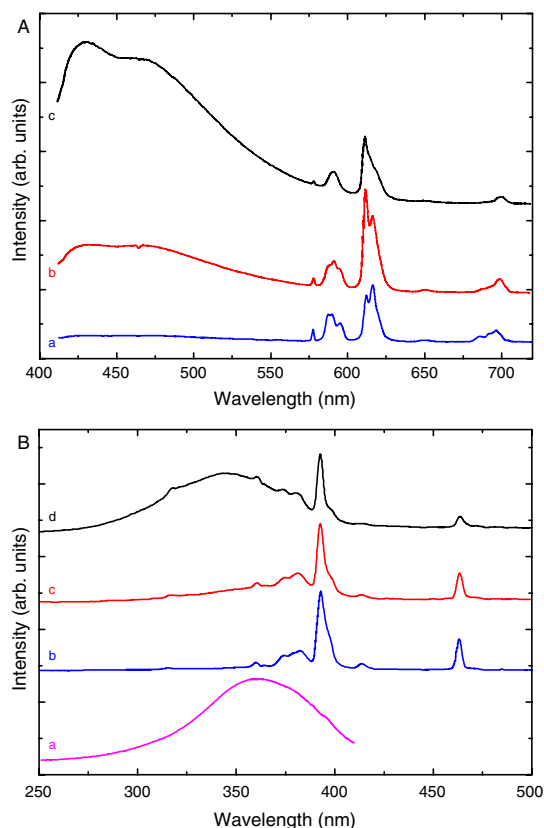

Bekiarı et al. recorded the luminescence spectra of a U(600) type di-ureasil modified by  $\text{Tb}^{3+}$  ions in an ethanolic solution (see curve 1 in Fig. 3), where a large broad band in

**Figure 1.** (A) RT PL spectra excited at 375 nm for  $\text{U}(\text{Y})_{40}\text{Eu}(\text{CF}_3\text{SO}_3)_3$ , (a)  $\text{Y} = 600$  and (b)  $\text{Y} = 2000$ . (1), (2), (3), (4), and (5) denote the intra- $4f^6$  transitions:  $^5\text{D}_0 \rightarrow ^7\text{F}_{0-4}$ , respectively. (B) RT PLE spectra for the  $\text{U}(\text{Y})_{80}\text{Eu}(\text{CF}_3\text{SO}_3)_3$ , (a)  $\text{Y} = 600$  and (b)  $\text{Y} = 2000$ , monitored around 614 nm. The dashed spectra correspond to the RT PLE spectrum of the  $\text{U}(2000)_{80}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasil detected around 700 nm. (1), (2), (3), (4), (5), (6), and (7) denote the intra- $4f^6$  transitions:  $^7\text{F}_0 \rightarrow ^5\text{H}_4$ ,  $^5\text{D}_4$ ,  $^5\text{G}_1$ ,  $^5\text{L}_6$ ,  $^5\text{D}_3$ ,  $^5\text{D}_2$ , and  $^5\text{D}_1$ , respectively. The inset shows the 14 K PLE spectra of the  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ , solid line  $n = 40$ , dashed line  $n = 60$ , and dotted line  $n = 80$ .

the same spectral region (350–380 nm) is observed together with a series of intra- $4f^8$   $\text{Tb}^{3+}$  lines assigned to the transitions  $^5\text{D}_4 \rightarrow ^7\text{F}_{6-3}$  [185].

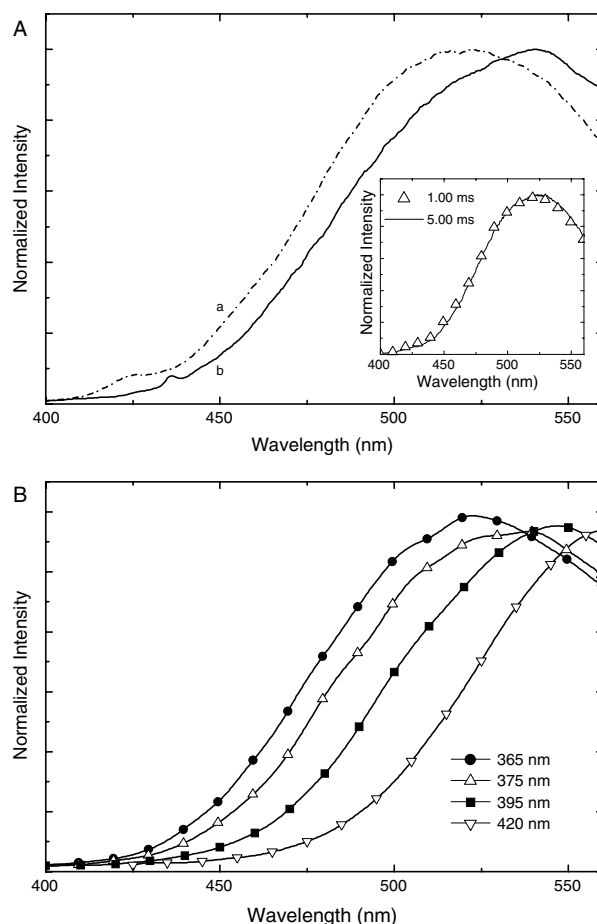

Time-resolved measurements performed on the di-ureasils modified by  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$  unequivocally demonstrated that the large broad band results from the overlap of two distinct emissions whose recombination mechanisms occur in unlike time scales, as previously reported for the undoped hosts [194, 195]. Figure 4A presents the time-resolved spectra for  $\text{U}(2000)_{80}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  and  $\text{U}(600)_{200}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  nanohybrids detected at a start delay (SD) time of 0.08 ms, clearly establishing the presence of two emission bands. Increasing the SD, only one band remains (inset of Fig. 4A). The respective lifetimes, measured at 14 K, although smaller than the ones measured for the undoped hosts [194, 195], are of the same magnitude, being around 100 and 1 ms (errors within 5%) for the lower and higher energy bands, respectively [181]. Besides the different recombination time scales, these two emission components also behave differently when the excitation wavelength

**Figure 2.** (A) RT PL spectra obtained under 394 nm for the  $U(600)_n \cdot Eu(CF_3SO_3)_3$ , (a)  $n = 4$ , (b)  $n = 15$ , and (c)  $n = 100$ . (B) RT PLE spectra for the  $U(600)_n Eu(ClO_4)_3$ . (a)  $n = 100$ , monitored around 430 nm, (b)  $n = 4$ , (c)  $n = 15$ , and (d)  $n = 100$ , monitored around 611 nm. **Figure 4.** 14 K time-resolved emission spectra obtained at delay times of (A) 0.08 ms for (a)  $U(600)_{200}Eu(CF_3SO_3)_3$  and (b)  $U(2000)_{80}Eu(CF_3SO_3)_3$ , excited at 365 and 375 nm, respectively; (B) 0.08 ms for  $U(2000)_{80}Eu(CF_3SO_3)_3$  for excitation wavelengths between 365 and 420 nm. The inset of (A) shows the time-resolved spectra for the  $U(600)_{200}Eu(CF_3SO_3)_3$  di-ureasil, excited at 365 nm, obtained at delay times of 1.00 and 5.00 ms.

is varied (Fig. 4B). Similarly to what was observed for the undoped di-ureasils, Section 9, only the lower energy band shifts to the red as the excitation wavelength decreases, while the peak energy of the other band remains approximately constant [191, 193–196].

To summarize the analyses of the steady-state emission of the  $Eu^{3+}$ -based di-ureasils (Figs. 1A and 2A), it may be said that the relative energy of the host band with respect to the intra- $4f^6$  lines strongly depends on the amount of  $Eu^{3+}$  incorporated. In all of the hybrids, the broad band intensity is greater for the lower concentrated hybrid, while as the concentration increases, the reverse situation occurs both for the di-ureasils incorporating  $Eu(CF_3SO_3)_3$  [162–164, 166, 168, 170, 173, 181] and  $Eu(ClO_4)_3$  [171, 177]. In the particular case of the  $U(600)_nEu(CF_3SO_3)_3$  di-ureasils, the hybrids' host emission overlaps with greater intensity the cation lines for the di-ureasils with  $n = 60$  and  $n = 200$  since, for these hybrids, the broad band is red-shifted with respect to the remaining samples [170].

The variation of the excitation wavelength is another factor that changes the relative intensity between the hybrid host emission band and the  $\text{Eu}^{3+}$  lines, as Figure 5 exemplifies for the  $\text{U}(600)_{200}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasil. It is also possible to observe that increasing the excitation wavelength results in a red shift of the hybrids' host emission. The ion lines dependence on the excitation wavelength will be discussed in the next paragraphs.

In an attempt to further characterize the host emission, a deconvolution fitting procedure was applied to the emission spectra of all of the samples for the excitation wavelength range between 330 and 420 nm (3.76 and 2.95 eV) [181], adopting the same fitting procedure applied to the undoped matrix [191, 193–196]. First, the spectra measured under the higher excitation wavelength (465 nm) were fitted by a single Gaussian-type function. Since the FWHM is determined primarily by carrier–phonons interaction, its value should not depend on the excitation wavelength [199]. Therefore, the FWHM was kept as a fixed parameter, whereas the intensity and peak position were free to vary within the excitation wavelength interval used. For the U(600)-based hybrids, the deconvolution fitting procedure revealed the presence of two Gaussian bands in the green and blue spectral regions for excitation wavelengths between 330 and 395 nm (3.76 and 3.14 eV). For excitation wavelengths higher than 395 nm (3.76 eV), the emission spectra were fitted only to the green Gaussian component. For the high-molecular-weight di-ureasils, the fitting procedure always revealed the presence of two bands within the referred excitation wavelength interval. Resembling the deconvolution performed on the di-ureasil hybrid host emission spectra [191, 193–196], Section 9, the lower and higher Gaussian components were assigned to the emission arising from electron–hole recombination occurring in the NH groups of the urea linkages (green band) and in the siliceous nanodomains (blue band), respectively. The energy of the NH-related emission varies between 2.4 and 2.6 eV for both di-ureasil series, whereas the band associated with the siliceous nanodomains varies between 2.5 and 3.0 eV for the

**Figure 5.** RT emission spectra for the  $\text{U}(600)_{200}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasil measured at different excitation wavelengths: (a) 330 nm, (b) 350 nm, (c) 365 nm, (d) 395 nm, and (e) 420 nm. (\*) and (\*\*) denote intra- $4f^6$  self-absorptions:  ${}^7\text{F}_0 \rightarrow {}^5\text{D}_4$ ,  ${}^5\text{L}_6$ , respectively. (1), (2), (3), (4), and (5) correspond to intra- $4f^6$  transitions:  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_{0-4}$ , respectively.

$\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  hybrids and between 2.8 and 3.1 eV for the  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasils. For each di-ureasil sample, the energy of the green band does not depend on the excitation wavelength, whereas the blue band, associated with the presence of the siliceous nanodomains, shifts to the red as the excitation wavelength increases. For each excitation wavelength used, while the energy of the green band is almost independent of the amount of  $\text{Eu}^{3+}$  incorporated, the variation of the energy of the emission related to the siliceous nanodomains with the  $\text{Eu}^{3+}$  content presents the same behavior as the one displayed in Figure 6 for the 365 nm (3.30 eV) excitation wavelength [181]. The energy of the undoped host ( $n = \infty$ ) is also plotted in the same figure. Figure 6 evidences the opposite behavior expressed by the two di-ureasils series: when an increase in the emission energy with the concentration increase is observed in one series, the other hybrid types present a decrease in the respective emission (and vice versa). This behavior can be related to the respective nanodomain size. In fact, it is well known that, in silicon-based nanostructured materials, the dimensional hierarchy of the backbone determines the emission energy in such a way that an increase in the dimensional network dimension results in a decrease of the corresponding energy gap [181, 200–203]. Accordingly, the emission energy of the siliceous nanodomains can be related to the SAXS-determined siloxane particle radius (Section 3).

Upon lowering the temperature down to 14 K, the overall RT luminescence features described remain the same, apart from a small blue shift of the hybrids' host emission.

The ensuing paragraphs will focus on the  $\text{Eu}^{3+}$  emission. For both di-ureasil series, the number of components measured for the  ${}^7\text{F}_{0,1,2}$  levels is one, three, and five, respectively, although the lower energy component of the  ${}^7\text{F}_2$  level is not clearly distinguished. The lines related to the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_{3,4}$  transitions are hard to identify due to the low intensity of some components, in particular the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_3$  transition. The number of components of each manifold and the relative intensity between the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_{0-4}$  transitions are not affected by changing the  $\text{Eu}^{3+}$  content or the polymer chain

**Figure 6.** Fitted energy of the siloxane-nanodomain-connected blue/purplish-blue emission excited at 3.14 eV (● and ▲) and 3.40 eV (○ and △) for the  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  and  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasils, respectively. The lines are drawn as guides to the eyes. Reprinted with permission from [181], K. Dahmouche et al., *J. Mater. Chem.* 11, 3249 (2001). © 2001, Royal Society of Chemistry.

length. Figure 7A shows in detail the intra- $4f^6$  lines for the  $U(600)_nEu(CF_3SO_3)_3$ ,  $200 \leq n \leq 60$ , di-ureasils.

For the di-ureasils  $U(2000)_nEu(CF_3SO_3)_3$ ,  $400 \leq n \leq 40$ , and  $U(600)_nEu(CF_3SO_3)_3$ ,  $200 \leq n \leq 60$ , the  $Eu^{3+}$  emission lines do not depend on the excitation wavelength. On the contrary, for the most concentrated hybrids of the latter di-ureasils series ( $n = 40$  and  $20$ ), changes in the emission spectra were observed, namely, in the energy of the  ${}^5D_0 \rightarrow {}^7F_0$  transition, as Figure 7B and C point out. This transition occurs between two nondegenerated levels, so changes detected in the energy of such a transition induced by variations on the excitation wavelength strongly suggest a structured profile for such a transition, meaning the existence of more than one local  $Eu^{3+}$  site. The presence of two distinct coordination local environments was also observed for the di-ureasils with a shorter polymer chain modified by  $Eu(ClO_4)_3$  [171]. In that particular case, the existence of two  $Eu^{3+}$  local environments was observed for concentration around  $n = 62$  [171]. Section 8 will focus on the cation local coordination as the  $Eu^{3+}$  content and the polymeric chain length vary.

Although salts and complexes based in the  $Eu^{3+}$  ion are the most reported ones [162–168, 170–173, 177, 180–187], other rare-earth ions have also been incorporated in the di-ureasils, namely,  $Nd^{3+}$  [169, 173, 176],  $Gd^{3+}$  [170],  $Tb^{3+}$  [172, 185],  $Er^{3+}$  [173, 174], and  $Tm^{3+}$  [172].

The di-ureasils modified by  $Nd^{3+}$  and  $Er^{3+}$  combine the white-light emission associated with the hybrid host skeleton with intra- $4f$  straight lines in the infrared spectral region characteristic of the RE ions [169, 173, 174, 176]. Figure 8 shows the emission for the  $U(2000)_{60}Nd(CF_3SO_3)_3$  detected in the visible spectral range. It is possible to discern the typical large broad band of the hybrid host, which occurs in the same spectral region observed for the  $Eu^{3+}$ -based hybrid

**Figure 7.** (A) 14 K  $Eu^{3+}$  emission lines, excited at 395 nm, for the  $U(600)_nEu(CF_3SO_3)_3$  hybrids: (a), (b), (c), and (d) denote  $n = 20, 40, 60$ , and  $200$ , respectively. (1), (2), (3), (4), and (5) correspond to intra- $4f^6$  transitions:  ${}^5D_0 \rightarrow {}^7F_{0-4}$ , respectively.  ${}^5D_0 \rightarrow {}^7F_0$  transition measured at 14 K for the  $U(600)_nEu(CF_3SO_3)_3$  di-ureasils, (B)  $n = 40$ , and (C)  $n = 200$ , excited at 350 nm (—●—) and 395 nm (—○—). (Fig. 1A). Although no visible emission arising from the  $Nd^{3+}$  levels is detected, it is possible to observe a series of intra- $4f^3$  self-absorptions, overlapping the hybrid host emission. The presence of such self-absorptions indicates that visible light emitted by the di-ureasil's emitting centers is absorbed by the cations, and then probably converted into near-infrared emission. Increasing the excitation wavelength causes a red shift of the maximum intensity energetic position, similarly to what was reported for the xerogels modified by  $Eu^{3+}$  (Fig. 5). The RT lifetime measured for the two hybrids' host emitting centers is of the same magnitude as the respective lifetimes measured for the undoped host [176]. Indeed, a smaller diminution of the lifetimes in the presence of  $Nd^{3+}$  with respect to the incorporation of  $Eu^{3+}$  was detected. This fact allowed the experimental detection of the lifetime associated with the luminescence arising from the siliceous nanodomains  $\tau_{Si}$ , and originated in the NH groups of the urea linkages  $\tau_{NH}$ , except for the more concentrated sample ( $n = 10$ ), whose lifetimes are smaller than the lower experimental detection limit of the experimental setup used ( $10^{-5}$  s) [176].

Figure 9A and B displays the infrared luminescence component of the  $Nd^{3+}$  and  $Er^{3+}$  di-ureasils, respectively [169, 173, 174, 176]. The emission lines are assigned to the intra- $4f^3$ ,  ${}^4F_{3/2} \rightarrow {}^4I_{13/2-9/2}$ , and to the intra- $4f^{11}$ ,  ${}^4I_{13/2} \rightarrow {}^4I_{15/2}$ , transitions of  $Nd^{3+}$  and  $Er^{3+}$ , respectively. Variations of salt concentration do not lead to changes in the IR spectra, namely, in the energy and shape of the observed transitions. Moreover, concentration-quenching effects on the reported IR luminescence seem to be insignificant in the di-ureasils, as the experimental detection conditions were approximately the same in the whole range of  $Nd^{3+}$  and  $Er^{3+}$  concentration reported [169, 173, 174, 176]. It is quite unusual to observe RT radiative emission from sol-gel-derived  $Nd^{3+}$ - and  $Er^{3+}$ -based hybrids, due to the numerous organic groups, particularly hydroxyl, present in classical sol-gel-derived materials

**Figure 8.** Visible emission spectra detected at 14 K for the  $U(2000)_{60}Nd(CF_3SO_3)_3$  di-ureasil, measured at different excitation wavelengths: (a) 350 nm, (b) 375 nm, (c) 420 nm, and (d) 460 nm. The  ${}^4I_{9/2} \rightarrow {}^4G_{5/2}, {}^4G_{7/2}$  (500–540 nm) and the  ${}^4I_{9/2} \rightarrow {}^4G_{7/2}, {}^2K_{13/2}, {}^4G_{9/2}$  (570–590 nm) intra- $4f^3$  self-absorptions are indicated by arrows. (B) RT infrared emission of  $\text{U}(600)_3\text{Er}(\text{CF}_3\text{SO}_3)_3$  recorded under the excitation 488 nm; (4) corresponds to the intra- $4f^{11}$  transition:  ${}^4I_{13/2} \rightarrow {}^4I_{15/2}$ .

that prevent any RT  $\text{Nd}^{3+}$  and  $\text{Er}^{3+}$  radiative emission [169, 173, 174, 176]. However, in the di-ureasil hybrids, the  $\text{Nd}^{3+}$  and  $\text{Er}^{3+}$  ions are active at RT, indicating that the di-ureasil hybrid framework efficiently protects the RE ions from nonradiative deactivations induced essentially by hydroxyl groups [169, 173, 174, 176].

The substitution of rare-earth salts by rare-earth complexes intends to increase the efficiency of the absorption and energy transfers processes, namely, the antenna effect, and consequently, to achieve greater emission intensity. In the following paragraphs, we will present some examples that illustrate this concept.

Bekiari et al. compared the luminescence intensity, excited at 365 nm, of a hybrid sample containing  $\text{Tb}^{3+}$  ions before and after the incorporation of the bpy ligand [185]. Through the analyses of Figure 3, the authors suggested that the presence of this ligand contributed to an enhancement of the PL intensity. From that figure, it is also possible to infer that the hybrid host is also transferring energy to the  $\text{Tb}^{3+}$  ions since, by changing the excitation wavelength to 318 nm, the intensity of the hybrid host broad band intensity is approximately zero [185].

$\beta$ -diketonate complexes of  $\text{Eu}^{3+}$ ,  $\text{Tm}^{3+}$ , and  $\text{Tb}^{3+}$  ions were incorporated in the  $\text{U}(2000)$  hybrid host [172]. The emission properties of such a hybrid revealed themselves as strongly dependent on the temperature, as plotted in Figure 10. For temperatures lower than 200 K, the emission features are similar, and the green  $\text{Tb}^{3+}$  transition,  ${}^5D_4 \rightarrow {}^7F_2$ , dominates the spectra, as the  $\text{Eu}^{3+}$  transitions, namely,  ${}^5D_0 \rightarrow {}^7F_2$ , have a lower intensity. No sign of visible  $\text{Tm}^{3+}$  luminescence could be detected [172]. For temperatures between 200 and 300 K, the green  $\text{Tb}^{3+}$  luminescence decreases, and we observe an increase of the red  $\text{Eu}^{3+}$  emission [172]. The  $\text{Tm}^{3+}$  emission was only observed in the infrared spectral region [172]. For direct excitation into the  ${}^5D_2$   $\text{Eu}^{3+}$  level (465 nm), the  ${}^5D_0 \rightarrow {}^7F_6$  transition was also observed [172]. The typical hybrid host luminescence band could only be detected for an excitation wavelength around 420 nm, which corresponds to the direct excitation of the hybrids host emitting centers [194–196].

**Figure 10.** PL spectra of  $\text{U}(2000)_{80}(\text{Eu}_{0.05}\text{Tb}_{0.15}\text{Tm}_{0.80})(\text{BTFA})_3 \cdot 2\text{H}_2\text{O}$  recorded at temperatures between 200 and 300 K (excitation wavelengths used: 377 nm at 200–225 K, and 382 nm at 250–300 K). (1), (2), (3), (4), and (5) correspond to the intra- $4f^6$ ,  ${}^5D_4 \rightarrow {}^7F_{6,7}$  ( $\text{Tb}^{3+}$ ), and intra- $4f^6$  transitions,  ${}^5D_0 \rightarrow {}^7F_{2-4}$  ( $\text{Eu}^{3+}$ ), respectively. In the area marked with an asterisk, there is an overlap between the  ${}^5D_0 \rightarrow {}^7F_{0,1}$  ( $\text{Eu}^{3+}$ ) and  ${}^5D_4 \rightarrow {}^7F_4$  ( $\text{Tb}^{3+}$ ) transitions. The inset shows the PLE spectra monitored within the  $\text{Tb}^{3+}$  (dashed line) and  $\text{Eu}^{3+}$  (solid line) emissions. Reprinted with permission from [172], L. D. Carlos et al., *Adv. Funct. Mater.* 12, 819 (2002). © 2002, Wiley–VCH Verlag GmbH & Co.

The lifetimes of the  $\text{Tb}^{3+}$  and  $\text{Eu}^{3+}$  cations excited states  ${}^5D_4$  and  ${}^5D_0$ , respectively, were measured as a function of the temperature [172]. The  ${}^5D_0$  lifetime is independent of the temperature, being around 0.6 ms between 14 and 300 K. The  ${}^5D_4$  lifetime is around 0.7 ms for the temperature range between 14 and 150–170 K, decreasing six–seven times as the temperature is increased until the RT [172]. This behavior indicates a thermally activated mechanism that will be focused on in detail in Section 7.

Zhang groups' reported the PL features of a series of organically modified silicate (*ormosils*) hybrids doped with  $\text{Eu}[(\text{phen})_2]\text{Cl}_3$  complexes. The relative emission quantum yield and the lifetime of the  ${}^5D_0$   $\text{Eu}^{3+}$  excited level were compared with those of conventional silica films synthesized under the same conditions as used for the hybrids [188]. The hybrids and the silica films were identified as  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$ , respectively. The corresponding PL spectra excited under UV excitation are plotted in Figure 11 [188]. All of the spectra present the typical  $\text{Eu}^{3+}$  red emission corresponding to transitions between the  ${}^5D_0$  level and the  ${}^7F_{0-4}$  manifolds. Although the  ${}^5D_0 \rightarrow {}^7F_2$  dominates in both spectra, the number of observed components for all of the transitions is different. The higher number of Stark components observed for the  ${}^5D_0 \rightarrow {}^7F_{1-4}$  transitions in  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  indicates a lower local-symmetry site for the  $\text{Eu}^{3+}$  ions relative to the  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$  samples.

Zhang et al. compared the relative quantum efficiency of the  $\text{Eu}^{3+}$  emission in the hybrid matrix and in the silica host, and concluded that, for the same amount of  $\text{Eu}[(\text{phen})_2]\text{Cl}_3$  incorporated (0.5%), the relative quantum efficiency of the  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$  is 0.08 with respect to the efficiency observed in the  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  hybrid [188]. The hybrid host behaved as an efficient  $\text{Eu}^{3+}$  host, contributing to an increase of its emission intensity.

**Figure 11.** PL and PLE spectra of the  $\text{SiO}_2\text{:}[\text{Eu}(\text{phen})_2]^{3+}$  (a) and  $\text{SiO}_2/\text{SPM:}[\text{Eu}(\text{phen})_2]^{3+}$  (b) materials in air. The lifetime of the  $^5\text{D}_0$   $\text{Eu}^{3+}$  level measured for both samples was well fitted by a double exponential, indicating inhomogeneities in the  $\text{Eu}^{3+}$  local environment. The  $^5\text{D}_0$  lifetime values are  $1.404 \pm 0.350$ ,  $4.152 \pm 0.600$  ms and  $0.889 \pm 0.090$ ,  $0.060 \pm 0.006$  ms for  $\text{SiO}_2/\text{SPM:Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2\text{:Eu}[(\text{phen})_2]^{3+}$ , respectively [188]. The lower values found for the lifetime of the  $^5\text{D}_0$  level in the  $\text{SiO}_2\text{:Eu}[(\text{phen})_2]^{3+}$  film were interpreted on the basis that the ormosil matrix prevents ligand vibrations around the  $\text{Eu}^{3+}$  cation, contributing to a decrease in the nonradiative channels [188].

Li et al. also reported the luminescence properties of a series of composite phosphors modified by terbium carbonyl complexes, identified as  $\text{SiO}_2/\text{SPM:Tb-}o\text{-ABA}$ ,  $\text{SiO}_2/\text{SPM:Tb-}p\text{-ABA}$ ,  $\text{SiO}_2/\text{SPM:Tb-BA}$  and  $\text{SiO}_2/\text{SPM:Tb-}m\text{-ABA}$  [189]. The emission spectra of all of the hybrids are displayed in Figure 12. The spectra are composed of a large broad band between 350 and 480 nm superimposed by a series of straight lines in the green spectral region assigned to the intra- $4f^8$  transitions:  $^5\text{D}_4 \rightarrow ^7\text{F}_{6-3}$ . The large broad band was related to the presence of carboxyl radicals in the hybrids [189]. The authors of this work analyzed the temperature influence on the luminescence intensity of all four hybrids. The luminescence intensity was measured as the heat treatment temperature increased from 50 to 150 °C, and a decrease of the emission intensity with increasing temperature was detected for all of the composites [189]. To explain this result, the authors noted that, as the heat temperature increases, a greater quantity of solvents ( $\text{H}_2\text{O}$ ,  $\text{CH}_3\text{COOH}$ , acid) escapes from the sample, so that carbonyl may exist in the form of a negative ion, meaning that its lowest triplet excited state transforms  $\pi\pi^*$  into  $n\pi^*$ . It is more unlikely that the singlet  $n\pi^*$  state transmits to the triple state  $\pi\pi^*$  and, consequently, the energy transfer processes from the ligands to the  $\text{Tb}^{3+}$  cations become more inefficient [189].

The lifetimes of the  $^5\text{D}_4$  level were measured at RT under 335 nm excitation wavelength within the  $^5\text{D}_4 \rightarrow ^7\text{F}_5$  transition [189]. The experimental data were well adjusted by a sin-

**Figure 12.** PL and PLE spectra of the  $\text{SiO}_2/\text{SPM}$ -terbium carbonyl complexes. (a)  $\text{SiO}_2/\text{SPM:Tb-}o\text{-ABA}$ . (b)  $\text{SiO}_2/\text{SPM:Tb-}p\text{-ABA}$ . (c)  $\text{SiO}_2/\text{SPM:Tb-BA}$ . (d)  $\text{SiO}_2/\text{SPM:Tb-}m\text{-ABA}$ . Reprinted with permission from [189], Y. Li et al., *Mater. Lett.* 56, 597 (2002). © 2002, Elsevier Science.

gle exponential function indicating lifetime values between  $1.200 \pm 0.015$  and  $0.600 \pm 0.016$  ms for the  $\text{SiO}_2/\text{SPM:Tb-}o\text{-ABA}$  and  $\text{SiO}_2/\text{SPM:Tb-}m\text{-ABA}$ , respectively. The higher lifetime value found for the  $\text{SiO}_2/\text{SPM:Tb-}o\text{-ABA}$  composite was attributed to the stability of the  $\text{Tb-}o\text{-ABA}$  complex that might contribute to a decrease of the ligand vibrations around the  $\text{Tb}^{3+}$  ions, enhancing, in turn, the experimental lifetime [189].

Recently, Corriu et al. reported a comparative study of the PL properties of hybrid organic–inorganic materials obtained from a mixture of  $\text{Ph}_2\text{P}(\text{CH}_2)_3\text{Si}(\text{OMe})_3$  and  $n'$  equiv of  $\text{Si}(\text{OEt})_4$  ( $n' = 4, 7, 9, 12, 14, 19$ , and 35) doped with  $\text{Eu}^{3+}$  in the presence and absence of a surfactant,  $n$ -hexadecylamine [190]. Note that, in order to avoid confusion with the  $n$  ratio, the nomenclature proposed by Corriu et al. was replaced here by  $n'$ . Accordingly, the materials will be identified as  $\text{A}_{n'}$  and  $\text{B}_{n'}$ , respectively. As an example, we show the emission spectra of the  $\text{EuA}_0$  and  $\text{EuB}_7$  hybrids recorded at 2 K under laser excitation at 325 nm [190]. As Figure 13 shows, the entire PL spectra are composed of the typical  $^5\text{D}_0 \rightarrow ^7\text{F}_{0-4}$  transitions. In both types of materials,  $\text{A}_{n'}$  and  $\text{B}_{n'}$ , the  $^5\text{D}_0 \rightarrow ^7\text{F}_0$  transition displays only one line peaking around the same energy value, indicating only one similar  $\text{Eu}^{3+}$  local environment in the two hybrid materials [190].

In spite of the similar PL properties and  $\text{Eu}^{3+}$  local coordination site in both  $\text{A}_{n'}$  and  $\text{B}_{n'}$  hybrids, they behave differently regarding the  $\text{Eu}^{3+}$  complexation. Due to the presence of  $\text{P}=\text{O}$  groups within the porous part of the  $\text{A}_{n'}$  materials, rather than their uncontrolled distribution in the  $\text{B}_{n'}$  hybrids, Corriu et al. concluded that the former system is more adequate for  $\text{Eu}^{3+}$  coordination [190]. This fact indicated that the  $\text{Eu}^{3+}$  coordination requires not only three  $\text{P}=\text{O}$  coordinating groups, but also a certain favorable geometry, as suggested by  $^{31}\text{P}$  NMR results and elemental analysis (see Section 3) [190]. This observation was also sustained by the analyses of the complexation degree with the increasing  $\text{Eu}^{3+}$  content as  $n'$  varied between 4 and 35. The

optimum complexation degree (80%) occurred around  $n' = 9$  for the  $\text{A}_{n'}$  hybrids. For  $n' < 9$ , in spite of the greater proximity between the  $\text{P}=\text{O}$  groups, the complexation degree decreases, and for the more diluted samples, namely,  $n' > 14$ , there is no  $\text{Eu}^{3+}$  complexation in  $\text{A}_{n'}$  and  $\text{B}_{n'}$  materials [190]. With this work, Corriu et al. demonstrated that the complexation of  $\text{Eu}^{3+}$  in hybrid materials containing phosphine oxide groups within the porous part is favored.

The most exhaustive studies concerning the PL properties of hybrid materials in which the RE organic ligands are covalently grafted to the hybrid framework regard  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  ions. The typical lanthanide ligands incorporated in these sol–gel-derived organic–inorganic nanostructured hybrids include  $\beta$ -diketonate complexes [153–159, 172, 184, 185, 187], phenanthroline [53, 143, 158], and bipyridine [53, 143, 187].

Figure 14A shows the low-temperature emission properties of  $\text{Eu}^{3+}$ -activated organic–inorganic hybrids materials with four different dicarboxylic acids, denoted as  $\text{EuH}_1$ ,  $\text{EuH}_2$ ,  $\text{EuH}_3$ , and  $\text{EuH}_4$ , directly excited within the organic absorption band (337.1 nm) [155]. All of the spectra are similar, presenting the  $^5\text{D}_0 \rightarrow ^7\text{F}_{0-4}$  intra- $4f^6$  transitions. The large and unresolved profile of the spectra evidences the amorphous nature of these materials. Moreover, these hybrids display a relatively high PL intensity, in particular,  $\text{EuH}_2$  and  $\text{EuH}_3$ , in which the organic complex retains 85% of the luminescence intensity [155].

A comparative study was performed involving the 1,10-phenanthroline complex covalently bonded to the silica backbone in the presence of the  $\text{Eu}^{3+}$  ions (Hybrid I) with a simple mixture of the silica gel,  $\text{Eu}^{3+}$ , and  $\text{Phen-NH}_2$  (Hybrid II) [158]. The respective PL spectra are plotted in Figure 15A and B, respectively. The Hybrid I emission is characterized by the typical  $\text{Eu}^{3+}$  lines, and no emission arising from the ligands levels could be detected. In contrast, in the Hybrid II, a large broad band resulting from the ligand levels superimposes the  $\text{Eu}^{3+}$  emission. This states that the energy transfer processes from the  $\text{Phen-Si}$  ligands are more efficient in the Hybrid I case, showing the effective

**Figure 14.** (A) Low-temperature (15 K) PL spectra excited under 337.1 nm. (B) RT PLE spectra monitored around 616.0 nm for the  $\text{EuH}_i$  ( $i = 1-4$ ) hybrid materials. importance of the covalent graft between the organic and inorganic components [158]. The decrease in the emission intensity in the spectrum of the Hybrid II, regarding that of Hybrid I (clearly demonstrated by the noisy spectrum of Fig. 15B), was attributed to the presence of  $\text{NH}$  oscillators of the  $\text{NH}_2$  groups that act as nonradiative channels for the  $\text{Eu}^{3+}$  ion [158].

In the RT PL spectra of 2-pyridinecarboxylic acid europium(III),  $\text{Eu}(\text{PA})_3$ , complexes prepared by the chemically synthesized method [159] (Fig. 16), it is possible to discern only the lanthanide ion emission. A similar result was reported for a series of phosphine oxides coordinated to one, two, or three  $\text{Si}(\text{OR})_3$  groups treated with anhydrous europium salts (see Fig. 17) [157].

The hybrids incorporating  $\text{Tb}^{3+}$  ions that we will discuss in the following paragraphs present, in all cases, the typical green emission resulting from radiative transitions between the  $^5\text{D}_4$  and the  $^7\text{F}_{3-6}$  levels [156, 160, 161].

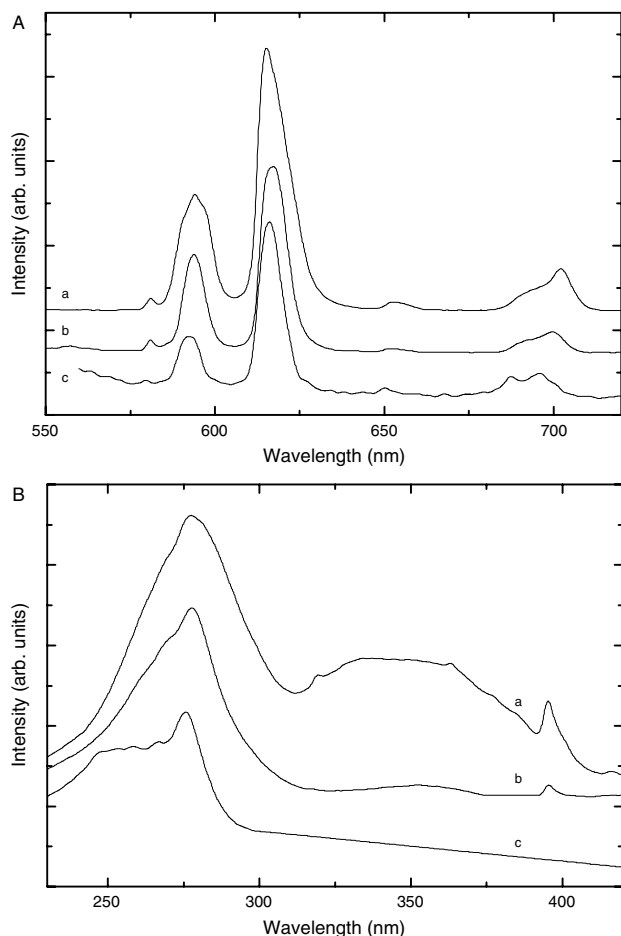

Zhang et al. reported the synthesis and photoluminescent properties of two  $\text{Tb}^{3+}$ -complex bridged hybrids involving the DPS and PAIB monomers [160, 161]. In their former work [160], the luminescence properties of the hybrid film and pure  $\text{Tb-DPS}$  complex were analyzed. Figure 18 shows

**Figure 15.** PLE and PL spectra of (A) Hybrid I, and (B) Hybrid II. Reprinted with permission from [158], H. R. Li et al., *Chem. Mater.* 14, 3651 (2002). © 2002, American Chemical Society.

the PL spectra of the Tb–DPS complex and of the corresponding hybrid film [160]. The spectra look similar, indicating that the  $\text{Tb}^{3+}$  ions are coordinated to the ligand within the hybrid material. The emission properties of the Tb–PABI hybrid were discussed as a function of the variation of the molar ratio  $\text{Tb}^{3+}$  ion/PABI from 1:5 to 1:200 [161]. All of the spectra present the typical  $\text{Tb}^{3+}$   $^5\text{D}_4 \rightarrow ^7\text{F}_{3-6}$  transitions, whose intensity increases with increasing complex content [161]. The  $^5\text{D}_4$  lifetime was measured for the Tb–PABI hybrid samples and for the hybrid involving the Tb–DPS complex. In all cases, the experimental decay curve was well reproduced by a single exponential function, suggesting that the  $\text{Tb}^{3+}$  ions lie in the same average chemical environment. The resulting lifetimes were 1.2 and 0.35 ms for the hybrids with Tb–PABI and Tb–DPS complexes, respectively [160, 161]. A decrease of the lifetime of the  $^5\text{D}_4$  level both in the Tb–DPS and Tb–PABI hybrid films with respect to the value found in the pure complexes was observed. Zhang et al. attributed such a decrease to a possible quenching by silanol groups in the hybrid case [160, 161].

In the following paragraphs, we will refer briefly, to some PL results concerning the Class I hybrids whose synthesis was described in Section 2.1.

Molina et al. reported the luminescence study of a family of siloxane/PEG Class I hybrids modified by  $\text{Eu}(\text{ClO}_4)_3$ , with the  $\text{Eu}^{3+}$  content ranging from  $n = 300$  to  $n = 8$  [150]. The emission spectra display the typical  $\text{Eu}^{3+}$  intra- $4f^6$  transitions,  $^5\text{D}_0 \rightarrow ^7\text{F}_{0-4}$ , that overlap a large broad band, whose origin was not discussed in detail [150]. The most intense transition is the magnetic dipolar one,  $^5\text{D}_0 \rightarrow ^7\text{F}_1$ , an indication that the  $\text{Eu}^{3+}$ -coordination sites have an inversion center. The authors suggested that this observation reflects the presence of  $\text{H}_2\text{O}$  molecules in the  $\text{Eu}^{3+}$  first coordination shell [150]. The presence of OH oscillators surrounding the cations, which act as nonradiative routes for the lanthanide ions, demonstrates that these Class I hybrids are not efficient hosts to encapsulate the  $\text{Eu}^{3+}$  ions. This fact can be overcome either by choosing an  $\text{Eu}^{3+}$  complex instead of  $\text{Eu}(\text{ClO}_4)_3$  or by synthesizing Class II hybrids.

The use of lanthanide-based complexes in Class I materials was reported, for instance, by Li et al., who incorporated europium  $\beta$ -diketonate complexes into such types of systems [143]. Among the  $\text{Eu}^{3+}$ -based complexes studied, the  $\text{Eu}(\text{TTA})_3\text{phen}$  is the one that emits with highest intensity. The authors stated that the hybrid contributes to the stabilization of the  $\text{Eu}(\text{TTA})_3\text{phen}$  complex, due to the substitution of  $-\text{OH}$  groups by  $-\text{OSi}(\text{CH}_3)_3$  groups of the hybrid host [143]. Other  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  complexes, such as  $[\text{Tb}(\text{byp})_2]\text{Cl}_2$  and  $[\text{Eu}(\text{phen})_2]\text{Cl}_3$ , were introduced in Class I hybrids by Adachi's group [140, 148]. The emission spectra of these materials are composed of the green and red emissions associated with the  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  transitions,  $^5\text{D}_4 \rightarrow ^7\text{F}_{6-3}$  and  $^5\text{D}_0 \rightarrow ^7\text{F}_{0-4}$ , respectively [140, 148]. Similarly to the previous case, the authors report that the Class I ormosil matrices contribute to reduce the water absorption of the  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  complexes, so that these hybrids can be used as phosphors for practical uses [140, 148].

Cordoncillo et al. [152] and Zaiton et al. [149] reported the synthesis of  $\text{Eu}^{2+}$ -doped Class I hybrid materials. A large band in the blue spectral region assigned to the  $4f^65d^1 \rightarrow 4f^7$  transition characterizes the  $\text{Eu}^{2+}$  emission [94]. While the lanthanide ion trivalent state is energetically favorable, in

certain chemical environments, the divalent state can be stabilized [94]. Cordoncillo et al. used the cleavage of the Si–H groups from the alkoxide precursors as an *in-situ* reducing agent [152]. In order to determine the best synthesis conditions that contribute to reduce  $\text{Eu}^{3+}$  to  $\text{Eu}^{2+}$  during the sol–gel reaction, Lin et al. studied the influence of the preparation conditions, namely, the pH of the sols, counterions, chelating agents, and solvent type, in the creation of electron–hole defects in the Class I host matrix [149]. In both studies, it was possible to observe the RT intrinsic  $\text{Eu}^{2+}$  blue emission.

## 4.2. Excitation Spectra

The excitation spectra of  $\text{Tb}^{3+}$ - [185] and  $\text{Eu}^{3+}$ -based hybrids [166, 170, 177] were measured. In all cases, the excitation spectra were found to be strongly dependent on the detection wavelength. To clearly identify the components present in the excitation spectra, we will discuss separately the excitation spectra monitored around the RE emission lines and along the hybrid host emission band. We will start by presenting the excitation spectra detected around the hybrid host emission band of the  $\text{Eu}^{3+}$ -based di-ureasils [170].

Figure 19 reproduces the RT PLE spectra for the di-ureasil  $\text{U}(600)_{200}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  monitored at detection wavelengths between 410 and 550 nm, in order to cover the hybrids' host emitting region. All of the spectra are composed of a large broad band between 300 and 520 nm [170].

**Figure 19.** RT PLE spectra for the di-ureasil  $\text{U}(600)_{200}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  monitored at different detection wavelengths: (a) 410 nm, (b) 435 nm, (c) 485 nm, (d) 510 nm, and (e) 550 nm. The inset shows the excitation maximum intensity position versus the respective detection energy along the hybrid host emission band for the  $\text{U}(600)_{200}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasil. The solid square represents the excitation of the hybrid's backbone detected around the strongest  $^7\text{F}_2$  line, 616 nm. The solid line corresponds to the data linear fit ( $r > 0.99$ ). Reprinted with permission from [170], R. A. Sá Ferreira et al., *Chem. Mater.* 13, 2991 (2001). © 2001, Elsevier Science.

Ribeiro et al. reported a analogous PLE spectrum detected around 435 nm for similar U(600)-based hybrids modified by  $\text{Eu}(\text{ClO}_4)_3$ , as shown in Figure 2B, whose maximum intensity position occurs at 355 nm [177]. Bekiari et al. also observed a large broad band in the same spectral region, peaking around 360 nm, in the PLE spectra of  $\text{Tb}^{3+}$ -based U(600) di-ureasils [185].

As Figure 19 demonstrates, with the increase of the detection wavelength, the maximum intensity energetic position shifts toward the red, and its FWHM increases from 3000 to 6000  $\text{cm}^{-1}$  [170]. When the detection wavelength is greater than 435 nm, a second band, peaking around 420 nm, is also discerned (marked with an asterisk in Fig. 19). As the detection wavelength increases, its relative intensity with respect to the spectra maximum intensity increases, and its peak position remains approximately independent of the monitoring wavelength, contrary to what was observed for the maximum intensity energetic position. The inset of Figure 19 displays the PLE spectra peak position,  $E_{p_x}$  as the monitoring energy increases,  $E_x$  [170]. This behavior is maintained until the detection wavelength reaches 610–615 nm, as we will discuss later. These results clearly establish the presence of two distinct emitting components, in accordance with the PL results aforementioned similarly in Section 4.1. Moreover, this was also observed for the nondoped hosts (Section 9) [191–196]. As we will see in this section, the less energetic band can be assigned to the preferential excitation of the NH groups' D–A pairs, and the more energetic one can be attributed to the preferential excitation of the siliceous nanodomains [191–196].

Figure 1B represents the RT PLE spectra for the di-ureasils  $\text{U}(\text{Y})_{80}\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $\text{Y} = 600$  and 2000, monitored around the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_{2,4}$   $\text{Eu}^{3+}$  lines. The spectra are composed of a Gaussian-like band centered around 340 and 365 nm, and a less intense band in the low energetic side of the spectra. These two bands are overlapped by a series of straight lines assigned to the excitation of the intra- $4f^6$  levels. The band in the lower wavelength side of the spectra has a greater contribution for the PLE spectra of the high-molecular-weight di-ureasils. Its peak position follows the same linear relation found for the variation of the maximum intensity position with the increasing monitoring energy (inset of Fig. 19). This finding allows us to infer that this band is associated with the excitation of the hybrid host emitting centers detected in the red spectral region. In fact, as the hybrid host emission is still visible in that spectral region, despite its lower intensity, the PLE spectra monitored in that region have a contribution to the hybrid host emitting centers [170].

The most intense band is blue shifted with respect to the PLE spectra monitored around the large broad band, suggesting that a possible origin in the hybrid host emitting centers can be readily excluded. This conclusion could only be achieved owing to the fact that the PLE spectra of the  $\text{Eu}^{3+}$ -based hybrids were monitored along the large broad band and at the cation lines; otherwise, the lack of information regarding the features of the PLE spectra detected along the band of the hybrid host emitting centers could lead to uncorrected conclusions. Therefore, this band was assigned to LMCT states, resulting from the interaction between the

lanthanide ion and the first ligands [166, 170]. Two experimental results confirmed this suggestion: the measurement of PLE spectrum (1) monitored around the  ${}^5\text{D}_0 \rightarrow {}^7\text{F}_4$  transition (700 nm), and (2) of two di-ureasils modified by  $\text{Gd}^{3+}$ , under the same experimental conditions used for the detection of the PLE spectra of  $\text{Eu}^{3+}$ -based hybrids. The  $\text{Gd}^{3+}$  excitation spectrum is a useful spectroscopic tool since the energetic difference between the first excited state and the fundamental level is too high to allow the detection of a charge-transfer state in the UV/Vis range. By measuring such spectra, we may expect to detect only the PLE components that are not related to the charge-transfer processes. The excitation spectra monitored around 700 nm are plotted in Figure 1B, overlapping the one detected around 612 nm, for an easier comparative analysis. No changes were observed in the main band, namely, in its peak position and FWHM, while the intensity of the lower energetic band is approximately half reduced. In the  $\text{Gd}^{3+}$ -based di-ureasils, the presence of the LMCT states was not detected, and only the less intense band could be observed. This fact clearly assigned the latter band to the excitation of the hybrid host emitting centers, and excluded it from any connection with charge-transfer mechanisms. In addition, the observed decrease of the relative intensity with respect to the LMCT band in the PLE spectra monitored around 700 nm should not occur if the nature of both bands is the same.

The  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasils always present a higher energetic LMCT band when compared to the  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  hybrids within the concentration range studied here. The energy of the LMCT states depends on the number and type of the lanthanide ion first neighbors. The following equation relates the energy of such states,  $E_{\text{LMCT}}$ , to the ionization potential of the cation,  $I_{\text{RE}}$ , and to the ionization potential of the ligands,  $I_L$  [204]:

$$E_{\text{BTC}} = I_L - I_{\text{RE}} + \alpha \quad (5)$$

where  $\alpha$  is a constant associated with the local geometry around the cation [166, 204]. According to Eq. (5), a blue shift of the energy of the LMCT states is related to an increase in the effective charge of the lanthanide cation. This behavior might be induced by: (1) an increase in the cations' first ligand distances, and/or (2) a reduction of the number of ligands and/or a decrease in the effective charge of the ligands. Therefore, it was suggested that the  $\text{Eu}^{3+}$  cations experience a more covalent environment in the  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  hybrids than in the  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasils. This fact is mainly induced by changes in the nature of the first ligands. In the high-molecular-weight hybrids, the  $\text{Eu}^{3+}$  cations interact mainly with the carbonyl oxygen atoms of the urea bridges, for  $40 \leq n \leq 400$ , and in the shorter polymer chain di-ureasils, the rare-earth ions are coordinated to the ether-type oxygen atoms, for  $40 \leq n \leq 200$ , and only for higher concentrations,  $n < 40$ , was the coordination to the oxygen atoms of the carbonyl groups observed together with the presence of  $\text{Eu}^{3+}$  cations in the polymer chains [170]. As the carbonyl oxygen atoms have a greater tendency to establish covalent bonds than the ether-type oxygen atoms [205], a more energetic LMCT state is expected in the latter case. Besides changes in the type of first ligands, changes in the number of first

neighbors also influence the covalency degree of the cation first coordination shell.

Upon decreasing the temperature from 300 to 14 K, we observe an increase of around 40% of the PLE intensity, whereas the other PLE features described at RT remain constant. This explains why the energy of the LMCT states was analyzed at 14 K. The inset in Figure 1B shows the low-temperature PLE spectra for the U(2000) di-ureasils, evidencing the energy dependence of the LMCT states, with the increase of the salt concentration between  $n = 200$  and  $n = 20$ . While for concentrations  $200 \geq n \geq 40$  and for  $40 \geq n \geq 20$  the energy of the LMCT states shifts to lower energies, for concentrations in the range  $80 \geq n \geq 40$ , the energy of the LMCT states moves to higher energies. According to Eq. (5), this behavior suggests a decrease in the covalency nature of the  $\text{Eu}^{3+}$  first coordination shell as the concentration decreases between  $n = 40$  and  $n = 80$ . As the mean radius of the first shell coordination is, approximately, constant in the entire concentration interval studied (as suggested by EXAFS measurements; see Section 3), changes in the energy of the LMCT states (and consequently, in the covalency degree of the first coordination shell) must be related to changes in the type of the first ligand atoms. In fact, upon increasing the concentration from  $n = 80$  to  $n = 40$ , the number of available oxygen atoms of the carbonyl groups of the urea linkages per incorporated ion decreases from 4 to 2. As the total number of first ligands does not depend on the concentration, it was demonstrated that the carbonyl–oxygen-type atoms are replaced by  $\text{H}_2\text{O}$  molecules that are known to have a lower tendency to establish covalent bonds with  $\text{Eu}^{3+}$  [166, 168, 170, 205]. In that series of hybrids, the covalency degree of the first coordination shell depends on the salt content, in contrast to the situation observed for the  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasils, where the energy of the LMCT states is approximately constant within the concentration range presented. We will return to this point in Section 8.

When the RE salt incorporated in the di-ureasils is replaced by RE-based complexes, namely  $\beta$ -diketonate [172, 184] and *byp* [185], or when the lanthanide ions are surrounded by organic ligands that are covalently grafted to the hybrid framework [53, 143, 153–159], the respective PLE spectra monitored around the cation emission lines are mainly composed of a large broad band in the UV/Vis region. As an example, we can refer the PLE spectra of the U(2000) di-ureasil codoped with  $\text{Eu}^{3+}$ ,  $\text{Tb}^{3+}$ , and  $\text{Tm}^{3+}$ , monitored around the  $^5\text{D}_4 \rightarrow ^7\text{F}_4$  ( $\text{Tb}^{3+}$ ) and  $^5\text{D}_0 \rightarrow ^7\text{F}_2$  ( $\text{Eu}^{3+}$ ) transition [172], plotted in the inset of Figure 10. Besides the respective intra-4f transitions, a large broad band peaking around 382 nm, assigned to the ligand excitation, composes each PLE spectrum. The low relative intensity of the intra-4f transitions regarding this band indicates an effective ligand-to-metal energy transfer mechanism.

Evidence of energy transfer mechanisms between the ligands and the RE ion is also found in the PLE spectra of  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$  [188]. In both PLE spectra, it is possible to discern the presence of three main absorption bands around 280, 300, and 325 nm [188], which were ascribed to the matrix, to the Eu-based complex, and to the  $\pi\pi^*$  band of the phen ligands [188]. The

similarity between the  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$  PLE spectra shows that the  $[\text{Eu}(\text{phen})_2]^{3+}$  complex cations exist in both samples [188].

Figure 12 shows the PLE spectra of all of the  $\text{SiO}_2/\text{SPM}$ -terbium complexes monitored within the main  $\text{Tb}^{3+}$  line [189]. The large broad band present in the spectra of all of the hybrids corresponds to an efficient  $\pi\pi^*$  transition based on the conjugated double bonds of the carboxyl ligands [189], unequivocally establishing the importance of the ligands in the excitation of the cations levels.

The Class II hybrid frameworks incorporating an organic molecule which is able to covalently complex RE ions also show efficient ligands-to-metal ions energy transfer mechanisms. Let us briefly discuss some examples.

Franville et al. studied the PLE spectra of four  $\text{Eu}^{3+}$ -based hybrids monitored around the cation's most intense transition (see Fig. 14B) [153]. All of the spectra are mainly composed of a large broad band in the UV spectral region, 294–370 nm, resulting from an  $\text{S}_0 \rightarrow \text{S}_1$  absorption within the chromophore ligand [153]. The authors interpreted the presence of this band as a clear indication of efficient sensitization of the luminescent centers by the organic ligands.

Fan et al. reached the same conclusion with respect to the PLE spectra of three complexes of 2-pyridinecarboxylic acid europium (III) (see Fig. 16B) [159]. In spite of the presence of intra-4f<sup>6</sup> transitions, all of the spectra are dominated by a band, resulting from the existence of energy transfer between the ligands and the lanthanide ions.

Li et al. established the importance of the covalent bond between the organic complex and the hybrid's backbone by comparing the PLE results of the Hybrid I and Hybrid II samples, shown in Figure 15B [158]. While the spectrum of Hybrid I is composed of only a band centered around 282 nm, which is characteristic of the efficient transition based on the conjugated double bonds of the heterocyclic ligand, the Hybrid II spectrum displays a noisy band in the same spectral region superimposed by the  $^7\text{F}_0 \rightarrow ^5\text{L}_6$  and  $^5\text{D}_2$  transitions [158].

The PLE spectrum of the  $\text{Tb}$ -PABI hybrid film monitored around the  $\text{Tb}^{3+}$  emission is formed by a large broad band peaking around 292 nm, which was ascribed to the ligands' absorptions, indicating effective energy transfer to the  $\text{Tb}^{3+}$  ions [161].

## 5. COLOR COORDINATES

The di-ureasil hybrid's emission appears to be white to the naked eye, due to the convolution of the  $\text{Eu}^{3+}$  intrinsic luminescence with the emission associated with the hybrid host emitting centers, namely, the electron–hole recombinations that occur in the NH groups of the urea linkages and in the siliceous nanodomains. This is well illustrated by a set of real time frames, extracted from a video film that recorded the light emitted, during UV exposure and after the excitation source was turned off, of the  $\text{U}(2000)_{80}\text{Eu}(\text{CF}_3\text{SO}_3)_3$  di-ureasil (Fig. 20). Under UV excitation, the cation orange–red emission dominates. Since this emission is characterized by a shorter lifetime, regarding the one typical of the hybrid host emitting centers, when the UV excitation is turned off, the sample displays only the green–blue color typical of the matrix [166].

**Figure 20.** Set of real-time frames illustrating the white-light emission of  $U(2000)_{80}Eu(CF_3SO_3)_3$  at 14 K and UV excitation (331.1 and 351.4 nm) and during 1 s after the laser beam (100 mW) was turned off. Reprinted with permission from [166], L. D. Carlos et al., *Phys. Rev. B* 60, 10042 (1999). © 1999, American Physical Society.

It should be noted that the di-ureasil's white light is achieved by a different process than the one usually associated with the emission of multiwavelength phosphors based in LEDs [80, 82, 87]. The greenish–blue component is not totally absorbed by the  $Eu^{3+}$  metallic ions, and thus, the overall emission is a sum of both contributions. This fact is a critical advantage, as recently suggested for the hybrids LEDs made of InGaN and conjugated polymers [82].

In order to quantify and compare the emission of the hybrid organic–inorganic materials discussed in this review with regard to color, it is important to employ a universal quantitative way to infer this information. The color coordinates are usually calculated using the system of the Commission International de L'Éclairage created in 1931 [195, 206–208]. This procedure is based on the human eye's response to the visible light. The human eye possesses three cone cells responsible for the color distinction. Each cone cell presents a different sensibility, designated as  $\bar{x}_\lambda$ ,  $\bar{y}_\lambda$ , and  $\bar{z}_\lambda$ , with maximum value at ca. 419, 531, and 558 nm, respectively. The sum of the three cone sensitivity functions is called the *photonic response*, and displays a maximum sensibility centered at 555 nm, in the green spectral region. The  $\bar{x}_\lambda$ ,  $\bar{y}_\lambda$ , and  $\bar{z}_\lambda$  are called the CIE color-matching functions, and characterize the 2° standard observer recommended by CIE in 1931. In addition, the CIE defined three new primaries colors  $X$ ,  $Y$ , and  $Z$ , needed to match any specific color. These quantities,  $X$ ,  $Y$ , and  $Z$ , are known as tristimulus values. These primary colors established by the CIE have a large advantage when compared with other color systems since the color-matching functions do not display negative parts. The  $\bar{x}_\lambda$ ,  $\bar{y}_\lambda$ , and  $\bar{z}_\lambda$  can be used as weighting functions of the luminescence data, in order to determinate the  $X$ ,  $Y$ , and  $Z$  that characterize a given emission spectra. The corresponding  $X$ ,  $Y$ , and  $Z$  are obtained by adding all emission wavelengths' tristimulus values through the following equations set [195, 206–208]:

$$\begin{cases} X = \int_i \bar{x}_i \cdot E_i d\lambda \\ Y = \int_i \bar{y}_i \cdot E_i d\lambda \\ Z = \int_i \bar{z}_i \cdot E_i d\lambda \end{cases} \quad (6)$$

where  $E$  stands for the emission spectra intensity and  $i$  represents the emission wavelengths. To simplify the calculus, the spectra can be divided into small wavelength intervals  $\Delta\lambda$  (usually  $\Delta\lambda = 5$  or 10 nm), and Eq. (7) can be rewritten as

$$\begin{cases} X = \sum_{\lambda=380}^{720} \bar{x}_\lambda \cdot E_\lambda \Delta\lambda \\ Y = \sum_{\lambda=380}^{720} \bar{y}_\lambda \cdot E_\lambda \Delta\lambda \\ Z = \sum_{\lambda=380}^{720} \bar{z}_\lambda \cdot E_\lambda \Delta\lambda \end{cases} \quad (7)$$

To make the color perception easier, the tristimulus are converted into a two-dimensional system through a linear transformation. The tristimulus are transformed into chromaticity coordinates  $(x, y)$  that are plotted in a two-dimensional chromaticity diagram. The chromaticity coordinates are related to  $X$ ,  $Y$ , and  $Z$  by [195, 206–208]

$$\begin{cases} x = \frac{X}{X + Y + Z} \\ y = \frac{Y}{X + Y + Z} \end{cases} \quad (8)$$

The chromaticity diagram has particular characteristics, namely: (1) the center of the diagram is taken as the white point (0.33,0.33); (2) the curve is made of the pure colors from the blue to the red, covering the entire spectral visible range (380–730 nm), being denoted as the *spectral locus*; and (3) the straight line that connects the two extremes of the *spectral locus* is denoted as a purple boundary. The colors represented by the purple boundary are not pure colors, as they include a mixture of pure red and blue. The area circumscribed by the diagram, spectral locus, and purple boundary encloses the domain of all colors. The CIE tristimulus  $X$ ,  $Y$ , and  $Z$  do not belong to the spectral locus, and therefore they do not represent real colors. This is a direct consequence of the postulate that states that any visible color can be obtained by adding only positive quantities of  $X$ ,  $Y$ , and  $Z$  [195, 206–208].

Depending on the application's demands, pure colors or white-light-emitting materials might be requested. A white phosphor material should have color coordinates closer to the center of the CIE diagram (0.33;0.33), while the emission of a potential pure color-emitting material must be specified by pure (saturated) color coordinates, situated along the spectral locus. The CIE system enables us to specify such a color characteristic through the determination of the hue and saturation or purity [206–208]. The hue corresponds to the dominant wavelength, which can be determined by connecting with a straight line the color coordinates of the emission under analysis with the center of the diagram  $(x_w, y_w) = (0.33, 0.33)$ . Then, the line is prolonged until it intercepts the spectral locus. The intercepting point defines the dominant wavelength. The color purity indicates how close an emission color is from that dominant wavelength, that is, how close is a given emission color from the desired pure color. The color purity  $p$  can be quantitatively inferred by

$$p = \frac{y_c - y_w}{y_{\text{dom}} - y_w} \quad (9)$$

or

$$p = \frac{x_c - x_w}{x_{\text{dom}} - x_w} \quad (10)$$

where  $(x_{\text{dom}}, y_{\text{dom}})$ , and  $(x_c, y_c)$  are the chromaticity coordinates of the pure color and of the emission of the sample in analysis [206–208].

The chromaticity color coordinates  $(x, y)$  were calculated for all of the hybrid organic–inorganic materials discussed here, through the data available in the References. The following results include all of the hybrids from which it was possible to access the respective PL spectra in all of the visible range (380–720 nm).

The color emission arising from organic–inorganic hybrids modified by lanthanide ions can be easily tuned across the CIE diagram, either by changing chemical parameters—molecular weight of the organic precursors, type, and amount of the lanthanide-based salt or complexes, synthesis conditions ( $\text{H}_2\text{O}/\text{Si}$  ratio, nature and concentration of the catalyst, and type of solvent)—and physical parameters—excitation wavelength and temperature. Figure 21 exhibits the CIE diagram where the color coordinates represent the RT emission for the di-ureasils incorporating  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$  [166], the U(600)-based di-ureasils doped with  $\text{Eu}(\text{ClO}_4)_3$  [177], and for ethanolic solutions of the U(600) hybrid with  $\text{Tb}(\text{NO}_3)_3$  and with a mixture of  $\text{Tb}(\text{NO}_3)_3$  and 2,2-byp [185]. For the hybrids modified with  $\text{Eu}^{3+}$  ions, the emission color chromaticity is easily tuned from the blue to the orange–red spectral region, crossing the white color spectral area (Table 1). The emission color of the ethanolic solutions of the  $\text{Tb}^{3+}$ -based U(600) hybrids, under 365 nm excitation, is also closer to the center of the diagram. Exciting the  $\text{Tb}^{3+}$ -based U(600) hybrid with 2,2-byp around the wavelength that maximizes the lanthanide ion PL intensity, the respective CIE color coordinates are within the green spectral region, (0.27, 0.55) (Table 1).

The emission arising from the  $\text{SiO}_2/\text{SPM}:\text{Tb}$  complexes reported by Li et al. is also characterized by  $(x, y)$  color coordinates close to the center of the diagram, due to the overlap between the emission of carboxyl radicals in the hybrid host with that originating from the  $\text{Tb}^{3+}$  ions [189]. The CIE color coordinates vary from (0.28, 0.33) to (0.32, 0.35) for the  $\text{SiO}_2/\text{SPM}:\text{Tb}-o\text{-ABA}$  and  $\text{SiO}_2/\text{SPM}:\text{Tb}-p\text{-ABA}$ , respectively. The  $\text{SiO}_2/\text{SPM}:\text{Tb}-\text{BA}$  and  $\text{SiO}_2/\text{SPM}:\text{Tb}-m\text{-ABA}$  hybrid complexes have similar  $(x, y)$  color coordinates: (0.30, 0.33) and (0.30, 0.30), respectively (Table 2).

The color coordinates of the ormosils-type hybrids doped with  $\text{Eu}[(\text{phen})_2\text{Cl}_3]$  complexes and of the silica films proposed by Li et al., identified as  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$ , respectively [188], are pure colors within the red spectral region. This is a direct consequence of the fact that only the red intra- $4f^6$  lines could be detected in their PL spectra. The emission color of the  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  is described by  $(x, y)$  coordinates of (0.65, 0.35) and (0.60, 0.40), respectively, as shown in the inset of Figure 21 and in Table 2.

Similarly to the preceding case, the color coordinates of the hybrid materials in which the RE organic ligands are covalently grafted to the hybrid framework diverge from the center of the diagram, representing in most of the cases pure colors, namely, red ( $\text{Eu}^{3+}$ ) and green ( $\text{Tb}^{3+}$ ), as shown in

**Figure 21.** CIE chromaticity diagram showing the  $(x, y)$  emission color coordinates (calculated for the 2° standard observer) for the di-ureasils incorporating  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$ , (□)  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $40 \leq n \leq 400$ , and (○)  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $20 \leq n \leq 200$ , for the (★) U(600)-based di-ureasil doped with  $\text{Eu}(\text{ClO}_4)_3$ , and for ethanolic solutions of the U(600) hybrid with (◆)  $\text{Tb}(\text{NO}_3)_3$ , and with (▲) a mixture of  $\text{Tb}(\text{NO}_3)_3$  and 2,2-byp. The inset shows the CIE color coordinates for the (★)  $\text{Eu}(\text{PA})_3$  complexes, (◆) Hybrid I and (◇) Hybrid II,  $\text{Eu}^{3+}$ -activated organic–inorganic hybrid materials with four different dicarboxylic acids [(☆)  $\text{EuH}_1$ , (□)  $\text{EuH}_2$ , (○)  $\text{EuH}_3$ , and (△)  $\text{EuH}_4$ ], phosphine oxides bonded to  $\text{Si}(\text{OR})_3$  groups treated with anhydrous europium salts [(♣)  $\text{X}_A9a$  and (♠)  $\text{X}_A9b$ ], (\*),  $\text{SiO}_2/\text{SPM}:\text{terbium carbonyl complexes}$ , and (+)  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$ .

the inset of Figure 21. This derives directly from the efficient intramolecular energy conversion from the ligands to the lanthanide ion that disables the emission arising from the hybrid host and/or the ligands. Consequently, the emission color is dominated by the cation PL, contrary to the di-ureasils modified by  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$  and  $\text{Eu}(\text{ClO}_4)_3$ , whose overall emission appears white to the naked eye, due to the contribution of the hybrid host emitting centers to the PL spectra (see Section 4.1). The CIE color coordinates of these hybrid materials in which the RE organic ligands are covalently grafted to the hybrid skeleton are indicated in Table 3.

For the  $\text{Eu}^{3+}$ -based di-ureasil hybrids, it is possible to achieve a wide tuning of the emission color by changing the excitation wavelength from 330 to 465 nm, as the CIE diagram in Figure 22 shows. For instance, the color coordinates of two di-ureasil hybrids,  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $n = 20$  and 200, change from (0.27, 0.19) to (0.33, 0.56) and from (0.41, 0.26) to (0.42, 0.54), respectively (Table 4).

The calculation of the emission color coordinates regarding the emission properties of the  $\text{U}(2000)_{80} \cdot (\text{Eu}_{0.05}\text{Tb}_{0.15}\text{Tm}_{0.80})(\text{BTEFA})_3 \cdot 2\text{H}_2\text{O}$  hybrid as a function of

**Table 1.** CIE ( $x, y$ ) chromaticity color coordinates (calculated for the 2° standard observer) of the emission of the di-ureasils incorporating  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $40 \leq n \leq 400$ , and  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ ,  $20 \leq n \leq 200$ ,  $\text{U}(600)$ -based di-ureasil doped with  $\text{Eu}(\text{ClO}_4)_3$ , and ethanolic solutions of the  $\text{U}(600)$  hybrid with (◆)  $\text{Tb}(\text{NO}_3)_3$  and with (▲) a mixture of  $\text{Tb}(\text{NO}_3)_3$  and 2,2-byp. The excitation wavelength used is also presented,  $\lambda_x$ .

$\lambda_x$ (nm)	$\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$						$\text{U}(2000)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$						$\text{U}(600)_n\text{Eu}(\text{ClO}_4)_3$ [177]			$\text{U}(600)$ ethanolic solution with [185] $\text{Tb}(\text{NO}_3)_3$ and 2,2-byp		
	$n = 200$	$n = 80$	$n = 60$	$n = 40$	$n = 20$	$n = 400$	$n = 200$	$n = 80$	$n = 60$	$n = 40$	$n = 100$	$n = 15$	$n = 4$	$\text{Tb}(\text{NO}_3)_3$	$\text{Tb}(\text{NO}_3)_3$	$\text{Tb}(\text{NO}_3)_3$	and 2,2-byp	
$x$	0.36	0.23	0.22	0.35	0.21	0.21	0.23	0.25	0.23	0.39	0.29	0.32	0.36	0.20	0.21	0.27		
$y$	0.29	0.23	0.27	0.29	0.25	0.27	0.30	0.30	0.27	0.36	0.29	0.30	0.32	0.20	0.24	0.55		

the temperature (see Section 4.1) nicely illustrates the relative variation of the  $\text{Eu}^{3+}$  and  $\text{Tb}^{3+}$  characteristic luminescence. In fact, by changing the temperature between 200 and 300 K, it is possible to tune the emission color from the green (0.32, 0.58) to the red (0.47, 0.32) spectral regions [172], as Figure 23 illustrates (see also Table 5).

Although the above description of the hybrid's emission features reveals that they may be considered innovative and versatile white-light phosphors, an accurate evaluation of the potential technological impact of these materials as competitive new hybrid multiwavelength phosphors requires knowledge of their external emission quantum yields.

## 6. ABSOLUTE EMISSION QUANTUM YIELDS

There are few reports dealing with the determination of the absolute emission quantum yields in siloxane-based organic–inorganic hybrids modified by RE ions [170, 209]. For  $\text{Ce}^{3+}$ -based hybrids, Isakawi et al. [209] reported external quantum yield values similar to those determined for di-ureasil hybrids incorporating  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$ , 4.6–11.0% [170]. Higher quantum yields, 17.0–27.0%, were found for distinct organic–inorganic hybrids formed by incorporating the  $\text{Eu}^{3+}$   $\beta$ -diketonate complexes in semiconducting polymers [91].

The absolute emission quantum yields  $\phi$ , defined as the ratio between the number of emitted photons and the number of absorbed ones, were measured for the di-ureasils incorporating  $\text{Eu}(\text{CF}_3\text{SO}_3)_3$  by the experimental technique for powdered samples described by Wrighton et al. [210], and were calculated using the following expression:

$$\phi = \frac{A}{R_S - R_H} \quad (11)$$

where  $A$  is the area under the sample's emission spectrum, and  $R_S$  and  $R_H$  are the diffuse reflectance of the reflecting standard (designated as white standard) and of the samples, respectively. Both the reflectance diffuse and the emission spectra were detected with a 24.5° angle with respect to the incident light. The excitation monochromator slits were set in such a way that only the sample was illuminated. These experimental conditions were kept constant for all of the di-ureasil and di-urethanesil hybrids. The experimental errors in the quantum yield values associated with this technique were estimated within 25% [210].

There are several compounds that can be used as white standards, the more common ones being KCl, MgO,  $\text{Na}_2\text{SO}_4$ , and KBr [210]. In our case, we used the high-purity KBr that was maintained in an oven prior to use due to its hygroscopic nature. We chose KBr because its powder size and packing fraction are similar to the size and packing fraction of the hybrid's powder, which is a crucial factor since the intensity of the diffuse reflectance depends on it. To ensure a similar powder size and packing fraction, we chose a wavelength  $\lambda_i$  that corresponded to an energy that was not absorbed by the hybrids, and the diffuse reflectance around  $\lambda_i$  was measured for the standard  $R_S$  and for the hybrids  $R_H$  ( $\lambda_i$  was set equal to 720 nm). The powder samples were grounded until  $R_S$  overlapped  $R_H$ , indicating that we had achieved the same powder size and packing fraction. Figure 24A shows  $R_S$  overlapping  $R_H$  for the  $\text{U}(600)_{80}(\text{EuCF}_3\text{SO}_3)_3$  di-ureasil. Then, both the standard diffuse reflectance and the emission were measured with respect to different excitation wavelengths, corresponding to: (1) the maximum intensity of the hybrid's backbone excitation spectra, (2) around the maximum intensity of the LMCT band, and (3) three wavelengths related with direct excitation of  $\text{Eu}^{3+}$  levels, namely, 395 nm ( ${}^5\text{L}_6$ ),

**Table 2.** CIE ( $x, y$ ) chromaticity color coordinates (calculated for the 2° standard observer) of the emission of the  $\text{SiO}_2/\text{SPM}$ : terbium carbonyl complexes,  $\text{SiO}_2/\text{SPM}:\text{Tb-}o\text{-ABA}$ ,  $\text{SiO}_2/\text{SPM}:\text{Tb-}p\text{-ABA}$ ,  $\text{SiO}_2/\text{SPM}:\text{Tb-BA}$ , and  $\text{SiO}_2/\text{SPM}:\text{Tb-}m\text{-ABA}$  and of the ormosils-type hybrids and silica films,  $\text{SiO}_2/\text{SPM}:\text{Eu}[(\text{phen})_2]^{3+}$  and  $\text{SiO}_2:\text{Eu}[(\text{phen})_2]^{3+}$ , respectively. The excitation wavelength used is also presented,  $\lambda_x$ .

$x$	0.35	0.35	0.37	0.48	0.24	0.39	0.38	0.38	0.41	0.42	0.46
$y$	0.55	0.55	0.55	0.34	0.56	0.54	0.54	0.54	0.54	0.54	0.53

420 nm ( $^5\text{D}_3$ ), and 465 nm ( $^5\text{D}_2$ ). Figure 24B–D shows the diffuse reflectance curves for the standard and the  $\text{U}(600)_{80}(\text{EuCF}_3\text{SO}_3)_3$  di-ureasil for three different excitation wavelengths. The number of absorbed photons  $R_S - R_H$  corresponds to the shadowed area in Figure 24B–D.

For both di-ureasil series, and independently of the  $\text{Eu}^{3+}$  concentration,  $\phi$  presents the same trend, that is, when the excitation wavelength varies between 340 and 500 nm, a maximum value is measured around 395 nm. This wavelength maximizes the emission quantum yield because it corresponds to the greater overlap between the excitation spectra of the two hybrid's emitting centres (see Fig. 25A). Figure 25B shows the PL quantum yield values for the two series of di-ureasils for that excitation wavelength (395 nm). In the high-molecular-weight di-ureasils,

the quantum yield values undergo a decrease from 13.0 ( $n = 400$ ) to 1.4% ( $n = 40$ ) [170]. In these hybrids, excluding the less doped sample ( $n = 400$ ), lower quantum yield values were measured when compared to the undoped hybrid that presents  $\phi \approx 9.0\%$  [194, 195]. The quantum yield values for  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$  ( $n \geq 40$ ) are similar to the one found for the undoped  $\text{U}(600)$  di-ureasil, 7.0% [194, 195], within the experimental error. However, the more concentrated sample ( $n = 20$ ) presents a lower quantum yield value of  $\approx 2.6\%$  [170]. The decrease in the emission quantum yield observed for the two di-ureasil series (Fig. 25B) as the  $\text{Eu}^{3+}$  amount incorporated in the hybrid host increases is clearly evidence of energy transfer between the emitting centers of the matrix (donors) and the metal ions (acceptors) [170, 212]. We will return to this point in the next section.

**Figure 22.** CIE chromaticity diagram showing the ( $x, y$ ) emission color coordinates (calculated for the 2° standard observer) for the  $\text{U}(600)_n\text{Eu}(\text{CF}_3\text{SO}_3)_3$ , ( $\Delta$ )  $n = 20$  and ( $\blacklozenge$ )  $n = 200$ . The arrows indicate the variation of the excitation wavelength between 330 and 465 nm. Reprinted with permission from [170], R. A. Sá Ferreira et al., *Chem. Mater.* 13, 2991 (2001). © 2001, Elsevier Science.

## 7. ENERGY-TRANSFER MECHANISMS

One of the most important features regarding hybrid-host-to-metal ion energy-transfer processes in the di-ureasils is that the efficiency of such processes depends noticeably on the ion local coordination site. According to the work of Reinsfeld and Jørgensen on oxide, phosphate, and fluoride glasses containing RE elements [212], the efficiency of the energy transfer between two species can be evaluated from different experimental data, namely, the donor measured lifetime and absolute emission quantum yield, in the presence and absence of the acceptor, and by the emission of the acceptor ion excited at the donor absorption band, together with the emission excited via the acceptor (see [212, p. 61]). In the  $\text{Nd}^{3+}$ - and  $\text{Eu}^{3+}$ -based di-ureasil cases, it was possible to determine the energy-transfer efficiency through the donor measured lifetime and absolute emission quantum yield, in the presence and absence of the acceptor, respectively, by the related following equations [212]:

$$\eta = \left[ 1 - \frac{\tau_D}{\tau_0^D} \right] \quad (12)$$

and

$$\eta = \left[ 1 - \frac{\phi_D}{\phi_0^D} \right] \quad (13)$$

where  $\tau_0$ ,  $\phi_0$ ,  $\tau_0^D$ , and  $\phi_0^D$  represent the donor measured lifetime and absolute emission quantum yield in the presence and absence of the acceptor, respectively [212].

**Table 4.** CIE ( $x$ ,  $y$ ) chromaticity color coordinates (calculated for the 2° standard observer) of the emission of the  $U(600)_nEu(CF_3SO_3)_3$ ,  $n = 20, 200$  at different excitation wavelengths  $\lambda_x$ .

$\lambda_x$ (nm)	U(600) <sub>20</sub> Eu(CF <sub>3</sub> SO <sub>3</sub> ) <sub>3</sub> [170]							U(600) <sub>200</sub> Eu(CF <sub>3</sub> SO <sub>3</sub> ) <sub>3</sub> [170]						
	330	350	365	375	395	420	465	330	350	365	375	395	420	465
$x$	0.41	0.35	0.31	0.30	0.36	0.25	0.42	0.27	0.24	0.22	0.21	0.21	0.23	0.33
$y$	0.25	0.23	0.23	0.24	0.28	0.37	0.54	0.19	0.18	0.20	0.21	0.25	0.34	0.56

It is important to note that, in the case of the  $Eu^{3+}$ -based di-ureasils, we could achieve only a mean value for the efficiency of the energy transfer  $\eta$  using Eq. (13) since we do not know the relative contribution of each host-emitting center. However, as in the  $Nd^{3+}$ -based hybrids, it was possible to measure the lifetime of the NH groups and siliceous nanodomain emitting levels independently; we could separately evaluate the respective contribution for the energy-transfer mechanisms through Eq. (12) [173, 176].

We estimated the efficiency of the energy transfer for all of the nanohybrids of both  $Eu^{3+}$ -based di-ureasil series where a decrease of the quantum yield value was observed with respect to the value measured for the corresponding undoped xerogels. Thus, whereas for the  $U(2000)_nEu(CF_3SO_3)_3$  series the  $n = 400$  sample is the only one where energy-transfer processes seem to be unimportant (as clearly expressed by the increase of the emission quantum yield with respect to that of the undoped hybrid), for the  $U(600)_nEu(CF_3SO_3)_3$  hybrids, the energy-transfer

mechanisms are activated only at  $n = 20$  (Fig. 25B). For the  $U(2000)_nEu(CF_3SO_3)_3$  di-ureasils, the efficiency of the energy transfer increases from 27 to 84% with the increase in the europium content from  $n = 200$  to 40. The value found for the  $U(600)_{20}Eu(CF_3SO_3)_3$  nanocomposite is 63%. These values were calculated for an excitation wavelength of 395 nm, and are independent of the excitation wavelength used [170]. The energy-transfer efficiency in the di-ureasils modified by  $Nd^{3+}$  ions was calculated for all of the di-ureasils with concentrations lower than  $n \geq 40$  since, for higher concentrations, it was not possible to detect the experimental lifetimes of the NH and siliceous nanodomain emitting levels (see Section 4.1). For the  $Nd^{3+}$ -based  $U(900)$  and  $U(2000)$  di-ureasils, the energy-transfer efficiency values from the NH groups  $\eta_{NH}$  and siliceous nanodomains  $\eta_{Si}$  to the  $Nd^{3+}$  ions ranges from 0.16 to 0.83 and 0.05 to 0.86, respectively [176, Table 1].

As noted for the  $Eu^{3+}$ -based hybrids, the cation local coordination site controls the activation of the energy transfer mechanisms. Thus, it is easy to explain why the energy-transfer mechanisms are active in both  $Nd^{3+}$ -based di-ureasils and for the whole concentration range studied since the cations are coordinated to the oxygen atoms of the carbonyl groups of the urea linkages [169, 176]. In both series, the energy-transfer efficiency increases with the increase of the  $Nd^{3+}$  concentration, as more cations are located near the hybrid host emitting centers [176]. We should stress that, although the concentration range expressed in terms of  $n$  is equal for both the  $U(900)$ - and  $U(2000)$ -based hybrids, the  $Nd^{3+}$  content is greater in the latter materials.

In order to verify if the energy transfer occurring between the hybrid host and the  $Nd^{3+}$  cations effectively contributes to an enhancement of the  $Nd^{3+}$  infrared luminescence, the spectra were detected under different excitation wavelengths: (1) 514.5 nm, direct excitation into the intra- $4f^3$  levels, ( $^5G_{9/2}$ ), and (2) 475.9 nm, which corresponds to the preferential excitation of the hybrid host emitting centers, and thus, nonresonant with any one of the lanthanide ion levels [176]. Regardless of the excitation wavelength used, the infrared spectra are similar to the ones displayed in Figure 9A. In order to allow a qualitative comparison between the integrated intensity of each spectrum measured under different excitation wavelengths, all of the spectra were measured consecutively, and the experimental conditions were kept constant. As Figure 26 shows, the emission-integrated intensity depends on the excitation wavelength used, in such a way that the excitation via the di-ureasil host contributes to increase the  $Nd^{3+}$  infrared emission [176].

The possible energy-transfer paths between the cation ( $Eu^{3+}$  and  $Nd^{3+}$ ), the hybrid host emitting centers, and

$y$	0.54	0.54	0.54	0.54	0.54	0.51	0.48	0.42	0.37	0.37

the LMCT states observed in the case of the  $Eu^{3+}$ -based di-ureasils is illustrated in Figure 27 for the latter hybrids. Figure 27 shows a schematic illustration of the LMCT states, hybrid's host emitting centers, and  $Eu^{3+}$  levels for  $U(2000)_n \cdot Eu(CF_3SO_3)_3$  (Fig. 27A) and  $U(600)_n \cdot Eu(CF_3SO_3)_3$  (Fig. 27B) di-ureasils. For the LMCT band and the hybrid's host emitting levels, the diagram depicts the lowest and the highest energy limits obtained for the different excitation wavelengths (300–420 nm) and for the  $Eu^{3+}$  content for which energy transfer between the hybrid host and the cations occurs.

The involvement of the di-ureasil emitting centers in the luminescent properties of the  $U(2000)$  hybrid codoped with  $Tb^{3+}$ ,  $Eu^{3+}$ , and  $Tm^{3+}$ , namely, the energy transfer from the host to the lanthanide ions, was also demonstrated [172]. The  $Tb^{3+} \ ^5D_4$  lifetime dependence with the variation of the temperature was described by a thermally activated nonradiative mechanism. In the case of the lanthanide ions, this mechanism is usually related to the LMCT states, but for  $U(2000)$  codoped with  $Tb^{3+}$ ,  $Eu^{3+}$ , and  $Tm^{3+}$ , the deexcitation occurs via the hybrid host emitting levels [172, 213]. The Mott–Seitz model approximately described the probability of nonradiative deexcitation of the  $^5D_4$  excited level with the temperature variation through the following expression:

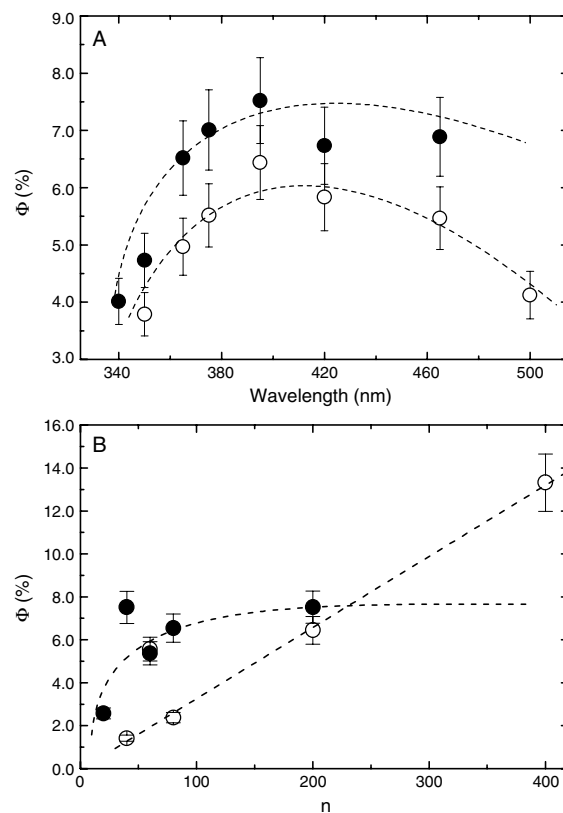

$$\tau^{-1} = \tau_0^{-1} + k \exp(-\Delta E/k_B T) \quad (14)$$

where  $\tau$  is the experimental lifetime,  $\tau_0$  is the lifetime at 0 K,  $k$  is the migration energy rate,  $\Delta E$  is the energy gap between the  $^5D_4$  level and the deexcitation levels, and  $k_B$  is the Boltzmann constant. The obtained activation energy is  $1365.5 \text{ cm}^{-1}$ , which is in agreement with the hypothesis that the energy levels involved in the nonradiative thermally activated deexcitation are the hybrid host emitting levels (siliceous nanodomains and NH groups) [172]. In fact, for

**Figure 24.** Room-temperature diffuse reflectance for the  $U(600)_{80} \cdot (EuCF_3SO_3)_3$  di-ureasil (solid line and solid circles) and KBr (solid line) for: (A) 720 nm, (B) 355 nm, (C) 395 nm, and (D) 420 nm excitation wavelengths.

the excitation wavelength that favors the excitation of the di-ureasil emitting centers (420 nm), the PL spectrum is composed of not only the intra- $4f^6$  lines, but also of the hybrid host characteristic band (400–600 nm) [172]. In spite of the fact that the value determined through Eq. (14) for the activation energy is underestimated, the Mott–Seitz model can be generally applied to describe the  $^5D_4 \rightarrow ^7F_6$  quenching for temperatures between 180 and 300 K [172].

For hybrid materials in which the RE organic ligands are covalently grafted to the hybrid framework, the energy-transfer mechanisms involve predominantly energy transfer from the ligand excited states to the energy levels of the lanthanide ions. This evidence is clearly demonstrated by the presence of a large broad band in the UV/Vis spectral region in the PLE spectra of such hybrids. As noted in
