## CONTENTS

## 1. INTRODUCTION

Amorphous ferromagnetic glasses are noncrystallized ferromagnetic alloys free from defects such as grain boundaries, precipitates, or phase segregation [1, 2]. The amorphous structure of these materials gives rise to unique magnetic and mechanical properties, such as high mechanical strength [3], large magnetoelastic coupling, large magnetostriction [4], and the so-called giant magnetoimpedance effect (GMI) [5], which make them suitable for various sensor applications. The large magnetostriction allows the permeability of the materials to significantly change with applied stress and also causes the ferromagnetic glasses to exhibit a strong mechanical vibration when excited by a time-varying magnetic field. The high degree of magnetoelastic coupling allows efficient conversion between mechanical and electrical energies [6], so the response of the ferromagnetic glasses can be remotely detected by measuring the magnetic flux change. Furthermore, the GMI effect, wherein the electrical impedance of a ferromagnetic glass significantly changes with applied magnetic field, allows them to be used as ultrasensitive magnetic field sensors. Since there are few defects in the amorphous glass to restrict magnetic domain wall motion, magnetically soft ferromagnetic glasses have properties useful in sensor design including low coercivity, low hysteresis loss, and high permeability. The soft magnetic properties increase the performance and the stability of ferromagnetic glass-based sensors by allowing them to have good reversibility with little hysteresis in response to applied mechanical stresses and magnetic fields.

Ferromagnetic glasses are fabricated by rapid quenching techniques (e.g., melt-spinning) to prevent crystallization. Material properties are largely dependent upon the alloy composition, generally a combination of transition metals, rare-earth metals, and glass-forming metalloids. The lack of long-range order in the amorphous glasses eliminates the crystalline anisotropy energy, rendering them magnetically soft. However, inhomogeneous cooling of the alloy melt creates internal stresses that increase stress anisotropy energy. Since the amorphous nanostructure of these materials allows atomic rearrangement at a temperature far below crystallization, the stress anisotropy can be removed by relaxing the materials with low-field annealing at a moderate temperature. Alternatively, depending upon the application an anisotropy field can be introduced in a ferromagnetic glass by annealing under applied stress or magnetic field at moderate temperatures [7–9]. For certain amorphous alloys, annealing can be preformed above the crystallization temperature (500–900 °C) to create nanocrystalline structures of 10–20 nm in size for enhancing the soft magnetic properties of the materials [10].

Although there are many types of ferromagnetic glasses with a range of mechanical and magnetic properties, as dependent upon the composition and annealing history, the most generally useful type of ferromagnetic glass for sensor applications is magnetically soft transition-metalloid-based alloys with a high Fe or Co content. For example Fe-rich alloys have magnetostriction constants as high as $\lambda_S \approx 10^{-5}$, and magnetoelastic couplings as high as 0.98, while Co-rich transition-metalloid alloys have low magnetostriction on the order of $10^{-7}$. Rare-earth amorphous alloys, which exhibit large magnetostriction as high as $10^{-4}$, are useful as transducers since a small applied field can causes a large change in the material dimensions. Some of the commercially available ferromagnetic glasses [11] for sensor applications are the Fe-rich Metglas 2605SC ($Fe_{81}B_{13.5}Si_{3.5}C_2$) and 2826MB ($Fe_{40}Ni_{38}Mo_4B_{18}$) that have a magnetostriction coefficient

on the order of $10^{-5}$ and a high magnetoelastic coupling coefficient, and the Vitrovac amorphous alloys that have a near zero magnetostriction and excellent soft magnetic properties ($B_S = 0.55$ T, $\mu_{max} = 10^5$).

Ferromagnetic glasses were initially used as the sensing materials for induction-based sensors to measure stress/strain and torque [12], magnetic field [13], and displacement [14] since their permeability varies with applied stress and field. These sensors, usually composed of solenoids loaded with ferromagnetic glass cores, are simple in design, stable over a wide range of temperature, and have a good linearity and low hysteresis.

Ferromagnetic glasses are also used as field and stress sensors based on the GMI effect. The GMI magnetic sensors are highly sensitive, with maximum impedance variation reaching 400%. Ferromagnetic glasses have been used to construct magnetostrictive delay lines (MDL) for the measurement of stress, torque, and displacement [15–22]. The MDL sensor is usually a long ferromagnetic glass wire or ribbon surrounded with an excitation coil at one end and a sensing coil at the opposite end. An acoustic wave is excited by passing a voltage pulse to the excitation coil and is captured by a sensing coil as an induced voltage. The parameters of interest, such as stress, torque, and weight, are determined from the attenuation of the acoustic wave, which is obtained by normalizing the measured voltage amplitude to the excitation voltage amplitude.

Magnetoelastic resonant sensors, which are based on the change in the magnetoelastic resonant frequency of a ferromagnetic glass ribbon in response to applied stress and field, have become popular in the past decade due to their remote-query capability, simple design, and low cost. These sensors have been used to measure pressure [23], liquid viscosity and density [24], liquid flow velocity [25], temperature [26], and thin-film elasticity [27]. Magnetoelastic resonance chemical and gas sensors have also been built by applying a layer of mass-changing chemically responsive material, the mass loading of which changes the mechanical resonant frequency of the sensor, as does the elasticity of the applied coating [28–33].

Ferromagnetic glass thin films are also used as the active layer of a magnetic surface acoustic wave (MSAW) sensor [34]. Due to the stress and field dependencies in the ferromagnetic glass, the MSAW sensor can be used to measure stress, magnetic field, or displacement. Recently, a viscosity sensor [35] was built based on the spontaneous mechanical rotation of a large magnetostrictive ferromagnetic glass wire when subjected to an ac magnetic field.

## 2. PRINCIPLES OF MAGNETISM

In this section the fundamental principles of magnetism and magnetic materials are reviewed. It begins by introducing the concept and origin of magnetic fields and fluxes, followed by a discussion on the constitutive relations and some basic magnetism principles, such as Faraday's induction law, Lorentz's force equation, and Maxwell's equations. Different types of magnetic materials are then introduced. Intrinsic properties of ferromagnetic materials, such as magnetic domains, anisotropy, and magnetization processes, are detailed.

## 2.1. Origin of Magnetic Fields

Although a magnetic compass was apparently used over 4000 years ago [see for example T. C. Lucretius, *On The Nature of the Universe* ($\approx$100 B.C.), translated by R. Latham, Penguin Books, New York, 1992], the mechanism and principles of magnetism were not put to paper until 1819, when Oersted [36] discovered that an electric current produces a magnetic field, resulting in the modern field of magnetism. The reader requiring greater knowledge on the subject of magnetism is encouraged to seek one or more of the many excellent books extensively dealing with the topic of magnetism that have been published over the past 50 years [37–43].

### 2.1.1. Magnetic Dipoles and Moments

Magnetic fields originate from electrical charges in motion, be they electrical currents (free moving electrons) flowing in a conductor, or the orbital motions of electrons (the so-called "Amperian currents"). Since magnetic fields are generated by electrical currents, the basic unit of the magnetic field, $H$, is amperes per meter (A/m). It is common to treat magnetic fields as lines of force that originate and terminate from magnetic poles or magnetic charges, just like those in an electrostatic system. However, magnetic poles exist as opposing dipoles—there are no magnetic monopoles. Figure 1 is a simple illustration of the magnetic fields generated by a permanent magnet, represented by the lines of force originated from the north (N) pole and terminated at the south (S) pole; the field lines form a closed loop inside the magnet from the S to N pole.

Similar to electrical charges, physically separating two magnetic poles generates a force. For two magnetic poles separated by a distance $l$ the force between them is quantified by the Coulomb magnetic moment $p_m$ given in volt-second-meters (V · s · m) as

$$p_m = Q_m l \tag{1}$$

where $Q_m$ is the Coulomb magnetic pole strength, in Webers (Wb) or volt-seconds (V · s), which depends on the magnetic properties of the materials. Under a homogeneous $H$ field,

**Figure 1.** Magnetic field represented by lines of force originating from the N pole and terminated at the S pole.

the magnetic moment experiences a torque $T$:

$$T = p_m \times H \qquad (2)$$

Equation (2) describes the fundamental principle of the first magnetic sensor, the compass; earth's magnetic generates a torque on the needle shaped compass magnet and orients it parallel to the direction of earth's field along a north–south direction.

### 2.1.2. Magnetic Fields around Current-Carrying Conductors

A current-carrying conductor consists of moving electrical charges that generate a magnetic field. The fundamental principle that describes the generation of magnetic fields by an electrical current is the Biot–Savart law, an empirical equation discovered in 1820. According to the Biot–Savart law, the field contributed by a segment of current-carrying conductor with length $\delta l$ is

$$\delta H = \frac{I \delta l \times u}{4\pi r^2} \qquad (3)$$

where $I$ is the current in the conductor segment, $u$ is the unit vector of the current direction, and $\delta H$ is the contribution to the magnetic field at $r$ due to the current element $I \delta l$.

Figure 2 illustrates the generation of magnetic fields with conduction currents. A flowing current in a conductor loop generates a magnetic field $H$ passing through the loop, while a current in a straight wire generates a circumferential field around the wire. The direction of the $H$ field is given by the right-hand rule as illustrated in Figure 2.

Although the Biot–Savart law provides great understanding on how electrical currents generate magnetic fields, it can only be solved analytically when the current conductor contains high symmetry and the observation point is at the symmetry axis. For example, the field generated by a long straight wire at a distance $r$ is given as $H = I/2\pi r$, the field along the axis of an $N$-turn solenoid with length $l$ is $H = NI/l$, and the field along the $z$-axis of a circular loop of diameter $d$ that is centered on the $xy$-plane is $H = Id^2(d^2 + 4z^2)^{-3/2}$.

## 2.2. Magnetic Principles

This section shows the connection between magnetic fields and fluxes in vacuum and in magnetic materials. This section also introduces the fundamental magnetic principles that describe the relations between magnetic and electric

**Figure 2.** A flowing current in a loop or a straight wire generates a magnetic field $H$, the direction of which is given by the right-hand rule.

quantities, such as Ampere's law [44] and Faraday's law [45]. Lorentz's force equation, which links magnetic fluxes to force and torque, is also discussed in this section.

### 2.2.1. Magnetic Constitutive Relations

In the MKS unit system, the vacuum magnetic flux density $B$, in Webers per meter$^2$ (Wb/m$^2$) or volt-seconds per meter$^2$ (V · s/m$^2$), is related to $H$ as

$$B = \mu_0 H \qquad (4)$$

where $\mu_0$ is the free space magnetic permeability that has a value of $4\pi \times 10^{-7}$ Wb/A · m. When a magnetic field passes through a magnetic material, the magnetic dipoles in the material tend to align with the applied field. This phenomenon is called magnetization, and the intensity of magnetization is generally represented by $M$ having the same unit basis as $H$. The direction and intensity of the magnetization depend on the material: for nonmagnetic materials the value is close to zero, but for ferromagnetic materials the number can reach $10^6$ (see Section 2.4). The magnetization process effectively increases the density of magnetic fields in the magnetic material, so the flux density inside the material becomes

$$B = \mu_0(H + M) \qquad (5)$$

To simplify Eq. (5) so the flux $B$ only depends on the applied field $H$, the magnetic permeability $\mu$ (in Wb/A · m) and the relative permeability $\mu_r$ (unitless) are introduced as

$$B = \mu H = \mu_r \mu_0 H \qquad (6)$$

Comparing Eqs. (5) and (6), the permeability $\mu$ can be expressed as

$$\mu = \mu_0(1 + M/H) = \mu_0(1 + \chi) \qquad (7)$$

The ratio of magnetization to applied field $M/H$ is defined as the relative magnetic susceptibility $\chi$ (unitless). Most magnetic materials used for engineering applications are ferromagnetic materials with large magnetization $M$. As a result, the susceptibility and relative permeability are often treated as approximately equal ($\mu_r \approx \chi$).

At high frequency, many materials dissipate field energies as the field passes through them. To compensate for the field dissipation, the relative complex permeability $\mu_r^*$ is used,

$$\mu_r^* = \mu_r' - j\mu_r'' \qquad (8)$$

where the real part represents the magnetization and the imaginary part represents the energy loss. For anisotropic materials where the permeability varies with directions, $\mu_r^*$ is replaced by the relative complex permeability tensor $\bar{\mu}_r^* = \bar{\mu}_r' - j\bar{\mu}_r''$.

### 2.2.2. Ampere's Circuital Law

Consider a long circular conductor carrying a current $I$. By the Biot–Savart law, the magnetic field integrated along a circular path outside the conductor with radius $r$ can be

expressed as

$$\oint_c H \cdot dl = \frac{I}{2\pi r} \oint_c dl = I \tag{9}$$

Replacing the current $I$ with the current density $J_c$ in the conductor, Eq. (9) becomes

$$\oint_c H \cdot dl = \int_s J_c \cdot ds \tag{10}$$

Equation (10) is the Ampere's circuital law, which states the line integral of $H$ around a closed path is equal to the total current crossing any surface bounded by the line integral path.

### 2.2.3. Faraday's Induction Law

According to Faraday's induction law, an electromotive force (emf) will be induced in a closed-path electrical circuit if there is a change of magnetic flux linking to the circuit. In equation form, Faraday's law is expressed as

$$\text{emf} = -A\frac{dB}{dt} \tag{11}$$

where $A$ is the surface area, and $B$ is the magnetic flux. The negative sign in the equation is a result of Lenz's law, which states the direction of the induced voltage is such that the induced flux opposes the incident flux. Faraday's induction law is demonstrated in Figure 3 with a moving bar magnet and a closed loop. The movement of the permanent magnet results in a change in the magnetic flux linking to the loop, causing an induction voltage in the loop with a sense that would produce a current whose magnetic field opposes the flux change. Faraday's induction law is important for induction and search coil sensors, which detect magnetic fields by the induction voltage.

### 2.2.4. Lorentz's Force in Magnetic Fields

According to Lorentz's force equation, an electric charge $q_e$ traveling at a velocity $v$ inside flux $B$ experiences a force $F$ perpendicular to $B$ and $v$:

$$F = q_e(v \times B) \tag{12}$$

For a current $I$ flowing in a closed loop of area $A$, a torque $T$ appears on the conductor according to the Lorentz's force:

$$T = IA \times B \tag{13}$$

**Figure 3.** Illustration of Faraday's induction law. The decrease in the magnetic flux creates an induced emf, which produces a current $I$ that in turn generates an induced flux opposing to the initial change.

The term $IA$ is defined as the magnetic moment $\mu_m$. Note the similarity between the magnetic moment $\mu_m$ and the Coulomb magnetic moment $p_m$ in Eq. (13) and Eq. (2), respectively. In vacuum, they are scaled by the free space permeability $\mu_0$. Equation (13), similar to Eq. (2), describes the operational principle of electrical motors that generate rotational motion by passing a current within a magnetic field.

### 2.2.5. Maxwell's Equations

Maxwell combined the observations discovered by Ampere, Faraday, and Gauss into a final form for governing electric and magnetic fields, charges, and currents [46]. These equations, known as the Maxwell's equations, are useful for understanding magnetism and electromagnetism. In differential form, Maxwell's equations can be written as

$$\nabla \times E = -\frac{\partial B}{\partial t} \tag{14}$$

$$\nabla \times H = J_C + \frac{\partial D}{\partial t} \tag{15}$$

$$\nabla \cdot D = \rho_{es} \tag{16}$$

$$\nabla \cdot B = 0 \tag{17}$$

where $J_c$ is the conduction current and $\rho_{es}$ is the surface charge density. A more familiar form of Faraday's induction law can be obtained from Eq. (14) by integrating over an open surface $S$ bounded by a curve $C$ and applying Stoke's theorem on the left-hand side as

$$\oint_c E \cdot dl = -\frac{\partial}{\partial t} \int_s B \cdot ds \tag{18}$$

Equation (18) is essentially identical to (11) because emf is defined as $\int E \cdot dl$. Applying Stokes' theorem on Eq. (15) yields

$$\oint_c H \cdot dl = \int_s J_c \cdot ds + \frac{\partial}{\partial t} \int_s B \cdot ds \tag{19}$$

Equation (19) is identical to Ampere's law except for the second term on the right-hand side, which is the displacement current added by Maxwell to complete Ampere's law under ac conditions. Equations (16) and (17) are Gauss' electric and magnetic field laws, which state that electrical charges can operate as sources or sinks, originating or terminating electric flux, while magnetic flux forms closed loops with no known sources and sinks.

## 2.3. Types of Magnetism

All materials exhibit unique magnetization behavior and from the magnetization profiles can be categorized. Among the categories, diamagnetic and paramagnetic materials are considered as "weak magnetic" materials because the magnetization is relatively small, $\mu \approx \mu_0$ and $\chi \approx 0$ (although there are exceptions such as superconductors that exhibit a perfect diamagnetism, $\chi \approx -1$). Ferromagnetic and ferrimagnetic materials exhibit large magnetization with applied field; for some ferromagnetic materials $\mu_r$ can reach $\approx 10^6$.

### 2.3.1. Diamagnetism

All materials exhibit diamagnetism; however, the effect of diamagnetism is small and often shadowed by other magnetic effects. A diamagnetic material has the ability to "repel" magnetic fields, with the flux density in diamagnetic materials actually being less than in vacuum. Classically, diamagnetism is explained by the reduction of the electron velocity due to an external magnetic field. To understand diamagnetism, first consider an atom with an electron moving clockwise in an orbit perpendicular to an applied field. Since the electron carries an electrical charge, the orbital motion of the electron is equivalent to a current on a conductor loop. By Faraday's law, the increase in the applied field generates an induction current on the loop to produce an opposing field. For an orbiting electron the opposing field is generated by decreasing the electron velocity. Now consider another electron orbit adjacent to this orbit, with its plane parallel to the first one but the electron moving counterclockwise. In the absence of an external applied field, the moments of these two electrons cancel each other, yielding zero net moment. As the applied field increases, both orbits produce a magnetic moment opposing the applied field. The classical explanation for diamagnetism is illustrated in Figure 4.

For a diamagnetic material with $Z$ electrons per atom, $N$ atoms per cubic meter, and at effective equilibrium distance of $2r$, the susceptibility $\chi$ is given by

$$\chi = -\mu_0 N \frac{q_e^2 Z \langle r^2 \rangle}{6 m_e} \tag{20}$$

where $q_e$ is the electron charge and $m_e$ is the electron mass. For most diamagnetic materials, the value of $\chi$ is very small, about $10^{-5}$. As a result, diamagnetic materials have almost no effect on magnetic fields under most conditions, and they are commonly used as materials that do not disturb magnetic fields. Examples of diamagnetic materials are noble gases such as helium, neon, and argon, diatomic gases such as hydrogen and nitrogen, ionic solids such as sodium chloride (NaCl), and almost all organic compounds. Many metals also exhibit diamagnetic properties, for example, copper, zinc, silver, cadmium, gold, mercury, lead, and bismuth.

Superconductors exhibit the most unusual diamagnetic behavior. Superconductors are typically metals such as lead and tantalum, or compounds such as $Nb_3Sn$. At normal operating temperatures these materials are either diamagnetic or paramagnetic. However, when they are cooled to
a critical temperature, they repel all magnetic flux by generating a thin layer of nondissipating surface currents. This effect is known as the Meissner effect. Ideally, superconductors have a perfect diamagnetism, which is $\chi = -1$. Superconductors such as lead and tantalum exhibit perfect diamagnetism. Superconductive diamagnetic materials are the key elements for superconducting quantum interference device field sensors.

### 2.3.2. Paramagnetism

Paramagnetic materials are composed of atoms or molecules that have a net magnetic moment because the spin and orbital moments of electrons do not completely cancel out. In the absence of applied fields, the magnetic moments are oriented randomly and thus macroscopically the net moment of a paramagnetic material is zero. When a magnetic field is applied on the material, the magnetic moments tend to align with the field. However, thermal agitation in the atoms or molecules opposes this tendency and tries to keep the moments in random states. This will result in a partial alignment of the magnetic moments; thus a small positive susceptibility is observed in paramagnetic materials. Increasing temperature increases the thermal energy in the atoms or molecules and therefore reduces the susceptibility.

In general, the magnetization $M$ in a paramagnetic material is nonlinear, which can be given by the Langevin function $L$ with $s = \mu_m B / k_B T$ as

$$M = N\mu_m \frac{s(e^s + e^{-s}) - (e^s - e^{-s})}{(e^s - e^{-s})} = N\mu_m L(s) \tag{21}$$

where $\mu_m$ is the magnetic moment of each atom, $T$ is the temperature, $k_B$ is the Boltzmann constant ($k_B = 5.38 \times 10^{-23}$), and $N$ is the number of atoms. In room temperature ($T \approx 300$ K) and at a moderate field $B \approx 1$ T, which is the operation condition for most technical applications, $s \approx 0$ and Eq. (21) becomes

$$\chi = \frac{\mu_m^2 N \mu_0}{3 k_B T} = \frac{C}{T} \tag{22}$$

Equations (21) and (22) are the results from classical Langevin paramagnetism [47]. The paramagnetic behavior can also be predicted using quantum mechanic theorems, and the results are identical to Eq. (22) for moderate fields at room temperature. The typical value for $\chi$ is generally on the magnitude of $10^{-3}$. Examples of paramagnetic substances are diatomic gases such as oxygen and nitric oxide, polyatomic gases such as $NO_2$ and $ClO_2$, and metals such as aluminum, titanium, platinum, palladium, magnesium, molybdenum, and vanadium.

### 2.3.3. Ferromagnetism and Ferrimagnetism

Ferromagnetic and ferrimagnetic materials are perhaps the most useful materials for technical applications. Like paramagnetic materials, each molecule in the ferro- and ferrimagnetic materials contains a net magnetic moment. However, because of the existence of a strong molecular field that aids the applied field in the magnetization process, the susceptibility of ferro- and ferrimagnetic materials is much larger than paramagnetic materials, ranging from $10^2$ to $10^6$. Even

**Figure 4.** In the absence of an external field, the orbital motions of two electrons with velocity $v$ and $-v$ create two opposing moments, resulting in zero net moment. When a field is applied, additional moments, $\Delta\mu_m$, are created at both atoms due to the change in the electron velocity. These two moments add up to reduce the applied field.

under zero applied field, the atomic moments of ferromagnetic materials are oriented in parallel due to the strong molecular field (in quantum magnetism, it is the exchange energy that causes the alignment of the moments), causing a large spontaneous magnetization. The moments of antiferromagnetic alloys are oriented in antiparallel, resulting in a zero net moment in the absence of an orienting magnetic field. Ferrimagnetic materials are composed of antiparallel atomic moments that do not completely cancel out. The moment alignments in ferro-, antiferro-, and ferrimagnetic materials are shown in Figure 5.

Due to the strong molecular field, ferro- and ferrimagnetic materials are self-saturating, or "spontaneously magnetized" in the absence of an external field. However, it is still easy to find a ferro- or ferrimagnetic sample in the unmagnetized state. This is because ferro- and ferrimagnetic contain many small regions, called "domains," which are spontaneously magnetized to saturation $M_s$ but oriented at different directions to minimize the energy potential within the material. The $M_s$ in these domains cancel each other, yielding zero macroscopic magnetization. When an external field is applied, these domains align with the field, and a large magnetization is observed. A permanent magnet sample consists of domains that do not cancel out macroscopically due to the crystal structure, applied stress, or mechanical defects. Section 2.5 details the domains and magnetization processes in ferro- and ferrimagnetic materials.

Magnetization in ferromagnetic magnetic materials is a critical function of temperature. The spontaneous magnetization below the Curie temperature $T_\theta$ of a ferromagnetic material is given by

$$M_s = N\mu_m \tanh\left(\mu_0\mu_m \frac{H + \mu_0\gamma M_s}{k_B T}\right) \tag{23}$$

where $\gamma$ is the Weiss constant. At $T_\theta$, the thermal energy $k_B T_c$ is equal to the molecular exchange energy, and this makes $M_s$ zero. All ferromagnetic materials become paramagnetic above $T_\theta$, and the susceptibility above $T_\theta$ is given by Curie–Weiss law [48] as

$$\chi = \mu_0 \frac{\mu_m N}{3k_B(T - T_\theta)} \tag{24}$$

Equation (24) is actually an extension of the Curie law in Eq. (22). Figure 6 depicts the transition of a material from ferromagnetism to paramagnetism with increasing temperature. At low temperature, the material exhibits strong ferromagnetism with a large magnetization $M_{s0}$. As the temperature increases, the saturation magnetization decreases and becomes zero at $T_\theta$. Above $T_\theta$, the susceptibility of the material decreases with temperature following the profile given by Eq. (24).

**Figure 5.** The atomic moment alignment of the ferromagnetic, antiferromagnetic, and ferrimagnetic materials.

**Figure 6.** The transition of a material from ferromagnetic state to paramagnetic. The material is ferromagnetic below $T_\theta$, but becomes paramagnetic above $T_\theta$ according to the Curie–Weiss law.

Quantum theory explains ferromagnetism on the basis of exchange forces, which are caused by the exchange orbit of two adjacent electrons from two atoms. The exchange energy $E_{ex}$ is given as

$$E_{ex} = -2J_{ex}s_1 \cdot s_2 \tag{25}$$

where $s_1$ and $s_2$ are the spins of two adjacent electrons, and $J_{ex}$ is the exchange integral. Since the moments of ferromagnetic materials are parallel (i.e., $s_1$ and $s_2$ have the same sign), $J_{ex}$ must also be positive for a ferromagnet to minimize $E_{ex}$. The same argument goes for antiferromagnetic, where $J_{ex}$ must be negative. Figure 7, known as the Bethe–Slater curve [49, 50], shows that the exchange integral varies with the ratio of the atomic distance to the $3d$-shell distance, $r_a/r_{3d}$. The curve shows that ferromagnetism only appears in some metals such as Fe, Co, and Ni because their $r_a/r_{3d}$ ratios correspond to positive $J_{ex}$. Following a similar argument, ferromagnetic materials can be created by alloying two or more nonferromagnetic materials by changing in the effective $r_a/r_{3d}$. Examples of ferromagnetic alloys are manganese–aluminum–chromium, manganese–copper–tin, and all rare-earth magnets. Although later Herring and others [51] showed that this method of determining ferromagnetism is unreliable, the Bethe–Slater curve still provides insights on the origin of ferromagnetism.

## 2.4. Anisotropy

Due to defects, shape, and crystallographic structure, the applied field required for magnetizing a magnetic material commonly varies with the direction of the applied field

**Figure 7.** Bethe–Slater curve shows that the exchange integral varies with the ratio of the atomic distance to the $3d$-shell distance.

relative to the direction of the magnetization vector within the material. The minimum field needed to magnetize a sample is for a field parallel to the magnetization vector direction. Conversely, the maximum field needed to magnetize a sample is when the applied field is perpendicular to the easy axis, the so-called hard axis. This phenomenon is called anisotropy, and there are three major causes of anisotropy: magnetocrystalline anisotropy, shape anisotropy, and magnetostriction anisotropy. Anisotropy determines the magnetic hardness of materials and is usually controlled for enhancing the magnetic materials as needed for specific applications.

### 2.4.1. Magnetocrystalline Anisotropy

The electron orbits of a crystalline magnetic material, such as iron, are fixed on certain crystallographic directions due to a strong orbit–lattice coupling. When an external field is applied the electron orbits tend to reorient. However, the strong orbit–lattice coupling force creates a resistance that hinders the reorientation of the electron orbits. The energy needed to overcome this orbit–lattice coupling is equal to the energy needed to rotate the electron spin away from the easy direction, which is known as the crystalline anisotropy energy $u_a$.

The anisotropy of a magnetic material is generally represented by an energy function that describes the equilibrium orientation of the magnetization under different fields, stresses, temperatures, etc. The easiest way to approximate the energy function is by applying a power series expansion on a set of directional basis functions. The anisotropy energy function for the simplest geometry, the hexagonal uniaxial structure, is expressed as

$$u_a = K_0 + K_1 \sin^2 \theta + K_2 \sin^4 \theta + \cdots \qquad (26)$$

where $\theta$ is the angle between $M_s$ and the main axis of the uniaxial structure. In Eq. (26), $K_0$ has no meaning for anisotropy properties because it is directional independent. The first term $K_1$ describes the shape of the energy function, where $K_1 > 0$ means an oblate spheroid and $K_1 < 0$ a prolate spheroid. An example of material having this geometry is cobalt, which at room temperature has

$$K_1 = 4.1 \times 10^5 \text{ J/m}^3 \qquad K_2 = 5.5 \times 10^5 \text{ J/m}^3 \qquad \text{cobalt}$$

The energy function of cobalt, plotted in Figure 8a, indicates that in the absence of an applied field, the magnetization seeks the lowest energy orientation, namely, along the $z$-axis.

The anisotropy of a magnetic material is also commonly defined by a fictitious anisotropy field $H_k$, which for the simplified case of a uniaxial structure is given by

$$H_k = \frac{2K_1}{M_s} \qquad (27)$$

The energy function for a cubic system can be written as

$$u_a = K_0 + K_1\left(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2\right) + K_2\left(\alpha_1^2\alpha_2^2\alpha_3^2\right) + \cdots \qquad (28)$$

where $\alpha_1$, $\alpha_2$, and $\alpha_3$ are the directional cosines of the magnetization along the main coordinate axes ($\alpha_i = M_i/M_s$).

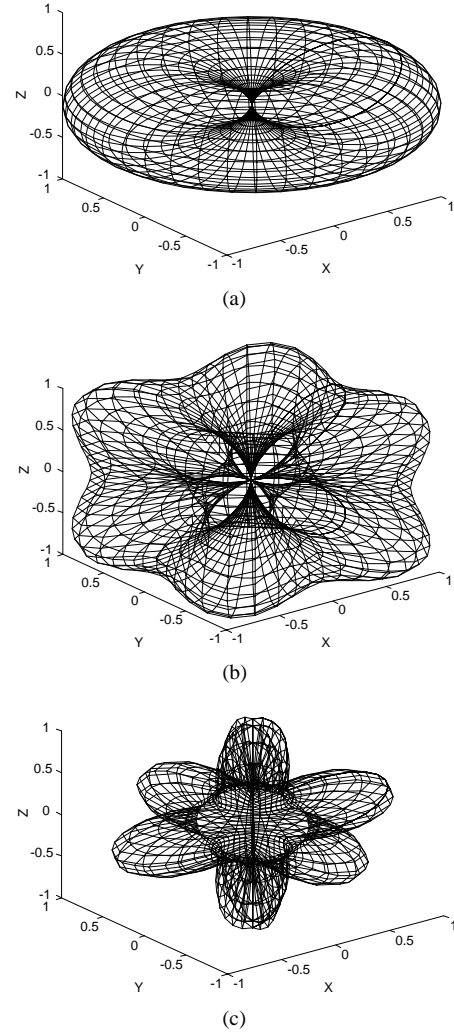

**Figure 8.** Anisotropy energy for (a) uniaxial cobalt, (b) fcc iron, and (c) bcc nickel. The length of the radius at the surface of the wire frame defines the anisotropy energy in that direction.

The anisotropy constants at room temperature for the face-centered cubic (fcc) iron and body-centered cubic (bcc) nickel are

$$K_1 = 4.8 \times 10^4 \text{ J/m}^3 \qquad K_2 = -5.0 \times 10^4 \text{ J/m}^3 \qquad \text{iron}$$

$$K_1 = -4.5 \times 10^3 \text{ J/m}^3 \qquad K_2 = -2.3 \times 10^3 \text{ J/m}^3 \qquad \text{nickel}$$

Figure 8b and c shows the energy plots of, respectively, iron and nickel. For iron and nickel the change in the sign of $K_1$ changes the number of easy directions (the nulls in the energy patterns). Iron has six easy directions and hence three easy axes, while nickel has eight easy directions and four easy axes. Cobalt has a uniaxial anisotropy that results in an omnidirectional energy pattern with one easy axis.

Notice how the sign of $K_1$ inverses the anisotropy pattern in Figures 8b and c by turning nulls into peaks and vise versa. At the point when $K_1$ changes sign ($K_1 = 0$), the anisotropy pattern becomes spherical (no anisotropy or $H_k = 0$). By alloying iron and nickel that have opposite signs

in $K_1$, $H_k$ can become very small, allowing easy magnetization at every direction. A good low $H_k$ alloy is the permalloy (NiFe) material (see Section 2.6 for details).

Figure 9 plots the magnetization $M_s$ in iron, nickel, and cobalt as a function of applied $H$ field. As shown in the plot, the materials have the lowest saturation fields when the applied field is along the easy axis, which is $\langle 100 \rangle$ for iron, $\langle 111 \rangle$ for nickel, and $\langle 001 \rangle$ or the $\|c$-axis for cobalt.

### 2.4.2. Shape Anisotropy and Demagnetizing Fields

A magnetized material is composed of small magnetic dipoles. As illustrated in Figure 10, these dipoles cancel out within the material body, but not on the surface. The surface dipoles create a demagnetizing field $H_d$, which is proportional but antiparallel to the magnetization $M$,

$$H_d = -N_d M \tag{29}$$

where $N_d$ is the demagnetizing factor, $N_d = (N_a, N_b, N_c)$, defined over a general ellipsoid with axes $a$, $b$, and $c$. The field inside the material $H_i$ is the sum of the applied $H$ field and the demagnetizing field:

$$H_i = H + H_d \tag{30}$$

The energy density of the demagnetizing field, $u_d$, of a general ellipsoid is given as

$$u_d = \frac{\mu_0 M_s^2}{2} \left( N_a \alpha_1^2 + N_b \alpha_2^2 + N_c \alpha_3^2 \right) \tag{31}$$

where $\alpha_1$, $\alpha_2$, and $\alpha_3$ are the directional cosines of the magnetization with respect to the ellipsoid axes $a$, $b$, and $c$. Generally, the demagnetizing field is larger along a shorter direction. The demagnetizing factor for a long rod parallel to the $a$-axis is $N_a \approx 1/2$ and $N_b \approx N_c \approx (\ln 2r - 1)/r^2$, for a thin disc centered on the $bc$-plane is $N_a \approx 1$ and $N_b = N_c \approx 0$, and for a sphere is $N_d = 1/3$. By choosing an appropriate

**(b)**

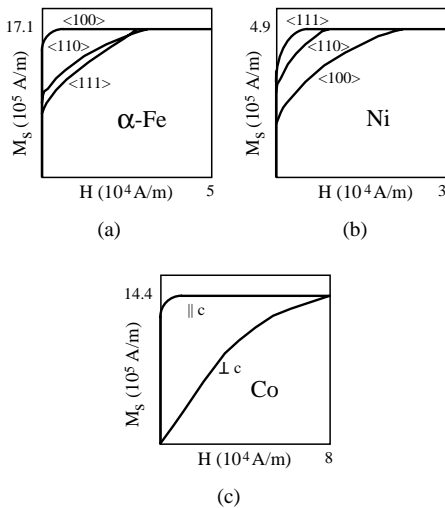
**(c)**


**Figure 9.** The magnetization of (a) iron, (b) nickel, and (c) cobalt at different crystalline axes.

**Figure 10.** The magnetized sample is composed of nano/microscopic dipoles. The dipoles cancel out within the sample, but the surface dipoles remain, creating a demagnetizing field.

shape, $u_d$ can become much larger than the magnetocrystalline anisotropy energy $u_a$, thus providing an easy way to control the direction of the anisotropy without worrying about the crystal structure of the material.

### 2.4.3. Magnetostriction Anisotropy

Many magnetic materials exhibit the magnetostriction effect, a phenomenon that elongates the material dimension parallel to the applied magnetic field and shortens the dimension perpendicular to the field, or vice versa. Not all materials exhibit the isotropic magnetostriction effect; for example, magnetization of an iron crystal in its $\langle 100 \rangle$ direction causes an elongation along $\langle 100 \rangle$ but magnetizing in the $\langle 111 \rangle$ direction causes an contraction along the $\langle 111 \rangle$ direction. The anisotropic magnetostriction effect, or the magnetostriction anisotropy, couples with the magnetocrystalline anisotropy, so the total energy function $u$ of a cubic material becomes

$$
\begin{aligned}
u &= u_a + u_{me} + u_{el} \\
&= K_0 + K_1 \left( \alpha_1^2 \alpha_2^2 + \alpha_2^2 \alpha_3^2 + \alpha_3^2 \alpha_1^2 \right) + K_2 \alpha_1^2 \alpha_2^2 \alpha_3^2 + \cdots \\
&\quad + B_1 \left( \alpha_1^2 e_{xx} + \alpha_2^2 e_{yy} + \alpha_3^2 e_{zz} \right) \\
&\quad + B_2 \left( \alpha_1^2 \alpha_2^2 e_{xx} + \alpha_2^2 \alpha_3^2 e_{yy} + \alpha_3^2 \alpha_1^2 e_{zz} \right) \\
&\quad + c_{11}/2 (e_{xx} + e_{yy} + e_{zz}) + c_{11}(e_{xx}e_{yy} + e_{yy}e_{zz} + e_{zz}e_{xx}) \\
&\quad + c_{44}/2 (e_{xy}^2 + e_{yz}^2 + e_{zx}^2) + \text{const} \times e_{ij}
\end{aligned} \tag{32}
$$

where $u_a$ is the anisotropy energy shown in Eq. (28), $u_{me}$ is the magnetoelastic energy, $u_{el}$ is the pure elastic energy, $B$ is the magnetoelastic coefficient that relates the coupling between the strain $e_{ij}$ and the magnetization direction given by $\alpha_i$, and the $c$ terms in the $u_{el}$ are the elastic coefficients. The strain or magnetostriction $\lambda = \Delta l / l$ is derived form Eq. (32) as

$$
\begin{aligned}
\lambda &= \frac{3}{2} \lambda_{100} \left( \alpha_1^2 \beta_1^2 + \alpha_2^2 \beta_2^2 + \alpha_3^2 \beta_3^2 \right) \\
&\quad + 3\lambda_{111} \left( \alpha_1 \alpha_2 \beta_1 \beta_2 + \alpha_2 \alpha_3 \beta_2 \beta_3 + \alpha_3 \alpha_1 \beta_3 \beta_1 \right)
\end{aligned} \tag{33}
$$

where $\beta$ gives the direction of the measured strain, and $\lambda_{100}$ and $\lambda_{111}$ are the saturation magnetostriction along the crystallography axes $\langle 100 \rangle$ and $\langle 111 \rangle$ given by

$$\lambda_{100} = -\frac{2}{3} \frac{B_1}{c_{11} - c_{12}} \qquad \lambda_{111} = -\frac{1}{3} \frac{B_2}{c_{44}} \tag{34}$$

For an isotropic polycrystalline material, the isotropic saturation magnetostriction $\lambda_S$ is

$$\lambda_S = \frac{2}{5}\lambda_{100} + \frac{3}{5}\lambda_{111} \qquad (35)$$

For an isotropic material where $\lambda_{100} = \lambda_{111} = \lambda_s$, the relative length change is dependent only on the angle $\theta$ between the measured strain and the magnetization:

$$\lambda = \frac{3}{2}\left(\cos^2\theta - \frac{1}{3}\right) \qquad (36)$$

## 2.5. Magnetic Domains and Magnetization Process

This section explains the formation of magnetic domains in ferromagnetic materials, and the motion of domain walls that is responsible for dynamic magnetization processes. This section also presents the magnetization curve of ferromagnetic materials and some common parameters that characterize ferromagnetic materials.

### 2.5.1. Domains and Domain Walls

In the absence of an external field, the magnetic moments inside a ferromagnetic material are self-segregated into different domains of 10–100 $\mu$m in size to reduce the fringing fields so the potential energy in the material is minimized. Within each domain, the magnetic moments are all oriented in parallel due to the strong exchange force. Figure 11 illustrates the formation of magnetic domains in the absence of an external field. The magnetic sample starts out with two opposing domains and gradually splits into more domains to reduce the fringing fields until reaching a pattern for which the a minimum potential energy level is reached. Since the domains in the sample are opposing each other, the net moment is zero and the sample is unmagnetized. In some cases, due to crystalline structures, defects, and stresses, these domains do not align such that the moments cancel each other, and the sample is said to have a net spontaneous magnetization.

When the sample is subjected to an external field, it magnetizes along the direction of the field. To explain the magnetization process, first consider the sample shown in Figure 12, which has only two opposing domains, Domains

**Figure 12.** Illustration of the magnetization process. Initially the two opposing domains are equal in size, so the net moment is zero. As the external field increases, the domain wall moves toward Domain 2, resulting in an increase in the net moment. Eventually, only Domain 1 remains, and increasing field will have no effect on the magnetization.

1 and 2, separated by a boundary known as the domain wall or the Bloch wall. In the absence of an applied field, these two domains are oriented antiparallel so the net moment is zero. When an external field is applied, the size of Domain 1 increases, and the domain wall moves toward Domain 2. The change in domain size creates a net magnetic moment parallel to the field direction. Eventually, Domain 1 dominates the whole sample, and further increases in the magnitude of the applied field no longer increase the net magnetic moment. The sample is referred to as being in saturation. If the sample is free from structural defects and stress, the magnetization will return to zero when the applied field is removed; this type of material is classified as "magnetically soft."

In the case of nonideal materials with imperfections such as grain boundaries and precipitates, the magnetization will be irreversible due to the pinning of domain walls at the defects. Figure 13 illustrates the irreversible magnetization due to imperfections (represented by the black dots). The domain wall is initially pinned on the defects, so further field energy is needed to force the wall to jump over the defects until it is pinned again. The jump, known as the Barkhausen jump, dissipates energy due to spin relaxation and microscopic eddy currents. As a result, the domain wall motion will be different dependent upon whether the applied field is increasing or decreasing; hence the sample demonstrates hysteresis (history dependent) in its magnetization. Magnetically hard materials exhibit large hysteresis.

**Figure 11.** The change of the domain pattern from two domains to an optimized pattern where the total energy is lowest.

**Figure 13.** Illustration of domain wall (dashed line) pinning at defects (black dots). The process from (a) to (b) is reversible, but the process from (b) to (c) is not.

The domain wall, separating regions (domains) having different magnetization directions, has a width that depends upon the anisotropy and exchange energies of the materials. To understand and determine the width of the domain wall of a given sample, first consider a hypothetical scenario where the change in direction between two adjacent domains is abrupt (i.e., the domain wall is infinitesimally thin as shown in Fig. 14). The sample has an easy direction along the $\pm z$ direction, which means the anisotropy energy is smallest when the domains are parallel or antiparallel along the $z$ direction. However, the exchange energy in a ferromagnet is minimal only when the moments are in parallel. Therefore, the domain wall in Figure 14 has a minimum anisotropy energy but a large exchange energy. To minimize the exchange energy, the direction of the moments must change gradually within the domain walls so the angle between two consecutive moments is less than 180° see Fig. 15). However, this will increase the anisotropy energy because some domains are no longer aligned along the easy axis. As a result, there are two competing energies trying to minimize the total energy: the anisotropy energy that tries to reduce the width of the domain wall, and the exchange energy that tries to widen the wall. The actual thickness of the domain wall $\delta$ is determined when these two competing effects are minimum. For a cubic sample with length $a$, $\delta$ is given by

$$\delta = \sqrt{\frac{J_{ex}S^2\pi^2}{Ka}} \qquad (37)$$

where $K$ is the anisotropy constant, $J_{ex}$ is the exchange integral, and $S$ is the electron spin. The details of determining $\delta$ are given in Cullity [37]. Generally, the domain wall is about 10–100 nm wide.

The magnetization of fine magnetic particles is explained by single-domain rotation. When an external field is applied to a single-domain particle, the $M_s$ vector of the particle rotates toward the field direction from its easy axis, working against the anisotropy field.

### 2.5.2. Magnetization Curve

As indicated in Section 2.2, the magnetic flux $B$ and field $H$ are scaled by the permeability $\mu$; similarly the magnetization $M$ and field $H$ are scaled by the susceptibility $\chi$. For ferro- and ferrimagnetic materials, $\mu$ and $\chi$ are not constants; instead they are nonlinear functions that depend on the previous state of magnetization (hysteresis). Figure 16 is a plot of $B$ and $\mu_0 M$ versus $H$, known as the *BH* or *MH* loop, where $\mu$ and $\chi$ are the tangents of the curve at different operating $H$. Note that from Figure 16, the *BH* and

**Figure 15.** To minimize the exchange energy associated with the infinitely thin domain wall of Figure 35, the directions of the moments (represented by the arrows) change gradually so the angle between two consecutive moments is less than 180°.

*MH* curves are offset by the vacuum induction $\mu_0 H$. For most ferro- and ferrimagnetic materials, the susceptibility is much larger than 1, so the *BH* and *MH* loops are commonly considered the same.

The *BH* loop begins with an initial curve, which is obtained by applying a field on a demagnetized sample. As the field increases, the sample magnetizes through reversible domain wall movement including irreversible Barkhausen jumps until reaching the saturation magnetization $B_S$. As the $H$ field reduces to zero, the magnetization does not reduce to zero but remains at the remanence $B_r$ due to the irreversible rotation of the magnetization vectors within the material. The magnetization becomes zero only when $H$ reaches to the coercive field $H = -H_c$. As the $H$ field continues to decrease, the sample will saturate at $-B_S$. When the $H$ field increases again, the *MH* curve reaches $B_r$, $H_c$, and $B_S$ sequentially. Note that the *BH* loop will not go back to the origin. To reset the *BH* loop to the origin the sample needs to be demagnetized by either annealing the sample over $T_c$ or by applying a time-varying amplitude-decaying ac field. Annealing over $T_c$ is the best way to erase all magnetic memory of the sample; however, the process may also alter the mechanical properties of the material. Applying a decaying ac field is the most common way because it is easy to implement and imposes no permanent physical damage, but it yields no random distribution of the domain magnetization

**Figure 14.** A hypothetical infinitely thin domain wall separating two domains with a 180° difference in direction.

**Figure 16.** *MH* and *BH* hysteresis loops. The remanence, saturation magnetization, and coercive force are shown.

over the easy axis. An improvement for the decaying-field demagnetization is to rotate the sample (or the field) while undergoing a demagnetizing field that yields a more random domain distribution.

Although the *MH* loop or *BH* loop provides a complete picture on the magnetization, numerical permeability values are more convenient for general engineering applications. A material can have many different permeability values depending upon which part of the *BH* loop the material is at (biasing field magnitude). A commonly used value is the initial permeability

$$\mu_i = \lim_{\substack{H \to 0 \\ B \to 0}} \frac{B}{H} \tag{38}$$

which is the tangent line at the origin of the initial *BH* curve, the maximum permeability

$$\mu_{\max} = \left. \frac{B}{H} \right|_{\max} \tag{39}$$

which is the tangent line of the $B(H)$ curve at $B = 0$, the reverse permeability

$$\mu_{\mathrm{rev}} = \lim_{\Delta H \to 0} \left. \frac{\Delta B}{\Delta H} \right|_{B_t, H_t} \tag{40}$$

which is the limit of the superposition permeability of a small ac field on the operating point $H_t$, $B_t$, and the differential permeability

$$\mu_{\mathrm{diff}} = \frac{dB}{dH} \tag{41}$$

which is the derivative of the $B(H)$ curve.

For an anisotropic material, the magnetization curve varies when the field is applied from different directions. As a result, many magnetic materials, especially thin films, are categorized with two *BH* loops, one measured along the easy axis and the other along the hard axis. Figure 17a illustrates the *BH* loop measured along the easy and hard axes. Notice that along the hard axis, a larger applied field is needed to saturate the material. The anisotropy field $H_k$ can also be determined from the hard axis by measuring the linearized minor loop and extrapolating the linear line until it reaches saturation $B_S$ (see Fig. 17b).

## 2.6. Magnetic Materials

Strong magnetic materials such as ferro- and ferrimagnetic alloys that exhibit large magnetization are by far the most useful materials and are commonly categorized by the coercive force $H_c$. Generally, materials with $H_c < 1000$ A/m are considered magnetically soft, materials with $H_c$ between 1 and 30 kA/m are semihard, and materials with $H_c > 30$ kA/m are considered hard (for calibration, earth's magnetic field is approximately 50 A/m at the pole, 25 A/m at equator). This section includes an overview of magnetically soft and hard ferromagnetic materials, as well as magnetoelastic and magnetostrictive materials (soft magnetic materials that react magnetomechanically with stress).

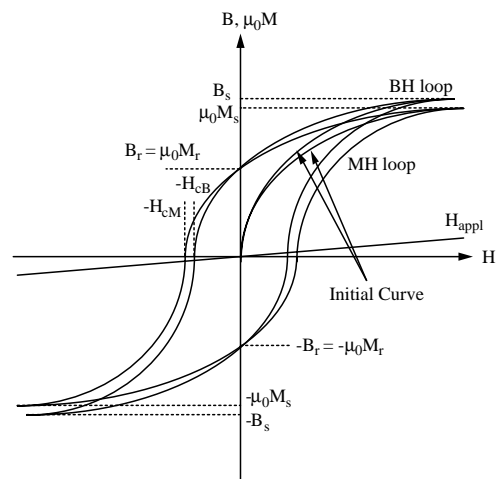

**Figure 17.** (a) The *BH* loop measured along the easy and hard axes. (b) The anisotropy field $H_k$ can be determined by extrapolating the small-signal linearized minor loop.

### 2.6.1. Soft Magnetic Materials

Magnetically soft materials have a low coercivity and high permeability, which result from the low crystalline and strain anisotropy energies. The low anisotropy energy minimizes the domain wall energy, allowing the rotation of domain wall with minimum energy loss when subjected to an external field. Due to reversible magnetization and a correspondingly low hysteresis loss, soft magnetic materials are largely used in field sensors, power transformers, induction motors, etc. Soft magnetic materials include various crystalline ferrites, as well as nanocrystalline and amorphous alloys. Some common magnetically soft materials and their $B_S$, $H_c$, and $\mu_{\max}$ are listed in Table 1.

Metallic crystals without impurities are good soft magnetic materials. For example, pure iron, which has a small magnetocrystalline anisotropy of $K_1 = -4.8 \times 10^4$ J/m$^3$, has a relatively large saturation flux density of 2.15 T and a $\mu_{\max}$ of 5000. The low anisotropy energy in pure iron allows domain wall movement with little resistance, hence the low coercivity and high permeability. Other good magnetically soft crystalline materials are iron–nickel (FeNi) alloys such as Permalloy, Supermalloy, Mumetal®, cobalt–iron (CoFe) alloys, silicon steels (SiFe), and Sendust (FeAlSi).

Amorphous ferromagnetic alloys produced by rapid quenching do not exhibit long-range order, resulting in zero magnetocrystalline anisotropy; generally a cooling rate of approximately $10^5$ °C/s is needed to achieve such materials. Amorphous magnetic materials have a higher electrical resistance (120–200 $\mu\Omega$) compared to crystalline magnetic

**Table 1.** A list of common magnetically soft materials with their saturation magnetization, coercive force, and maximum permeability.

| Material | Composition | $B_S$ (T) | $H_c$ (A/m) | $\mu_{max}$ |

[g] Amorphous.

materials (30–50 $\mu\Omega$), making them a better choice for high frequency and high power applications due to reduced eddy currents. Amorphous alloys are widely used as field and stress sensors and high-power distribution transformers. Typically these glasses are composed of metals such as iron, cobalt, and nickel. To stabilize the alloys in an amorphous state metalloids such as silicon, boron, and molybdenum are added. Amorphous glasses of the transition metals (Zr, Nb, Hf), or rare-earth metals (Tb, Dy, Er, Gd) can also be made; however, the addition of rare-earth metals increases the magnetic anisotropy. Due to the presence of the glass-forming metalloids the saturation magnetizations of amorphous alloys are lower than their crystalline counterparts.

As-cast amorphous alloys typically contain large stress anisotropies, which reduce the soft magnetic properties of the materials. In practice, amorphous alloys are relaxed by low-temperature annealing to remove the internal stress. When used as stress sensors, amorphous alloys are annealed under magnetic field to create an anisotropy to increase the stress sensitivity.

Nanocrystalline grains of 10–15 nm can be formed in the amorphous alloys by annealing them at their crystallization temperature ($\sim$450–550 °C). These nanostructured alloys have excellent soft magnetic properties with the permeability on the order of $10^5$, and a low hysteresis loss. However, due to the increase of phase segregation and precipitation, these nanocrystalline materials are mechanically brittle making them difficult to handle.

Soft ferrites are generally composed of 70% of iron oxide $Fe_2O_3$ and 30% of metal oxides such as zinc oxide and nickel oxide. Although ferrites are relatively inexpensive to fabricate the low magnetization ($\sim$0.5 T) limits their applications. However, ferrites have high resistivity and therefore can be used at higher frequencies.

### 2.6.2. Hard Magnetic Materials

Magnetically hard materials are categorized by their large coercive force ($10^4$–$10^6$ A/m) that makes them hard to magnetize and a large remanence that allows them to exhibit significant spontaneous magnetization in zero applied field. Magnetically hard materials encompass permanent magnets, magnetic data storage, and sensors. A common way to characterize hard magnetic materials is to determine the maximum $B$-$H$ energy product, $(BH)_{max}$. Figure 18 illustrates how to determine $(BH)_{max}$ from the second quadrant of a $BH$ loop.

Hard magnetic materials are made so that they have a large number of grain boundaries that act to pin the magnetization vector in a given direction. Early magnets were iron-based, such as magnetite ($Fe_3O_4$) and iron carbon magnets ($Fe_3C$). These were replaced by tungsten, Co–Mo, and Co–Cr steels with larger coercive force and magnetization during the 1940s. Another magnet widely used since the 1930s was the Alnico ($Fe_2NiAl$) magnet, which has subsequently been phased out by the rare-earth–transition metal magnets. Examples are $SmCo_5$, $R_2Co_7$, and $Sm_2(CoFe)_{17}$. These magnets have coercive fields of 0.8–2.4 MA/m and an energy product reaching a few hundred kJ/m$^3$; common permanent magnets are listed in Table 2.

### 2.6.3. Magnetoelastic and Magnetostrictive Materials

The most common magnetoelastic materials are the rare-earth intermetallic compounds and amorphous magnetically soft ferromagnetic glasses. Crystalline rare-earth intermetallic compounds, such as Terfenol-D ($Tb_{0.3}Dy_{0.7}Fe_{5.95}$), have a magnetostriction on the order of $10^{-3}$, a magnetoelastic coupling of $k = 0.7$, and a low compliance. As a result, such materials are useful actuators for a range of applications including sonar transducers. Other examples of rare-earth compounds are GdCo and GdFe. Amorphous ferromagnetic alloys with high iron content exhibit magnetostrictions on the order of $10^{-5}$ and a magnetoelastic coupling close to 1 after annealing. Amorphous ferromagnetic alloys, such as $Fe_{81}B_{13.5}Si_{3.5}C_2$, have a low anisotropy field ($H_k = 70$ A/m), which allows the rotation of magnetization and accompanying magnetostrictive strain with low applied fields and stresses, resulting in a high magnetoelastic coupling. Ferromagnetic glasses are widely used as stress/strain sensors and field sensors and as cores of power transformers. Some

**Figure 18.** (a) Second quadrant of a $BH$ loop. The location of the $(BH)_{max}$ corresponds to a rectangular area where the product of $BH$ is maximal. (b) The $(BH)_{max}$ can be determined by plotting $B$ versus $BH$ and determining the maximum of the curve along the $x$-axis.

**Table 2.** A list of common magnetically hard materials with their remanence, coercive force, and energy product.

| Material | Composition | $B_r$ (T) | $H_c$ (kA/m) | $(BH)_{max}$ (kJ/m³) |
|---|---|---|---|---|
| Iron carbon | $Fe_3C$ | 5.24 | 4 | 4 |
| Tungsten steel | $Fe_{92}W_8$ | 2 | 7 | 8 |
| Alnico 5 | $Fe_{50}Co_{25}Ni_{15}Al_8Cu_2$ | 5.2 | 50 | 42 |
| Fe–Cr–Co | Fe–Cr–Co | 5.6 | 65 | 80 |
| Hexagonal ferrites | isotropic $BaO$–$Fe_2O_3$ | 0.22 | 145 | 9 |
| Co–rare earth | $SmCo_5$ (aligned) | 5.0 | 2900 | 200 |
| Fe–rare earth | $Fe_{14}Nd_2B$ (aligned) | 5.6 | 1600 | 350 |

common magnetoelastic materials, along with their saturation magnetization, magnetostriction, and magnetoelastic coupling coefficients, are listed in Table 3.

# 3. FERROMAGNETIC GLASS PREPARATION AND PROPERTIES

This section describes some fabrication processes, properties, and methods of enhancing the properties of the ferromagnetic glass alloys.

## 3.1. Preparation of Ferromagnetic Glasses

Ferromagnetic glasses are commonly fabricated using melt quenching methods such as melt-spinning [52] and atomic condensation techniques such as electrodeposition [53, 54] and sputtering [55]. The key to successfully fabricating a ferromagnetic glass is rapid removal of heat from the melt, to preclude crystallization in the alloy. In most cases, cooling rates of $10^5$ °C/s are needed. Most of the magnetically soft ferromagnetic glasses are based on $3d$ transition metals (T) with glass forming metalloids (M) such as boron, carbon, silicon, or phosphors to stabilize the amorphous state. The composition of transition-metalloid-based alloys, $T_{1-x}M_x$, is usually in the range of $15 < x < 30$ at% such as $Fe_{80}B_{20}$, $Fe_{40}Ni_{40}P_{14}B_6$, and $Co_{74}Fe_5B_{18}Si_3$. The late transition metals (TL = Fe, Co, Ni) can also be stabilized in an amorphous state by alloying with early transition metals (Zr, Nb, Hf), forming $TE_{1-x}TL_x$, with $x$ in the range 5–15 at% such as $Co_{90}Zr_{10}$. Ferromagnetic glasses are also built by alloying transition metals (TL = Fe, Ni, Co) with rare-earth metals (R = Tb, Dy, Er, Gd), forming $R_{1-x}TL_x$ with $x$ typically 10–25 at%. Among these ferromagnetic glasses, the

**Table 3.** A list of magnetoelastic materials and their saturation magnetization, magnetostriction, and magnetoelastic coupling coefficient.

| Material | Composition | $B_S$ (T) | $\lambda_S$ (ppm) | $k_{max}$ |
|---|---|---|---|---|
| Metglas 2605SC[a] | $Fe_{81}B_{13.5}Si_{3.5}C_2$ | 5.61 | 30 | 0.98 |
| Metglas 2826MB[a] | $Fe_{40}Ni_{38}Mo_4B_{18}$ | 0.88 | 12 | 0.5 |
| Ferromagnetic glass[a] | $Fe_{4.5}Co_{68.15}Si_{12.5}B_{15}$ | 0.7 | −0.1 | — |
| Ferromagnetic glass[a] | $Co_{72.5}Si_{12.5}B_{15}$ | 0.5 | −1 | — |

[a] Amorphous.
[b] Crystalline.

transition-metalloid-based alloys have the most useful properties for sensor applications, such as high magnetostrictive and magnetoelastic coupling coefficient and low magnetic anisotropy. Although transition-rare-earth-based amorphous alloys such as TbDyFe and TbCo have a lower magnetoelastic coupling coefficient, of ∼0.5–0.7, they have the largest known values of magnetostriction on the order of $10^{-4}$ [56, 57].

## 3.2. Summary of Physical and Magnetic Properties of Ferromagnetic Glasses

As-cast ferromagnetic glasses are flexible, with Young's moduli of around 100 GPa, about 20–30% lower than their crystalline counterparts [58]. As-cast ferromagnetic glasses also exhibit high mechanical strength and ductility. For example, the tensile strength of as-cast Metglas 2605SC and 2826MB alloys is approximately 1000 to 1700 MPa, and for as-cast FC20 alloys ($Fe_{93.3}Si_{2.9}C_{3.4}B_{0.4}$) it can reach to 3400 MPa. However, annealing processes, although improving the soft magnetic properties by creating nanocrystalline structures, can destroy the mechanical properties and render these materials brittle by increasing precipitation and phase segregation. In general, the tensile strength and Vicker's hardness of the ferromagnetic glasses show a small increase at low temperature annealing but decrease significantly when the annealing temperature reaches the crystallization temperature $T_c$ [59]. Nanocrystalline alloys, produced by annealing ferromagnetic glasses at temperatures at or above $T_c$, have a lower mechanical strength compared to their amorphous counterparts.

Ferromagnetic glasses contain localized random anisotropies, which act like the crystalline anisotropy but on the scale of few nanometers. The strength and direction of the localized anisotropy vary with position, resulting in zero macroscopic crystalline anisotropy (although most ferromagnetic glasses still contain stress anisotropy as a result of the fabrication process). Ferromagnetic glasses made of transition metals and metalloids have weak coupling between the local anisotropies; as a result they are magnetically soft and can be easily magnetized. However, rare-earth-based ferromagnetic glasses have strong localized coupling forces; hence saturation magnetization is much harder to achieve, and the materials are magnetically harder to a significant degree. Common magnetically soft ferromagnetic glasses have magnetic susceptibilities on the order of $10^5$, saturation magnetizations of about 1 T, and compared to their crystalline counterparts low hysteresis loss. Annealed and nanocrystalline ferromagnetic glasses have a higher susceptibility due to the reduction of stress anisotropy energy.

The electrical resistivity of ferromagnetic glasses are generally one order of magnitude higher than their crystalline counterparts, with typical values of 100–200 $\mu\Omega \cdot$ cm. The high resistivity significantly reduces eddy currents making the ferromagnetic glasses more suitable for high frequency applications.

Note that the values given above are those of common materials, as generally fabricated and used; properties can be altered by changing alloy composition and performing annealing, as will be detailed in Section 3.3. In addition to

these properties, ferromagnetic glasses also exhibit attractive properties for sensor applications such as magnetoelastic and magnetostriction effects, magnetoelastic resonance, and the GMI effect, which will be explained in the following sections.

### 3.2.1. Magnetoelastic and Magnetostriction Effects

Most ferromagnetic glasses exhibit magnetostriction, a phenomenon where the dimensions of an object change when subjected to the influence of an external magnetic field. Magnetostriction is generally quantified with the saturation magnetostriction $\lambda_S$, which is defined as the ratio of the change in length $\Delta l/l$ at magnetic saturation. Although it is well known that the magnetostriction of a ferromagnetic glass varies with alloy composition, predicting the effects of alloy composition on the magnetostriction is still difficult, and most existing theoretical models are only applicable to specific binary or ternary alloys. In general, rare-earth-based alloys exhibit the highest magnetostriction with $\lambda_S \approx 10^{-4}$, followed by Fe-rich alloys with $\lambda_S \approx 10^{-5}$, while Co-rich alloys have a low magnetostriction of $\lambda_S \approx 10^{-7}$. Magnetostriction also depends upon applied stress, structural relaxation [60, 61], and fabrication parameters [56, 62]. Generally, $\lambda_S$ increases when ferromagnetic glasses are relaxed under low field annealing but decreases when the annealing temperature is beyond the crystallization temperature.

The magnetoelastic effect, which describes the coupling between the elastic energy and magnetic energy, is usually quantified by the magnetoelastic coupling coefficient $k$, defined as the ratio of the coupled elastic-magnetic energy to the pure elastic and magnetic energies. Magnetoelastic and magnetostriction are related but not necessarily proportional to each other due to the influence of other parameters such as applied stress. For example, rare-earth-based alloys have a very high $\lambda_S$, but their magnetoelastic coupling is lower than the Fe-rich alloys, which have a lower $\lambda_S$.

The most common model for understanding the effects of applied stress and field on the susceptibility, magnetoelastic coupling, and the Young's modulus of a ferromagnetic ferromagnetic glass ribbon is shown in Figure 19. The model considers a ribbon-shaped ferromagnetic glass having a widthwise magnetic easy axis and a uniaxial anisotropy with an energy contribution of $K_U \cos\theta$ per unit volume. In the absence of an applied field and applied stress the magnetization in the domains aligns across the width of the ribbon. When a longitudinal field $H$ and stress $\sigma$ are applied

**Figure 19.** (a) Magnetic domain of a transverse-field annealed ferromagnetic glass ribbon at (a) zero bias field ($H = 0$) and (b) $0 < H < H_k$.

the magnetization rotates from the width toward the length direction (see Fig. 19), yielding a magnetostrictive strain $\varepsilon$ given by [63]

$$\varepsilon = \frac{\sigma}{E_M} + \frac{3\lambda_S}{2}\left(\frac{H^2}{H_k^2} - \frac{1}{3}\right) \qquad H < H_k \qquad (42)$$

where $E_M$ is the Young's modulus at a constant magnetization, and the anisotropy field $H_k$ is given by

$$H_k = \frac{2K_U - 3\lambda_S\sigma}{M_s} \qquad (43)$$

where $M_s$ is the saturation magnetization. The susceptibility $\chi$ is related to the applied strain as

$$\chi = \frac{M_s^2}{2K_U - 3\lambda_S\sigma} \qquad (44)$$

From Eq. (44), the sensitivity of the susceptibility toward applied stress is given by

$$\frac{d\chi}{d\sigma} = \frac{M_s^2}{(2K_U - 3\lambda_S\sigma)^2}3\lambda_S \qquad (45)$$

It is clear that the sensitivity of the susceptibility increases with higher $\lambda_S$ and a lower $K_U$. The magnetoelastic coupling factor $k$ can be related to the parameters already derived as

$$k = \left(1 + \frac{M_s H_k^3}{9E_M\lambda_S^2 H^2}\right)^{-1/2} \qquad H < H_k \qquad (46)$$

Equation (46) shows that a high magnetoelastic coupling requires a high $\lambda_S$ and $E_M$ and a low $H_k$. For applications based on changes in the elastic modulus, for example a strain sensor, the parameter of interest is the fractional difference between the elastic modulus at constant magnetization $E_M$ and the modulus at constant field $E_H$, or the so-called $\Delta E$ effect, which is given by

$$\frac{\Delta E}{E_M} = \frac{E_M - E_H}{E_M} = \frac{9\lambda_S^2 E_H H^2}{M_s H_k^3} = k^2 \qquad H < H_k \qquad (47)$$

### 3.2.2. Magnetoelastic Resonance

A magnetoelastic ribbon- or wire-shaped glass exhibits a resonance when excited by a time-varying magnetic field. For a magnetoelastic glass ribbon with its length parallel to the $x$-axis of a rectangular coordinate system, excited by an $x$-directed ac magnetic field, the ribbon exhibits a vibration that can be described with the equation of motion as [28]

$$\rho_s \frac{\partial^2 u_x}{\partial t^2} = \frac{E_H}{1 - \sigma_p^2} \frac{\partial^2 u_x}{\partial x^2} \qquad (48)$$

where $u_x$ is the displacement in the $x$-direction, $\rho_s$ is the density of the ferromagnetic glass ribbon, and $\sigma_p$ is Poisson's ratio. Although the ribbon exhibits vibrations at almost every frequency, the vibrations are most pronounced at the resonant frequencies [64, 65]

$$f_n = \frac{1}{L}\sqrt{\frac{E_H}{\rho_s(1 - s^2)}} \qquad (49)$$

where $L$ is the length of the ribbon. For most sensor applications, only the first harmonic ($n = 1$) is considered due to its significantly higher amplitude. The frequency response of a 37.5 mm $\times$ 12.5 mm $\times$ 28 $\mu$m as-cast Metglas 2826MB ribbon is plotted in Figure 20.

### 3.2.3. Giant Magnetoimpedance Effect

Giant magnetoimpedance is a phenomenon that significantly changes the radio-frequency electrical impedance of a magnetic conductor with a small variation of magnetic field. Ferromagnetic glasses, especially Co-based alloys with near zero magnetostriction ($\approx 10^{-7}$), display excellent GMI effects, which makes them suitable for the measurement of magnetic fields in the range of few Oersteds. The GMI effect in amorphous wires is due to the change of skin depth in response to external fields. The change in external dc field changes the transverse permeability of the wire (due to the domain wall motion), which leads to the change of the skin depth since skin depth is a function of permeability [66]. Since the ac current in a wire flows within a region near the wire surface (skin depth effect), the change in skin depth will change the wire impedance. The GMI effect depends on the anisotropy of the wire: for a wire with axial anisotropy, the impedance is highest at zero-applied field and decreases monotonically with applied field, whereas for a wire with circumferential anisotropy the maximum occurs at $H_k$ [67]. Most rapid-quenched amorphous wires have circumferential anisotropy due to the heat dissipation along the radial direction during the fabrication process.

To measure the GMI effect, generally a ferromagnetic glass wire is connected to an ac current source and voltmeter, and the impedance is determined from the ratio of the measured voltage to the applied current. The sensitivity of the GMI in a ferromagnetic glass is largely dependent upon the frequency of the driving current and the magnitude of the transverse permeability in the glass. For a circular ferromagnetic glass wire, the impedance measured across the length is given by [68]

$$Z = \frac{a}{2\sqrt{2\rho_e}} \left( R_{dc} + j\frac{\rho L}{\pi a^2} \right) (\omega \mu_\theta)^{1/2} \qquad (50)$$

**Figure 20.** The frequency response of a 37.5 mm $\times$ 12.5 mm $\times$ 28 $\mu$m as-cast Metglas 2826MB ribbon. The resonant frequency $f_0$ is the maximal of the frequency spectrum and antiresonant frequency $f_a$ is the minimal.

where $j$ indicates a complex number, $\omega$ is the radian frequency of the driving current, $a$ is the radius of the wire, $\rho_e$ is the resistivity of the ferromagnetic glass, $R_{dc}$ is the dc resistance, and $\mu_\theta$ is the circumferential permeability. Besides wires, ferromagnetic glass ribbons are also common since ribbon structures can be easily incorporated in MEMS devices. The impedance measured across the length of an amorphous ribbon is given by [69]

$$Z = \frac{(1 - j)L}{4w} (2\rho_e \omega \mu_t)^{1/2} \qquad (51)$$

where $w$ and $L$ are respectively the width and length of the ribbon, and $\mu_t$ is the transverse permeability of the ferromagnetic glass.

The GMI effect is usually expressed as a function of applied field as the GMI ratio, GMI%, which is defined as

$$\text{GMI\%} = \frac{Z(H_{appl}) - Z(H_{max})}{Z(H_{max})} \qquad (52)$$

where $Z$ is the impedance, and $H_{appl}$ and $H_{max}$ are respectively the applied and saturation magnetic fields. The GMI% for ferromagnetic glasses is relatively high, normally in the range between 100% and 500%, depending upon the ferromagnetic glass composition, heat treatment, dc bias current, and the design of the sensor.

### 3.3. Tailoring of Ferromagnetic Glasses for Sensor Applications

This section describes methods to control the mechanical and magnetic properties of ferromagnetic glasses.

### 3.3.1. Effects of Alloy Compositions on the Ferromagnetic Glass Properties

The magnetomechanical properties of ferromagnetic glasses, such as magnetostrictive and magnetoelastic coupling, magnetic hardness, hysteresis losses, and anisotropy are all dependent upon alloy composition. Although there are no general theories for predicting the effects of alloy composition on the properties of the ferromagnetic glasses, several models have been developed to describe the effects of alloy composition on Fe-rich and Co-rich ferromagnetic glasses [70]. In general, Fe-rich transition-metalloid-based alloys can have substantial magnetostriction constants and high magnetoelastic couplings because they have low anisotropy energy $K_U$ and low anisotropy field $H_k$, which permit the rotation of the magnetization and accompanying magnetostrictive strain with low applied fields or stresses. For example, Metglas 2605SC, which has a high magnetostriction of $3 \times 10^{-5}$ and magnetoelastic coupling of 0.98 has relatively low $K_U$ and $H_k$ of 38 J/m and 370 A/m, respectively. Rare-earth-based alloys have a larger magnetostriction but are also magnetically harder than Fe-based alloys; for example nanocrystalline TbDyFe has a large magnetostriction of $3.5 \times 10^{-4}$ and a $H_k$ of 2400 A/m.

Addition of glass-forming metalloids, such as B, Si, Mo, and C, generally increases the mechanical strength but reduces the magnetic and magnetoelastic properties of the ferromagnetic glasses. It is found that the induced

anisotropy constant $K_U$ of Fe-rich alloys increases strongly with the presence of additional transition elements such as Ni or Co [63]. This is the reason the magnetoelastic coupling of the 2826MB $Fe_{40}Ni_{38}Mo_4B_{18}$ ($k \approx 0.5$) is inferior compared to the 2605SC $Fe_{81}B_{13.5}Si_{3.5}C_2$ ($k = 0.98$).

### 3.3.2. Control of Magnetoelastic Coupling via Annealing

The model in Section 3.2.1 indicates that a widthwise magnetic domain distribution and a low uniform $H_k$ are required for achieving a high magnetoelastic coupling $k$. However, in an as-cast ferromagnetic glass ribbon the surface defects and irregularities create localized stresses and cause an inhomogeneous $K_U$ distribution on the ribbon, leading to variations in the direction and amplitude of localized magnetic domains and $H_k$, and in turn reduce the magnetoelastic coupling. Lower magnetoelastic coupling leads to a smaller $\Delta E$ effect and lower stress sensitivity. It is thus necessary to remove the internal stresses and orient the magnetic domains widthwise without including significant crystallization.

Transverse field annealing is the most common method used to remove internal stresses in ferromagnetic glasses thereby increasing $\lambda_S$ and $k$. Extensive investigations have been conducted to analyze the effects of annealing temperature and time on $\lambda_S$, $k$, and the permeability $\mu$ of various ferromagnetic glasses. The results are unanimous [8, 9, 60, 64, 71–76]; $\lambda_S$, $k$, and $\mu$ increase under transverse-field annealing at temperatures below $T_c$ ($\approx$450–500 °C) but decrease above $T_c$. For materials with a broad alloy spectrum, the reduction of $\lambda_S$, $k$, and $\mu$ can happen at temperatures far below $T_c$ at around 300 °C. Certain ferromagnetic glasses such as TbDyFeNb and FeZrBCu are nanocrystallized when annealed at $T_c$. Nanocrystalline alloys are magnetically softer, having larger values of $\mu$ and $k$, but are generally mechanically brittle. Inversely coupled to the permeability $\mu$, annealing under stress and field can lower $H_k$. According to Eq. (43), $H_k$ is proportional to the term ($K_U - 3/2\lambda_S\sigma$); thus by choosing an appropriate stress $\sigma$ one can set the term to zero and obtain a low $H_k$.

### 3.3.3. Controlling the GMI Effect

Equations (51) and (52) show that the impedance of the ferromagnetic glasses increases with the factor $\sqrt{\omega\mu_{t,\theta}}$ for both ferromagnetic glass wires and ribbons. Hence one can increase the sensitivity of a GMI sensor by increasing the operating frequency. In addition, it is also found that the transverse and circumferential permeabilities are dependent upon the amplitude of the driving current, applied stress, and annealing temperature.

The effect of ac frequency on the GMI% was studied by Knobel et al. [77] and Ovari et al. [78], and they found the GMI% generally increases with frequency. However, depending upon the types of ferromagnetic glasses and annealing conditions, the GMI% decreases when the frequency is beyond 1–200 MHz due to the domain wall damping that causes permeability relaxation at very high frequencies [66]. The amplitudes of the dc bias and ac currents and the internal stress of the ferromagnetic glass have also been found to influence the sensitivity of the GMI%

[79, 80]. However, these parameters interact with each other and also depend on the alloy composition of the ferromagnetic glass. Extensive investigations on the annealing effect on the GMI% have been reported [5, 79, 81–83]. The effect of annealing on GMI is similar to that on magnetoelastic coupling, which is that the increase in annealing temperature increases the GMI%. However, the GMI% drops as the annealing temperature reaches the crystallization temperature of the ferromagnetic glass, which is around 500–600 °C. Recently, Brunetti et al. [84] improved the sensitivity of the GMI sensors by 600% by coating a glass layer on a $Fe_{73.5}Cu_3Nb_1Si_{13.5}B_9$ ferromagnetic glass microwire. Cobeno et al. [85] also altered the sensitivity of the GMI% by applying a tensile stress on a glass-coated $Co_{68.5}Mn_{6.5}Si_{10}B_{15}$ ferromagnetic glass microwire, and they found the maximum improvement for the GMI% occurs at around 60 MPa.

## 4. SENSOR APPLICATIONS

Section 4.1 demonstrates the applications of ferromagnetic glasses in induction-based sensors for measuring field, stress, torque, and displacement. Section 4.2 shows application of ferromagnetic glass wires as magnetoimpedance sensors. Section 4.3 illustrates how ferromagnetic glass wires are used to construct magnetostrictive delay lines for the measurement of stress, torque, and displacement. Magnetoelastic resonant sensors, which are used to measure pressure, liquid flow and density/viscosity, temperature, elasticity, and chemical concentration, are presented in Section 4.4. Section 4.5 demonstrates the uses of ferromagnetic glasses as the sensing elements of MSAW sensors and magnetomechanical-rotation-based sensors.

### 4.1. Induction-Based Sensors with Ferromagnetic Glass Cores

Ferromagnetic glasses were widely used in the 1980s as the permeability/susceptibility-changing ferromagnetic glass cores for the induction-based sensors. Since the inductance of the coil is proportional to the susceptibility of its core material, changes in the ferromagnetic glass susceptibility can be determined from the change of the coil inductance. It is also common to use a pair of excitation and sensing coils, where the excitation coil excites the ferromagnetic glass with an ac magnetic field, and the susceptibility of the ferromagnetic glass is determined from the amplitude of the induced voltage recorded by the sensing coil.

### 4.1.1. Measurement of Stress/Strain

As indicated in Eqs. (44) and (47), the susceptibility and elasticity of the ferromagnetic glasses are strongly dependent upon the applied stress and field. As a result, stresses and strains are readily monitored by measuring the susceptibility of the ferromagnetic glass with an inductive coil. As shown in Figure 21, the inverse susceptibility of the ferromagnetic glass $1/\chi$ shows good linearity with applied stress [12]. For ferromagnetic glasses with positive magnetostriction $1/\chi$ is inversely proportional to $\sigma$ until reaching the demagnetization factor $N$, where $1/\chi$ becomes independent
**Figure 21.** The inverse susceptibility of a ferromagnetic glass: $1/\chi$ linearity decreases with applied stress when the ferromagnetic glass has a positive magnetostriction but linearly increases when the ferromagnetic glass magnetostriction is negative.

of $\sigma$. For negative $\lambda_S$, $1/\chi$ is directly proportional to $\sigma$ starting from $N$. To directly compare the sensitivity of a ferromagnetic glass sensor to semiconductor based stress sensors, the figure of merit for the ferromagnetic glass sensors is derived as [12, 13]

$$F = \frac{\Delta\chi/\chi_0}{\Delta\varepsilon} \approx \frac{3\lambda_S E_M}{2K_U} \tag{53}$$

Metglas alloy 2605SC has been widely used for stress sensing due to its high magnetoelastic coupling coefficient, 0.98 after transverse field annealing, and high magnetostriction of $3 \times 10^{-5}$. The figures of merit of 2605SC Metglas sensors have been calculated to be in the range of $10^5$ [12], three orders of magnitude greater than semiconductor strain gauges. Different experimental configurations were designed to measure the susceptibility shift of the ferromagnetic glass sensors for tensile, compressive, and torsion stresses. Figure 22a is a basic tensile stress sensor designed by Mitchell et al. [86] and later improved by Barandiaran and Gutierrez [87] by connecting the output to a bridge circuit for eliminating the background signal and enhancing the sensitivity of the sensor. The susceptibility of the setup in Figure 22a has a linear response to tensile stress. Figure 22b is an improved toroid-shape sensor designed by Mohri and Korekoda [88] and Meydan et al. [89]. The four terminals in the setup in Figure 22b are connected in a bridge configuration so the signal is zero in an unstressed case, but positive to tensile stress and negative to compressive stress. A stress sensor designed for compressive stress is illustrated in Figure 22c, where the sensor is stretched by a spring, and
the actual stress experienced by the sensor is reduced when compressive stress is exerted [13].

Another application based on ferromagnetic glass stress sensors is the shock detection system proposed by Mohri and Takeuchi [90]. The shock sensor is essentially a stress sensor surrounded by an excitation coil and a sensing coil. When a shock is applied to the sensor, it causes a sudden change in the ferromagnetic glass permeability, which will be captured by the sensing coil as a voltage spike.

### 4.1.2. Torque Measurement

Figure 23a illustrates a novel torque sensor comprised of two ferromagnetic glass strips attached at an angle of 45° to the shaft surrounded by an excitation coil and two series-connected sensing coils. In the absence of torque, the symmetrical configurations of the two ferromagnetic glass strips and the two sensing coils eliminate the background signal. When torque is applied, the ferromagnetic glass strips are stressed or compressed, destroying the symmetry of the magnetic field pattern and causing an induction voltage at the sensing coils. A sensitivity of 1.4 V/N·m at 20 kHz has been reported [91].

Another ferromagnetic glass-based torque sensor is a four-arm orthogonal yoke design shown in Figure 23b [92]. There is no output signal in the absence of torque due to the symmetrical magnetic field pattern on the ferromagnetic glass shaft. However, when a torque is applied at the ends of the shaft, due to the changes in the magnetic field pattern, a signal will appear in the sensing coil at the secondary yoke if an ac field is excited at the primary yoke.

### 4.1.3. Measurement of Magnetic Flux

Due to their high susceptibility and low hysteresis loss ferromagnetic glasses are widely used as the cores of magnetoinductance sensors to measure magnetic flux. Most ferromagnetic glasses used for flux sensing are composed of Co-rich alloys, which have a near-zero magnetostriction ($10^{-7}$). Moldovanu and co-workers [93, 94] designed

**Figure 23.** (a) A coaxial torque sensor consisting of two ferromagnetic glass ribbons. In the absence of torque, the sensing coil receives no signal due to the symmetrical configurations of the two ferromagnetic glasses. When a torque is applied to the shaft, the ferromagnetic glasses are compressed or stretched, destroying the symmetry of the magnetic field pattern and causing an induction voltage at the sensing coil. (b) A torque sensor based on a four-arm orthogonal yoke design, where a signal will appear in the secondary coil if a torque is applied to the ferromagnetic glass shaft and an ac source is excited at the primary coil.

**Figure 22.** (a) A ferromagnetic glass ribbon used to measure tensile stress. (b) A ferromagnetic glass toroid used to measure tensile and compressive stresses. (c) A ferromagnetic glass sensor used to measure compressive stress.

an induction-based magnetic flux sensor by inserting two $Co_{68.25}Fe_{4.5}Si_{12.25}B_{15}$ ferromagnetic glass ribbons inside a sensing coil and an excitation coil. When an external magnetic flux is applied on the ferromagnetic glasses, it changes the apparent permeability of the ferromagnetic glasses and in turn changes the voltage received by the sensing coil. The sensitivity of the sensor is highest when the magnetic flux is parallel to the basal axis of the coil since the coil intercept maximum flux at this orientation. The output voltage of the sensor is linear with magnetic flux with sensitivity between 4.5 and 5.5 $\mu$V/nT, and for fields greater than 100 nT it is independent of temperature variation within 20–70 °C. Using the same principle, Nielsen and co-workers [95, 96] also designed a flux sensor based on Vitrovac 6025 alloys, with a sensitivity of 5–10 $\mu$V/nT; Ghatak and Mitra [97] designed a flux sensor based on CoFeCrSiB with a sensitivity of 3 $\mu$V/nT.

### 4.1.4. Displacement Sensors

Ferromagnetic glasses are also used to measure the object displacement [13]. As shown in Figure 24a, when the location of the magnet changes, so does the magnetic field exerted on the ferromagnetic glass sensing element. Hence, the displacement of the object can be determined from the changes of the ferromagnetic glass permeability. Alternatively, the object of interest can be attached to the end of the ribbon. As the object moves away from the sensor, it pulls the ferromagnetic glass ribbon and changes the applied stress, in turn altering the ribbon susceptibility (see Figure 24b). Using this principle, Mohri [14] came up with a displacement sensor that can detect a displacement of approximately 1 $\mu$m.

### 4.2. Giant Magnetoimpedance/ Stress-Impedance Sensors

The basic design of a GMI sensor is illustrated in Figure 25. The two ends of a ferromagnetic glass wire are connected to a dc-biased ac current source and a voltmeter, and the

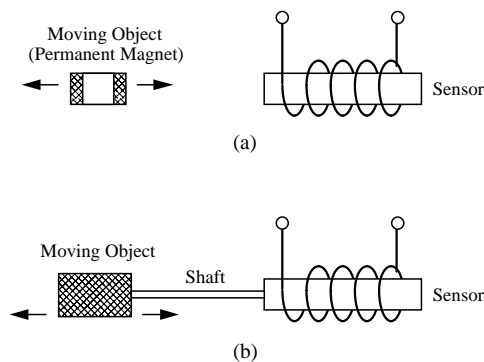

**Figure 24.** (a) A displacement sensor using a permanent magnet as a marker. The displacement of the magnet changes the dc bias field on the ferromagnetic glass, which in turn changes the permeability. (b) A displacement sensor where the object of interest is attached to the end of a ferromagnetic glass ribbon. As the object moves, it pulls the ferromagnetic glass, creating a stress on the ferromagnetic glass and changing the permeability.

**Figure 25.** A magnetoimpedance sensor. The two ends of a ferromagnetic glass ribbon are connected to a dc-biased ac current source and the voltage across the two ends is measured.

impedance of the ferromagnetic glass $Z$ is determined by taking the ratio of the measured voltage to the applied current. A typical response of a GMI sensor using a circumferential anisotropic amorphous wire is illustrated in Figure 26, where it shows the GMI% increases rapidly with applied magnetic field $H$ when $H$ is smaller than $H_k$ but decreases with $H$ for $H > H_k$.

### 4.2.1. Giant Magnetoimpedance Sensors Based on Ferromagnetic Glasses

Utilizing the GMI effect, ferromagnetic glass wires are widely used as magnetometers for detecting magnetic field in the range of few Oersteds (a few hundred A/m). Some commonly used ferromagnetic glass alloys for GMI sensors are $Fe_{4.35}Co_{68.15}Si_{12.5}B_{15}$ and $Co_{72.5}Si_{12.5}B_{15}$ [98], $Co_{68.5}Mn_{6.5}Si_{10}B_{15}$ [85], and $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ [5].

To increase the sensitivity, linearity, and signal-to-noise ratio of the GMI sensors, usually the ferromagnetic glass wires are connected to oscillator circuits, such as the Colpitts oscillator [68, 99] and the double Hartley oscillator [100]. Figure 27a is a Colpitts oscillator that utilizes the resonance of the inductance of the ferromagnetic glass and the capacitance $C_1$ and $C_2$ to create an ac signal to excite the ferromagnetic glass. This design allows the GMI% of the ferromagnetic glass to increase several times at frequencies of $\approx$100 MHz. Since the oscillator output roughly follows the GMI curve, this sensor design provides nonlinear results similar to the curve shown in Figure 26. By applying a longitudinal bias field, Bushida et al. [68] were able to shift the curve in Figure 26 horizontally and allowed the ferromagnetic glass to operate linearly over the range of interest.

**Figure 26.** A typical response of a magnetoimpedance sensor. The GMI ratio increases rapidly at low magnetic field $H$ until reaching the anisotropy field of the ferromagnetic glass, whereupon the GMI ratio starts falling off with increasing $H$.

An oscillator circuit that provides linear output, the double Hartley oscillator, is shown in Figure 27b [100, 101]. For this design, two identical ferromagnetic glasses biased by two opposing magnetic fields $H_b$ are needed. As shown in Figure 28, the output of this sensor is almost linear in the range of $-H_b < H < H_b$. In Bushida's design [100], for example, the sensitivity of the GMI% can reach to $10^{-6}$ Oe at $\pm 1$ Oe (80 A/m) full scale for an ac field. The biasing fields $H_b$, however, require small solenoids wound around the ferromagnetic glasses, which is a major restriction for sensor miniaturization. By using twisted amorphous wires with dc bias currents, Kitoh and co-workers [98] were able to avoid using solenoids and yet retain the linear characteristic for a limited range of magnetic field.

### 4.2.2. Stress-Impedance Sensors Based on Ferromagnetic Glasses

When a tensile stress is applied to a near-zero magnetostriction ferromagnetic glass it changes the saturation magnetostriction coefficient, causing a variation in the ferromagnetic glass permeability and in turn the impedance. Utilizing this stress-impedance (SI) effect, a stress sensor was constructed by passing a high-frequency current through a $Co_{66.3}Fe_{3.7}Si_{12}B_{18}$ ferromagnetic glass ribbon (10 cm × 0.8 mm × 18 $\mu$m) and measuring the voltage across the wire [102]. The impedance of the ferromagnetic glass is found to be linearly decreasing with applied stress, and the impedance change is about 10% over the range of zero to 500 MPa. Based on the SI effect, ferromagnetic glasses were incorporated into multivibrator circuits for the detection of blood vessel pulsation [103, 104]. Ferromagnetic glasses have also been used to measure liquid flow rate [105], with the stress associated with flow over the surface of the sensor changing its electrical impedance.

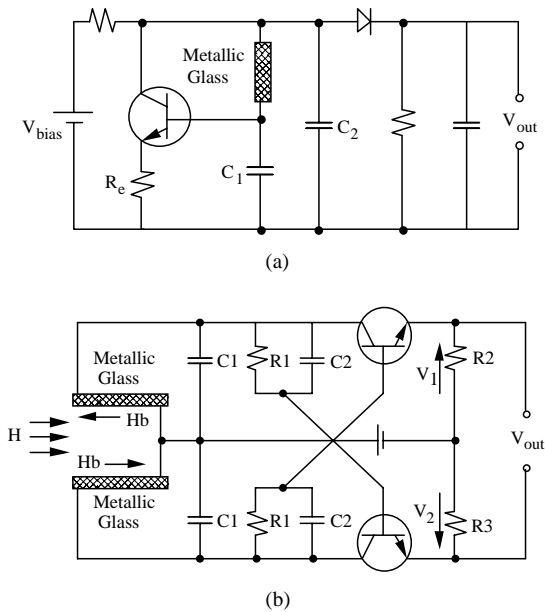
(b)


**Figure 27.** A magnetoimpedance sensor connected to (a) a Colpitts oscillator and (b) a double Hartley oscillator. Although more complicated in design, the double Hartley oscillator provides better linearity in output voltage.

**Figure 28.** The output of the double Hartley oscillator, where $V_{out}$ is linear when the applied field is smaller than the bias field.

## 4.3. Magnetostrictive Delay Line Sensors

Ferromagnetic glasses, in particular Fe-rich alloys, are widely used to construct magnetostrictive delay lines since they have a large magnetoelastic coupling, which allows efficient energy conversion between magnetic fields and acoustic waves. The basic arrangement of the MDL is illustrated in Figure 29: A current pulse is first sent to the excitation coil to generate an ac magnetic field, and an elastic wave is created and propagated along the MDL due to the magnetostrictive effect. As the elastic wave propagates to the other end of the MDL, it generates an induction voltage at the sensing coil due to the inverse magnetostrictive effect. The parameter of interest, such as force, which is applied between the source and receiver, dissipates the elastic energy of the propagating acoustic wave and in turn attenuates the induction voltage received at the sensing coil. By taking the ratio of the received voltage to the excitation voltage, the attenuation of the elastic wave can be determined and used to measure the applied force. Bias fields are usually applied at the excitation and receiving regions to enhance the magnetostrictive effect of the ferromagnetic glass.

### 4.3.1. MDL Stress and Torque Sensors

Hristoforou and Reilly [17] designed a simple MDL force sensor using a Metglas 2605SC ribbon. The sensor is similar to that shown in Figure 29, but with the excitation coil

**Figure 29.** The basic arrangement of a magnetoelastic delay line. An elastic wave is generated by the excitation coil and propagated along the MDL due to the magnetostrictive effect. As the elastic wave propagates to the other end of the MDL, it causes an induction voltage at the sensing coil by the inverse magnetostrictive effect.

replaced by a conductor line carrying a voltage pulse. Experimental results show the MDL force sensor can detect a small force of 0.01 N, and the force dependency follows an exponential profile up to 0.35 N.

Chiriac et al. [34] and Hristoforou et al. [18] also designed a stress and torque sensor based on the MDL. The sensor, illustrated in Figure 30, consists of a FeSiB ferromagnetic glass wire with its top end fixed and bottom end loaded with a mass or torque. An excitation coil is placed near the top end of the wire to generate an acoustic wave, and a sensing coil is placed at the bottom end to convert the propagating acoustic wave to an induced voltage. Two bias coils are used to generate the required biasing field for enhancing the magnetostrictive effect of the ferromagnetic glass. The attenuation of the acoustic wave, which is due to the mass load or torque, is recorded as the reduction in the measured induced voltage. Their experimental results show the as-cast ferromagnetic glass sensor has a linear response toward force and a monotonic but nonlinear response toward torque. They also found that annealing the ferromagnetic glass at 300 °C, which increases the magnetoelastic coupling and magnetostriction, increases the sensitivity but reduces the linearity of the sensor response. Recently, Hristoforou and co-workers [19] and Chiriac et al. [34] simplified the design of their MDL stress/torque sensor by using overlapping sensing and excitation coils. Since both ends of the ferromagnetic glass wire are bound, the acoustic wave generated by the excitation coil will be reflected from the ends back to the sensing coil. The response of the overlapping coil design is almost identical to the original design.

A stress sensor designed for measuring thin film thickness using the MDL arrangement was developed by Hristoforou and co-workers [20]. The sensor, shown in Figure 31, consists of two ferromagnetic glasses at the ends of a rectangular glass substrate. An acoustic wave is generated by one of the ferromagnetic glasses and propagates along the substrate. When the acoustic wave reaches the other ferromagnetic glass, an induced voltage proportional to the amplitude

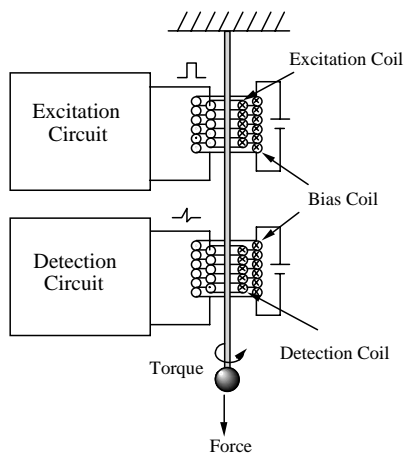

**Figure 30.** A MDL stress and torque sensor. The sensor is composed of a ferromagnetic glass wire with one of its ends fixed and the other loaded with a mass or applied torque. An excitation coil is placed near the top of the wire to generate an acoustic wave, and a sensing coil is placed at the bottom end to convert the propagating acoustic wave to an induced voltage.

**Figure 31.** A MDL stress sensor consisting of two ferromagnetic glasses at the ends of a rectangular substrate. An acoustic wave is generated by one of the ferromagnetic glasses, the signal propagates along the glass substrate at a speed dependent upon coating thickness, and it is captured by the other ferromagnetic glass.

of the acoustic wave is generated. Since the acoustic wave attenuation is directly proportional to the mass load on the glass substrate the thin film thickness can be determined by measuring the amplitude of the induced voltage.

### 4.3.2. MDL Displacement and Vibration Sensors

Using the MDL setup, ferromagnetic glasses are also used to measure the displacement of an object by attaching the object to a ferromagnetic glass ribbon, or attaching the moving object with a marker magnet. The displacement sensor designed by Germano et al. [22], similar to that shown in Figure 30, consists of a long ferromagnetic glass ribbon surrounding by an excitation coil and a receiving coil; the object of interest is attached to the end of the ribbon. As the object moves away from the sensor, it pulls the ferromagnetic glass ribbon and changes the applied stress, altering the attenuation of the acoustic wave and in turn changing the voltage received by the receiving coil. Germano used $Fe_{40}Ni_{40}P_{14}B_6$, $Fe_{80}B_{14}Si_6$, and $Fe_{82}B_{12}Si_4C_2$ in their experiment, and they found that $Fe_{40}Ni_{40}P_{14}B_6$ has the best linearity compared to the others, which is due to the linear stress dependency on the magnetostriction for that material. Another MDL displacement sensor by Germano and Lanotte [21] consists of a ferromagnetic glass ribbon surrounded by a pair of excitation and detection coils, but the moving object is a permanent magnet. When the permanent magnet changes position, the dc magnetic field experienced by the ferromagnetic glass ribbon changes, changing the ribbon susceptibility and the acoustic wave attenuation.

The displacement sensor developed by Chariac and Marinescu [16] consists of a long ferromagnetic glass with an excitation coil at one end; see Figure 32. The ferromagnetic glass is set to resonance so a standing wave is generated along the sensor. A mobile pick-up coil is then moved along the length of the sensor. Since the sensor experiences a standing wave vibration, the voltage recorded by the pick-up coil $V$ will be in the form of $V(x) = V_0 \sin(\pi x/L)$, where $x$ is the displacement, $L$ is the sensor length, and $V_0$ is a constant depending on the sensor setup; the displacement $x$ is determined from the measured voltage $V$.

Due to its high sensitivity and fast response, the MDL displacement sensor is also used to detect small vibrations. Ausanio and co-workers [106] have successfully illustrated
**Figure 32.** A displacement sensor consisting of a ferromagnetic glass set to resonance so a standing wave is generated along the sensor. A mobile pick-up coil is then moved along the length of the sensor, and the displacement $x$ is determined from the measured voltage $V$.

the detection of a vibrating steel ribbon by placing a MDL displacement sensor near the ribbon. The vibration of the steel ribbon changes the magnetic flux distribution around the ferromagnetic glass, and in turn changes the susceptibility of the ferromagnetic glass and the output voltage from the sensing coil.

## 4.4. Magnetoelastic Resonant Sensors

Magnetoelastic resonant sensors operate by monitoring the changes in the magnetoelastic resonant frequency of a ferromagnetic glass ribbon in response to changing stress and field. Generally, magnetoelastic resonant sensors are made of Fe-rich ferromagnetic glasses because they have a high magnetostriction coefficient, which allows them to exhibit pronounced mechanical vibrations, when excited by an ac magnetic field, and high magnetoelastic coupling, which allows efficient conversion between magnetic energy and elastic energy.

To determine the resonant frequency of a ferromagnetic glass ribbon, an ac magnetic field is first generated from an excitation coil to vibrate the ribbon. The frequency response of the sensor in vibration is then recorded as an induced voltage at the sensing coil. The excitation and detection of the sensor can be performed in the frequency domain, where a function generator produces a frequency-varying sinusoidal wave at the excitation coil, and the voltage across the sensing coil is measured as a function of frequency (see Fig. 33). The sensor can also be excited and detected in

**Figure 33.** Magnetoelastic ferromagnetic glass sensors can be interrogated magnetically, acoustically, or optically. Magnetically the sensor is excited by an excitation coil and is detected by a sensing coil, while acoustically it is detected by a microphone in air or hydrophone in liquids. A laser emitter and a phototransistor are used to interrogate the sensor optically.

the time domain, where a pulse generator produces a magnetic pulse, and a digital oscilloscope is used to capture the transient time-dependent response of the sensor. The time-domain signal is then converted to the frequency domain using fast Fourier transform, from which the resonant frequency is determined.

Recently, Jain et al. [107] proposed the detection of the resonant frequency of the magnetoelastic resonant sensors acoustically with a microphone. The advantage of acoustic detection is the longer detection range; up to 1 m has been reported. In addition to the acoustical detection method, the sensor can be detected optically by shining a laser beam on the sensor surface [108]. The vibration of the sensor modulates the intensity of the laser beam reflected off the vibrating surface, and the changes in intensity are detected by a phototransistor as a change in voltage that can be monitored electronically. The advantage of the optical detection method is the large detection range; up to few meters have been reported. However, the optical detection method requires precise sensor alignment. The magnetic, acoustic, and optical detection methods are illustrated in Figure 33.

### 4.4.1. Pressure Measurement

A magnetoelastic resonant sensor for measuring atmospheric pressure was developed by Grimes et al. [109] using an as-cast Metglas 2826MB ribbon. The variation of the atmospheric pressure changes the vibrational modes of a stressed sensor in turn changing the resonant frequency. Experimental results show that the Metglas 2826MB sensor is linearly dependent upon atmospheric pressure over the range of 0 to 80 psi (550 kPa), with a resonant frequency shift of 5 Hz/psi (0.73 Hz/kPa). Recently Kouzoudis and Grimes [110] showed that the sensitivity of the pressure sensor could be increased by prestressing the sensor through dimpling, curving, or folding the sensor. The curving of the sensor causes a vibration in the basal plane of the sensor in addition to the longitudinal vibration. Since the surface area on the basal plane is at least three orders larger than the cross section of a typical sensor ribbon, the basal plane vibration significantly increases the sensor interactions with air, leading to a large increase in sensitivity.

### 4.4.2. Monitoring of Liquid Flow Rate

A ferromagnetic glass ribbon can also be used to measure liquid flow rates since laminar flowing liquid creates a stress, which is proportional to the flow rate, on the sensor surface and causes changes in the magnetoelastic resonant frequency of the ribbon. A magnetoelastic resonant sensor for fluid-flow measurement was fabricated using a Metglas 2826MB ribbon by Kouzoudis and Grimes [24]. The sensor length is placed parallel to the flow direction of the liquid. When the liquid flow is laminar, the stress on the sensor surface follows a parabolic profile, resulting in a quadratic decrease in the resonant frequency. However, when the flow turns to turbulence, the applied stress is not uniform over the sensor surface, causing the resonant frequency to shift upward.

### 4.4.3. Simultaneous Measurement of Liquid Viscosity and Density

When a ferromagnetic glass ribbon is immersed in a liquid, the shear wave created in the liquid due to the ribbon vibration generates a damping force opposing the oscillations of the ribbon and changes the resonant frequency and the quality factor of the ribbon. For a flat ferromagnetic glass ribbon with perfect surface smoothness immersing in a liquid, the resonant frequency shift $\Delta f$ is given by [24]

$$\Delta f = \frac{\sqrt{\pi f_0}}{2\pi \rho_s d} (\eta_l \rho_l)^{1/2} \tag{54}$$

where $f_0$ is the resonant frequency of the ferromagnetic glass ribbon in the air, $\rho_s$ and $d$ are the density and thickness of the ribbon, and $\eta_l$ and $\rho_l$ are the liquid viscosity and density. In Eq. (54), $\eta_l$ and $\rho_l$ are inseparable; thus measurement of $\eta_l$ and $\rho_l$ with a smooth ribbon is impossible. However, due to surface roughness, the liquid trapped in the ferromagnetic glass surface pores will act like a mass loading instead of a damping force. To compensate for the mass loading effect, Eq. (54) is modified as

$$\Delta f = \frac{\sqrt{\pi f_0}}{2\pi \rho_s d} (\eta_l \rho_l)^{1/2} - \frac{\rho_l \Delta V f_0}{2M} \tag{55}$$

where $\Delta V$ is the volume of liquid trapped by the surface roughness of the ribbon, and $M$ is the mass of the ribbon. From Eq. (55) the liquid density and viscosity can be separated by using two ferromagnetic glass ribbons with different surface roughnesses, indicated by subscripts 1 and 2, and finding the difference of the two resonant frequencies as

$$\Delta f_2 - \Delta f_1 = \rho_l \frac{(\Delta V_1 - \Delta V_2) f_0}{2M} \tag{56}$$

Figure 34a illustrates the measurement of liquid density using two 30 mm × 3 mm × 30 $\mu$m Metglas 2826MB ribbons, one coated with $TiO_2$ on both sides and the other uncoated. Figure 34b shows that the frequency shift difference between the two ferromagnetic glass ribbons is linearly proportional to the liquid density.

For highly viscous liquid, the damping force generated by the liquid becomes too large for the ferromagnetic glass to exhibit a detectable resonance. In practice, highly viscous liquids can be measured by dipping a small fraction of the ferromagnetic glass ribbon into the liquid [111]. Experimental results [111] show that the sensitivity of the ferromagnetic glass increases as the immersion depth increases, up to the point where the damping force in the liquid becomes too large for the ferromagnetic glass ribbon to resonate. The effect of surface roughness for mechanically oscillating sensors on liquid property measurements is described in detail by Jain and Grimes in [112].

### 4.4.4. Elasticity Measurement

The elasticity of a thin-film coating can also be determined by monitoring the shifts in the resonant frequency of a coated ferromagnetic glass ribbon. The ratio between the resonant frequency of a ribbon coated with the material of

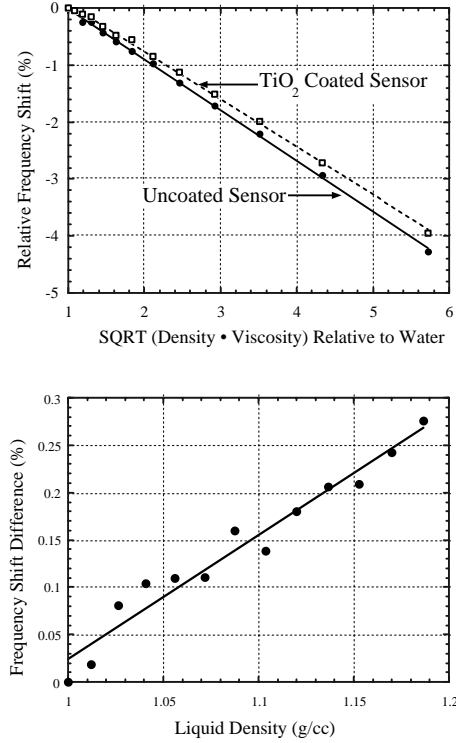

**Figure 34.** (a) Relative frequency shifts vs (density × viscosity)$^{1/2}$ of an uncoated sensor and a $TiO_2$-coated sensor. (b) The difference between the frequency shifts of a $TiO_2$-coated and an uncoated sensors vs the liquid density.

interest $f_t$ and the resonant frequency of an uncoated ribbon $f_0$ can be shown as [27]

$$\left(\frac{f_t}{f_0}\right)^2 = (1 - \beta^2)\frac{m_0}{m_t} + \beta^2 \tag{57}$$

where $m_0$ and $m_t$ are respectively the mass of the uncoated and coated ribbons, and $\beta$ is

$$\beta = \sqrt{\frac{E_c \rho_s}{E_S \rho_c}} \tag{58}$$

where $E_S$ and $E_C$ are respectively the Young's moduli of the ferromagnetic glass and the coating, and $\rho_s$ and $\rho_c$ are respectively the mass density of the ferromagnetic glass and the coating. To determine the elasticity of the coating, the mass and resonant frequency of the uncoated ribbon are first measured. A uniform coating is then applied and the resonant frequency and mass are determined. The process is repeated $N$ times until sufficient data points are collected. The value of $\beta$ can then determined by applying a least-square fit on the collected data using Eq. (57) as

$$\beta^2 = \frac{\sum_{i=1}^{N} \left(\left(\frac{f_t^i}{f_0}\right)^2 - \frac{m_0}{m_t^i}\right)\left(1 - \frac{m_0}{m_t^i}\right)}{\sum_{i=1}^{N} \left(1 - \frac{m_0}{m_t^i}\right)^2} \tag{59}$$

The parameters $E_S$, $\rho_s$, and $\rho_c$ are measured before the experiment. By substituting the calculated $\beta$ into Eq. (58), the Young's modulus of the material of interest $E_C$ is
**Figure 35.** The relative resonant frequency of the ferromagnetic glass decreases linearly with the relative mass of sliver coating. A least square fit (dashed line) is used to calculate the Young's modulus of the silver.

**Figure 36.** The resonant frequency shifts of a ferromagnetic glass sensor vs temperature and bias field $H$. The highest positive temperature dependency happens at $H = 9.9$ Oe (790 A/m), highest negative temperature dependency at $H = 16.51$ Oe (1.32 kA/m), and zero-temperature dependency at $H = 7.01$ Oe (560 A/m).

determined. Figure 35 plots the frequency shift of a silver-coated sensor as a function of coating mass. The data points were fitted with Eq. (59) and $E_S$ of silver is determined as 74.8 GN/m², only 1.6% different from the theoretical value. Experiments for calculating the Young's moduli of aluminum, polyurethane paint, and acrylic paint have been conducted by Schmidt and Grimes [27], and the errors are all less than 2% of the theoretical values.

### 4.4.5. Temperature Measurement

Ferromagnetic glasses are also used for monitoring ambient temperature. Temperature influences mechanical properties such as material elasticity (at constant magnetization) $E_M$ and magnetic properties such as $\lambda_S$, $M_s$, and $H_k$. For an unloaded ferromagnetic glass ribbon, the resonant frequency is dependent upon the temperature $T$ and applied bias field $H$ as [26]

$$f_0(T, H) = \frac{1}{2L(T)} \sqrt{\frac{E_M(T)}{\rho_s}} \left( 1 + \frac{9\lambda_S^2(T)H^2 E_M(T)}{M_s(T)H_k^3(T)} \right)^{-1/2} \tag{60}$$

As indicated in Eq. (60), the resonant frequency shift of the ferromagnetic glass ribbon can be positive or negative, large or small, depending upon the material properties of the sensor and the applied field. For a temperature sensor, an appropriate $H$ field can be applied to the ribbon to yield an optimum temperature sensitivity, while for other sensor applications the value of $H$ must be chosen so that the ribbon has a minimum temperature dependency. The temperature

dependency of a 3 cm × 1.27 cm × 30 $\mu$m 2826MB Metglas ribbon is plotted in Figure 36 for varying $H$. From the plot, the maximum positive temperature dependency happens at $H = 9.9$ Oe (790 A/m), maximum negative temperature dependency happens at $H = 16.51$ Oe (1.32 kA/m), and zero-temperature dependency can be achieved at $H = 7.01$ Oe (560 A/m).

### 4.4.6. Chemical Monitoring

By applying a mass-changing chemically responsive layer (CRL), magnetoelastic ferromagnetic glass sensors have been used to monitor chemical analyte concentrations including glucose, carbon dioxide ($CO_2$), ammonia ($NH_3$), and pH. Table 4 lists various magnetoelastic chemical and gas sensors that have been built and tested.

Generally, the mass change for these CRLs is small, so the resonant frequency shift $\Delta f$ is linear,

$$\Delta f = -f_0 \frac{\Delta m}{2m_t} \tag{61}$$

where $\Delta m$ is the change of mass and $m_t$ is the total mass of the sensor and the coating. Figure 37 shows that the resonant frequency of the $CO_2$ sensor, based on acrylamide and isooctylacrylate coating, decreases linearly with the $CO_2$ percentage. Figure 37 also shows that the sensitivity of the sensor increases with the coating thickness until 20 $\mu$m, where the mass load is too large for the sensor to resonate.

**Table 4.** Magnetoelastic sensors are used to monitor humidity, $CO_2$, $NH_3$, pH, and glucose based on the mass change of the chemical responsive layers.

| Sensor | Chemical responsive layer | Maximum $\Delta f$ | Range | Stability | Ref. |
|---|---|---|---|---|---|
| $CO_2$ | acrylamide + isooctylacrylate | −5.6 Hz/vol% | 0–50 vol% | stable | [31] |
| $NH_3$ | poly(acrylic acid-co-isooctylacrylate) | −14 Hz/log(vol%) | 0–100 vol% | stable | [33] |
| pH | acrylic acid (20 mol%) + iso-octylacrylate (80 mol%) | −333 Hz/pH | 5.5–8.5 pH | stable | [32] |
| Glucose | PVA and a co-polymer made of DMAA, BMA, DMAPAA, MAAPBA | −13 Hz/(mg/L) | 0–100 mg/L | dissolves after four cycles | [28] |
| Humidity | titanium dioxide alumina | −1.2 Hz/% RH | 2–98% RH | stable | [29] |
**Figure 37.** A ferromagnetic glass $CO_2$ sensor; the $CO_2$ sensitive coating is synthesized from acrylamide and isooctylacrylate [31].

## 4.5. Ferromagnetic Glass Sensors Based on Other Principles

### 4.5.1. Magneto-Surface-Acoustic-Wave Sensors

Chiriac and co-workers [113] proposed the fabrication of a magneto-surface-acoustic-wave sensor based on the ferromagnetic glass $Fe_{70}B_{15}Si_{15}$ thin film and $(Fe_{70}B_{15}Si_{15}/SiO_2)$ multilayer as the active layer. The design of a MSAW is illustrated in Figure 38, where an acoustic wave is generated using an interdigital transmitter and is received with another interdigital receiver. The ferromagnetic glass active layer is sputtered on the substrate. When a force or magnetic field is applied on the ferromagnetic glass layer, it changes the internal stresses within the ferromagnetic glass, which in turn changes the velocity of the acoustic wave that travels across the ferromagnetic glass layer. As a result, by monitoring the amplitude of the received voltage at the interdigital receiver, the MSAW can be used to measure magnetic field, stress, and pressure.

### 4.5.2. Ferromagnetic Glass Sensors Based on Magnetomechanical Rotation

A viscosity sensor [35] has been reported by Vazquez and co-workers based on a gyromagnetic effect: a spontaneous mechanical rotation of a large magnetostrictive ferromagnetic glass wire when subjected to an ac magnetic field having a frequency of the order of kHz, applied along the

**Figure 38.** A magneto-surface-acoustic wave sensor based on the ferromagnetic glass thin film. An acoustic wave is generated using an interdigital transmitter and is received with an interdigital receiver. The ferromagnetic glass active layer is sputtered between the transmitter and the receiver on the substrate.

**Figure 39.** A viscosity sensor based on the spontaneous mechanical rotation of a large magnetostrictive ferromagnetic glass. When the ferromagnetic glass wire is subjected to an ac magnetic field, it rotates and the copper wire attached to it will modulate the laser beam enabling rotation frequency to be determined. The rotation frequency of the ferromagnetic glass wire decreases linearly with increasing viscosity, as highly viscous liquid creates more friction on the wire surface.

wire axis [114, 115]. Although the exact origin of the spontaneous rotation is still unclear, it is widely believed this phenomenon is connected to the conversion of the magnetoelastic standing wave energy to the mechanical rotation energy at magnetoelastic resonance [116]. As illustrated in Figure 39, the ferromagnetic glass wire is vertically supported by two short glass tubes while immersing in the liquid of interest. A copper wire is perpendicularly connected to the top end of the wire, so when the ferromagnetic glass rotates the copper wire can block a laser beam thereby determining angle. Vazquez experimented on FeSiB and CoSiB, and they found that the rotation frequencies of both ferromagnetic glasses are dependent upon the magnitude and frequency of the ac magnetic field. However, FeSiB is more suitable for viscosity measurement because it has a higher rotation frequency, which reduces the experimental error because more averages can be taken for a given time period. Results show that the rotation frequency of the ferromagnetic glass wire decreases linearly with increasing viscosity, since the viscosity of the liquid creates a frictional force on the wire surface that slows the rotation.

## 5. SUMMARY

The properties of ferromagnetic glasses and their applications as useful sensors have been reported. Ferromagnetic glasses are suitable for sensor applications due to their changing susceptibility, impedance, and magnetoelastic resonant frequency in response to various parameters including stress/strain, temperature, and magnetic field. Ferromagnetic glasses are fabricated by rapid quenching from a melt to prevent the formation of crystalline structure. Alloy compositions in the ferromagnetic glasses play an important role on the properties of the materials. Generally, Fe-rich and rare-earth-based amorphous alloys have a large magnetostriction, while Co-rich alloys have a small or zero magnetostriction. To control the desired properties, as-cast

ferromagnetic glasses are generally annealed under applied transverse field or stress. For example it has been found that transverse field annealing can improve the magnetoelastic coupling and magnetostriction of Metglas 2605SC to 0.98 and $3 \times 10^{-5}$, respectively.

One of the most common applications of ferromagnetic glasses is in the cores of induction-based sensors for the measurement of stress/strain, torque, magnetic field, and displacement. Although there are many different designs available, the operational principle is based on the changing susceptibility of the materials with applied stress and field. It is found that the sensitivity of a ferromagnetic glass stress sensor can be three orders higher than a standard semiconductor stress sensor. Ferromagnetic glasses are also used as displacement sensors by attaching a small magnet on a moving object, or directly attaching the moving object on a ferromagnetic glass.

Ferromagnetic glasses are widely used as the sensing elements of magnetoimpedance sensors. The magnetoimpedance sensors based on ferromagnetic glasses are suitable for the detection of small magnetic field; up to $10^{-6}$ Oe within 1 Oe (80 A/m) full scale has been reported. By constructing magnetostrictive delay lines using ferromagnetic glass wires, parameters such as stress, torque, and displacement have been measured. In addition, ferromagnetic glasses are also used as the active layer of a magneto-surface-acoustic-wave sensor. A viscosity sensor based on the spontaneous rotation of a ferromagnetic glass wire under an ac excitation field has also been built and successfully tested.

Magnetoelastic resonant sensors, which operate by monitoring the changes in the magnetoelastic resonant frequency, are commonly made of high magnetostrictive ferromagnetic glass alloys. Magnetoelastic resonant sensors are used to track the variation in atmospheric pressure and the liquid flow rate since these parameters apply a stress on the surface of the ferromagnetic glasses that changes the resonant frequency. Magnetoelastic resonant sensors have also been used for simultaneous measurement of liquid viscosity and density by using two ribbons with different surface roughness because the resonant frequency depends upon the viscosity and density of the liquid, as well as the surface roughness of the ribbon. In addition, magnetoelastic resonant sensors can also be used to measure the elasticity of an applied coating of known mass. A temperature sensor was also fabricated from a Metglas 2826MB ribbon, the sensitivity of which is controllable by the applied dc magnetic biasing field. In combination with a mass-changing chemical responsive layer the magnetoelastic resonant sensors have been used to measure chemical analyte concentrations such as pH, glucose, carbon dioxide, ammonia, and humidity. For small mass loading, the resonant frequency shifts down linearly with increasing mass. The advantage of this type of chemical sensor is its remote query capability making it ideally suited for applications requiring *in-situ* and *in vivo* monitoring.

## LIST OF SYMBOLS

| | |
|---|---|
| $a$ | radius of the ferromagnetic glass wire |
| $B_r$ | remanence |
| $B_s$ | saturation induction |
| $C$ | Curie constant |
| $d$ | thickness of the ferromagnetic glass ribbon |
| $D$ | electric flux density |
| $E_C$ | Young's modulus of the ferromagnetic glass coating at a constant applied field |
| $E_{ex}$ | exchange energy |
| $E_H, E_S$ | Young's modulus of the ferromagnetic glass ribbon at a constant applied field |
| $E_M$ | Young's modulus of the ferromagnetic glass ribbon at a constant magnetization |
| $F$ | figure of merit |
| $f_n$ | $n$th harmonic resonant frequency of a vibrating ferromagnetic glass sensor |
| $f_t$ | resonant frequency of a ferromagnetic glass ribbon after applying a thin coating |
| GMI% | giant magnetoimpedance ratio |
| $H, H_{appl}$ | applied magnetic field |
| $H_c$ | coercive force |
| $H_i$ | internal magnetic field |
| $H_k$ | anisotropy field |
| $H_d$ | demagnetizing field |
| $H_{max}$ | saturation magnetic field |
| $I$ | electric current |
| $j$ | complex number |
| $J_c$ | conduction current |
| $J_{ex}$ | exchange integral |
| $k$ | effective magnetoelastic coupling |
| $k_B$ | Boltzmann constant |
| $K$ | anisotropy constant |
| $K_U$ | anisotropy energy |
| $L$ | length of the ferromagnetic glass sensor |
| $m_0$ | mass of the ferromagnetic glass sensor |
| $m_t$ | mass of the ferromagnetic glass sensor after applying a thin coating |
| $M$ | magnetization |
| $M_s$ | saturation magnetization |
| $N, N_d$ | demagnetization factor |
| $p_m$ | Coulomb magnetic moment |
| $q_e$ | electric charge |
| $Q_m$ | Coulomb magnetic pole strength |
| $R_{dc}$ | dc electrical resistance |
| $s$ | electron spin |
| $T$ | temperature, torque |
| $T_\theta$ | Curie temperature |
| $T_c$ | crystallization temperature |
| $u_a$ | anisotropy energy |
| $u_{el}$ | elastic energy |
| $u_{m\ell}$ | magnetoelastic energy |
| $u_x$ | displacement of a vibrating ferromagnetic glass sensor |
| $V, V_1, V_2$ | measured voltage across the length of the ferromagnetic glass sensor |
| $w$ | width of the ferromagnetic glass ribbon |
| $Z$ | electrical impedance |
| $\chi$ | magnetic susceptibility |
| $\chi_0$ | magnetic susceptibility of a ferromagnetic glass sensor at zero applied stress |
| $\Delta\chi$ | change of magnetic susceptibility |
| $\Delta E$ | the $\Delta E$ effect, defined as the fractional difference between $E_M$ and $E_H$ |
| $\Delta\varepsilon$ | change of applied strain |

| | |
|---|---|
| $\Delta f$ | resonant frequency shift |
| $\Delta m$ | variation of mass |
| $\Delta V$ | volume of the liquid trapped in the ferromagnetic glass surface |
| $\alpha$ | directional cosines of magnetization |
| $\delta$ | domain wall thickness |
| $\varepsilon$ | magnetostrictive strain |
| $\gamma$ | Weiss constant |
| $\eta_l$ | liquid viscosity |
| $\lambda_S$ | magnetostriction constant |
| $\mu$ | magnetic permeability |
| $\mu_0$ | magnetic permeability in vacuum |
| $\mu_m$ | magnetic moment |
| $\mu_r$ | relative magnetic permeability |
| $\mu_t$ | transverse permeability of the ferromagnetic glass ribbon |
| $\mu_\theta$ | circumferential permeability of the ferromagnetic glass wire |
| $\upsilon$ | velocity |
| $\rho_c$ | density of the coating material of the ferromagnetic glass sensor |
| $\rho_e$ | electrical resistivity |
| $\rho_{es}$ | surface charge density |
| $\rho_s$ | density of the ferromagnetic glass sensor |
| $\rho_l$ | liquid density |
| $\sigma$ | applied stress |
| $\sigma_p$ | Poisson's ratio |
| $\omega$ | radian frequency |

## GLOSSARY

**Giant magnetoimpedance** a phenomenon that significantly changes the radio-frequency electrical impedance of a magnetic conductor with a small variation of magnetic field.

**Magnetoelastic** the coupling between the elastic energy and magnetic energy in a magnetostrictive material.

**Magnetostriction** deformation of a ferromagnetic material when subjected to the influence of an external magnetic field.

$\Delta E$ **effect** variation in the elastic modulus of a magnetoelastic material when exposed to different magnetic fields.

# Magnetotransport in Nanogranular Materials

## Jinke Tang

*University of New Orleans, New Orleans, Louisiana, USA*

## CONTENTS

## 1. INTRODUCTION

Granular systems consist of granules of one phase embedded in the matrix of a second phase. The grain boundaries sometimes act as the second phase separating the grains. One or both phases can be conducting. In the case when both are conducting, electron transport is dominated by the scattering. Tunneling between metallic grains becomes the main transport mechanism when the second phase is an insulator. The transport in these types of granular systems exhibits so-called giant magnetoresistance (GMR) and tunneling magnetoresistance (TMR) if the particles are magnetic [1–9]. GMR and TMR in layered and granular thin films have revealed a host of fascinating physics of spin-dependent electron transport. They have also had an enormous impact on the information technology and electronics industries.

One of the primary potential applications of GMR and TMR materials is as the sensor element in magnetoresistance (MR) read heads and magnetic memories. In recent years, the traditional inductive heads in magnetic recording devices have steadily been replaced by magnetoresistance heads for several reasons: Magnetoresistive elements provide a velocity-independent signal, a more durable and robust recorded signal, and greater sensitivity and lower noise than inductive elements. Among magnetoresistive heads, GMR/TMR heads exhibit superior properties to permalloys due to their much-enhanced MR values. These spin-dependent transport materials also have potential application in nonvolatile memories. Magnetic random access memory (MRAM), an integrated magnetic memory technology that uses magnetic storage and magnetoresistive reading with semiconductor support circuits, is currently being developed based on GMR/TMR technologies. Other advantages of a GMR/TMR memory cell include high density, high speed, and low power consumption [10]. In the following, some of the important issues of the spin-dependent transport in granular systems are discussed.

## 2. GRANULAR GIANT MAGNETORESISTANCE

Granular magnetic materials, where magnetic metallic particles are embedded in a nonmagnetic metallic host, show remarkable negative giant magnetoresistance (GMR). Granular GMR was first found in Cu–Co granular systems by Berkowitz et al. and Xiao et al. in 1992 [3, 4] after the discovery of GMR in Fe/Cr multilayers in 1988 [1]. The equilibrium solubility of Co in Cu is extremely small. But an extended solid solution can be formed in Cu–Co thin films. By thermally annealing the solid-solution films, Co nanoparticles precipitate out of the Cu matrix. The sizes of the magnetic Co nanoparticles embedded in the Cu matrix range from a few to a few tens of nanometers and can be controlled by the annealing temperature or parameters used during the deposition of the films.

Such granular systems can be prepared by a number of other nonequilibrium techniques. Methods that have been demonstrated to effectively produce granular GMR materials include mechanical milling [11–13], melt spinning [14–17], spinodal decomposition [18, 19], electrodeposition [20], Joule heating [21–23], pulsed laser deposition [24], low-energy cluster beam deposition [25], ion beam co-sputtering [26], gas flow condensation [27], and ion implantation [28].

Besides Cu–Co mentioned previously, Ag–Co, Cu–Fe(Ni), and Ag–Fe(Ni) have all been shown to exhibit granular

GMR when magnetic granules of Co or Fe(Ni) are embedded in a Cu or Ag matrix [29–36]. Similar systems such as Mg–Fe films and Cr–Fe bulk alloys also show negative GMR [37, 38]. In addition, GMR was observed in a macroscopic ferrimagnet Co–TbN, where magnetic TbN particles precipitate in a Co matrix [39]. However, this last example may be an exception. Studies conducted so far indicate that GMR is probably exclusive to the transition metal system. The strong itinerant nature of 3d electrons, which is distinctively different from that of 4f electrons, plays an important role in determining the GMR. There has been no report of GMR in a granular system where insulating magnetic particles are embedded in a nonmagnetic metallic matrix, although this is possible in theory, considering the large contribution to the GMR from the interface scattering.

The correlation among the microstructure, magnetic, and magnetotransport properties has been extensively investigated [40–48]. The dependence of GMR on particle size, particle morphology, particle concentration, and chemical composition has been obtained. Some of the key characteristics of granular GMR are worth mentioning here. The magnitude of the MR depends on the volume fraction of the magnetic particles and their sizes. GMR is only observed when the volume fraction of the magnetic particles is below the percolation limit. The maximum MR occurs near a volume fraction of 20–30%. The optimum particle size for GMR lies in the range of a few nanometers. These magnetic particles are single domain and are superparamagnetic at high temperatures. Both the low-temperature blocked state and the high-temperature superparamagnetic state exhibit a GMR effect of similar characteristics because the electron relaxation time is much shorter than the superparamagnetic relaxation time. For GMR to occur, the sizes of the magnetic particles should be comparable to or smaller than the electron mean free path. The GMR is enhanced if the electron mean free path is increased or if the interparticle distance is reduced. Large magnetoresistance ratios, $\Delta R/R = (R_H - R_0)/R_0$, have been found (20–30% at room temperature and up to 60–70% at low temperatures). The values are similar to those found in multilayered films. Another important feature of GMR is that the negative MR is isotropic, independent of the orientation of the applied field relative to the current and film plane. This contrasts with the anisotropic magnetoresistance (AMR) of a ferromagnet, where the magnitude and sign are different for current parallel or perpendicular to the applied field. It also differs from the GMR of multilayered films, where the orientation dependence originates from the shape anisotropy of the magnetic films.

The GMR effect in granular materials arises from spin-dependent scattering due to dissimilar scattering of conduction electrons from majority and minority bands by magnetic particles with different magnetization directions [49–61]. The angular distribution of magnetization of such scattering centers can be varied by an external magnetic field, and the minimum resistance is usually achieved for their parallel alignment in a sufficiently strong field. In the case of multilayered systems, the GMR effect is controlled by the relative magnetization directions in the neighboring magnetic layers separated by a nonmagnetic spacer. The maximum resistance of such systems is realized by the antiparallel arrangement of the layers. Both the interfaces between the magnetic and nonmagnetic layers and the bulk of the magnetic layers are considered to contribute to the spin-dependent scattering although studies show an enhanced contribution of interface scattering to the total resistance. In granular materials, magnetic grains with initially randomly oriented magnetization directions play the role of scattering centers, and the ordering of their directions in a magnetic field results in a decrease in the overall resistance of the material. The magnitude of the spin-dependent scattering is dependent on the orientation of the electron spin relative to the magnetization of the magnetic particles.

Theoretical studies on GMR in multilayers have been reported in several papers [55–61]. Both quasiclassical treatment [55, 56] based on the Boltzmann equation and quantum treatment [57, 58] based on the Kubo formula have been approached. While there has been some controversy about the applicability of the quasiclassical approach to metallic multilayers, Camblong and Levy [60], in their nonlocal linear transport theory, found a direct connection between the two approaches. Their study lends support to the quasiclassical approach and shows the enhanced contribution of interface scattering to the total resistivity. Zhang and Levy took into account the correlations in the scattering from the ordering of impurities due to interdiffusion across the interfaces and found that the constructive interference between scattering amplitudes produces enhanced spin-dependent scattering from the interface between magnetic and nonmagnetic metals [61]. The importance of interface scattering has been emphasized in a number of experimental studies [51, 62, 63]. Fullerton et al. [51] reported an experimental study on Fe–Cr supperlattices that clearly shows that the GMR is enhanced by the presence of interfacial roughness. Itoh et al. [63] ascribe the microscopic origin of the GMR in metallic supperlattices to the spin-dependent random exchange potential caused by roughness of the interfaces.

The origin of GMR in granular systems has been studied by a number of theoretical groups [64–78]. In granular systems, the space distribution of the magnetic field, the electron spin diffusion process, and the spin transitions are much more complex than in multilayered systems. However, the dependence of $\Delta R/R$ on the particle size [79] suggests that magnetic scattering at the interfaces is responsible for the GMR in granular systems. Zhang and Levy have calculated the ensemble-averaged conductivity in terms of the average scattering in the medium and came to the very significant conclusion that GMR arises from spin-dependent scattering primarily at the interfaces [80]. The temperature dependence of the GMR has been attributed to spin-mixing scattering and reduced magnetization as a result of spin-wave excitations in the magnetic granules [81–83]. The effects of magnetic coupling between the granules on the GMR have also been extensively studied [84–89].

Since GMR is the result of the alignment of magnetic granules by an external magnetic field, which reduces the spin-dependent scattering of the system, a general observation is GMR $\propto (M/M_S)^2 = \langle \cos \theta \rangle^2$, where $M$ is the global magnetization, $M_S$ the saturation magnetization, $\theta$ the angle

between the magnetic moment of a granule and the external field, and $\langle \cos \theta \rangle$ the average value of $\cos \theta$ [4]. This angular dependence has been explained by Zhang and co-workers [58, 80, 90] and Asano et al. [91] based on the spin-dependent scattering at the granule–matrix interfaces.

That GMR is related to the *relative orientations* of the magnetic granules is a generally accepted concept and is experimentally demonstrated in trilayer or multilayered magnetic films, where the GMR varies linearly with the cosine of the relative angle between the moments of the magnetic layers [92–99]. For a granular system of random distribution, it can be easily shown that $\langle \cos \phi_{ij} \rangle = \langle \cos \theta \rangle^2$, where $\phi_{ij}$ is the relative angle between the magnetic axes of uncorrelated magnetic granules. Pogorelov et al. [100] have shown, using the microscopic theory of granular GMR, that the spin-dependent conductance in granular systems can be sensitive to the short-range magnetic order in addition to the long-range order and that GMR should be linearly proportional to an extra term $\langle \cos \phi_{ij} \rangle$. It is of interest to measure directly the resistance as a function of the relative orientation of the magnetic granules; however, controlling the relative angle between magnetic moments is difficult in granular systems. Dai and Tang have designed an experiment in which one can statistically adjust the relative angle $\phi$ between the magnetic moments of different granules in $Cu_{80}Co_{20}$ [101]. The moments of the granules are mostly aligned in the same direction by field cooling to low temperature in a high magnetic field. A small field applied at an angle relative to the cooling field rotates the moments of a portion of the granules that have small particle size and coercivity. It is found that the GMR varies linearly with $\cos \phi$. This behavior disappears if the sample is cooled in zero fields, or if the rotating field is too large or too small, or if the measuring temperature is higher than the blocking temperature. The results show that the GMR in granular structures has the same linear dependence as found in layered films and confirm the existing theories and recent microscopic models of granular GMR suggesting a crucial role of the relative orientations of the magnetic granules in determining the spin-dependent scattering.

## 3. TUNNELING MAGNETORESISTANCE

The large TMR found in the ferromagnet–insulator–ferromagnet (FM–I–FM) structure is due to the spin-dependent tunneling of electrons across the barrier [5–9]. It has attracted much attention partly because of the interesting problem of "spin tunneling" involved in such systems. It is now possible to reliably deposit tunnel junctions between ferromagnetic materials that show consistent TMR. Most of the tunnel barriers are made of $Al_2O_3$, although other materials are also used [102]. The field-dependent tunneling resistance arises from the tunneling probability, which depends on the density of states at the Fermi levels of the electrodes on either side of the barrier for a given spin channel. An applied field reorients the magnetic electrodes, thus changing the tunneling resistance. The essential features of the observed TMR can be explained by the models proposed by Julliere [5], Slonczewski [6], and others, although successful models are still needed to incorporate both the true band structure in the presence of the interfaces and the

dependence of the tunneling current on the barrier height and thickness [7]. In addition, spin-independent tunneling due to the presence of impurities in the barrier has been considered [103, 104].

Figure 1 shows a schematic view of the tunneling process between two magnetic electrodes involving spin-up and spin-down channels when a voltage is applied. The upper panel represents the situation when the two magnetic electrodes are aligned parallel to each other, and the lower panel represents the situation when the two electrodes are antiparallel. The total conductance of the magnetic tunnel junction is the sum of the two channels: one for spin-up electrons and the other for spin-down electrons. The conductance of each channel is proportional to the product of the densities of states at the Fermi level of the two electrodes. For parallel orientation of the magnetization of the two electrodes, the conductance $G_{\parallel}$ is proportional to $N_{1\uparrow}N_{2\uparrow} + N_{1\downarrow}N_{2\downarrow}$, where $N_{1\uparrow}$ is the density of states at the Fermi level of the first electrode for the spin-up channel. The meanings for the other symbols are self-explanatory. For antiparallel orientation, the conductance $G_{\uparrow\downarrow}$ is proportional to $N_{1\uparrow}N_{2\downarrow} + N_{1\downarrow}N_{2\uparrow}$. The difference between $G_{\parallel}$ and $G_{\uparrow\downarrow}$ is the change in conductance due to the reorientation of the two electrodes. It can be shown easily [5] that the magnetoresistance $\Delta R/R$ depends on the effective polarization of the tunneling electrons in a simple way

$$\Delta R/R = 2P_1 P_2/(1 + P_1 P_2) \qquad (1)$$

where $P_1$ and $P_2$ are the spin polarization ratios of the effective tunneling density of states in the two FM electrodes, $P_i = (N_{i\uparrow} - N_{i\downarrow})/(N_{i\uparrow} + N_{i\downarrow})$. Most of the magnetic tunnel junctions include a thin layer, for example, CoFe, between the NiFe electrode and the barrier to enhance the effects on the spin polarization of the tunneling electron. CoFe is used because it has a higher spin polarization than NiFe, but the latter is magnetically softer, which is suitable

**Figure 1.** Schematic view of the tunneling process between two magnetic electrodes involving spin-up and spin-down channels when a voltage is applied. Upper panel, parallel alignment of the two electrodes; lower panel, antiparallel alignment.

for a free layer. An extremely large $\Delta R/R$ is expected when both electrodes are made of half-metallic materials in which the electrons are 100% spin polarized ($P_1 = P_2 = 1$). Examples of half-metallic materials include $CrO_2$, $Fe_3O_4$, $La_{0.7}Sr_{0.3}MnO_3$ perovskites and some of the Heusler alloys [105–110]. The half-metallicity of $CrO_2$, for example, has been demonstrated experimentally with a superconducting point contact experiment [111, 112] and vacuum tunneling measurement [113].

The principal advantage of a tunneling device is that the sense signal path does not have to carry a high current to get a large signal, and hence the settling time for the sense line voltage is eliminated, which offers potential for still faster read memory than those using conventional GMR structures. In addition, because of the tunneling device's high resistance, the signal levels could be sufficiently high to make simple direct sensing possible. The ability of using current-perpendicular-to-plane (CPP) geometry in a tunneling device eliminates several drawbacks associated with the current-in-plane (CIP) geometry such as shunting, channeling, and diffusive surface scattering. One added attractive feature of TMR devices is that the saturation field can be smaller than the GMR multilayers or spin valves.

TMR in granular materials originates from the tunneling of electrons from one grain to an adjacent grain across a barrier separating the two. It has been shown in a number of systems. It was first reported by Helman and Abeles in 1976 in a system where fine Ni grains (50 Å) are dispersed in $SiO_2$, which exhibits a large negative magnetoresistance [114]. Recent studies on granular TMR have been inspired by the TMR observed in simple tunnel junctions. Large negative and isotropic magnetoresistance was found in reactively sputtered Co–(Al, Si)–O and Fe–Mg–O thin films. The films have a two-phase nanostructure consisting of Co (Fe)–rich metallic magnetic grains and $Al_2O_3$ (or $SiO_2$/MgO) narrow intergrains [115]. Granular TMR and its characteristics have been investigated and reported in a number of similar systems where metallic magnetic nanoparticles are embedded in an insulating matrix [116–128].

Due to its half-metallic nature, very large TMR values have been reported in $CrO_2$ cold-pressed powders and polycrystalline thin films. A TMR ratio of 15%–50% can be reached [108, 109, 129]. The tunnel barrier here is a native surface layer of $Cr_2O_3$ surrounding the $CrO_2$ particles [130]. The TMR in these $CrO_2$ systems is well understood as the spin-dependent tunneling between the particles (in powder compacts) or grains (in films) across a grain boundary barrier, which is thus termed spin-dependent intergranular tunneling (Fig. 2). Magnetite ($Fe_3O_4$) is
another very interesting half-metallic material besides $CrO_2$. Interesting magnetotransport properties have been reported in $Fe_3O_4$ powders and thin films, which are associated with the intergranular spin-dependent tunneling of electrons across the grain boundaries [107]. The magnetoresistance of $La_{0.67}Sr_{0.33}MnO_3$ polycrystalline ceramics [131] and $La_{0.67}Ca_{0.33}MnO_3$ and $La_{0.67}Sr_{0.33}MnO_3$ polycrystalline films [132] exhibits a sharp drop at low magnetic fields followed by a linear dependence at higher fields. The sharp drop has been attributed to spin-polarized tunneling between misaligned grains.

The switching field (the magnetic field at which a significant MR ratio has been reached) of systems of random grain orientation is quite large ($>1$ T), which is much higher than that required for most applications. The value of the switching field corresponds to the external field at which the magnetic moments of particles (grains) are reversed. Random orientation of moments causes the overall switching field to become much larger than the coercivity along the easy axis of a needle-shaped single particle. This problem can be solved by finding a way to align the $CrO_2$ single-crystal particles to the same orientation. The switching field can then be reduced theoretically to the coercive field of a single particle along its easy axis.

Since the magnetic moments of the needle-shaped $CrO_2$ single-crystal particles are along the easy axes ($c$ axes), the particles can be reoriented by applying a strong magnetic field. The aligned needle-shaped $CrO_2$ particles show very interesting MR characteristics with two well-separated peaks, similar to that of a single magnetic tunneling junction, as shown in Figure 3 [133]. Compared to the cold-pressed powders in which the particles have random orientations, the junction-like MR of the aligned powders is about 41%

**Figure 2.** Schematic view of intergranular tunneling.

**Figure 3.** TMR of the aligned powders of $CrO_2$ at $T = 5$ K. Inset shows the MR of cold-pressed powders with random orientation over the same field range. Reprinted with permission from [133], J. Dai and J. Tang, *Phys. Rev. B* 63, 054434 (2001). © (2001), American Physical Society.

at $T = 5$ K, and the switching field significantly decreases to about $\pm 1000$ Oe. Notice that the resistance change is less than 5% for the random-oriented pressed powders over the same range of magnetic field (Fig. 3, inset). By using an alignment technique, a much larger MR ratio can be reached over a low field range (0–$\pm 1000$ Oe), which shows a much better switching behavior than that of the randomly oriented powder compacts.

Particle interface and grain boundaries play a very important role in the spin-dependent transport of half-metallic systems. The large TMR found in the cold-pressed and field-aligned $CrO_2$ nanoparticles is due to spin-dependent tunneling across the particle interface. Understanding the microstructure, composition, impurity level, and so on, of this barrier layer is important to further improve the TMR effect for practical purposes.

It has been suggested that the barriers in the granular $CrO_2$ systems are made of a native $Cr_2O_3$ layer on the surface of $CrO_2$ [109, 129, 134] since $Cr_2O_3$ is the most stable phase of $CrO_x$ [109, 135]. There has also been speculation that the surface layer is made of amorphous $CrO_2$ [135, 136] or even compounds such as CrOOH [137]. Experiments conducted recently provide direct evidence that the native surface layer of $Cr_2O_3$ is the tunnel barrier in $CrO_2$ granular systems [130]. Using transmission electron microscopy (TEM), a native oxide layer 1–3 nm thick has been directly observed on the surface of the $CrO_2$ single-crystal particles. X-ray photoelectron spectroscopy (XPS) results suggest that $Cr^{3+}$, not $Cr^{4+}$ as in $CrO_2$, dominates in the near surface region ($\sim$10 monolayers) of the $CrO_2$ particles. Combined TEM and X-ray diffraction slow-scan data indicate that the 1- to 3-nm-thick surface layer on the $CrO_2$ particles is not $CrO_2$ but $Cr_2O_3$ and confirm that the $Cr_2O_3$ layer is the tunnel barrier in the intergranular tunneling in $CrO_2$ systems.

$Cr_2O_3$ is an ideal and natural barrier material in granular $CrO_2$ systems due to its chemical stability and dense and uniform morphology. It is known that $CrO_2$ can be transformed into $Cr_2O_3$ by heating. The intergranular TMR ratio increases [129] after introducing more $Cr_2O_3$ into the $CrO_2$ particle interface by annealing. This may be due to either the increase in the thickness of the $Cr_2O_3$ surface layer or the precipitation of more $Cr_2O_3$ in the interface region. It may also be correlated to an improvement in the quality of the $Cr_2O_3$ barrier by heating. Detailed analysis of the effects of thermal annealing on the barrier quality is still lacking.

An unsolved problem of the TMR in $CrO_2$ half-metallic systems is the decrease in the TMR ratio with increasing temperature [138, 139]. It is usually reduced to less than 3% in $CrO_2$ systems and less than 7% for $Fe_3O_4$ at room temperature. Several mechanisms have been suggested to explain the temperature dependence of the TMR of the magnetic tunnel junctions. Coey et al. [129] suggested the existence of spin-flip processes introduced by the excitation of antiferromagnetic magnons in the interface layer or maybe the weakly exchange coupled $Cr^{3+}$ ions at the interfaces. The study of Watts et al. [140] showed the two-band magnetotransport in $CrO_2$ films and suggested a temperature-dependent spin-flip scattering corresponding to the temperature dependence of carrier mobilities and MR. It is also possible that the MR is reduced by the suppression of spin polarization $P$ at high temperature due to thermally excited surface spin waves [141]. Itoh et al. [142] presented a double-exchange model showing that $P$ decreases with increasing temperature; their calculated results also indicated that the MR can still be large considering the decrease in $P$. Guinea suggested that bulk magnon-assisted tunneling also reduces the MR [143]. Davis et al. have found that the magnetic band structure change due to Fermi smearing can be sufficient to account for the temperature dependence of the TMR in Co/I/Co junctions [144] although the temperature dependence in such junctions is much more gradual than that in $CrO_2$. To explain the rapid decrease in the MR with temperature in $CrO_2$ systems, one needs to take into account the hopping conductance via localized states in the barrier [141]. The suppression of MR at high temperature is found to be mainly due to the rapid increase in the spin-independent hopping channel with increasing temperature as will be discussed later although other mechanisms mentioned previously should still be considered.

## 4. COULOMB BLOCKADE

When an electron tunnels into a small particle or grain, it gives rise to an interesting phenomenon, Coulomb blockade (Fig. 2). Adding the electron to the particle increases the energy of the system by a charging term $E_c = e^2/2C$, where $e$ is the charge of the electron and $C$ the capacitance of the particle. The charging energy becomes large when the particle is very small. Tunneling is blocked unless the charging energy is overcome by thermal energy or applied bias voltage. The charging effect of the particles leads to single-electron tunneling represented by the Coulomb blockade of electric current below a threshold voltage and Coulomb staircase at higher voltages.

The conductance of intergranular tunneling is proportional to the tunneling matrix element $\exp[-2\chi s]$, where $s$ is the separation between the particles and $\chi = (2m\Phi/\hbar^2)^{1/2}$ ($m$ and $\Phi$ are the effective mass and barrier height, respectively) [145], and the population of a single particle $\exp[-E_c/2k_BT]$. The conductance is thus given by

$$G \propto \exp[-2\chi s - E_c/(2k_BT)] \qquad (2)$$

Sheng et al. [146] have made an assumption, when averaging over the distribution for particle size and separation, that the ratio of particle separation and particle size is constant. That is, $sE_c$ is a constant and $s\chi E_c = C$. Tunneling occurs mainly between particles with an optimum charging energy $E_c^0 = 2(Ck_BT)^{1/2}$ such that the conductance in (2) is maximized. The final temperature dependence of the conductance is given by

$$G \propto \exp[-2(C/k_BT)^{1/2}] \qquad (3)$$

The preceding temperature dependence has been observed in a wide range of granular systems where intergranular tunneling is at play. When the particles involved are magnetic, the tunneling is spin dependent and the conductance depends also on the global magnetization of the sample and the spin polarization of the magnetic particles. The

spin-dependent intergranular tunneling conductance $G_{SDT}$ as a function of temperature is then given by [147–149]

$$G_{SDT} = G_0(1 + P^2 m^2) \exp\left[-2(C/k_B T)^{1/2}\right] \quad (4)$$

where $P$ is the spin polarization, $m = M/Ms$ is the relative magnetization, and $G_0$ is a constant.

Coulomb blockade has been shown to enhance the TMR in granular systems at low temperatures due to amplified co-tunneling, where coherent tunneling through a double junction via a virtual intermediate state is energetically favorable [150–152]. Independent tunneling through the same double junction is, on the other hand, suppressed due to Coulomb blockade. Because the total resistance is proportional to the product of the junction resistance in the former case and proportional to the sum of the junction resistance in the latter, the TMR is enhanced when co-tunneling dominates. Other models have been proposed to explain the effects of Coulomb blockade on the TMR [153, 154]. Recent studies show oscillatory TMR behavior associated with the Coulomb staircase, which is based on the interplay of spin-dependent tunneling and single-electron tunneling [155–157].

The temperature dependence of the intergranular tunneling conductance of a cold-pressed $CrO_2$ nanoparticle compact is shown in Figure 4. Also shown is that of a sample annealed at high temperature so that it contains a substantial amount of $Cr_2O_3$. It is seen that the intergranular tunneling conductance follows a linear relationship between $\ln G$ and $1/T^{1/2}$ at low temperature ($<50$ K) and thus obeys the expression given in (4) for intergranular tunneling. This implies that intergranular tunneling is the major contribution to the conductance at low temperature [158].

When the temperature increases, the conductance becomes much greater than the intergranular tunneling given in (4), which indicates that another conduction channel becomes involved and plays a major role at high temperature. It is found that the additional conductance follows a power law of temperature, which is consistent with electron inelastic hopping through the localized states due to imperfections, impurities, and defects in the tunnel barrier.
This channel is a spin-independent conducting channel since the electron flips its spin when it hops through the localized states.

It is known [159, 160] that the inelastic hopping conductance can be expressed as $G_{SI} \propto T^\gamma$, where $\gamma = N - [2/(N+1)]$ and $N$ is the number of localized states the electron hops through. A higher temperature, a higher level of impurity, and a thicker barrier can result in a higher order of inelastic hopping (greater $\gamma$). The total conductance $G$ of a powder compact is given by [158]

$$G = G_{SDT} + G_{SI} = C_1 \exp\left[-2(C/k_B T)^{1/2}\right] + C_2 T^\gamma \quad (5)$$

The experimental data on the $CrO_2$ powder compact and theoretical fits using (5) are shown in Figure 5. It is found the hopping conductance is dominated by the second-order hopping ($T^{1.33}$). The $I–V$ curves measured at room temperature also suggest the corresponding power law behavior [158]. As the temperature increases, the hopping channel becomes important. This spin-independent inelastic hopping conductance should be one of the main reasons for the rapid decrease in MR with increasing temperature [158, 161]. It is desirable to increase the TMR at room temperature by controlling the inelastic hopping conductance. As mentioned before, the suppression of TMR at high temperature may have more than one cause. The decrease in surface spin polarization, Fermi smearing, surface antiferromagnetic magnons, and bulk magnon-assisted tunneling also contribute to the decrease. Each mechanism has its own characteristic temperature and bias dependence. For example, surface spin polarization and bulk magnon-assisted tunneling both give $T^{3/2}$ dependence, but the former does not give rise to nonlinear $I–V$ characteristics [143]. Surface antiferromagnetic magnons, on the other hand, give rise to the $T^2$ and $V^2$ behaviors.

## 5. DOMAIN WALL RESISTANCE

The resistance due to domain walls has been controversial and not well understood although a large number of studies were devoted to the subject [162–166]. In fact, both positive

**Figure 4.** Temperature dependence of the conductance showing $G \propto \exp[-2(C/k_B T)^{1/2}]$ at low temperature for $CrO_2$ and $(CrO_2)_{25}(Cr_2O_3)_{75}$. Reprinted with permission from [158], J. Dai and J. Tang, *Phys. Rev. B* 63, 064410 (2001). © (2001), American Physical Society.

**Figure 5.** Experimental data fit with (5). As the temperature increases, a spin-independent channel, which follows a power law, becomes dominant. Reprinted with permission from [158], J. Dai and J. Tang, *Phys. Rev. B* 63, 064410 (2001). © (2001), American Physical Society.

and negative domain wall resistances have been reported and their origins are still being explored. One difficulty associated with the measurement of the domain wall resistance is the fact that it is always accompanied by anisotropic magnetoresistance and both are sensitive to the domain structure. One particular aspect of the domain wall resistance is analogous to GMR in magnetic multilayered films. As an electron passes from one domain to an adjacent one with different magnetic orientation, the effect resembles that of a GMR trilayer. However, the domain wall is usually too thick to exhibit large magnetoresistance because the electrons lose their spin memory before traveling through the domain wall. Attention has been paid to controlling the domain wall size to within several nanometers. A domain wall can be trapped in a structure of nanometer size, thus limiting the wall thickness. Recent reports have shown that two nanosized ferromagnetic tips contacting each other perpendicularly can have a large MR effect. An MR ratio of 300–3000% in Ni nanocontacts has been observed [167, 168]. $Fe_3O_4$ is especially interesting in light of very recent studies [169], in which 500% and larger MR is observed and attributed to transport of spin-polarized electrons through a narrow domain wall in a nanocontact of $Fe_3O_4$. Little is known about the connection, if any, between the negative MR and the existence of antiphase boundaries found in $Fe_3O_4$. It has been argued that the antiphase boundaries may become immobile magnetic domain walls [170]. It is of interest to study the MR due to pinned domain walls as their thickness can become smaller than the spin diffusion length and give large MR [167]. It is still a challenge to find a way to precisely fabricate patterned ferromagnetic nanocontact arrays to realize narrow domain wall thickness on, for example, Si chips.

# 6. MAGNETOTRANSPORT IN GRANULAR MATERIALS OF TWO-DIMENSIONAL WEAK LOCALIZATION

We have discussed the magnetoresistance of granular materials where at least one component is magnetic. However, interesting magnetotransport behaviors are not exclusive to such systems. Negative magnetoresistance (NMR) has been predicted by the weak localization theory in two-dimensional (2D) systems [171, 172], indicating that the localization effect could be destroyed when a magnetic field perpendicular to the film plane is applied. Previous experiments on metallic films [173–179] have shown NMR in a perpendicular field due to the suppression of the weak localization. It is known that the low-dimension effects become significant when the thickness of a sample is less than the Thouless length $L_T = (2l_{el}l_{in})^{1/2}$, where $l_{el}$ and $l_{in}$ are the elastic and inelastic scattering lengths, respectively. When the Landau orbital size $(\hbar c/eH)^{1/2}$ becomes close to $L_T$, the localization effect will be suppressed by applying a perpendicular magnetic field. The threshold field is given by

$$H_c^\perp = \hbar c/2el_{el}l_{in} \tag{6}$$

and the change in conductance is given by

$$\Delta\sigma_\perp = -\frac{e^2}{2\pi^2\hbar}\left[\ln\left(\frac{\hbar c}{2eHl_{el}l_{in}}\right) - \psi\left(\frac{1}{2} + \frac{\hbar c}{2eHl_{el}l_{in}}\right)\right] \tag{7}$$

where $\psi$ is the digamma function and $H$ is the perpendicular field. In the case of heavy metals, which have strong spin-orbit scattering, for example, in Au–Cu films [173, 175, 180], the MR may change sign.

Scaling theory suggests that there is no NMR in a strictly 2D system when the field is applied parallel to the film. In 1984, Altshuler and Aronov [181] predicted that, due to the finite thickness of a thin film, there is a negative magnetoresistance in the parallel field (NMR$_\parallel$). The magnetoresistance in a parallel field is given by

$$\Delta\sigma_\parallel = \frac{e^2}{2\pi^2\hbar}\ln\left(\frac{t^2L_T^2}{12L_H^4} + 1\right) \tag{8}$$

where $t$ is the film thickness and $L_H = (\hbar c/eH)^{1/2}$ is the Landau orbit size. One sees that the NMR$_\parallel$ will become 0 when the thickness $t = 0$. Equation (8) can be understood considering this is an orbit effect and the NMR$_\parallel$ does not vanish until the film thickness equals 0. No significant parallel field NMR$_\parallel$ has been observed in previous experiments on homogeneous metallic films. According to [179], this is because of the following

$$\Delta\sigma_\parallel/\Delta\sigma_\perp = 2t^2/L_T^2 \ll 1 \tag{9}$$

where one can see that the NMR$_\parallel$ is generally very small for ultrathin films. For a parallel field, the characteristic field strength is much stronger [181] than the field applied perpendicular to the film plane

$$H_C^\parallel \approx \frac{\hbar c}{et\sqrt{l_{el}l_{in}}} \tag{10}$$

The localization effect of highly inhomogeneous 2D systems of granular films has only been studied to a limited extent. Bergmann [175] has pointed out that weak localization may still exist in these systems. Unique MR effects have been reported in granular island-like ultrathin nonmagnetic Cu films [182]. The NMR has been observed in both perpendicular ($H_\perp$) and parallel ($H_\parallel$) magnetic fields. A large NMR$_\perp$ in a perpendicular field has been found which follows $\ln H$ in high field as suggested in (7). A large NMR$_\parallel$ is observed and is close to the prediction given by [181]. The large NMR$_\parallel$ is due to the island-like granular structure, and it has not been previously observed in homogeneous Cu films [173–175]. The Thouless length $L_T$ and effective Landau orbit size $L_H$ can be statistically reduced by the granular structure. Since the ratio of $\Delta\sigma_\parallel/\Delta\sigma_\perp$ is determined by $2t^2/L_T^2$, a reduction in $L_T^2$ leads to a relatively increased $\Delta\sigma_\parallel$. This provides a good explanation as to why the NMR$_\parallel$ has been observed in granular Cu samples but not in previous experiments on homogeneous Cu films. That island-like geometry leads to relatively large NMR$_\parallel$ is also consistent with the experimental results by Komori et al. [180], which has shown a large NMR$_\parallel$ in highly inhomogeneous Cu–Cu oxide mixture films although the mechanism was not explicitly given. Compared to the homogeneous films, it is seen that the Thouless length and electron orbit size are affected by the geometry of the granular structure.

## 7. SUMMARY

It has become increasingly evident that the spin degree of freedom of electrons, in addition to the charge, will become an integrated part of semiconductor-based electronics. Spin-dependent transport forms the backbone of such technology. Some GMR- and TMR-based devices have already found applications as field sensors and nonvolatile magnetic memories, MRAMs. Although it is not clear at present whether GMR and TMR in granular systems will be technologically competitive with their counterparts in multilayered films, the study of these phenomena has led to interesting discoveries and better understanding of the physics involved. As one explores magnetotransport in granular systems, one finds the fascinating physics of spin-dependent scattering and spin-dependent tunneling, which are the basis for GMR and TMR. Readers are referred to some of the excellent review articles for a more thorough discussion of these subjects [183–187]. Magnetic tunnel junctions made of half-metals, whose spin polarization is close to 100%, are expected to play a major role in the future materials of spin-dependent tunneling because of their large magnetoresistance. Although not discussed at length in this review, the interplay between spin-dependent tunneling and Coulomb blockade is intriguing. Since the sizes of the particles we deal with here are in the nanometer range, blockade due to charging of the particles when an electron tunnels into them becomes an important factor in determining the transport. Some of the recent research interests in this area are single-electron tunneling and the interplay between magnetotransport and the Coulomb staircase. The exact nature of the domain wall resistance is still being explored, yet it has shown one of the largest magnetoresistances to date when the domain wall thickness is appropriately controlled. Equally interesting is the magnetotransport in nonmagnetic granular systems. An example is presented in the last part of the review. Many challenges lie ahead. It is desirable to be able to control the particle sizes within a very small distribution and model realistically the spin-dependent scattering in granular GMR systems. It is also challenging to deal with the issue of the temperature dependence of the TMR in some of the half-metallic systems. To make the granular systems more technologically relevant, the switching field needs to be further reduced. The prospect for research in granular transport is promising. With the advances in nanotechnology and the ability to make granular materials of patterned structure, exciting discoveries and possible new applications of spin-dependent transport in granular systems can be expected.

## GLOSSARY

**Coulomb blockade** Blockade of the conduction of electrons due to the Coulomb charging energy associated with the small size of the grains and particles.

**Giant magnetoresistance (GMR)** Large magnetoresistance due to scattering of the conduction electrons by magnetic nanoparticles or layers in films.

**Half-metal** A magnetic material that is metallic for one spin direction but has a gap at the Fermi level for the other spin direction.

**Magnetic random access memory (MRAM)** An integrated magnetic memory that uses magnetic storage and magnetoresistive reading with semiconductor support circuits.

**Spin polarization** The percentage of extra electrons having majority spins.

**Tunneling magnetoresistance (TMR)** Magnetoresistance due to electron tunneling between two magnetic electrodes across a nonmagnetic barrier.

## CONTENTS

## 1. INTRODUCTION

Colossal magnetoresistive manganites exhibit large decrease in resistivity under the application of an external magnetic field. Transport, magnetic, and thermal properties are also strongly magnetic field-dependent. Owing to this high field-dependent behavior, the manganite samples are technologically important [1] for making memory and switching devices. The magnetoresistance ratio ($MR = -(\rho_H - \rho_0)/\rho_0$, $\rho_H$ and $\rho_0$ are, respectively, resistivity in presence of a magnetic field H and at zero magnetic field) is an important parameter for the colossal magnetoresistive (CMR) materials. The values of MR may be as high as 10,000% or more [1]. The magnetic field dependence of resistance of such a high magnitude has not been observed in any other bulk metallic system where low-temperature magnetoresistance arises from the field-dependent electronic mean free path. Here resistivity change in presence of magnetic field [2] is usually limited to a few percent. On the other hand, multilayer metallic thin films show relatively large sensitivity to magnetic fields [3]. The giant magnetoresistance (GMR)

effect in these films is largely due to the spin-valve effect between spin-polarized metals. Spin-valve devices have been used in magnetic storage devices for several years in the form of magnetoresistive read heads. Though the physical behavior of the GMR materials is well understood, the technological challenges for the production of smaller-faster-better sensors are limited, which draws attention of the researcher in the field of CMR materials over the last couple of years [4–7].

### 1.1. Colossal Magnetoresistive Manganites

Recently, it has been recognized that some perovskite oxides (divalent doped lanthanum and rare-earth manganites and some related oxides of Ruddlesden–Popper series [8]) possess large negative magnetoresistance or colossal magnetoresistance (CMR). These materials undergo phase transition from the paramagnetic (PM) insulating (semiconducting) phase to the ferromagnetic (FM) metallic phase below the corresponding Curie temperature. In these perovskite oxides, metal-insulator transition (MIT) temperature ($T_p$) and Curie point ($T_c$) coincide [9] and CMR materials also show temperature-dependent anomalies in their various physical parameters like thermoelectric power [10–12], Hall effect [13, 14], heat capacity [15, 16], thermal conductivity [17], etc. around $T_p$. Well-prepared samples show giant negative magnetoresistive effect near $T_p$ or $T_c$ [4–6, 18]. This phenomenon was first noticed in 1950 after the well-known work of van Santen and Jonker [19, 20] on single crystals. Magnetoresistance and other transport properties were well presented in 1954 by Volger [9]. However, the microscopic mechanism governing the transport property in CMR materials is still not clear. The details about the progress of development and explanation of transport and other properties of these types of manganite systems are available from the excellent review of Dagatto et al. [21].

Manganese compounds of composition $AMnO_3$ (A = La, Ca, Ba, Sr, Pb, Nd, Pr) crystallize in the cubic perovskite structure and they are known as manganites. In these manganite samples, commonly called CMR materials, mixed valence of Mn was considered for attributing double exchange mechanism by Zener [21]. Depending on the composition, they show a variety of magnetic and electronic phenomena, including ferromagnetic, antiferromagnetic, charge, and orbital orderings. If A site is partially occupied by two different atoms, one trivalent (for example, La) and one divalent (say Ca), then both the valence states of manganese, viz. $Mn^{3+}$ and $Mn^{4+}$, coexist in the samples. These compounds show different interesting physical properties as the temperature, doping concentrations, particle size, etc. are changed. The different phase transitions (metal-insulator transition, ferromagnetic-antiferromagnetic transition, charge ordering, orbital and spin degree of freedom, order-disorder transition, etc.) displayed by the mixed valence manganite are also sensitive to external parameters such as pressure, magnetic field, etc. It is important to note that other than manganites [22], a number of oxides such as pyrochlores like $Tl_2Mn_2O_7$ [23], double-layered perovskite oxide like $La_{2.2x}Sr_{1-2x}Mn_2O_7$ [24], $La_{2.2x}Ca_{1-2x}Mn_2O_7$ [25], perovskite related structure $CaCu_3Mn_4O_{12}$ [26], also show CMR behavior.

For various technological applications in the field of magnetic memory devices, magnetic sensors, etc. (discussed later), these oxides have already been found to be important. The most effective perovskite materials, having large magnetoresistive property around $T_p$, are the divalent element (like Sr, Pb, Ba, Ca) doped $LaMnO_3$ [1, 4–7] type systems.

## 1.2. CMR Manganites: The Role of Grain Size

As mentioned earlier, colossal magnetoresistance (CMR) effect has been the subject of current interest because of its potentiality in practical applications [4–6, 27]. However, the properties of the CMR materials are found to be highly particle-size-dependent as discussed later. Depending on the origin, the CMR effect is of two types. The intrinsic CMR effect [4, 18, 28], observed in perovskite manganites like $La_{1-x}(Sr, Ca, Pb)_xMnO_3$ ($0.0 \leq x \leq 0.5$), is restricted to the vicinity of $T_p$ and to high magnetic field of several Tesla. Whereas extrinsic CMR effect, like grain boundary magnetoresistance (GBMR) [29], observed at moderately low fields ($B \leq 0.1$ T) and in wide temperature range down to low temperature, is more appropriate for device applications. The GBMR has been observed in polycrystalline bulk materials [11, 30–33] thin films [34–36], and bicrystal manganite films [37–39]. GBMR is usually interpreted in terms of spin-polarized tunneling through electronic barriers in the grain boundaries [30–39] and/or grain boundary scattering [31, 32, 34]. It appears that the existence of grain boundary (GB) plays a major role in CMR mechanism, particularly from the technological point of view. Due to the GB effect, the low field sensitivity of magnetic and transport properties in these materials is found to be enhanced. Here emerges the importance of grain-size-dependent study of the properties of CMR manganites. The variation of grain size in polycrystalline samples affects the grain boundary

scattering/tunneling, which in turn largely influences different physical properties, particularly the MR behavior of the samples.

Mahesh et al. [31] first reported the grain size effect on the magnetic field-dependent transport properties of a polycrystalline $La_{0.7}Ca_{0.3}MnO_3$ sample. While comparing the grain-size-dependent physical properties, it is always ensured that $Mn^{4+}$ content, a crucial factor in determining the magnetic and transport properties, remained constant for samples of different grain sizes. The resistivity ($\rho$) of the CMR sample was found to increase with decrease of grain size. Again, the magnetoresistance ratio at lowest temperature (4.2 K), and around $T_c$, decreases with increasing particle size. The corresponding peak near the Curie temperature was also found to be broadened with decrease of grain size, whereas the value of MR near the peak did not show a significant change with the variation of particle size. It was further observed [31] that at the lowest temperature (well below $T_p$), MR is considerably higher in the sample of smaller particle size, while MR values in single-crystal and epitaxially grown films were very small around the temperature range well below $T_p$. This observation implies that a substantial part of the MR at low temperatures arises from grain boundaries. Recently it has also been demonstrated [32] to show the effect of particle size on the magnetic field-dependent transport properties like resistivity and thermoelectric power of the $La_{0.5}Pb_{0.5}MnO_3$ type samples. The particle sizes of these samples were varied from 102 to 229 nm, and it was observed that grain size of the sample increases with increasing annealing time and temperature. This observation also supports the finding of Mahesh et al. [31]. Moreover, grain size has comparatively little effect on Seebeck coefficient (S) since heat flow from grain to grain is additive in nature. It is to be noted that not only the resistivity data but also the transport mechanism governing the resistivity data is influenced by the variation of grain size [32, 40]. Recently it was reported that grain size also influences the Hall coefficient of these samples [41]. Thus it can be clearly concluded that particle size largely influences the transport properties of the CMR manganites [32, 41, 42]. In another effort, Hossain et al. [33] studied the magnetic and magnetoresistive properties of grain-size-dependent polycrystalline $La_{0.67}Ca_{0.33}MnO_{3-\delta}$ samples (average grain size varying from 3.3 to 3.4 $\mu$m). They showed that Curie temperature $T_c$ is independent of grain size, but the variation of the saturation magnetization with change of grain size appreciably depends on the magnetic history. At lower temperature around 20 K and at 8 T magnetic field, the magnetization was found to decrease as grain size increases. An appropriate linear variation of resistivity and magnetoresistance with grain size allowed the authors [33] to estimate the intrinsic magnetoresistance and also to separate the grain and grain boundary resistivity contributions. It is noteworthy to mention that while studying the variations of resistivity, giant magnetoresistance, and thermopower for the La-Sr-Mn-O type of samples with particle size, ferromagnetic transition temperature of the samples did not vary appreciably [11] with particle size. However, the corresponding metal-insulator transition temperatures ($T_p$ values) were largely influenced by the change of particle size of the sample.

A more direct comparison of MR and field-dependent magnetization values of single-crystal and bulk polycrystalline $La_{2/3}Sr_{1/3}MnO_3$ samples, in the low-temperature ferromagnetic metallic state, has been made by Hwang et al. [30]. Both single-crystal and the polycrystalline samples showed sharp drop of $\rho$ at $T_c$. However, low-temperature resistivity of the polycrystalline sample was found to be significantly higher than that of the single crystals. They further demonstrated [30] that the intrinsic MR in single crystal was due to suppression of spin fluctuation. On the other hand, magnetoresistance in the polycrystalline samples exhibited two distinct regions: large MR at low fields dominated by spin-polarized tunneling between grains, and the high-field MR which was found to be temperature independent. It was found [30] that MR values in polycrystalline samples are dominated by transport across the grain boundaries. MR is also extremely sensitive to the applied magnetic field [30]. In another work, Gupta and Sun [29] made detailed study on the role of grain boundary in the MR of manganites by comparing the properties of epitaxial and polycrystalline films of $La_{0.67}D_{0.33}MnO_{3-\delta}$ (D = Ca, Sr, or vacancies). The mean grain sizes of different polycrystalline manganite samples studied by Gupta and Sun were 3, 14, and 24 $\mu$m. These authors observed that the MR values of epitaxial films showed a sharp peak near $T_c$ with a very small value at low temperatures. On the other hand, the polycrystalline films showed large MR values over a wide range of temperature even at low-temperature (5 K). Based on the results of polycrystalline films, they suggested [29] that the low-field MR was the consequence of spin-dependent scattering of polarized electrons at the grain boundary, which served as pinning centers for magnetic domain walls [29, 32].

Continuous effort is being made to reduce the grain size less than 10 nm and to study grain size effect on different physical properties. This is because of the fact that grain size in the nanometer range modifies the grain boundary scattering/tunneling substantially [43–48]. Zhang et al. studied the grain-size- (nanometer range) dependent magnetic properties of granular $La_{0.85}Sr_{0.15}MnO_z$. They associated magnetoresistance of the system to a tunneling behavior of grain surface. This is, however, not an intrinsic crystal effect [43]. These authors also studied [45] magnetization, heat capacity, structural distortion, and magnetoresistance of nanometer ($\sim$150 nm) size perovskite sample (viz. $La_{0.82}Sr_{0.18}MnO_3$). Their studies demonstrated that in such systems the interfacial tunneling plays an important role in the electronic and transport properties. The interfacial tunneling again depends on the difference of the magnetic moments between the cores and the surfaces of the grains but not on the magnetic moments of the neighboring grains [45]. In a recent work, Hueso et al. showed how CMR could be tuned in $La_{0.67}Ca_{0.33}MnO_3$ by changing grain size. Below a certain particle size ($\sim$150 nm), CMR disappeared, but large intergrain MR remained well above $T_c$. This was explained on the basis of single magnetic domain like behavior of the samples consisting of nanoparticle grains [44]. Very recently, Hueso et al. [48] prepared samples of particle diameter ranging from 60 to 500 nm by sol–gel method. They studied magnetocaloric effect (MCE) and FM to PM phase transition in the $La_{2/3}Ca_{1/3}MnO_{3-\delta}$ system. It was observed that for the samples with larger particles, the transition from the ferromagnetic to the paramagnetic state is of first order in nature. On the other hand, for the samples having smaller particles ($\sim$60 nm or less), the corresponding transition becomes a second-order type [48]. Above-mentioned grain-size-dependent interesting results obtained from the study of different physical properties of CMR manganites are important from a fundamental as well as technological (magnetoresistive devices) point of view.

## 1.3. CMR Manganite Nanocomposites

In the previous section we have discussed the role of grain boundary (GB) scattering in modifying the low-field extrinsic magnetoresistance. To increase the low-field tunneling magnetoresistance in manganites, it is important to enhance the electronic barriers in the GB by controlled doping at the intergranular regions. Recently, it was reported that introduction of a second phase, usually a nonmagnetic or an antiferromagnetic insulator, into the ferromagnetic manganite matrix would lead to an improvement of MR [49–53]. This interesting result encouraged scientists worldwide to study CMR composites [54, 55]. In recent years, several groups have tried to merge the high degree of spin-polarization present in manganites with advantages of a heterogeneous granular structure [55–57]. The extrinsic phase which modifies the GB of ferromagnetic manganites is mainly insulator [51, 55, 57]. Enhanced room-temperature magnetoresistance has also been found in glass composites [50]. Especially near the percolation threshold [55], the mixture of a metallic ferromagnetic manganite with an insulator (F/I) shows an enhancement of magnetoresistance. The properties of the above-mentioned composites can be modified by increasing the grain surface. So efforts are still going on to reduce the particle size in the nanometer scale. The other form of nanocomposite is CMR nanoparticle dispersed in insulating/dielectric matrix [56], where superparamagnetic behavior of the nanoparticles was observed both for the antiferromagnetic and ferromagnetic phases at low-temperature. Precipitation of CMR materials like La-Pb-Mn-O in nonmagnetic $B_2O_3$-$P_2O_5$ glass matrix has also been attempted [58].

Apart from the F/I composite system just discussed, this review also focuses on a different type of CMR composite of manganite/nonmagnetic metal. This system is emerging as a separate class of composites of current interest [59]. These new composites show increase of conductivity with nonmagnetic metal doping, and though the low-temperature MR does not change significantly, the MR around room temperature enhances for a typical concentration of the external phase (nonmagnetic metal). This property can have promising practical applications in switching and memory devices.

## 2. SYNTHESIS OF COLOSSAL MAGNETORESISTANCE (CMR) NANOCOMPOSITES

Composites can be prepared in different ways. For making these composites, the insulating material chosen should be inert to the manganites in which they are inserted and insulator should also easily form nano-grade particles in

the manganite matrix. Conventional methods of preparing CMR materials can also be employed for synthesizing CMR composite [27, 51] with other oxides (magnetic or nonmagnetic). Magnetic nanoparticles, a widely studied material (with metal oxides grain size <10 nm), can be easily formed in an insulating/dielectric matrix by several methods such as sputtering, pulsed laser deposition, ion implementation, etc. But there is no such report on the preparation of CMR nanocomposites using those methods. We shall discuss in the following the preparation techniques of different types of CMR composites of nanometer order as reported so far. The composites of manganite/manganite ($La_{0.7}Sr_{0.3}MnO_3/Sm_{0.7}Sr_{0.3}MnO_3$), manganite/insulator ($La_{0.7}Sr_{0.3}MnO_3/MgO$, $La_{2/3}Sr_{1/3}MnO_3/CeO_2$, $La_{2/3}Ca_{1/3}MnO_3/Al_2O_3$, or $La_{2/3}Ca_{1/3}MnO_3:xSiO_2$), manganite-glass ($La_{0.7}Sr_{0.3}MnO_3$-borosilicate glass), and manganite/nonmagnetic-metal ($La_{0.7}Pb_{0.3}MnO_3/Ag$) are the main focus in this review due to their promising features and interesting physical properties (see Table 1).

## 2.1. Solid-State Reaction Method

It is observed that for preparing nanocomposite of nonmagnetic, insulating, and/or glass particle in ferromagnetic manganite matrix, solid-state reaction method, with low-temperature sintering, is a useful one. The efficiency of these composites depends on how the insulating component is dispersed around the grain boundaries of the ceramic. Bulk polycrystalline $La_{0.7}Pb_{0.3}MnO_3$ + x wt % Ag (LPMO/Ag) (x = 0–20) composites have been prepared at relatively lower sintering temperature (900 °C) to keep the grain size smaller [59]. For the preparation of the composite, high-purity (99.99%) $La_2O_3$, PbO, $Mn(CH_3COO)_3$, and $AgNO_3$ powders were mixed in stoichiometric ratio. The powder was preheated at a temperature of 500 °C for 6 hr. Then it was sintered at 800 °C for 24 hr and at

900 °C for 24 hr with intermediate grindings. The pelletized samples were finally sintered at 800 °C for 12 hr and then slowly furnace cooled to room temperature. The whole system becomes a composite with nonmagnetic Ag dispersed in ferromagnetic $La_{0.7}Pb_{0.3}MnO_3$. The average grain size of the CMR samples varied between ~17 and 20 nm. $La_{1-x}Ca_xMnO_3/SrTiO_3$ and $La_{2/3}Sr_{1/3}MnO_3/CeO_2$ (LSMO/$CeO_2$) composites were made by using high-temperature flash sintering process [54, 55]. Presynthesized LSMO and $CeO_2$ powdered samples were mixed by ball-milling in an agate mortar, and the resulting powder was sintered simultaneously by using a rapid heating process up to 1100 °C for 10 min, followed by a cooling process at about 500 °C/hr [55]. But for the preparation of $La_{1-x}Ca_xMnO_3/SrTiO_3$ nanocomposite system, high-temperature sintering at 1600 °C for about 1 hr has been used [54]. The manganite/alumina nanocrystalline composite was also prepared by solid-state reaction method [51]. However, the sol–gel method, discussed in Section 2.2, was used to synthesize the pre-prepared $La_{0.67}Ca_{0.33}MnO_3$ (LCMO) sample.

## 2.2. Sol–Gel Method

The sol–gel method is a very useful tool for the preparation of nanocomposites of CMR materials. $La_{0.7}Sr_{0.3}MnO_3/Sm_{0.7}Sr_{0.3}MnO_3$ (LSMO/SSMO) nanocomposite was prepared by this method, with inorganic nitrates as starting materials [52]. Ethylene-tetra-diamine-acetic acid (ETDA) was used as complexing agent. SSMO powder was prepared first and this powder was then mixed with La-Sr-Mn-O precursor gel. The mixed solution was calcined at 800 °C. Das et al. [57] also used low-temperature sol–gel processing to prepare LCMO/$xSiO_2$ nanocomposites. Since $Si^{4+}$ ion of silica is unlikely to enter the perovskite structure of LCMO due to its strong preference for tetrahedral coordination, the authors preferred the sol–gel method for

**Table 1.** Different types of manganite nanocomposites.

| CMR manganite nanocomposite system | | | | |
| --- | --- | --- | --- | --- |
| Base matrix (manganite) | Impurity phase or second phase | Synthesized by | Magnetization property | Magnetoresistance property |
| $La_{0.7}Sr_{0.3}MnO_3$ | paramagnetic insulator at RT ($Sm_{0.7}Sr_{0.3}MnO_3$) | sol–gel reaction [52] | The value of magnetization decreases with increase of the second phase. | The value of low field and low temperature magnetoresistance enhances and shows a maximum for a particular concentration of the second phase. |
| $La_{0.7}Sr_{0.3}MnO_3$ | nonmagnetic insulator as 1. MgO 2. $CeO_2$ 3. borosilicate glass | 1. aerosol deposition technique [60] 2. solid-state reaction [55] 3. solid-state reaction | | |
| $La_{2/3}Ca_{1/3}MnO_3$ | nonmagnetic insulator as 1. $Al_2O_3$ 2. $SiO_2$ 3. $SrTiO_3$ | 1. solid-state reaction [51] 2. sol–gel reaction [57] 3. solid-state reaction [54] | | |
| $La_{0.7}Pb_{0.3}MnO_3$ | nonmagnetic metal as Ag | solid-state reaction [59] | | |

synthesizing the sample in contrast to flash sintering method used in $LCMO/SrTiO_2$ and $LSMO/CeO_2$ discussed earlier [54, 55]. In case of $LCMO/SrTiO_2$ and $LSMO/CeO_2$ prepared by solid-state reaction method, the possibility of entering $Ce^{4+}$, $Sr^{2+}$, or $Ti^{4+}$ ion into the LCMO or LSMO could not be ruled out. However, in the case of $LCMO/xSiO_2$ type nanocomposites, prepared by sol–gel method, $Si^{4+}$ can either form a chemical compound with other ions retaining the $SiO_4$ tetrahedra intact or precipitate as $SiO_2$ at grain boundaries of the LCMO phase [57].

## 2.3. Aerosol Deposition Technique

Koster et al. [53] used metal organic aerosol deposition technique (MAD) to grow the films of $La_{0.7}Sr_{0.3}MnO_3/MgO$ (LSMO/MgO) composite. Precursors, acetylacetonates of the corresponding metals, taken at the respective ratios, were dissolved into dimethylformamide and then sprayed as an aerosol in the substrate $Al_2O_3$, heated to 700–750 °C. The details about the aerosol deposition technique can be obtained from the published work of Moshnyaga et al. [60], where the authors discussed the method of synthesis of $La_{0.67}Ca_{0.33}MnO_3$ and $La_{0.67}Sr_{0.33}MnO_3$ thin films by MAD technique.

## 2.4. Other Methods

The $La_{0.7}Sr_{0.3}MnO_3$ (LSMO)-glass composites were grown through solid-state-reaction route, but in the final stage the sample was quenched rapidly from high temperature to room temperature [50]. The rapid cooling was essential to avoid crystallization of the glass. The glass used for this purpose was borosilicate glass with the following composition: $SiO_2$ (80.5%), $B_2O_3$ (12.9%), $Na_2O$ (3.8%), $Al_2O_3$ (2.2%), and $K_2O$ (0.6%). The composites were prepared through standard solid-state-reaction method by mixing appropriate amount of pre-prepared LSMO and borosilicate glass. The mixture was compressed and heated at 3 °C/min up to 300 °C and subsequently heated at 10 °C/min up to 800 °C. The sample was kept at 800 °C for 10 min and subsequently quenched to room temperature. The details regarding the synthesis can be obtained elsewhere [50]. Further, Mondal and Chaudhuri [58] also employed this technique using bismuth phosphate glass to precipitate $La_{0.5}Pb_{0.5}MnO_3$ nanocomposites. These composites show giant dielectric constants.

## 3. PHYSICAL PROPERTIES OF CMR COMPOSITES

### 3.1. Microstructure

X-ray diffraction patterns of the ferromagnetic/insulator manganite composites show that the reflection of the peaks of respective perovskite manganite and insulating phases do not shift, which indicates that no reaction has occurred between the two subsystems. This is clearly observable from the XRD patterns of $LCMO/Al_2O_3$ and $LSMO/CeO_2$ composite systems [51, 55]. The thin film of $(La_{0.7}Sr_{0.3}MnO_3)_{1-x}/(MgO)_x$ composite also showed similar behavior [53]. The grain size can be estimated using

Scherer's formula, viz. $S = k\lambda/\beta\cos\theta$, where $k$ is a constant depending on the grain shape, $\lambda$ is the wavelength of the radiation used, and $\beta$ is the full width at half maxima (FWHM) of the respective XRD peak [61, 62]. It is to be noted that the manganite/manganite composite system like LSMO/SSMO is actually a F/I system at room temperature. Here, SSMO is not in ferromagnetic phase at higher temperature ($T_c \sim 63$ K). The XRD pattern indicates the coexistence of two peaks, and the intensity of a particular peak increases with SSMO concentration [52]. The more direct evidence of the coexistence of two phases comes from the SEM cross-section micrograph, where two different types of crystallites can be identified [51, 52]. Again, Koster et al. [53] studied the microstructure by high-resolution transmission electron micrograph (HRTEM) in cross-section geometry and observed a GB with an ultra thin (about 3 nm) MgO layer between two neighboring LSMO grains, which was further confirmed by chemical mapping performed by energy filtered TEM (EFTEM).

Figure 1 shows the XRD pattern of a typical LPMO/Ag composite. Other than perovskite peaks, some extra peaks of Ag appear, confirming the composite nature of the sample. From the XRD pattern, using Scherer formula [61], sizes of the LPMO grains ($\sim$17 nm) and Ag grains ($\sim$20 nm) were estimated independently. It was observed that the size of the perovskite grains does not change significantly with

**Figure 1.** X-ray diffraction patterns of $La_{0.7}Pb_{0.3}MnO_3 + x$ wt % Ag with x = 0, 2.5, 5, 10, 20 wt %, respectively. The peaks due to Ag are marked with □.

Ag doping. The elemental mapping of Ag (Fig. 2) indicates the homogeneous distribution of Ag particles in the sample. The shape and size of the composite have been investigated by means of scanning electron microscopy (SEM) (Fig. 3). Similar to the result discussed earlier, the evidence for the coexistence of the two phases is also reflected from the SEM picture. Two different types of crystallites can be clearly identified from the SEM micrographs. The brighter regions indicate Ag grains, which are embedded into LPMO matrix.

## 3.2. Resistivity and Magnetoresistance

### 3.2.1. Manganite/Insulator Composite System

Insulating materials like MgO, $Al_2O_3$, $CeO_2$, $SiO_2$, and also borosilicate and other glasses have already been used to prepare CMR composites. The resistivity and magnetoresistance of the nanocomposites like LSMO/MgO, LSMO/CeO$_2$, LCMO/Al$_2$O$_3$, LCMO/SiO$_2$, LSMO/glass, etc. reported in the literature are discussed here. Temperature-dependent magnetotransport properties of such composites behave in a similar fashion as that of the pure material. The resistivity is found to increase with the increase of insulating material. In LCMO/Al$_2$O$_3$ nanocomposite, for example, the metal-insulator transition is completely suppressed for Al$_2$O$_3$ doping concentration higher than 8% (Fig. 4) [51]. It has been suggested that this increase of resistivity and disappearance of metal-insulator transition are primarily due to the increase of the electron scattering with the alumina grains in the microstructure. In the resistivity data, a percolation point, beyond which resistivity increases significantly, was observed [51]. The MR values of the $(1 − x)$LCMO/$x$Al$_2$O$_3$ system with different values of concentration x have been shown in Figure 5. It is observed that around x = 10%, MR value is a maximum. Hueso et al. were able to increase (∼three times) the intergranular MR around the percolation threshold, which for both the LCMO/Al$_2$O$_3$ and LCMO/SiO$_2$ composite system is around 10% of alumina and SiO$_2$ doping [51, 57]. It is a common feature of all the granular material to have an optimal doping region of the external phase [54, 55]. Similarly, in the LSMO/CeO$_2$ composite, the percolation threshold is around 80% of CeO$_2$ doping, beyond which the resistivity becomes extremely large ($>10^6$ ohm-cm) [55]. For the

**Figure 3.** SEM photograph of LPMO/10 wt % Ag composite sample. The brighter regions indicate Ag clusters. Pores and empty regions are also observable.

LCMO/$x$SiO$_2$ sample, $\rho$-T curve shows two peaks. The MR at 1 T magnetic field shows a sharp peak at T$_c$ and a minimum just below T$_c$ similar to those reported in several polycrystalline LCMO composites [57]. The sharp peak near T$_c$ is attributed to the CMR effect inside grains comprising pure manganite LCMO phase, while the broad peak below T$_c$ is attributed to the scattering at the grain boundary, which also accounts for the observed low-temperature MR value. Moreover, in LSMO/MgO and LSMO/CeO$_2$ films, metal-insulator-like transition (observed broad peak in the normalized resistivity curve [55]) appears with the increase of external insulating phase, that is, MgO [53] or CeO$_2$ [55]. It is due to the fact that at high temperature, the "bad" interparticle contacts significantly contribute to the intergranular regime and thus resistivity decreases in these composites. The field sensitivity of magnetoresistance, that is, $d$MR/$d$H in $x$LSMO/$(1 − x)$CeO$_2$ has been observed to be five times larger than that of the pure metallic LSMO sample both at low-temperature and near the percolation threshold [55]. Gupta et al. showed that the room-temperature low-field MR values could be enhanced by diluting the CMR sample with appropriate glassy materials [50]. They observed an enhancement of the low-field (<200 Oe) MR at room

**Figure 2.** (a) Elemental mapping of Ag in a typical sample La$_{0.7}$Pb$_{0.3}$MnO$_3$ + 10 wt % Ag showing uniform distribution of Ag cluster between perovskite grains. (b) SEM of the same sample is given for reference of scale.

temperature for the optimal doping of 25 wt % of borosilicate glass in $La_{0.7}Sr_{0.3}MnO_3$-glass composites. The glass, separating the grain boundaries, acts as barrier for spin-polarized tunneling, thereby enhancing the low-field magnetoresistance [50].

### 3.2.2. $La_{0.7}Sr_{0.3}MnO_3/Sm_{0.7}Sr_{0.3}MnO_3$ Composite System

The microstructure of this bulk polycrystalline composite system consists of two phases as discussed earlier. In $(LSMO)_{1-x}/(SSMO)_x$ composite, SSMO is a half-metallic ferromagnet just like LSMO, but its Curie temperature $T_c$ is much lower than that of LSMO. SSMO is a paramagnetic insulator above 63 K [63]. So, at higher temperature, LSMO/SSMO is actually a F/I composite. Resistivity of the composite increases with increasing SSMO concentration (x) and metal-insulator transition temperature also shifts to lower temperature similar to that of a F/I composite discussed earlier. Figure 6 displays the corresponding MR as a function of temperature under a magnetic field of 5 T for the samples with x = 0, 0.2, 0.4, 0.6, 0.7, and 1. The MR values increase with x and are found to show a maximum for the sample with x = 0.6 at 293 K (see the inset of Fig. 6). Enhancement of low-temperature MR arises mainly due to tunneling within LSMO grain boundaries and additional grain boundary effects introduced by SSMO particle.

### 3.2.3. $La_{0.7}Pb_{0.3}MnO_3/Ag$ Composite System

Figure 7 represents temperature variation of resistivity of a typical Ag-containing composite for different concentrations of Ag. The resistivity peak at $T_p$ of the Ag-free sample that is, undoped LPMO, is observed at 235 K, which is lower than that of the previously reported value (~320 K) [64]. This is due to smaller grain size (~17 nm) of the present sample. When the grain size is small enough, spin-dependent tunneling dominates in the transport properties, so the resistivity peak for $La_{0.7}Pb_{0.3}MnO_3$ (x = 0 wt % of Ag) occurs far below the corresponding Curie temperature [59]. The resistivity of the samples decreases with the addition of silver and $T_p$ shifts to higher temperature region. Ag addition actually
increases the grain boundary contact, which results in the decrease of scattering at grain boundary, thereby increasing conductivity.

Since the grain size does not vary appreciably in the samples, we believe that oxygen concentration in the grains is one of the key factors that lead to the observed increase in conductivity. However, crystal structure has been examined to observe the variation of oxygen content in this system. The crystal structure of $La_{0.7}Pb_{0.3}MnO_3$ (without Ag) is found to be hexagonal (space group $R\bar{3}C$) with lattice constants $a = 5.5167$ Å and $c = 13.4048$ Å. It has been observed that with increase of Ag content in LPMO, the value of $c$-axis lattice parameter decreases. Previous results on Ag + La-Ca-Mn-O films [65] and also on the bulk materials have established the correlation between the $c$-axis lattice parameter and oxygen stoichiometry, where increase in oxygen content was found to reduce the $c$-axis lattice parameter.

**Figure 7.** Thermal variation of resistivity ($\rho$) of $La_{0.7}Pb_{0.3}MnO_3$ + x wt % Ag (x = 0, 1.25, 2.5, 5, 10, 20 wt %) showing metal-insulator transitions for all the samples. Transition temperature is marked with straight line.

From Figure 8, it is observed that magnetoresistance ratio of the sample also decreases with increasing Ag concentration, which indicates that magnetic order is less in the Ag-containing samples than in the Ag-free LPMO sample. However, near room temperature, the value of MR reaches a maximum value for x = 5 wt % Ag. From a practical point of view, such an enhancement of the MR value around room temperature is very important.

## 4. TRANSPORT MECHANISM

Temperature-dependent resistivity behavior in the ferromagnetic manganite/insulator composite is often explained by two-channel models, that is, two resistances in parallel, weighting each one with a different fitting factor [50, 51, 55]

$$\frac{1}{\rho(T)} = \frac{A}{\rho_c} + \frac{B}{\rho_i} \tag{1}$$

where $\rho_c$ indicates the resistivity inside the conducting manganite grain and $\rho_i$ represents an insulating channel created by the extra electron scattering with insulating region. $A$, $B$ are the normalized section fraction for the conducting and the insulating channel, respectively, and $A = 1 - B$. $\rho_i$ can be expressed as $\exp(E/kT)$, which represents a semiconductor like resistivity. Though the fits to the experimental results with Eq. (1) are found to be satisfactory [51], this simple model does not, however, exactly fit the data of all the samples, suggesting the importance of further development of the model.

On the other hand, the LPMO/Ag nanocomposite is quite different in its transport behavior. Here the observed temperature-dependent conductivity behavior has been explained on the basis of polaron hopping mechanism in the high-temperature phase and the corresponding low-temperature metallic phase with different scattering mechanisms [32, 66, 67]. It has been discussed earlier that grain

boundary scattering is less in LPMO/Ag nanocomposite system compared to that of the pure LPMO oxide. So with the addition of Ag, spin-related intrinsic scattering becomes prominent due to the reduction of grain boundary scattering. In this regard, LPMO/Ag system is different from other nanocomposite systems mentioned [50, 55], where addition of external insulating phase increases the extrinsic grain boundary scattering, resulting in an enhancement of grain boundary magnetoresistance. The temperature-dependent conductivity in this system has been discussed with different models applicable in different temperature ranges. It is observed from the resistivity curves (Fig. 5) that above and below the MIT temperature ($T_p$), different kinds of transport mechanisms are followed by this system. The conductivity data in the high-temperature semiconducting region (i.e., above $T_p$) followed "small polaron" hopping conduction mechanism of Mott [40, 68]. According to this model, the expression for conductivity is given by the relation

$$\sigma(T) = \sigma_0 \exp(-E_p/kT) \tag{2}$$

where $E_p$ is activation energy of the polaron. In Figure 9, a plot of $\ln \sigma T$ versus $1000/T$ is shown which indicates Arrhenius behavior of conductivity ($\sigma$). With increase of Ag content in the samples, activation energy $E_p$ (estimated from Eq. (1)) decreases and attains a minimum value with Ag concentration at around 10 wt %. Intergranular connectivity is improved by Ag addition, which causes the activation energy to decrease. Here we must note that activation energy also decreases with the application of magnetic field, which can be explained on the basis of alignment of magnetic spins and hence increase of conductivity.

In the low-temperature regime ($T < T_p$), conductivity data of all the samples showed metallic behavior. The experimental data in this temperature range have been fitted with the existing theoretical expressions [66, 67] to find the best model fitting the conductivity data for the present composite system as well as to find the nature of different types of interaction (electron-electron, electron-magnon, or electron-phonon) governing the transport mechanism in

**Figure 8.** Magnetoresistance ratio (MRR = $-(\rho_{1.5} - \rho_0)/\rho_0$) as a function of temperature for the samples $La_{0.7}Pb_{0.3}MnO_3$ + x wt % Ag with x = 0, 2.5, 5, 10, 20. All samples show peak around 320 K arises due to magnetic ordering between $Mn^{3+}$ and $Mn^{4+}$.

**Figure 9.** Variation of $\ln \sigma T$ as a function of inverse temperature $1000/T$ for $La_{0.7}Pb_{0.3}MnO_3$ + x wt % Ag (x = 0, 1.25, 2.5, 5, 10, 20) above the respective MIT temperatures. Solid lines indicate the best fit of the experimental data with Eq. 1.

the low-temperature metallic phase. The resistance versus temperature curves of the samples, in the low-temperature $(T < T_p)$ region where magnetization $M(T)$ behavior indicates that the local ferromagnetic order is almost complete, well fit with the expression

$$\rho = \rho_\alpha + \rho_m T^m \qquad (3)$$

where the temperature-independent part $\rho_\alpha$ is due to domain, grain boundary, and other temperature-independent scattering mechanism. The term $\rho_{2.5}T^{2.5}$ (for $m = 2.5$ in Eq. (3)) arises due to electron-magnon scattering process [32, 66, 69]. When $m = 2$ (Eq. (3)), the term $\rho_2 T^2$ [66, 68, 70] corresponds to the electron-electron scattering. It has been attempted to fit the low-temperature data $(T < T_p)$ with both the expressions as shown in Figure 10. Interestingly, it has been observed that the experimental conductivity data of all the samples in this system cannot be fitted with a single expression ($\rho = \rho_\alpha + \rho_2 T^2$ or $\rho = \rho_\alpha + \rho_{2.5}T^{2.5}$). It was found that for higher silver doped composites (i.e., $x \geq 5$ wt % Ag), low-temperature data are well fitted with the equation $\rho = \rho_\alpha + \rho_2 T^2$. Whereas for lower Ag ($x = 0, 1.25, 2.5$ wt %) doped samples, the corresponding conductivity data is well fitted with the $T^{2.5}$ term. The $T^{2.5}$ term indicates the signature of electron-magnon scattering in the low-temperature range. So it can be said that the scattering phenomenon changes from electron-magnon to electron-electron with the decrease of resistivity (or with the increase of Ag content in the composites) in low-temperature phase (below $T_p$).

## 5. MAGNETIZATION

### 5.1. Manganite/Insulator and La$_{0.7}$Sr$_{0.3}$MnO$_3$/ Sm$_{0.7}$Sr$_{0.3}$MnO$_3$ Composite System

Since magnetization (M) is closely related to magnetoresistance, the study of magnetization is also very important for a deeper understanding of the transport mechanism. The magnetic hysteresis loops for samples (LSMO)$_{1-x}$(SSMO)$_x$ with $x = 0, 0.5$, and 1 at 300 K (Fig. 11) indicate that LSMO is ferromagnetic and SSMO is paramagnetic. Magnetization of the sample with $x = 0.5$ is much smaller than the average M value of LSMO and SSMO [52]. This demonstrates that the ferromagnetic order is weakened and the magnetic disorder is enhanced in the sample with $x = 0.5$. So it has been suggested that the magnetic disorder caused by the addition of SSMO should be responsible for the enhancement of MR in the high temperature range. Curie temperatures in these composites do not change appreciably with doping of external phase in the manganites. However, there is a decrease in saturation magnetization due to the presence of nonmagnetic external phase [51–57]. The magnetic contribution is reduced proportionately with the corresponding increased amount of nonmagnetic insulator percentage in the composite. Similar magnetic behavior is also obtained for the other CMR nanocomposites discussed earlier. For the sample LCMO/SiO$_2$, Das et al. [57] reported that the decrease of saturation magnetization is actually due to the presence of insulating Ca$_2$La$_8$(SiO$_4$)$_6$O$_2$ phase, which is formed since SiO$_2$ partially reacts with LCMO. From the

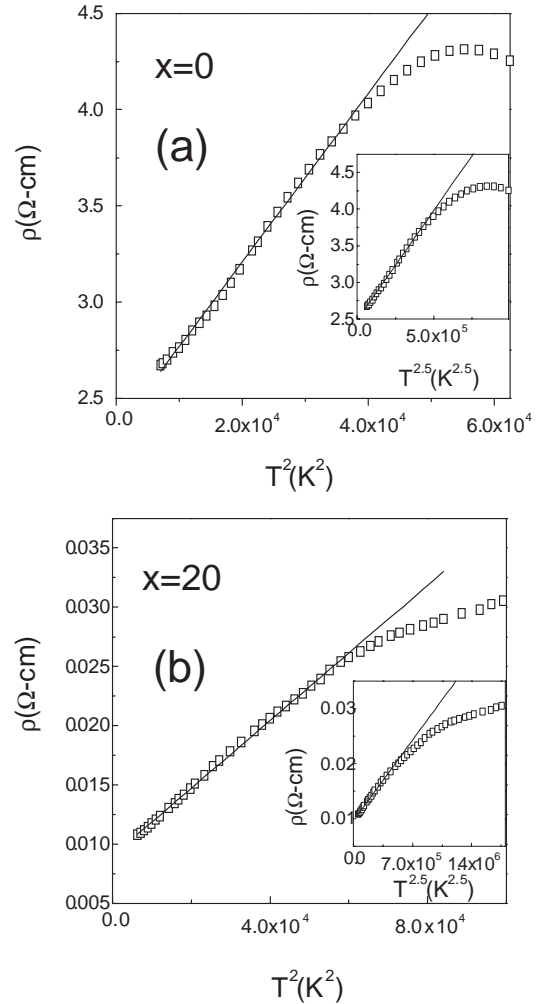

**Figure 10.** Low-temperature resistivity data of two typical samples La$_{0.7}$Pb$_{0.3}$MnO$_3$ + x wt % Ag (for x = 0, 20) fitted with the expression $\rho_\alpha + \rho_2 T^2$ and $\rho_\alpha + \rho_{2.5}T^{2.5}$ (Eq. (2)). Solid lines indicate the best fit of the experimental data. The straight lines show the first expression fits better for the samples with x = 20 wt %.

**Figure 11.** Magnetic hysteresis loops for (LSMO)$_{1-x}$(SSMO)$_x$ composite with x = 0, 0.5, and 1 at 300 K. Reprinted with permission from [52], C. H. Yan et al., *J. Appl. Phys.* 91, 7406 (2002). © 2002, American Institute of Physics.
**Figure 12.** Thermal variation of d.c. magnetization of (LPMO/x Ag) composite with x = 0, 10, 20 wt %, respectively, in presence of magnetic field B = 5 kOe.

thermal variation of magnetization curves of LCMO/SrTiO$_3$ and LCMO/SiO$_2$ composites, a small upturn is observed around 50 K [54, 57], which was explained on the basis of local microscopic magnetic inhomogeneities arising from the variation in the Mn oxidation state [71] or due to the presence of MnO$_2$ phase [72]. Das et al. also explained this small upturn of the LCMO/SiO$_2$ system considering the presence of Ca$_2$La$_8$(SiO$_4$)$_6$O$_2$ impurity phase [57].

## 5.2. La$_{0.7}$Pb$_{0.3}$MnO$_3$/Ag Composite System

Figure 12 shows the temperature variation of magnetization at 5 kOe for the LPMO/x wt % Ag (x = 0, 10, 20) samples. The Curie temperature T$_c$ of these samples increases with increase of Ag content (viz. T$_c$ ∼ 317, ∼341, and ∼361 K, respectively, for x = 0, 10, and 20 wt % observed from high-temperature magnetic measurement). In the Ag composite system, it is reasonable to assume that Ag particles form clusters. This is also indicated from the SEM study. Since Ag content is increasing, the connectivity between two FMM (ferromagnetic metallic) regions increases. This indicates magnetic homogeneity in the samples improves significantly with addition of Ag. With increase of temperature, FMM regions decrease due to spin disorder. But because of the presence of Ag, the connectivity exists. With further increase of temperature, FMM regions become so small that connectivity between different FMM regions is lost and then it becomes paramagnetic (semiconducting). Therefore, it is reasonable to argue that with increasing Ag concentration, T$_c$ increases. Furthermore, it had also been observed that the saturation magnetization decreases with increase of Ag content owing to the precipitation of the nonmagnetic Ag when the concentration exceeds ∼5 wt% [59].

## 6. APPLICATIONS

Though it is still in the rudimentary state, the CMR manganite nanocomposite is a promising candidate for technological applications. In Section 1.2, we discussed in length that low field grain boundary magnetoresistance is more appropriate

for device applications. The presence of grain boundary in the nanocomposites plays a major role in CMR mechanism, particularly for enhancing the low-field sensitivity of CMR manganites [30–39].

Continuous effort to reduce the grain size is being made by the researchers, since nanometer-range grain size modifies the grain boundary/tunneling substantially [43–48]. Here emerges the important role of CMR manganite nanocomposites. Controlled doping of nonmagnetic, insulating materials into the GB of ferromagnetic manganite matrix would lead to an improved low field MR and make manganite nanocomposites a suitable candidate for technological applications. Recently Sun et al. constructed a device consisting of a pillar composed of two layers of ferromagnetic manganite separated by a SrTiO$_3$ spacer [73]. This prototype device, beside showing large resistivity changes in low fields, also demonstrates how it could be possible to use films of ferromagnetic manganites as electronic spin polarizers and analyzers [73]. Large MR is, however, only one useful property for device applications. Future work, for example, on the issues involving power consumption, noise, and compatibility with established fabrication methods [74] is to be done.

## 7. CONCLUSION

The nanocomposite of CMR materials with other external phase like nonmagnetic insulator or metallic phase shows large improvement of the extrinsic magnetoresistance, which promises large potential for their applications from a technological standpoint. These results focus on the new possibilities to improve the performance of the colossal magnetoresistive devices. In the manganite/nonmagnetic-metal (viz. Ag) nanocomposites, improvement in grain boundary scattering and hence MR around room temperature has been observed. Magnetoresistance can be greatly enhanced on ferromagnetic/insulator (F/I) manganite composites near the percolation threshold. Large variation of physical properties is observed in the transport and magnetic properties of the composites at cryogenic temperature, though near room temperature the corresponding effects are very small. For magnetic read head application, for example, the low field MR effect should be larger. Moreover, the preparation of very small grain size (∼2–3 nm) CMR composite is a challenging current problem. However, recent development on CMR nanocomposites is still in the early stage. It is just a beginning of the long emerging prospect of CMR nanocomposites in the field of technological applications for which more smaller and uniform-size nanoparticles are required. Research in this direction would be potentially rewarding in terms of new physics and novel devices using CMR nanocomposites. Theoretical understanding of the transport and magnetic properties, phase separation behavior of CMR composites, etc. is also not yet complete. Study of spin dynamics of CMR nanocomposites is an important field of fundamental research. In the near future, CMR nanoparticles stabilized by chemical materials are expected to open a new field of interdisciplinary research for physicists, chemists, biologists, and engineers.

# GLOSSARY

**Colossal magnetoresistance (CMR)**   A huge decrease in resistance with the application of magnetic field.

**Magnon**   Quantized spin wave.

**Perovskite oxides**   Structures having of combination of face centered cubic (fcc) and body centered cubic (bcc) lattice. For example, oxides of structure $ABO_3$ (A = element with larger radius, B = element smaller with radius), where A lies at the corner, B at the center and O at the face of the cubic structure.

**Phonon**   Quantized lattice wave.

**Polaron**   Formed mainly in an insulator, the combination of the localized electron and its strained field.

**Pyrocholore**   A group of rare minerals found in pegmatitic granites, syenites and carbonatites. For example, PYRO-CHOLORE GROUP $(Ce, Ca, Y)_2(Nb, Ta)_2O_6(OH, F)$ Isometric.

# Mechanical Behavior of Nanomaterials

A. Li Bassi, C. E. Bottani

*Politecnico di Milano, Italy*

## CONTENTS

## 1. INTRODUCTION

Nanocrystalline and nanostructured materials have recently stimulated a great interest both in the scientific and in the technology community, due to the possibility of a tailoring of their properties via structural control at the atomic and supra-atomic level. The change in physical, thermodynamic, electronic, optical properties (and many others), when matter is confined in building blocks whose size is of the order of tens of nanometers or less, suggests the great potentiality that nanomaterials offer for many envisaged applications.

In particular, significant effects of the nanoscale reduction on the mechanical behavior of nanophase materials have been observed since the beginning of the nanoscience era (see, e.g., [1] and references therein for a broad bibliography of recent experimental work in this field).

If we consider nanocrystalline materials, we can see that grain boundaries and interphases can comprise up to 50% of the volume fraction, when the grain size is reduced to 5 nm. Moreover, dislocations are seldom seen inside these grains, particularly when the grain size is in the lower range of the nanometer scale. The porosity level can also be significant, and in the absence of agglomeration, the pore size is smaller than or equal to grain size. Microcrystalline materials already have a mechanical behavior which is grain-size dependent; it is no surprise that all these characteristics may have an even more considerable effect on the bulk material effective mechanical behavior when the grain size

is nanometric, that is, on hardness, ductility, grain boundary migration, and sliding. In general, microstructural features including grain size, grain shape, pore distribution, flaws, surface condition, impurity level, and crystal defects all affect mechanical properties.

More generally, nanostructured materials (not necessary nanocrystalline) possess original mechanical behaviors.

Among the peculiar mechanical properties that were first observed for nanostructured materials we mention:

- elastic moduli were found to be 30–50% lower than in conventional grain-size materials;
- very high hardness and strength, with hardness values for nanocrystalline pure metals ($\sim$10 nm grain size) up to seven times higher than those of conventional coarse-grained ($>$1 $\mu$m) metals; in general, tensile and compressive strengths in nearly all materials show anomalously high values at the nanometer scale;
- ultrahigh hardness has also been measured in nanoscale multilayers made of metallic or ceramic materials;
- a negative Hall–Petch slope, that is, decreasing hardness with decreasing grain size in the nanoscale grain-size regime;
- ductility (possibly superplastic behavior?) at low temperatures in brittle ceramics or intermetallics with nanoscale grain size, probably due to diffusional deformation mechanisms, though the real attribution of this behavior is being debated.

While some of these early observations have been verified, some have been found to be due to artifacts introduced by defects or to the different structures induced by the particular growing procedure.

It also often results that the measured mechanical properties in nanostructured materials depend on the degree of porosity: this is especially true in materials obtained by nanopowder sintering. Metals can be easily compacted and sintered, while ceramic powders are more difficult to densify. The porosity level in a ceramic can be as high as 60%, while it is about 20% in metals (the best obtainable porosity level in a compacted metallic nanomaterial is about 5%, and 15–25% in ceramics). It has been observed that strength and hardness increase approximately linearly with the density of the compact. During pressure sintering, below 10 nm

the pore curvature dominates the driving force for densification, while at about 100 nm, the magnitude of the applied pressure is more important. In the intermediate range both effects are significant, and this implies that a threshold stress (inversely related to the grain size and necessary to create additional surface area by grain boundary sliding) has to be overcome before the densification rate can be increased. Anyway, a detailed analysis of the effect of porosity and defects on the mechanical properties at these scales is currently missing.

In the following, after a brief introduction concerning general definitions of elastic and mechanical properties, the peculiar aspects of the mechanical behavior of nanomaterials will be discussed together with some examples.

## 2. MECHANICAL PROPERTIES: GENERAL DEFINITIONS

### 2.1. Stress, Strain, and Elastic Constants

As for all other physical properties, the mechanical response of materials depends on the scale at which it is measured. For three-dimensional (3D) compact materials (e.g., diamond), when the characteristic observation length scale is much bigger than the typical interatomic distance, the mechanical behavior is conveniently modeled by standard continuum mechanics based on contact interactions (e.g., local elasticity). Yet for special materials with a complex mesostructure or nanostructure this approach is not appropriate. For instance, nanocrystalline materials, nanostructured materials or multilayers, carbon aerogels, and some types of cluster-assembled carbon films belong to this category.

Polycrystalline or multiphase solids, though their properties are influenced and determined by their local microstructure, can be characterized by macroscopic elastic parameters such as the bulk modulus $B$ and the shear modulus $\mu$. Such materials are elastically isotropic at the macro scale and two parameters are often sufficient to describe their behavior (though physicists are traditionally more interested in anisotropic single crystals). In order to describe the kinematics of the deformation process (see [2] also for the following treatment), let a vector field $\mathbf{r}$ span all points within the material volume $V$ in an undeformed thermodynamic equilibrium state at temperature $T$. If now a material deformation is produced, the old (undeformed) material positions are mapped into the new ones as $\mathbf{r}' = \mathbf{r} + \mathbf{u}(\mathbf{r})$ by the displacement vector field $\mathbf{u}(\mathbf{r})$, describing both deformations (volume and shape variations) and rigid rotations. In the small strain regime, the symmetric part of the gradient of the displacement vector field $\mathbf{u}(\mathbf{r})$ is the *strain tensor* $\varepsilon_{rs}$

$$\varepsilon_{rs} = Sym(\nabla\mathbf{u}) = \frac{1}{2}\left(\frac{\partial u_r}{\partial x_s} + \frac{\partial u_s}{\partial x_r}\right) \tag{1}$$

This tensor describes how infinitesimal cubic volume elements $dV = dx\,dy\,dz$ can change their volume and their shape. The diagonal components of the strain tensor represent tensile strains (e.g., $\varepsilon_{xx} = (dx' - dx)/dx$), while the off-diagonal components represent shear deformations. More precisely, assuming in the following a summation from 1 to 3

over repeated vector and tensor suffixes, the relative volume variation $(dV' - dV)/dV$ is equal to $\varepsilon_{ll}$, the *trace* of $\varepsilon_{rs}$. $\varepsilon_{ll}$ is either a pure dilation ($\varepsilon_{ll} > 0$) or a pure hydrostatic compression ($\varepsilon_{ll} < 0$). Instead, $e_{ik} = \varepsilon_{ik} - \frac{1}{3}\delta_{ik}\varepsilon_{ll}$ is a pure shear strain (a *strain deviator*, where $\delta_{ik}$ is the unit tensor); in fact $e_{ll} = 0$, proving that $e_{ik}$ is a pure shear. In the undeformed state the angle, for instance, $\alpha_{xy}$, between $d\mathbf{x}$ and $d\mathbf{y}$ is 90°. After a shear deformation the angle is reduced by an amount $\delta\alpha_{xy} = \gamma_{xy} = 2\varepsilon_{xy} = 2e_{xy}$. Any deformation can be conceived as the sum of a pure shear and a dilation (or compression) as it is evident from the identity $\varepsilon_{ik} = e_{ik} + \frac{1}{3}\delta_{ik}\varepsilon_{ll}$.

Provided the produced strains are small and reversible, a generalized Hooke's law describes the linear elastic material response

$$\sigma_{ik} = c_{ikrs}\varepsilon_{rs} \tag{2}$$

In the above equation $\sigma_{ik}$ is the *stress tensor*. $\sigma_{ik}$ is the $k$-component of the force per unit area acting on a face of a cubic element whose outgoing normal is the unit vector of the $i$—th cartesian axis. The diagonal components represent tractions, while the off-diagonal components represent shear stresses. The elastic material properties are embodied in the fourth-rank tensor $c_{ikrs}$, the *elastic constant tensor* with $3^4 = 81$ elements. Because of the symmetry of $\sigma_{ik}$ and $\varepsilon_{ik}$, the number of independent components of $c_{ikrs}$ diminishes to 36. This number is further lowered to 21 by energetic considerations. Using then Voigt's contraction scheme

$$i, k \text{ or } r, s \quad 11 \quad 22 \quad 33 \quad 23 \text{ or } 32 \quad 13 \text{ or } 31 \quad 12 \text{ or } 21$$
$$\alpha \text{ or } \beta \quad\;\; 1 \quad\;\; 2 \quad\;\; 3 \quad\quad 4 \quad\quad\;\; 5 \quad\quad\;\; 6$$

Eq. (2) can be given a simpler *matrix* form

$$\sigma_\alpha = c_{\alpha\beta}\varepsilon_\beta \tag{3}$$

where the elastic constant $6 \times 6$ matrix $c_{\alpha\beta}$ is symmetric.

The material symmetry produces further reduction. In the case of cubic crystals, for instance, the independent constants are 3 and only 2 in an isotropic material, as anticipated. In the simplest case of isotropic elasticity, Eq. (3) becomes

$$\begin{pmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{pmatrix} = \begin{pmatrix} B+4\mu/3 & B-2\mu/3 & B-2\mu/3 & 0 & 0 & 0 \\ B-2\mu/3 & B+4\mu/3 & B-2\mu/3 & 0 & 0 & 0 \\ B-2\mu/3 & B-2\mu/3 & B+4\mu/3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\mu & 0 & 0 \\ 0 & 0 & 0 & 0 & 2\mu & 0 \\ 0 & 0 & 0 & 0 & 0 & 2\mu \end{pmatrix} \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{pmatrix} \tag{4}$$

The last three components of the *column vectors* stand for pure shear stresses and strains respectively, while the first three components involve length and volume variations. In engineering two different elastic constants, namely the Young's modulus $E$ and the Poisson's ratio $\nu$, are usually introduced. If a uniaxial stress $\sigma_{xx} = \sigma_1 = \sigma$ is applied (with all other $\sigma_i = 0$), only strains $\varepsilon_{xx} = \varepsilon_1 = \varepsilon$, $\varepsilon_{yy} = \varepsilon_2$, and $\varepsilon_{zz} = \varepsilon_3 = \varepsilon_2$ are nonzero. Then $E$ is defined as $\sigma/\varepsilon$ and $\nu$ as $-\varepsilon_2/\varepsilon = -\varepsilon_3/\varepsilon$. Since there are only two independent

elastic constants, $E$ and $\nu$ can be obtained from $B$ and $\mu$ by the following formulae

$$E = \frac{9B\mu}{3B + \mu} \qquad (5)$$

$$\nu = \frac{3B - 2\mu}{2(3B + \mu)} \qquad (6)$$

The meaning of bulk modulus $B$ appears clearly in *hydrostatic pressure conditions*: $\sigma_1 = \sigma_2 = \sigma_3 = -p$ and $\sigma_4 = \sigma_5 = \sigma_6 = 0$. In this case $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = -p/3B$ and $\varepsilon_4 = \varepsilon_5 = \varepsilon_6 = 0$. Thus the relative volume variation $\varepsilon_{kk} = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 = -p/B$.

Since $\mu$ too is always positive, $\nu$ can vary between $-1$ (when $B = 0$) and $\frac{1}{2}$ (when $\mu = 0$). In practice there are no homogeneous materials known for which $\nu < 0$.

In the case of simple shear, for example, $\sigma_4 = \tau$ and all other $\sigma_i = 0$, then $\varepsilon_4 = \tau/2\mu$ and all other $\varepsilon_i = 0$. If one introduces the angular shear strain measure $\gamma_4 = 2\varepsilon_4 = \gamma$, the last equation reads $\gamma = \tau/\mu$, which illustrates the physical meaning of $\mu$.

## 2.2. Hardness and Yield Stress

The stress-strain *tensile* curve of a particular sample is measured in terms of the elongation produced by a tensile stress (typically one plots the stress $\sigma$ versus the strain $\varepsilon$). Two regions can be distinguished in such a curve:

- *elastic* deformation (completely reversible deformation), from which one can get information about the elastic constants and the strain moduli;
- *plastic* deformation (irreversible deformation), which occurs above the *yield stress*.

The collection of sufficient volumes of material is the main problem in tensile strength testing. The limit at which deformation becomes permanent is conventionally taken as 0.2% of the strain, and the corresponding stress is defined as the *yield stress* ($\sigma_y$). Other important parameters which can be evaluated are the total strain to fracture, the stress level at which the sample fails, or the fracture stress. Another important aspect to be considered when materials are subjected to deformation or stress cycles is work hardening (i.e., the material becomes stronger after yielding).

In nanomaterials, as well as in thin films or multilayers, an investigation of the near-surface hardness can be performed by using an indentation load-depth sensing apparatus, that is, a nanoindenter, which directly measures the load on a triangular pyramidal diamond indenter tip as a function of its in-depth displacement from the surface. Hardness is related to the size of the footprint left on the material surface by the diamond indenter, for a given load and a given load time, and can be determined from the load data using the relationship

$$H = L(h)/A(h) \qquad (7)$$

where $L(h)$ is the measured load and $A(h)$ is the projected area of the indenter (footprint) as a function of the plastic depth $h$. Measurements are usually made at a constant load rate (e.g., of the order of about 20 mN/s) to a typical nominal depth, which can for instance be about $\frac{1}{10}$ of the film thickness; several indents are usually made on the same sample and the data are averaged. The actual depth includes the plastic depth and the elastic recovery as the tip is removed, and from this assumption a more detailed analysis can be performed (see, e.g., [3]). Thus, in general, the indentation process can be quite complex. Also hardness or stress-strain experiments under constant load or constant strain-rate conditions can be performed, as a function of time and temperature: this provides the possibility of obtaining information about the creep behavior. In monitoring hardness of thin nanometric layers on a substrate, problems may arise when the substrate is harder than the film. Then, the measured properties can be very sensitive to the presence of the substrate and can be influenced by the value of the substrate hardness [4].

We here recall that super- and ultrahard materials are defined as those with hardness $\gtrsim 40$ and 60 GPa, respectively. The only super- and ultrahard materials available as single crystals are cubic boron nitride (c-BN, $H \approx 48$ GPa) and diamond ($H \approx 70$–90 GPa).

## 2.3. Ductility

*Ductility* can be defined as the ability of a material to change shape without fracturing. Different quantities can be measured which are related to this property, for example, the relative percent elongation due to uniform plastic flow before a mechanical instability or fracture occurs, or the corresponding relative (percent) reduction in area. By analogy with conventional polycrystalline materials, it can be predicted that in nanocrystals ductility should be enhanced. In particular, the grain-size reduction should result in an increase in ductility, as well as a strengthening of the material.

From a quantitative point of view, ductility (or brittleness, which is the property opposite to ductility) can be defined in terms of the strain-rate sensitivity $m$, which is the exponent in the equation

$$\sigma = k(d\varepsilon/dt)^m \qquad (8)$$

(where $k$ is a proper constant), and can vary from 0 (perfectly brittle material) to 1 (perfectly ductile material).

## 3. MECHANICAL PROPERTIES IN NANOMATERIALS AND NANOSTRUCTURES

### 3.1. Elastic Properties

Among early observations of the atypical mechanical behavior of materials possessing an ultrafine grain structure was the reduction of the elastic constants, in comparison with the corresponding coarse-grained materials; this reduction was often of the order of 20–30%. The first measurements of the elastic constants and in particular of the Young's modulus $E$ of nanocrystalline materials were performed with samples prepared by the inert gas condensation method.

One of the first proposed explanations [5, 6] was that elastic moduli of the grain boundary regions are much smaller

than the corresponding moduli of the grain bulk region. In terms of the linear theory of elasticity established for polycrystalline materials, the elastic constants are then expected to be reduced by a fraction determined by the volume fraction of the grain boundaries

$$C^{-1} = (1 - \alpha)C_0^{-1} + \alpha C_{gr}^{-1} \tag{9}$$

where $C_0$ is the grain bulk modulus, $C_{gr}$ is the grain boundary modulus, $\alpha \approx 3\Delta d/d$ is its relative volume fraction, where $d$ is the grain size and $\Delta d$ is the grain boundary width. This should lead to significant changes only for sizes about or below 10 nm. However, an anomalous elastic modulus reduction was observed also for greater sizes, up to $d = 200$ nm. Other theories have thus been developed. For instance, some of explanations are based on the theory of inelasticity and on the inelastic effects caused by the peculiar structural state of the grain boundary region.

Nowadays, the results documented in the literature regarding the variation of the elastic modulus $E$ with grain size are, at least, conflicting [7]. Most results actually indicate a reduction in $E$, but some experiments suggest on the contrary that no change of the elastic modulus can be attributed to the reduced size. Many authors have thus assumed a grain-size dependence of the elastic constants (e.g., reduction of shear modulus $G$ due to increased interaction distance in the interface region [8] and reduction of $E$ due to increased spacing between atoms in the grain boundary [9]); but, in contrast, other authors attribute the observed reduction to porosity and assume $E$ of the material itself to be independent of the grain size, or even to increase with decreasing size [3] (as reported for high-density nanocrystalline gold in [10]).

The reduction in the Young's modulus may be the result of an enhancement of the stress intensity factor from pores in the material. For instance, the Young's modulus of pore-free, electrodeposited nanophase NiP has been measured to be comparable to that of the corresponding coarse-grained material [11]. It was suggested by Krstic and co-workers [12] that the presence of extrinsic defects (e.g., pores and cracks) was responsible for the low values of $E$ in nanomaterials compacted from powders. Other studies used a phase mixture model consisting of a mixture of crystalline phase, intercrystalline phases, and pores [7], and the result was that the calculated elastic modulus of nanocrystalline materials should in effect decrease with a decrease in the grain size, this effect being anyhow relevant only for sizes below 10 nm. The effect of porosity, however, is predicted to be greater than the grain-size effect. Molecular dynamics studies seem to confirm these conclusions.

Subsequent works on porosity-free materials have supported these conclusions, and it is now believed that the intrinsic elastic moduli of nanostructured materials are essentially the same as those of conventional grain-size materials, at least until the grain size becomes very small, for example, <5 nm; at this size the number of atoms associated with grain boundaries and triple junctions becomes very large. Thus, for most nanostructured materials (grain size > 10 nm), the elastic moduli do not represent peculiar or unique properties.

It must be here observed that many studies about the mechanical behavior of nanomaterials reflect the influence of sample imperfections, given the difficulty of making high-quality samples with such a small grain size. Moreover, most studies limit their investigation to microhardness measurements, because of the usually small sample size which renders stress-strain curve measurements difficult, and do not investigate the value of the elastic constants.

## 3.2. Hardness and Strength

The hardness and the strength of conventional grain-size materials (grain diameter $d > 1~\mu$m) have been known to be a function of the grain size for a long time. For ductile polycrystalline materials a semiempirical relationship, called the *Hall–Petch* equation, has been found to express the grain-size dependence of the flow stress at any plastic strain, up to ductile fracture. In terms of yield stress, this expression can be written as

$$\sigma_y = \sigma_0 + kd^{-1/2} \tag{10}$$

where $\sigma_y$ is the yield stress, $\sigma_0$ is a friction stress opposing to dislocation motion, $k$ is a constant, and $d$ is the grain diameter. The same behavior has been found to hold for hardness

$$H = H_0 + kd^{-1/2} \tag{11}$$

In order to explain these empirical observations, several models have been proposed, which involve either dislocation pileups at grain boundaries or grain boundary dislocation networks acting as dislocation sources. In all cases the Hall–Petch effect is related to the phenomena of dislocation generation and dislocation motion in materials that exhibit plastic deformation.

From an experimental point of view, in general, pure *nanophase metals* turn out to be harder by a factor from 2 to 7 than the coarse-grained counterpart at room temperature (and this is apparently independent of the nanometal synthesis method). For instance, nanophase Cu ($d = 6$ nm) shows a hardness five times greater than bulk Cu ($d = 50~\mu$m). The yield stress of nanophase Pd ($d = 7$ nm) is five times greater than that in the corresponding bulk metal ($d = 100~\mu$m). This anomalous behavior substantially derives from the difficulty in creating dislocations and from the existence of barriers to dislocation motion.

Generally speaking, the mechanical behavior is mainly determined by the type of bonding in the materials. Metals, with highly delocalized bonds, are ductile and thus usually soft; ionic solids are more difficult to deform (due to charge neutrality); covalent solids have strong localized bonds, so that ceramics and intermetallics are subject to brittle fracture. In a crystalline structure, dislocations can be introduced and atomic planes can slide over one another. In the nanophase, both these behaviors are altered. In nanophase metals the hardness increases with decreasing grain size because defects and dislocations are required for deformation to occur, and they are almost absent in nanostructured materials, although regenerative sources of dislocations exist. In other words, the dislocations needed for easy deformation are frozen and new ones are prevented from forming in nanomaterials.

We must here observe that most of the mechanical investigations on nanocrystalline materials refer to hardness, although also tensile test data have been reported. We can say that the overall trend indicates an increase in hardness as the grain-size drops. However, stress-strain curves on small tensile samples show little change of the yield stress. Several recent reviews have summarized the mechanical behavior of nanostructured materials in terms of hardness and yield stress [13–15]. It appears evident that as the grain size is reduced down to the nanoscale regime (<100 nm), hardness typically increases with decreasing grain size and can reach values up to several times greater for pure nanocrystalline metals (10 nm grain size) than for coarse-grained (>1 $\mu$m) metals. However, at the smallest nanocrystal grain sizes (<20 nm), different experiments have evidenced different behaviors for the dependence of hardness on grain size. All the following behaviors were found by different researchers [14, 15]

- positive slope ("normal" Hall–Petch behavior), often with a decreasing gradient at some critical size (see Figs. 1 and 2);
- essentially no dependence (almost zero slope);
- in some cases, a negative slope (sometimes below a critical size).

The negative (or inverse) Hall–Petch effect for very small grain sizes has been discussed. For instance, in the case of intermetallics, at large grain sizes $H$ increases with decreasing $d$, but often decreases or saturates below a critical size, thus showing a transitional behavior. Some nanocrystalline thin films with a grain size $\leq 6$ nm were also found to exhibit a negative Hall–Petch behavior. This behavior was often found in nanocrystalline samples that have been annealed in order to increase the average crystal grain size and make measurements at different sizes. It is possible that thermally treating nanophase samples in the as-produced condition, which results in structural changes such as densification, stress relief, phase transformations, or grain boundary structural changes, may lead to the observed negative Hall–Petch behavior [16]. When annealing or a higher consolidation temperature is adopted in order to increase the

**Figure 2.** Stress-strain curves for nanophase and annealed coarse-grained Pd. Reprinted with permission from [18], R. W. Siegel and G. E. Fougere, *Nanostruct. Mater.* 6, 205 (1995). © 1995, Elsevier Science.

grain size, the size and density of flaws can decrease and the internal stresses in the obtained material can change. Then, also these effects have to be considered together with the change in grain size. In fact, only a few cases of negative Hall–Petch behavior have been reported for as-produced nanocrystalline samples with a broad range of grain sizes (e.g., electrodeposited nanocrystalline alloys and devitrified nanocrystalline alloys [17]), that is, for samples in which the change in the grain size is not accompanied by possible structural defects or stress changes.

Although in many cases the observed negative Hall–Petch slopes are due to artifacts of the specimen preparation methods, it is also possible that conventional dislocation-based deformations are not operable in nanocrystalline materials at the smallest grain sizes ($\leq 30$ nm). At these sizes, theoretically, mobile dislocations are unlikely to occur; in fact, they were not observed in *in-situ* TEM deformation experiments [16]. In any case, it is clear that the hardness, strength, and deformation behavior of nanocrystalline materials, although unique, are not yet well understood.

We have already said that in nanophase materials, in the grain-size range where the hardness increases monotonically, this happens because the defects and dislocations required for deformation to occur are almost totally absent. However, in defect-free conventional grain-sized materials there are also dislocation sources, which are regenerative sources of dislocations. The critical stress required to activate, for instance, Frank–Read sources is $\sigma_{cr} = K(\mu b/L)$, where $K \approx 1$ (=0.5 for edge dislocations and =1.5 for screw dislocations), $b$ is the Burgers vector, and $L$ is the distance between pinning points [18]. In nanomaterials, the grain size can be identified with the limiting value for $L$. Thus, in very small particles $\sigma_{cr}$ actually exceeds the conventional yield stress for the material. We can simply put it by saying that in nanostructured materials the dislocations needed for deformation are frozen, and new ones are prevented from forming.

Also the *plastic* deformation behavior and in particular the yield stress have been investigated [7]. It is well established that coarse-grained materials exhibit a constant

**Figure 1.** Room-temperature hardness versus grain size for nanophase metals compared with the hardness of their coarse-grained counterparts (values near origin). Reprinted with permission from [18], R. W. Siegel and G. E. Fougere, *Nanostruct. Mater.* 6, 205 (1995). © 1995, Elsevier Science.

Hall–Petch gradient $d\sigma/d(d^{-1/2})$ (see Eq. (10)); again, three types of behavior have been observed in the case of nanostructured materials: positive Hall–Petch gradient (corresponding to what is observed in coarse-grained materials), decreasing gradient at smaller sizes, and a negative gradient below some critical size.

In summary, the Hall–Petch equation, which relates the yield stress or the hardness to the inverse square root of the grain size, predicts great increases in the material strength with grain refinement [19]. On the other hand, theory indicates that the high volume fraction of interfacial regions leads to increased deformation by grain boundary sliding in metals with grain size in the low end of the nanocrystalline range. The Hall–Petch relationship is usually explained in terms of dislocation pileups at grain boundaries, and it should break down at sizes such that a grain cannot support a pileup. Great efforts have been recently devoted to the use of molecular dynamics simulations of deformations in the nanophase, in order to verify and explain these predictions. Still many questions remain open (see, e.g., [20]).

Again, as in the case of the attempted explanation of the anomalously low values of the elastic constants, most models of nanocrystalline matter describe the mechanical behavior in a defect-free material, while real materials actually contain pores, flaws, trapped gases, and impurities and they are better described by a wide distribution of grain sizes. Moreover, one of the main practical problems, especially in the case of nanoceramics, is represented by the difficulty of making specimens that are both fully dense and large enough to perform traditional measurements and mechanical tests.

## 3.3. Tensile and Compressive Response, Ductility and Creep, Superplasticity

Again, the starting point in the discussion of these properties is the already well-known strong effect that grain size has on the ductility and toughness of conventional grain-size ($>1\ \mu$m) materials. For example, the ductile-brittle transition temperature in conventional mild steel can be lowered by about 40 °C by reducing the grain size by a factor of 5. We here recall that the brittleness can be defined in terms of the strain-rate sensitivity $m$, that is, the exponent in the equation

$$\sigma = k(d\varepsilon/dt)^m \qquad (12)$$

and can vary from 0 (perfectly brittle) to 1 (perfectly ductile).

A significant enhancement of ductility has been observed also for nanosize crystalline samples, and in some cases, the term *superplasticity* has been employed to indicate the manifestation of an exceptional ductile behavior when the grain size is reduced in the nanometer range, that is, the manifestation of an exceptionally enhanced strain to failure. We can define superplasticity as the capability of polycrystalline materials to exhibit very large tensile deformations without showing fracture, or necking. Elongations in the range 100–1000% are considered to be the typical defining feature of this phenomenon, with respect to conventional behavior, with elongations of the order of some percent. Superplasticity is usually observed only above a certain critical temperature in the materials that present this behavior also when

coarse-grained, and these "activation" temperatures are usually higher than 0.5 $T_M$, where $T_M$ is the melting temperature. When the grain size is decreased, it is found that the threshold temperature can be lowered; at the same time, an increase in the strain rate for the occurrence of superplasticity is observed. When these behaviors were first reported, it was believed that creep rates could be enhanced by many orders of magnitude by simply reducing the grain size below 100 nm, and that superplastic behavior could be observed also in nanocrystalline materials at temperatures much lower than 0.5 $T_M$. Subsequent creep experiments have not fully confirmed this prediction, and instead the observed creep rates are comparable to or lower than those measured in coarse-grained samples of the same material at temperatures <0.5 $T_M$.

However, there is some evidence of a superplastic behavior enhancement in nanocrystalline materials at temperatures >0.5 $T_M$, and, as we have said, superplasticity has been observed at lower temperatures and at higher strain rates in nanocrystalline materials than in coarse-grained materials. In any case, it must be observed that tensile superplasticity is limited to materials that already exhibit superplasticity for coarser grain sizes (1–10 $\mu$m). For example, for zirconia ($ZrO_2$) and titania ($TiO_2$), $m = 0.02$ at 300 K for $d = 100$ nm (with reference to Eq. (12)), but $m$ increases almost exponentially below 50 nm for both the oxides [13].

Superplastic behavior has been observed [21] in some alloys, for example, in nanocrystalline Pb(62%)Sn at 0.64 $T_M$ and in nanocrystalline Zn(22%)Al at 0.52–0.60 $T_M$; however, it was also observed [22] in 200-nm nanocrystalline Ti (190% elongation, $m = 0.32$) at 0.42 $T_M$, that is, a temperature 50 °C lower than for 10-$\mu$m grain size Ti. The flow stress for the 200-nm Ti at 550 °C was 90 MPa, compared to 120 MPa for 10-$\mu$m Ti at 600 °C. A heavily deformed Ti alloy with an initial grain size of about 20 nm could be elongated by 600% at 500 °C. The same alloy, but with a grain size in the micrometer range, exhibits superplasticity only in the temperature range 900–950 °C; otherwise typical elongations are extremely limited (0–2%).

In contrast with oxides and alloys, single-phase nanostructured metals usually exhibit high strength and hardness but brittle behavior at low temperatures (<0.5 $T_M$). So far there is no evidence of superplasticity behavior in tension for nanomaterials prepared by powder metallurgical methods. Experimental results on the ductility of single-phase nanocrystalline materials indicate little ductility in tension for grain sizes less than about 25 nm, and this is true both for materials that are ductile when coarse-grained (e.g., elemental metals) and materials that are brittle when coarse-grained. Tensile creep measurements on nanophase metals have been performed at room temperature for Cu, Ni, and Pd, which exhibited a logarithmic stress-strain behavior as a function of time, apparently resulting from dislocation activity or grain boundary sliding. The plastic strain rate increases with decreasing grain size [19] (while it is usually roughly constant for sizes >10 nm). This suggests that in nanophase metals no damage accumulation is happening, which is a characteristic of superplasticity.

In some metals, for example, in Cu, ductile behavior is observed in compression, with yield strengths about twice those observed in tension. The limited ductility exhibited

by single-phase nanometals can be attributed, as already explained, to the difficulty in creating and moving dislocations at the smallest grain sizes, but may as well depend on the fact that the results of these measurements are sensitive to a significant presence of flaws and porosity (and in fact annealing after consolidation has resulted in an improved ductility and strength of nanomaterials subjected to tension). This could also be the reason for the asymmetry observed when comparing the results obtained in compression or in tension tests, respectively; in addition, the nature of the deformation process in terms of *shear banding* (see Section 3.6) may also be important.

Also for intermetallics or ceramics, experiments concerning a possible increase in ductility by grain-size reduction are contradictory.

Compressive creep tests of nanophase *intermetallic* materials have instead confirmed the enhanced plasticity and compressive strength behavior for this class of materials. Also hardness tests at elevated temperatures can be used to study compressive creep behavior of nanomaterials. In this case a nanoindenter is usually employed as a static tool, but if loading times are increased, while the load is kept constant (at a given temperature), the indentation size can be monitored and this can provide information about the dynamic compressive behavior. At low temperatures, for instance, nanophase TiAl showed little change in hardness until the temperature rose to the point that thermally activated deformation by diffusional creep started.

Many studies have been devoted in particular to ceramics and nanoceramics (see, e.g., [23, 24]). Early observations of ductile behavior of brittle nanoceramics at low temperatures suggested that brittle ceramics or intermetallics might exhibit ductility with nanoscale grain structures, but many more recent results seem to contradict what was previously predicted. An apparent plastic behavior in compression was observed in nanocrystalline $CaF_2$ at 80 °C and $TiO_2$ at 180 °C [24]. Nanocrystalline ceramics are considered interesting because they have, with respect to conventional ceramics, a lower sintering temperature (e.g., ~600 °C for titania) and an enhanced strain to failure. Most of the data currently available on the stress-strain behavior of nanoceramics is from small compression specimens, while tensile behavior has never been quantified in detail.

Most ceramics tested in compression at room temperature usually exhibit brittle behavior. Instead, in nano-intermetallic $Fe_{28}Al_2Cr$, whose yield strength is about 10 times greater than for its coarse-grained (75 $\mu$m) counterpart, a compressive strain of about 1.4 could be obtained at room temperature. In general, in nanoceramics, creep processes have been observed at lower temperatures than in coarse-grained ceramics. As usual, porosity and imperfections in the as-prepared nanocrystalline material affect the testing, but it has been found that when the porosity is lower than 20%, the creep rate in compression of ceramic powder compacts is only weakly dependent on the porosity degree.

The results of studies on two-phase nanostructured materials suggest that the combination of high hardness/strength and toughness/ductility may be possible in multiphase nanostructured materials. Many of Al-, Mg-, and Ni-based alloys with a nanoscale structure consist of nanocrystallites in an amorphous matrix. Some Al-rich alloys contain nanoscale

particles surrounded by crystalline face-centered cubic Al. These multiphase nanostructured alloys possess extremely high strength coupled with some ductility [25]. Ductility is high in compression, but uniform elongation in tension is limited. This behavior is analogous to that exhibited by ductile amorphous alloys. These results again suggest the possibility of the development of nanostructured multiphase composites that combine extremely high hardness and strength with toughness and ductility. Such materials could in principle be useful for many applications where they may be employed as unique structural materials.

Let us discuss the characteristics of creep mechanisms in nanostructured materials. Since creep is primarily controlled by diffusion, it is expected to occur quickly in nanophase materials because of the large volume fraction of grain boundaries and the short diffusion distances. Diffusion along grain interfaces is very rapid, and mechanisms similar to those that drive sintering and neck formation at room temperature in nanophase metals may enhance also the creep rates in these materials. Creep rates may also be influenced by the level of porosity in nanophase samples, since free surfaces tend to increase diffusion rates relative to grain boundary rates.

The possible enhanced ductility in nanophase ceramics can find an explanation in terms of the so-called *Ashby–Verral* model, which is based on the principle of grain boundary sliding with diffusional flow. If a compressive stress is applied to a system of equiaxed grains, there is a diffusional flow in the boundary regions. This can lead to a change in the external shape, but the grains remain equiaxed and maintain their size and orientation, sliding over one another by diffusional accommodation at the interfaces. The reason why this mechanism should be activated when the grain size is decreased in ceramics is that sliding would occur if, when a crack is opened at an interface, diffusion can contribute to fill it. In small grains, the number of atomic rearrangements required for healing is possible in real time during the sliding, while it would take long times in conventional grain-sized materials.

Karch et al. [24] also attributed ductility to enhanced diffusional creep providing the plasticity, where conventional grain-size materials would fail in the elastic regime. Their model relates the strain rate (or creep rate) to grain boundary diffusion

$$\frac{d\varepsilon}{dt} = \frac{B\sigma\Omega\Delta D_b}{d^3 kT} \tag{13}$$

where $\sigma$ is the applied stress, $\Omega$ is the atomic volume, $d$ is the grain size, $k$ is the Boltzmann constant, $T$ is the temperature, $B$ is a constant, and $D_b$ is the grain boundary diffusion coefficient. Going from a grain size of 1 $\mu$m down to 10 nm should increase $d\varepsilon/dt$ by $10^6$ or more if $D_b$ is significantly larger for nanomaterials. However, their results obtained for nanocrystalline $CaF_2$ at 80 °C and $TiO_2$ at 180 °C have not been reproduced, and it is believed that the porous nature of these samples was responsible for the apparent ductile behavior. Recent creep measurements of nanocrystalline Cu, Pd, and Al-Zr at low temperatures [26] found creep rates comparable to or lower than the corresponding coarse-grained material rates. One possible explanation is that the observed low creep rates are caused by the

high fraction of low-energy grain boundaries in conjunction with the limitation in dislocation activity due to the small grain sizes.

In summary, exceptional ductility due to diffusional creep in nanocrystalline brittle ceramics or intermetallics at temperatures significantly less than 0.5 $T_M$ has not been realized, while effective enhanced ductility has been obtained at somewhat higher temperatures, and an improvement of creep properties can be seen in terms of a lower "activation" temperature for superplasticity and a higher strain-rate regime. Experimental results and interpretations are still in contrast and not very clear, so that it can be said that the real effect of the nanostructure on these properties has not been fully understood.

It must be underlined that grain boundaries, in this kind of materials, are in a nonequilibrium configuration, and even in a material with a fixed grain size a wide range of properties can be obtained and measured depending on the sample preparation (and on the measurement procedure); also the presence of metastable phases may be important for the comprehension of the ductile and plastic properties of nanomaterials. This suggests that control of mechanical properties through grain boundary engineering is possible.

## 3.4. Fracture and Toughness

In practical applications of (e.g., structural) materials, a significant limitation is often represented by the fracture strength of the material, and not by the yield strength. A material can yield and with this mechanism sustain itself against an imposed stress. This is possible because of the behavior of microstructures like dislocations and grain boundaries, which prolongs plasticity. However, a material possessing an elevated strength can also fail suddenly in a brittle way, with little plasticity (and this is a serious problem for real applications).

The results and comprehension concerning the fracture properties of nanostructured materials have so far been very limited and, as usual, influenced by the presence of porosity [27]. Some bending tests [27] of compacted NiP showed that by decreasing the grain size an enhancement of the fracture stress and of the strain-to-fracture can be realized. High-resolution electron microscopy of *in-situ* fracture of nanophase Au and Au/Si composite films on Al substrates showed a strong dependence of the fracture behavior on the grain size. For microstructured materials, improvements in toughness and a lower brittle-to-ductile transition temperature are obtained by decreasing the grain size, but the same behavior has still to be proved for nanomaterials. In a study of intermetallic TiAl (grain size in the range 100 nm–70 $\mu$m), the toughness was found to decrease with decreasing grain size, as intragranular cracking gave way to intergranular fracture, but there are no studies in the more significant range 5–100 nm.

Mechanical failure, which limits ductility, can be viewed as a competition between dislocations and nucleation or propagation of cracks, depending on the grain size. (In small grains, crack propagation can be more difficult.) However, the large increase in yield stress (hardness) observed in nanomaterials suggests that the fracture stress can be lower than the yield stress and therefore result in a reduced ductility.

## 3.5. Fatigue and Wear

Fatigue has not been extensively studied in nanostructured materials [27]. The high cycle fatigue behavior of bulk specimens of nano-Ni produced by electrodeposition (in the grain-size range 50–100 nm) has been reported to be very similar to that of the conventional material [27]. No quantitative data on the fatigue life and fatigue crack growth rate are available for any nanomaterial.

A summary of the wear behavior analysis of nanomaterials (bulk cutting tool materials and surface coatings) has been performed by Morris [28]. Hardness was found to be generally greater than in the conventional corresponding material, but toughness was found to be independent of hardness; abrasive wear resistance and sliding wear resistance were very high; tool life increased significantly when the grain size was below 300 nm. (This property has already been exploited in industry for the manufacture of tools with complex cutting edge shapes.) There is currently no complete explanation for the wear behavior of nanostructured materials. An analysis of friction and wear for nanolaminated Ti-TiN and Al-Al$_2$O$_3$ composites was performed by Northwood and Alpas [29], and the friction coefficient and the wear rate were found to decrease with thickness.

## 3.6. Observations

Some generalizations can be made about the deformation mechanisms in nanostructured materials. Dislocation activity dominates for temperatures $<0.5$ $T_M$, when the grain size is in the range 50–100 nm. Then, as grain size decreases, dislocation activity also decreases. The lack of dislocations in grains whose size is below 50 nm is the result of the *image forces* that act on dislocations near surfaces or interfaces.

The lack of dislocations in confined spaces, such as single-crystal whiskers, has been known for many years. Also the creation of new dislocations is more difficult as the grain size reaches the low end of the nanoscale, since stresses needed to activate dislocation sources, as the Frank–Read source, are inversely proportional to the distance between dislocation pinning points, so that these activation stresses can reach the theoretical shear stress of a dislocation-free crystal (this happens roughly at a grain size of ∼2 nm, i.e., when the grain size limits the distance between pinning points). Thus, other mechanisms, such as grain boundary sliding or grain rotation accompanied by short-range diffusion healing events [14], may control the deformation behavior at this scale.

Another comment is necessary for the observation of examples of deformation by *shear banding* for some nanocrystalline materials, where deformation in compression proceeds by intense localized shear banding. In these cases the stress-strain curves exhibit essentially elastic–perfectly plastic behavior; that is, no measurable strain hardening was observed. Shear banding is also the deformation mode observed in amorphous metallic alloys and in amorphous polymers. This suggests an evident similarity between deformation mechanisms in nanocrystalline materials and in amorphous materials, even though not all tensile data on nanocrystalline materials exhibit a lack of strain hardening. In general, amorphous materials exhibit many of the

phenomenological characteristics of deformation in nano-materials, that is, shear banding, asymmetry between tensile and compressive behavior, and perfectly plastic behavior. Unfortunately, deformation mechanisms are not completely understood in amorphous materials either.

# 4. SPECIAL NANOSTRUCTURES

## 4.1. Nanocomposite Materials and Dispersions

The benefits of introducing precipitates of nanometric size (1–100 nm) in a conventional material are well known [27] (this is called *precipitation hardening*). Well-established structural materials (tempered steel and age-hardened aluminum alloys) contain nanoscale features in order to achieve better mechanical properties. For instance, when nanosize Mo (5–20 vol.%) is dispersed in micrometer-sized $Al_2O_3$, considerable improvements in hardness, fracture strength, and toughness are obtained, though each property has a different behavior as a function of composition. The hardness of $Al_2O_3$-, MgO-, and $Si_3N_4$-based nanocomposites was found to increase with decreasing grain size and with increasing SiC content (the hardness change being in agreement with the rule of mixtures). By introducing nano-structured SiC dispersions (200 nm) in a matrix of $Al_2O_3$, the fracture strength can be increased by a factor of 3 and also the high-temperature mechanical properties are enhanced. The decrease in hardness with increasing temperature is significantly less in nanocomposite $Al_2O_3/SiC$ than in monolithic $Al_2O_3$. The tensile strength and elongation to fracture in Mg-Zn-La alloys containing Mg nanoparticles (5–10 nm; interparticle distance 3–10 nm) are considerably greater than in amorphous Mg-Zn-La alloys of similar compositions, and the main reason is that the nanoparticles suppress homogeneous shear. By introducing nanoscale multifilaments of $Nb_3Sn$ in $Cu$-$Nb_3Sn$ composites, unique combinations of superconducting and mechanical properties can be obtained. Some controversy exists about the super-modulus effect reported in thin layers containing granular metal particles.

A particular class of nanocomposites is represented by polymer nanocomposites. The reinforcement of polymers with a second phase, organic or inorganic, in order to obtain a polymer composite is commonly employed in the production of modern plastics. Polymer nanocomposites [30–32] represent an alternative and an improvement with respect to conventional polymer composites. A doubling in tensile modulus and strength has been demonstrated for some nanocomposites, and the heat-distortion temperature can be increased by up to 100 °C. Moreover, polymer nanocomposites can be much lighter than conventional polymer composites.

The key point for the mechanical properties of polymer nanocomposites is that uniform dispersions of nanosized particles (nanoelements) can lead to an ultralarge interfacial area between the constituents per volume of material (up to 700 $m^2/cm^3$, e.g., for dispersions of silicates in polymers). An interface limits the number of conformations that polymer molecules can adopt, and this affects the mechanical behavior (see [30] for details). The influence of an interface is

related to some fundamental lengths: the size of a nanoelement, its aspect ratio (e.g., length/transverse dimension), the interelement distance, and the length scale of the adjacent matrix, which for polymers is of the order of the radius of gyration of a chain (5–10 nm). In a polymer nanocomposite the interfacial region becomes the dominant bulk phase (see Fig. 3).

The inclusion of elastomeric nanoparticles in polypropylene and the subsequent effect on the resulting elastic properties has also been studied, and it has shown the possibility of combining good toughness and stiffness properties in this nanocomposite material [33].

## 4.2. Nanotubes

Single-walled carbon nanotubes (SWNTs) can be thought of as obtained by warping a single graphitic layer to form a seamless cylindrical object [34]. Beyond possessing unique electronic properties, depending on the symmetry, or chirality, of the carbon lattice, nanotubes attract today an enormous attention also because they are expected to be very strong and have high elastic moduli [35, 36], and it is now possible to grow multiwalled or single-walled nanotube microarrays or patterns with a desired geometry and alignment. In 1996 Thomas Ebbesen estimated Young's modulus of a carbon nanotube by measuring the vibrations of the free end of a nanotube clamped at the other end with a TEM, and more recently Young's modulus has been estimated by observing their bending with an atomic force microscope [37]. The estimates (up to 1.25 TPa) were consistent with the exceptionally high values of Young's modulus measured for a graphene sheet, that is, about 1 TPa. Single-walled carbon nanotubes are also expected to be very strong and to resist fracture under extension. Moreover, molecular dynamics simulations indicate that the nanotube should regain its original shape when the stress distorting it is removed.

The expected very high strength-to-weight ratio of SWNTs has stimulated an enormous interest in view of applications as reinforcement fibers in composite materials, high-strength cables, actuators, etc. [34, 38–40]. Elastic properties of SWNTs, and acoustic vibrational modes in carbon nanotubes, have been calculated both by *ab initio* calculation (lattice dynamics, e.g., [41]) and by continuum models [42]. Acoustic vibrational properties are strictly related to elastic properties of SWNTs, and these (e.g., Young's modulus)

**Figure 3.** Schematic picture of a polymer nanocomposite. Reprinted with permission from [30], R. A. Vaia and E. P. Giannelis, *MRS Bull.* 26, 395 (2001). © 2001, Materials Research Society.

have been estimated by observing their bending with AFM [37] or, as we have said, their freestanding room-temperture bending vibrations with TEM [40, 43]. With these methods problems arise from the lack of precision in determining the SWNT diameter, length, temperature, and vibrational frequency, and the tendency of SWNTs to form bundles complicates the analysis. Nevertheless, a Young's modulus of the order of $E = 1.25$ TPa was found. Moreover, different theoretical approaches have been proposed to model a SWNT with an elastic continuum model, or by *ab initio* calculations, and the predicted Young's moduli are scattered over a large interval. It is still a matter of speculation whether the curvature modifies the original properties of the graphene sheet, since the Young's modulus of SWNTs appears to be systematically higher than the in-plane elastic modulus of graphite, and no precise comparison could be made between SWNTs and MWNTs (see, e.g., [44]). The higher value of their Young's modulus could be attributed to an increased strength due to the wrapping [43] (stiffening of the graphite sheets is predicted for a radius lower than 0.5 nm).

Brillouin scattering (see Section 5.2.2) has been used to measure longitudinal acoustic modes in SWNTs [45, 46], and from the measurement of their frequencies, it was possible to estimate the two-dimensional Young's modulus for the nanotube walls, $E_{2D} = 110$ N/m. This value is of the same order of magnitude as the C-C atomic force constant computed for a graphite plane. If one considers the thickness of a graphite layer, this corresponds to a Young's modulus for an ideal isolated graphitic plane of the order of 1 TPa. This measurement was made possible by the preparation of a sample of pure oriented and almost noninteracting SWNTs. This measurement allows an estimate of the in-plane elastic properties (2D Young's modulus) of the tube walls, and thus of a curved graphitic sheet, which is in agreement with reported computations; with samples possessing a more defined geometry, the proposed method would in principle allow a more precise measurement of SWNT elastic constants. In the case of SWNTs, the 2D Young's modulus is the only unambiguously defined elastic property of the material constituting the tube. In fact, in the rod model previously used in the literature, the 3D Young's modulus is an effective elastic property embodying uncertain geometrical parameters. In these aligned SWNT bundles, only vibrational modes propagating along the tubes were detected (and not perpendicularly to the tube direction), thus confirming that the lateral cohesion between tubes is poor (thus hindering the propagation of effective modes transverse to the bundle orientation) and that the high strength of the material is highly anisotropic. This limitation must be taken into account when considering these structures for mechanical applications as reinforcing high-performance fibers.

## 4.3. Multilayers

Nanolayered materials also exhibit interesting structural and mechanical behaviors [47, 48]. Physical vapor deposition permits to choose among elements, alloys, and compounds as layer constituents. The interface area density is usually very high, so that interface effects dominate the multilayer properties, and this can lead to unusually large strains and to the realization of metastable structures. The interest in the

mechanical properties of nanolayered materials arises from the fact that plastic deformation can be confined to small volumes by controlling both the frequency and the magnitude of obstacles to dislocation motion. The assumptions used to model mechanical behaviors at the small scales may not be valid at the nanometer scale even if this confinement is limited to one dimension (perpendicular to the film plane), and the result is that there is a critical layer thickness below which improvement in strength does not occur [49], similarly to what happens in nanocrystal grains. Usually, metals are employed for the deposition of superlattices with improved mechanical properties (see, e.g., [47, 48, 50, 51] and references therein): TiN/NbN multilayers reach a hardness value of 50 GPa [52], while hardness of single TiN or NbN films is around 20 GPa. Mo/NbN, W/NbN, Fe/Pt, Ag/Cr, Cu/Ag, Al/Ti are just some examples of metal superlattices.

Almost all thin films deposited on a substrate are normally in a state of stress if no film treatment is performed (e.g., annealing) [50]. While the structure of the films can be measured by X-ray diffraction (for the atomic order and crystalline structure; in particular, grazing angle incidence X-ray scattering, GIXS, is a nondestructive powerful tool to characterize epitaxially grown films) or X-ray reflectivity (for density, layering period, roughness, and interface roughness determination), double-crystal diffraction topography can be used to make precise thin-film stress measurements. The substrate itself is in principle strained. The film stress may curve the substrate. The difference in the curvature of the substrate before and after deposition can be measured and the stress in the film can be computed using the *Stoney equation*

$$\sigma = E_s d^2 (1/R - 1/R_0)/6(1 - \nu_s)t \qquad (14)$$

where $\sigma$ is the film stress, $E_s$ and $\nu_s$ are Young's modulus and Poisson's ratio of the substrate, $d$ is the substrate thickness, $t$ is the film thickness, $R$ is the radius of curvature of the substrate after deposition, and $R_0$ is that radius before deposition.

Stress may have different origins and can be principally of three types: coherency stress, thermal stress, and intrinsic (or growth) stress.

Coherency stress results when a thin film is lattice matched to a substrate that has an equilibrium in-plane lattice parameter different from the film.

Thermal stress is generated when a film-substrate system experiences a change in temperature, and the film and the substrate have different thermal-expansion coefficients. If a film is deposited at temperature $T_1$ and then heated or cooled at a temperature $T_2$, there will be a thermal stress

$$\sigma_{th} = -E\Delta\alpha(T_2 - T_1)/(1 - \nu) \qquad (15)$$

where $\Delta\alpha$ is the difference in the thermal expansion coefficients of the film and substrate. Intrinsic stresses are stresses generated during film growth.

A superlattice constituted by layers made of elements with similar structures, but with a mismatch in the lattice constant, exhibits interfaces with different degrees of structural coherency. Superlattice layers may be coherently strained with respect to each other (e.g., for small values of the

thicknesses and small degrees of mismatch); otherwise the mismatch can be relaxed by the introduction of interfacial misfit dislocations (e.g., for large thicknesses and mismatch). The critical thickness at which strain relaxation is favored can be predicted (a formalism has been developed by Matthews and Blakeslee). The balance between misfit dislocation energy and the strain energy can predict the observed strain relaxation.

As far as elastic properties are concerned, early observations reported a very large ($>100\%$) enhancement of the elastic moduli in multilayers. This phenomenon was named the *supermodulus* effect. Recent works have shown that these were artifacts or anomalies, and only a 10% enhancement in the elastic moduli appears to be real.

The quantity that is most easily measurable in thin films or multilayers is the hardness $H$, which can be related in a typical simple plasticity model to the yield $\sigma_y$ strength of a material by the relation $H \approx 3\sigma_y$. Hardness, measured, for example, by nanoindentation, has been studied in many systems as a function of the bilayer period (both in epitaxial and polycrystalline multilayer systems). In any case, in general it can be said that all systems show a decrease in hardness as the bilayer period increases above roughly 4 nm (and this decrease has been interpreted in terms of the Hall–Petch behavior, see Eq. (11), as for nanocrystalline materials). Also, in some systems hardness decreases as the period decreases below 1–2 nm. More recent works have instead focused on the plastic properties of superlattices.

Some of the possible explanations for hardening in multilayers and superlattices involve structure barrier strengthening, coherency stress strengthening, misfit dislocation density strengthening, but the dominant mechanism seems to be the effect of the dislocation image force associated with a discontinuity in the elastic modulus at the interfaces. Moreover, at larger bilayer periods, dislocation pileup and bowing processes occur.

In 1970, Koehler [53] suggested that a strong solid could be obtained by layering materials with the same structure but much different shear moduli, since plastic flow would be inhibited by the stresses on dislocations in the softer layers. He also suggested that in order to obtain a strong material, the layers should be thin enough to prevent the operation of dislocation sources. The result of his analysis was that the stress required to operate a dislocation source is roughly inversely proportional to the layer thickness, if this is in the nanometer range.

As we have already stated, the hardness behavior has also been interpreted in the framework of the well-known Hall–Petch behavior for nanocrystalline materials. Here we recall that the repulsive force of like dislocations piling up at a barrier results in a yield strength given by $\sigma_y = \sigma_0 + k_{HP}/\sqrt{d}$.

Applied to the hardness of multilayers, we might expect the hardness to follow the same law as a function of the bilayer period (replacing the grain size)

$$H = H_0 + \frac{k'_{HP}}{\sqrt{\Lambda}} \quad (16)$$

where it can be shown that [47] $H_0 \approx 3\sigma_0$ and $k'_{HP} \approx 3\sqrt{2}k_{HP}$ (assuming $d = \Lambda/2$), and where $\Lambda$ is the bilayer period. A

**Figure 4.** Plot of hardness versus bilayer period for several multiplayer systems. Their behavior is often well described by a Hall–Petch equation (solid lines). Reprinted with permission from [47], B. M. Clemens et al., *MRS Bull.* 24, 20 (1999). © 1999, Materials Research Society.

plot of hardness versus $1/\sqrt{\Lambda}$ is usually linearly fitted to obtain a typical Hall–Petch plot (see Fig. 4).

Anderson and Li [54] developed a model which considers dislocation sources and interaction of the resulting dislocation pileup with interfaces. The stress required to operate the source increases as the number of dislocations present in the pileup increases. The result is a double pileup of screw dislocations. The critical shear stress $\tau$ is the stress required either for the source to generate a new dislocation in the pileup or for dislocation transmission across the interface, depending on layer thickness. On average, the predicted critical shear stress varies as

$$\tau = k_{AL}\Lambda^{-p} \quad (17)$$

where $k_{AL}$ is a constant and $p \approx 0.3$ over a wide range of layer thicknesses.

The three models illustrated (Koehler, Hall–Petch, and Anderson–Li) predict exponents of $-1$, $-\frac{1}{2}$, $-0.3$ for the power dependence of hardness versus bilayer period in a large $\Lambda$ range. Fits to existing data suggest possible values between $-0.2$ and $-0.6$ [47].

Hall–Petch strengthening is observed as dislocations pileup provides the force required to pass dislocations from layer to layer. As the bilayer period decreases, this becomes increasingly difficult and the image force barrier for dislocation motion between layers becomes the strength-limit mechanism. This results in a deviation from the Hall–Petch

behavior. In all cases, the resistance to dislocation motion in the individual layers must be overcome for dislocation motion to occur. Hence the observed hardness will be the sum of the stress required to overcome this resistance plus the weaker of the other mechanisms.

Also the plastic behavior of multilayers has been investigated by some researchers, by means of tensile tests in order to overcome problems related to the nanoindentation measurement, and the yield stress was found to increase with decreasing bilayer period $\Lambda$ (e.g., from ∼500 to 700 MPa going from 90 to 10 nm in an Al/Ti system [51]).

Anderson et al. [49] present a detailed analysis of dislocation-based deformation mechanisms in metallic nanolaminates. They observe that (e.g., in Ni/Cu superlattices) the tensile yield stress increases with decreasing bilayer period only down to a thickness of roughly 20 nm (for which the yield stress is maximum), then the yield stress decreases. The material is coherent when $\Lambda < 8$ nm, while the barrier strength increases progressively as $\Lambda$ increases. The maximum in the strength coincides with the presence of just one dislocation in a layer. Strength then falls at values of $\Lambda$ higher than 20 nm because of stress amplification at the head of successively longer pileups (see Fig. 5). We refer the reader to [49] for the details of the analysis.

## 5. EXPERIMENTAL TECHNIQUES

The standard technique for the measurement of hardness in nanostructured materials and thin films or multilayers is nanoindentation, which has been described before. We here mention other interesting and recent techniques for the analysis of elastic and mechanical properties, which have been demonstrated suitable especially when applied to nanostructured materials.

### 5.1. Atomic Force Microscopy

The atomic force microscope (AFM), or scanning force microscope (SFM), was invented in 1986 by Binnig, Quate, and Gerber. Like all other scanning probe microscopes, the

**Figure 5.** Tensile yield stress in a Ni/Cu superlattice as a function of the bilayer period. Below 8 nm the layer is coherent; for a thickness of 20 nm just one dislocation is present in the layer. Reprinted with permission from [49], P. M. Anderson et al., *MRS Bull.* 24, 27 (1999). © 1999, Materials Research Society.

AFM utilizes a sharp probe moving over the surface of a sample in a raster scan. In the case of the AFM, the probe is a tip on the end of a cantilever which bends in response to the force between the tip and the sample.

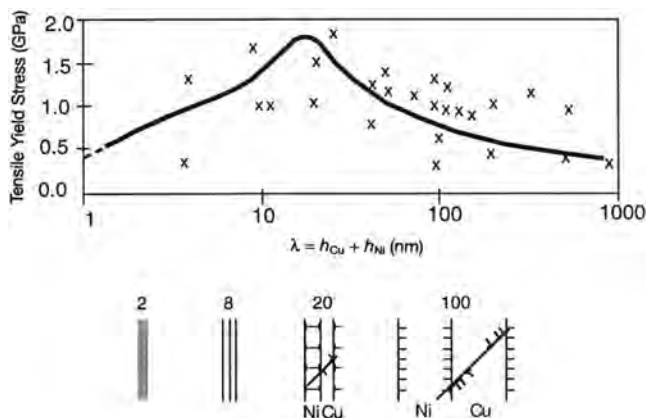
The first AFM used a scanning tunnelling microscope at the end of the cantilever to detect the bending of the lever, but now most AFMs employ an optical lever technique. As the cantilever flexes, the light from a laser is reflected onto a split photodiode. By measuring the difference signal, changes in the bending of the cantilever can be measured. Since the cantilever obeys Hooke's law for small displacements, the interaction force between the tip and the sample can be found.

The movement of the tip or sample is performed by an extremely precise positioning device made from piezoelectric ceramics, most often in the form of a tube scanner. The scanner is capable of sub-angstrom resolution in x-, y-, and z-directions. The z-axis is conventionally perpendicular to the sample.

Different operational modes can be chosen; for example, contact, noncontact, and intermittent-contact AFMs are used for measuring the morphology or topography of a sample surface.

Anyway, other modes are possible [55]. Lateral force microscopy (LFM) measures lateral deflections (twisting) of the cantilever that arise from forces on the cantilever parallel to the plane of the sample surface. LFM studies are useful for imaging variations in surface friction that can arise from inhomogeneities in the material surface. As the cantilever is scanned over the specimen surface (with the cantilever now scanning with its long axis perpendicular to the fast scan direction), variations in friction between the tip and sample will cause the tip to slick/slip during its scan, resulting in twisting of the cantilever.

Force modulation microscopy (FMM) is an extension of AFM imaging that includes characterization of a sample's mechanical properties. In FMM mode, the AFM tip is scanned in contact with the sample, and the z feedback loop maintains a constant cantilever deflection (as for constant-force mode AFM). The amplitude of the resulting cantilever modulation varies according to the elastic properties of the sample. Phase detection microscopy (PDM), or phase imaging, is another technique used to map variations in surface properties such as elasticity, adhesion, and friction. It refers to the monitoring of the phase lag between the signal that drives the cantilever to oscillate and the cantilever oscillation output signal. Changes in the phase lag reflect changes in the mechanical properties of the sample surface. In order to monitor local elasticity, atomic force acoustic microscopy (AFAM) can be used [56]: the sample is insonified by ultrasonic waves or the cantilever is oscillated at ultrasonic frequencies; in contact with the sample, the resonances of the cantilever-tip system are measured and the local stiffness can be measured.

In general, scanning probe microscopy (SPM) can also find a nonstandard application in the field of nanolithography: normally an SPM is used to image a surface without damaging it in any way. However, either an AFM or STM can be used to modify the surface deliberately, by applying either excessive force with an AFM, or by a thermomechanical process, or by applying high-field pulses with an STM,


in order to realize precise nanometer-scale patterns on a surface.

Scanning probe microscopies are also being more and more often employed for single-molecule and single-atom positioning, by simply dragging these nanometric objects around the surface with the aid of the SPM tip. Otherwise, by applying a voltage difference between the tip and the atom or molecule, it is possible to "stick" the object to the tip and move it in a new position with sub-nanometric precision.

The possibility of modulating the force exerted by the tip onto the surface allows one to use an AFM as a precise scanning nanoindenter (see, e.g., [55, 57]), so that the reaction of the surface or of a molecule, or nanotube, to an applied pressure can be monitored. Nanowear studies can be performed by exploiting the same principles, for example, by scratching the surface with the tip while applying a constant force (i.e., a constant cantilever deflection).

By combining atomic manipulation and nanomechanical characterization, for instance, an AFM was used (as already discussed) to measure the Young's modulus of a carbon nanotube [37], by first positioning it in a proper suspended configuration, and then by bending the tube with a fixed force and measuring the tube deflection.

## 5.2. Elastic Properties: The Measurement of Surface Acoustic Waves

A bare substrate can support bulk acoustic waves and, at the external surface, also surface acoustic waves (SAWs) [58]. SAWs are characterized by a wavevector $\mathbf{q}_\parallel$ parallel to the surface and by a displacement field confined in the neighborhood of the surface. The Rayleigh wave (RW), the prototype of SAWs, has a velocity $v_R$ independent of the wavelength and a displacement field which decays exponentially with depth, the decay length being the same as the wavelength $\lambda_\parallel = 2\pi/q_\parallel$. When a layer of thickness $h$ is deposited onto the substrate, it modifies the spectrum of SAWs (i.e., their dispersion relation) [59]. A "thick" film ($q_\parallel h > 1$) can act as an acoustic waveguide: the dispersion relation can include several branches, whose velocities depend on the wavelength $\lambda_\parallel$ through the product $q_\parallel h$. A "thin" film ($q_\parallel h \lesssim 1$) only modifies the behavior of the RW, resulting in a modified Rayleigh wave (MRW), whose velocity is a function of $q_\parallel h$. Most of the displacement field is in the substrate, but close to the surface, where the wave amplitude and energy density are maximum, so that the MRW propagates in the film and senses the film properties. When $q_\parallel h$ increases the decay depth decreases, and the MRW becomes more confined in the film and more sensitive to its properties. The values of the Rayleigh velocities of the film $v_{R(film)}$ and the substrate $v_{R(subs)}$ determine two different behaviors: in the fast films case ($v_{R(film)} > v_{R(subs)}$), the MRW velocity is an increasing function of $q_\parallel$, while in the slow films case ($v_{R(film)} < v_{R(subs)}$), it is a decreasing function of $q_\parallel$. It must be remembered that acoustically fast means stiff and/or light, acoustically slow means soft and/or heavy.

### 5.2.1. Laser-Induced Surface Acoustic Waves

Frequency spectra of acoustic waves can be measured either exciting the waves, by piezoelectric excitation in quantitative acoustic microscopy [60] or by laser pulses in laser

acoustic methods (see below) [61, 62], or exploiting the thermally excited waves, in Brillouin scattering experiments [63]. In acoustic microscopy, a piezoelectric transducer is coupled, through an acoustic lens and a contact fluid, to the specimen surface: the transducer excites and detects the waves. In laser acoustic methods, waves are excited by laser pulses and the displacement of the specimen surface is sensed, after a propagation path of a few millimeters, by either a piezoelectric transducer or an interferometric set-up.

At the mesoscopic scale short laser pulses can excite broadband surface waves in solids [64]. The absorbed laser radiation leads to localized heating and thermoelastic expansion at the solid surface, which generates a traveling 2D surface wave. The smallest laser-excited SAW wavelength is a few micrometers; such wavelengths correspond to frequencies components approaching 1 GHz and limit the SAW pulse length to the nanosecond range. In principle, SAW pulses with shorter wavelengths may be obtained using near-field optics to overcome the diffraction limit of light. Propagating SAW pulses can be detected, without contacting the surface, also by using CW lasers.

In particular, the laser-acoustic technique has proved an efficient method for testing hard and superhard thin films [62]. It yields the Young's modulus, that essentially determines the mechanical strength, fracture toughness, and adhesion. The technique, being based on surface acoustic waves, is very sensitive to surface thin films. As explained before, SAWs in layered systems show dispersion, that is, the film modifies the phase velocity of the wave with respect to the bare substrate case, and this velocity can be measured very accurately. These dispersive oscillatory waveforms contain specific information about the mechanical and elastic properties of the layer and substrate material. Monitoring the pulse profiles at two distances from the excitation source allows the frequency dependence of the phase velocity to be determined (i.e., the dispersion relation).

For a homogeneous and isotropic material, with Young's modulus $E$, Poisson's ratio $\nu$ and density $\rho$, the phase velocity $v_s$ is

$$v_s = \frac{0.87 + 1.12\nu}{1 + \nu} \sqrt{\frac{E}{2\rho(1 + \nu)}} \qquad (18)$$

A film whose properties differ from those of the substrate varies the effective elastic properties in the vicinity of the surface, and therefore also the propagation velocity is varied.

From an experimental point of view, short laser pulses (down to 0.5 ns) are focused by a cylindrical lens onto the surface of the sample and generate wide-band surface wave impulses. The SAW impulses are then detected, for example, by a wide-band piezoelectric transducer. The dispersion curve can then be determined ($v_s$ as a function of frequency). Comparisons have been made with microindentation and membrane displacement test, and confirm the utility and precision of this technique [61].

The amount of information that can be extracted from the signal spectrum depends on the thickness of the film and the minimum wavelength of the pulse. If the ratio of the thickness $d$ to the minimum wavelength $\lambda$ is $d/\lambda < 0.1$, only one film property, such as the Young's modulus, can

be determined by fitting the linear dispersion to theory; for $d/\lambda > 1$, generating nonlinear dispersion, two or even three film properties, such as the density and Poisson's ratio, may be accessible.

An important property that can be studied with this technique is also the mechanical strength. Except for a few materials, the theoretical strength may be orders of magnitude higher than the measured value. With laser-excited nonlinear SAW pulses, it is possible to generate steep shocks with stresses that exceed the mechanical strength of covalent brittle materials such as silicon. These stresses lead to transient fracture by impulsive loading. The influence of rapidly rising stress pulses of very short duration on the dynamics of fracture is currently not well understood. Nonlinear SAW pulses provide a new tool to study transient fracture dynamics without seed cracks.

### 5.2.2. Brillouin Scattering

A very powerful, nondestructive, and sensitive technique for the characterization of elastic properties of materials, and in particular for thin films or multilayers, but also for nanostructured materials, is Brillouin spectroscopy. Brillouin light scattering is the inelastic scattering of an incident optical wave field by thermally excited elastic waves (usually called acoustic phonons). Since the advent of lasers, Brillouin scattering has received considerable interest for the characterization of elastic and optoelastic bulk and surface properties of materials.

Due to the small frequencies of acoustic phonons for small wavevectors, the Brillouin lines are separated by small frequency shifts, of the order of less than 1 cm$^{-1}$, from the elastic line. For this reason it is not possible to use a grating monochromator as for Raman scattering, but rather a Fabry–Perot interferometer must be used. In terms of the corpuscular theory of light, first-order Brillouin scattering corresponds to an inelastic collision of a photon with an acoustic phonon. As for Raman scattering, the photon either loses a quantum of vibrational energy (Stokes line) or acquires such a quantum (anti-Stokes line). For a complete presentation of Brillouin scattering theory the reader is referred to [63, 65, 66].

Brillouin scattering by SAWs is called surface Brillouin scattering (SBS). The measurement is intrinsically contactless and local. Since spontaneous Brillouin scattering relies on thermally excited acoustic waves, interaction occurs with waves having an amplitude much smaller than that of the waves excited in the other techniques cited before, implying that Brillouin scattering measurements are more time consuming. However, the acoustic wavelengths probed in a Brillouin scattering experiment can be significantly smaller than those probed by other techniques: this gives Brillouin scattering a unique potential in terms of spatial resolution, particularly relevant in the case of ultrathin films.

In the case of thin or ultrathin films, this technique proves really powerful. The velocities of surface acoustic waves can be measured by Brillouin spectroscopy. If independent measurements of film thickness and mass density are available, the elastic constants can be derived from the measured acoustic velocities. Such measurements can be performed, for example, by X-ray reflectivity (see, e.g., [67]). Combining Brillouin scattering and X-ray reflectivity measurements

of thickness and density, the elastic constants of films have been measured for film thicknesses ranging from hundreds to tens of nanometers. It has been demonstrated that it is possible to extend the limits of the sensitivity of both the X-ray and Brillouin scattering techniques, in order to characterize films down to a few nanometers thick.

### 5.2.3. Surface Brillouin Spectroscopy

In the bulk of a material, the interaction between acoustic waves and electromagnetic waves occurs by the elasto-optic effect, that is, the dynamical modulation of the electrical susceptibility by the strain field of the acoustic wave. At a surface, interaction also occurs by the ripple effect, that is, the dynamical modulation of the surface geometry due to the acoustic wave. The ripple mechanism is the only one in metallic materials, and is however typically dominant in SBS, since the strain field of SAWs is confined in the vicinity of the surface.

In a Brillouin scattering measurement, a monochromatic laser beam of wavelength $\lambda_0$, circular frequency $\Omega_i$, and wavevector $\mathbf{k}_i$ ($|\mathbf{k}_i| = 2\pi/\lambda_0$) is focused onto the specimen, and scattered light of wavevector $\mathbf{k}_s$ is collected along a given direction. The scattering geometry selects the exchanged wavevector, that is, the acoustic wavevector $\mathbf{q}$ being probed

$$\mathbf{q} = \pm(\mathbf{k}_s - \mathbf{k}_i) \qquad (19)$$

the $-$ and $+$ signs referring to Stokes and anti-Stokes events, respectively. The wavevectors $\mathbf{k}_i$ and $\mathbf{k}_s$ have essentially the same modulus, and the relative difference is at most twice the ratio of the acoustic velocity to the light velocity. The spectrum of the scattered light is dominated by the elastically scattered light at the incident circular frequency $\Omega_i$. If light is inelastically scattered by an acoustic wave of velocity $v$, the spectrum also contains a doublet at frequencies

$$\Omega_s = \Omega_i \pm \omega \qquad (20)$$

the $-$ and $+$ signs referring again to Stokes and anti-Stokes events, respectively; the frequency shift $\omega = v\mathbf{q}$ immediately gives the acoustic velocity.

In SBS only the wavevector component parallel to the surface is conserved: Eq. (19) takes the form

$$\mathbf{q}_\| = \pm(\mathbf{k}_s - \mathbf{k}_i)_\| \qquad (21)$$

and the SAW velocity $v = \omega/q_\|$ is obtained. In SBS the backscattering configuration is often adopted because it maximizes $q_\|$, and because it allows a simpler set-up, since the same lens is exploited to focus and to collect. In backscattering with incidence angle $\theta$, the nominal exchanged wavevector is $q_\| = (4\pi/\lambda_0)\sin\theta$. This means that SAWs are probed having wavelength $\lambda_\| = \lambda_0/(2\sin\theta)$ and, although $\theta$ seldom exceeds 70°, acoustic wavelengths are probed down to about $\lambda_0/2$. With visible light this means that wavelengths $\lambda_\|$ below 300 nm can be probed. They are completely determined by the scattering geometry alone, and with common values of material properties they correspond to SAW frequencies up to above 20 GHz. This gives SBS its unique sensitivity to submicrometric films; with other techniques the frequency rather than the wavelength is determined by the experimental set-up, and the frequencies typically lie in the tens to

hundreds of megahertz range. A dispersion relation $v(q_\parallel)$ is obtained varying the incidence angle $\theta$. Measurements are performed at a set of incidence angles $\theta^i$ obtaining a set of measured circular frequencies $\omega_m^i$ and a set of measured velocities $v_m^i = v_m(q_\parallel^i) = \omega_m^i/q_\parallel^i$.

### 5.2.4. Derivation of the Elastic Constants

From the measured acoustic velocities the elastic properties of materials can be derived. Both bulk acoustic waves [68] and SAWs [69] have been exploited. The velocities of the SAWs in layered structures, and namely for a single film on a substrate, can be computed by the continuum elastodynamics equations as a function of the material properties of both the film and the substrate, of the film thickness, and of the wavevector. In particular, materials are characterized by the mass density $\rho$ and the elements $C_{ij}$ of the elastic constants tensor, and the computed velocities $v_c$ are obtained as $v_c = v_c([\rho, C_{ij}]_{substrate}, [\rho, C_{ij}]_{film}, t, \mathbf{q}_\parallel)$ [70]. The continuum elastodynamics equations are appropriate when the wavelength is much larger than interatomic distances. It must be remembered that the acoustic wavelengths probed by SBS are of hundreds of nanometers and safely fulfill the above condition.

The computation of SAW velocities as functions of physical parameters, that is, the solution of the direct problem, allows to solve the inverse problem, that is, the derivation of physical properties from measured SAW velocities, by fitting the computed velocities $v_c$ to the measured ones $v_m$. The substrate properties are assumed to be known; if the film thickness and mass density can be independently measured, typically by X-ray reflectivity, the only unknown properties remain the film elastic constants $[C_{ij}]_{film}$, which are then obtained by fitting the computed velocities to those measured by SBS.

For elastically isotropic films, such as nanocrystalline or amorphous films, two independent quantities are sufficient to fully determine the whole matrix $[C_{ij}]_{film}$. These quantities are typically taken as any couple among $C_{11}$ and $C_{44}$, Young's modulus $E$, shear modulus $G$ (in this case $G = C_{44}$), bulk modulus $B$, and Poisson's ratio $\nu$. They are subjected to limitations like $G > E/3$ or $\nu \le 0.5$ arising from the physical requirement that the elastic strain energy be definite positive. It has been shown that the $(E, G)$ couple is the most appropriate for the solution of the inverse problem. The computed velocities are therefore obtained as $v_c^i(E, G)$, and the $(E, G)$ values are obtained by the generalized least square estimator $GLS$

$$GLS = \sum_i \frac{(v_m^i - v_c^i(E, G))^2}{(\sigma_m^i)^2} \qquad (22)$$

where the $\sigma_m^i$ are the variances associated to the $v_m^i$ values. $GLS$ gives both the most probable values of the elastic constants $(\bar{E}, \bar{G})$, that is, the point of the $(E, G)$ plane at which the $GLS$ is minimum, and, by the $F$ distribution (the Fisher function), the confidence intervals at any given confidence level [71].

Not all the $(E, G)$ plane is physically meaningful: the region at $G < E/3$ corresponds to $\nu > 0.5$, which means thermodynamic instability, while the region at $G > E/2$ corresponds to $\nu < 0$, which does not mean thermodynamic

instability but is almost never observed. The analysis of data is therefore supplemented by physical plausibility criteria. For instance, it is assumed that the tetrahedral amorphous carbon films have a positive Poisson ratio $\nu$ and a bulk modulus $B$ lower than that of diamond ($B_{diamond} = 445$ GPa), and only the part of the confidence region which complies with these two limitations is taken as the outcome of the measurements.

We mention here one of the possible applications of Brillouin scattering to the characterization of the mechanical properties of nanometer-thick films. Protective hard tetrahedral carbon coatings of thickness down to 2 nm are needed to maintain the increasing trend of storage density in magnetic hard disks and reach the 100 Gbit/in$^2$ target [72]. The thinner the protective carbon coating, the closer the reading head can approach the magnetic part of the disk and thus the smaller the size of the bits and the higher the bit density. For films having a thickness in the nanometer range, the measurement of the elastic properties is critical. Indentation techniques become very sensitive to the substrate properties, in the sense that often, if little care is taken in the measurement, substrate properties are measured. Acoustic waves provide a clean way to measure the elastic properties, and the velocities of surface acoustic waves can be measured by surface Brillouin scattering. If independent measurements of film thickness and mass density are available (and they have been done for ta-C films with X-ray reflectivity), the elastic constants can be derived from the measured acoustic velocities. It has been shown that the limits of these techniques can be pushed to the sub-10-nm range [73, 74]. An average density of 2.8 g/cm$^3$ was measured down to 2–3 nm thickness, while the average elastic constants of the ultra-thin layers were found to increase steeply with thickness, being comparable with those of thicker films already from 8-nm-thick films. Anyway, even the thinnest 2.2-nm film has a Young's modulus of at least $\sim$100 GPa.

Brillouin scattering has also been used to characterize nanostructured films obtained by the assembly of carbon clusters. This case can show how complex the study of the mechanical properties of a nanostructured assembled material can be, when it is not simply a nanocrystalline sample or a more or less compacted powder. Particularly challenging is instead the attempt of getting and interpreting Brillouin spectra of cluster-assembled films with a rough surface and/or a granular or porous structure.

The mechanical properties of carbon nanostructures have received considerable interest [40, 75]. In particular, the use of carbon clusters and nanotubes as building blocks for the synthesis of nanocrystalline and composite materials with unusual elastic properties has been suggested theoretically and several experiments to identify possible synthetic routes have been reported [75–77].

Experimental characterization and theoretical modelization of cluster-assembled materials have to face the problem of cluster coalescence and of their organization in structures spanning length scales from the nanometer up to the micrometer. The different structures in which the precursor clusters are organized need experimental probes sensitive to the different length scales typical of intracluster and intercluster interactions. For carbon-based materials Raman spectroscopy can be used for a characterization at a nanometer

scale. In order to study the organization of clusters at a scale of hundreds of nanometers, which is the typical scale of thermally excited long-wavelength acoustic phonons, Brillouin light scattering has been used by Bottani et al. [78]. The extraction of the elastic properties of low-density cluster-assembled carbon films from the spectroscopic data can be based only partially on what is known in the case of *good* films and a complete theory is still lacking. Bulk and surface Brillouin scattering signals have been obtained from films characterized by a complex structure from the atomic to the hundreds of nanometers level, showing that this technique can be used also for nanostructured materials with irregular surfaces. Bulk and shear modulus of the material have been determined giving information on the acoustic properties at a mesoscopic scale. This allows to infer the nature of the bonding between the carbon aggregates.

In particular, thick cluster-assembled carbon films (thickness $\geq 0.8$ $\mu$m) and thin films (thickness $\simeq 0.1$ $\mu$m) have been examined [79]. In thick films only damped bulk acoustic phonons with a typical wavelength $\lambda_{ph}$ of the order of 170 nm have been detected, giving rise to coherent Brillouin scattering of laser light. This indicates that for a length $d \geq \lambda_{ph}$ the films can be modeled as a continuum with translational invariance and *effective* elastic constants although structural disorder at smaller scales scatters the phonons significantly. The presence of a rather strong central peak in the spectra could be ascribed to nonpropagating (overdamped), or confined vibrational excitations within the films, probably connected with different characteristic correlation lengths less than $d$. The most damped bulk acoustic phonons could be coupled to the confined modes by a relaxation mechanism. The films own a high degree of surface roughness and multiscale granularity: this leads to considerable broadening of the phonon peaks and to the presence of an intense elastic background. This strong elastic and quasi-elastic bulk signal impeded the measurement of surface phonons which could be almost overdamped if not already replaced by surface fractons or by localized cluster modes. Instead, in thinner films surface peaks were detected (see Fig. 6). The *effective* elastic constants of the films were

obtained. The shear modulus and the bulk modulus turned out to be respectively $\mu \simeq 4.0$ GPa and $B \simeq 3.67$ GPa, corresponding to a Poisson's ratio $\nu$ of about 0.10.

The numerical value of $\mu$ is in the range of the $C_{44}$ elastic constant of hexagonal crystalline graphite ($C_{44} = 2 \approx 5$ GPa) and equals the value of its shear modulus along the C-axis. Yet the film material is not elastically identical to nanocrystalline graphite; in fact, the values of $B$ (and, consequently, $\nu$) are significantly different. These experiments have demonstrated the possibility of using Brillouin spectroscopy as a tool for the characterization of the elastic properties of thin films owning a disordered granular structure in a range from atomic dimensions up to hundreds of nanometers. This opens interesting perspectives for the study of the mechanical and elastic properties of nanocrystalline materials.

## 6. APPLICATIONS

Nanostructured materials or reinforced materials including special nanostructures, as well as hard thin films or multilayers, are of course extremely interesting in view of a number of applications as structural materials or reinforcement fibers, hard protective coatings, or high-resistance components in special devices such as MEMS (micro-electromechanical systems), NEMS (nano-electromechanical systems), magnetic media, X-ray optical elements (e.g., multilayers), etc.

Metals, alloys, intermetallics, and ceramics show improved or peculiar mechanical properties when a modulation of the nanoscale structure is induced (e.g., by sintering and compaction of nanopowders), as we have seen, and therefore bulk nanocrystalline materials are studied since they may become the basis of new structural materials for construction or hybrid structures. For example, a new and simple process to obtain nanostructured bulk low-carbon steel with superior mechanical properties (e.g., higher tensile strength) has been reported [80]. The inclusion of nanoparticles in a matrix (nanodispersions, e.g., in steel or alloys) also improves mechanical properties and thus nanoparticle precipitation represents a different route for the realization of innovative nanostructured construction materials or structures. It is possible to tailor the shape of these inclusions, and obtain extremely light materials with high degrees of stiffness and strength by including in the matrix more or less aligned rods or plates (nanocomposites, e.g., polymer nanocomposites). Also fibers can attain significant enhancement in their mechanical properties by the size reduction of their constituents (nanofibers). As far as nanocomposites and nanofibers are concerned, carbon nanotubes, possessing an extremely high Young's modulus, and polymers reinforced with nanoplates of a second phase attract today much attention, as discussed before.

Hard nanocoatings are currently being employed for protection of surfaces (e.g., razor blades, but especially magnetic hard disks). In particular, diamond-like (tetrahedrally bonded) amorphous carbon is used for covering of magnetic disks, since it is possible to deposit layers down to a thickness of a few nanometers, which enormously increases the information storage density (up to 100 Gbit/in$^2$) on the disk [81], due to the possibility of approaching the reading tip more closely to the magnetic surface. Indeed, a combination

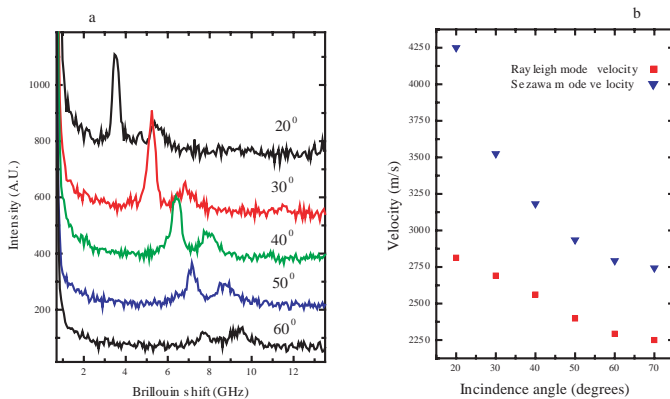


**Figure 6.** (a) Brillouin spectra from cluster-assembled carbon films as a function of incidence angle. Two peaks are visible, corresponding to a surface Rayleigh mode and to a Sezawa mode (guided mode in the film). (b) Dispersion relation for the velocity of the Rayleigh and Sezawa peaks in the same sample.

of the layer (coating) geometry and of an internal nano-structuring can greatly improve the mechanical properties (hardness, wear resistance, toughness) of protective materials (e.g., see [82] for a study of the mechanical behavior of nanostructured WC–Co coatings). Other materials are used for coating of other surfaces, for example, mirrors, glasses, where good and improved mechanical properties (hardness, anti-wear properties) have to be combined with other characteristics (e.g., transparency, lubrication, i.e., low friction, thermal barrier properties, self-cleaning properties, e.g., for the development of self-cleaning surfaces, but also catalysis, UV filtering, etc.). In these cases, the nanometric limitation to the layer thickness can be coupled with the intrinsic nanostructure of the deposited (e.g., cluster-assembled) material, for example, for gas sensing and catalysis applications. Another field is represented by functional active coatings that must at the same time possess good mechanical and wear properties (e.g., for solar cells, or sensors). Multilayers, or superlattices, are employed for their special magnetic properties in magnetic devices, or for X-ray optical elements, and mechanical properties are obviously important.

A new frontier is represented by NEMS. MEMS and NEMS represent a marriage between semiconductor processing and mechanical engineering at a very small scale (e.g., by nanolithography). They are based on the measurement of forces by means of structures with particular modes of vibrations and elastic constants (deflections, vibrations), coupled with transducers for optical and electrical signals. MEMS already find applications in many sectors (optical elements, micromirrors, motion or acceleration micro- or nanosensors, e.g., for the deployment of airbags) and NEMS are the natural evolution of the process of miniaturization, since the reduction in the weight (i.e., of the inertia) of these devices greatly improves their sensitivity, and their intrinsically low energy consumption [83, 84]. Of course the mechanical properties of these structures are extremely important; silicon is usually used since it benefits from the established know-how of semiconductor processing, but also nanostructured materials, such as SiC, nanotubes, or ultrananocrystalline diamond (whose mechanical properties are substantially indistinguishable from those of diamond [85, 86]) for the fabrication of freestanding cantilevers with submicrometric feature resolution. These hard materials (Si, SiC, ultrananocrystalline diamond, but also SWNTs) also find application for the fabrication of AFM submicrometric hard probes (nanotips).

# 7. CONCLUSIONS

What is known about the mechanical properties of nanophase materials, though still limited, allows one to draw some general conclusions. We refer the reader, for a review of interpretations of the mechanical behavior of nanomaterials, to [1, 3, 18]. First, dislocation activity still dominates the mechanical behavior of pure nanophase metals. However, the dislocation activity seems to decrease with decreasing grain size due to the decreased availability of dislocations and ability to create new dislocations in nanometer grains. The absence of mobile dislocations in nanophase grains has been documented experimentally and is the result of the

long known and well-understood *image forces* that act on dislocations near surfaces and thus, particularly, in confined media. The difficulty in creating new dislocations in confined crystallites was already known also from investigations in single-crystal whiskers. The minimum stress required to activate a dislocation source (e.g., a Frank–Read source) is inversely proportional to the distance between dislocation pinning points, and this stress will increase with decreasing grain size (limitation of the maximum distance between pinning points). When the grain size reaches 1–2 nm (the limit size is also dependent on the value of the shear modulus), the theoretical yield stress of a dislocation-free metal may be approached. Thus, it appears that the increasing hardness and strength observed in pure nanophase metals with decreasing grain size is simply a result of diminishing dislocation activity.

For nanophase intermetallic materials the situation is more complicated, since other phenomena are involved, such as the grain-size dependence of the phase stability. However, their mechanical behavior in the higher end of the nanophase regime is often similar to that of pure metals.

Nevertheless, many of these hard, strongly bound materials exhibit a clear transition from hardening behavior to softening behavior with decreasing grain size. This increased ductility appears to be related to an increase in grain boundary sliding with decreasing grain size as evidenced by stress-strain and creep measurements. The mechanical response of these intermetallics thus appears to be transitional between that of pure nanophase metals at larger grain sizes and that of nanophase ceramics at smaller grain sizes. Grain boundary sliding, with short-range diffusion-assisted healing events, dominates the deformation behavior of strongly bound and conventionally brittle materials in the nanoscale regime.

These observations suggest a qualitative interpretation, proposed by Siegel [18], and shown in Figure 7, for the understanding of the mechanical properties of nanomaterials. With decreasing grain size, the frequency of dislocation activity decreases and that of grain boundary sliding increases. The dominating effect depends on the grain-size regime, the type of material, and the nature of bonding. Metals with nondirectional bonding fall at the left of Figure 7

**Figure 7.** Schematic framework for the grain-size dependence of dislocation activity and grain boundary sliding contributions to the deformation behavior of the various classes of nanophase materials. The nature of its interatomic bonding determines the appropriate location for a particular material. Reprinted with permission from [18], R. W. Siegel and G. E. Fougere, *Nanostruct. Mater.* 6, 205 (1995). © 1995, Elsevier Science.

and those with more covalent bonding fall in the transitional region where decreasing dislocation activity yields to increasing grain boundary sliding; nanophase ceramics with their strong ionic or covalent bonding lie in the region to the right dominated by grain boundary sliding.

In addition to nanostructured and nanocrystalline materials, we finally recall the extreme interest recently shown by the nanotechnology community in the peculiar properties of special single nanostructures, among which carbon nanotubes are the most promising. Their unique electronic and mechanical properties, and the increasing possibility of controlling their deposition (alignment, manipulation of single nanotubes, patterning), have attracted much attention for a wide range of applications, from single nanotransistors, nanotube field emission flat panel displays, to reinforcement of fibers or structural building materials.

## GLOSSARY

**Carbon nanotube**   Carbon cylindrical nano-object; it can be thought as formed by warping a single graphitic layer into a cylindrical object with diameter in the nm range.

**Cluster-assembled materials**   Materials synthesized by deposition of clusters (i.e., particles composed by up to thousands of atoms, they represent an intermediate step between molecules and bulk materials).

**Composite material**   A material with distinct interfaces separating the components, created to obtain properties that cannot be achieved by any of the components acting alone.

**Creep**   Time-dependent strain produced in materials following a change in loading conditions.

**Ductility**   Ability of a material to change shape without fracturing (i.e., to experience significant plastic deformation before fracturing).

**Elastic constants**   Elements of the elastic constant tensor, which relates the stress tensor and the strain tensor in the linear (elastic) regime.

**Fatigue strength**   Resistance of a material to failure under cyclic loading.

**Hall–Petch relationship**   Equation expressing dependence of yield stress or hardness on the inverse square-root of the grain size in micro- and nanocrystalline materials.

**Hardness**   Resistance to penetration of a diamond indenter under standardized conditions. It is related to the material strength, and also to its wear (abrasion) resistance.

**Multilayers**   Thin films constituted by alternating nanolayers of different (usually two) elements or materials; also called *superlattices*.

**Nanomaterials, nanostructured materials**   Materials whose properties (compositional, chemical, morphological, structural, mechanical, electronic, vibrational, etc.) are related to characteristic lengths in the $\approx$1–100 nm range. Related terms are *nanocrystalline materials, nanocomposites, nanoparticles, nanotubes, nanowires*.

**Plastic deformation**   Irreversible (permanent) deformation, following the elastic deformation regime, occurring for high values of stress.

**Poisson's ratio**   $\nu$, ratio between longitudinal elongation and transverse contraction in uniaxial testing.

**Sbear modulus**   $\mu$ (or $G$), proportionality coefficient between stress and strain in pure shear. It can be derived from the Young's modulus using the relationship $E/[2(1 + \nu)]$.

**Strain tensor**   Tensor describing changes in length of a body in some direction relative to an undistorted length (not necessarily the same), i.e. describing how infinitesimal cubic volume elements change volume and shape in a material subject to deformation.

**Stress tensor**   Tensor describing forces per unit area acting on a face of an infinitesimal cubic element subject to external actions.

**Superplasticity**   Exceptional ductile behaviour (exceptionally enhanced strain to failure, with elongations in the range 100–1000%).

**Yield stress**   Threshold stress beyond which deformation is irreversible (plastic).

**Young's modulus**   $E$, proportionality coefficient between stress and strain for small deformations in uniaxial tensile testing (elastic regime).

# Mechanical Molecular Nanodevices

Laura Frankfort, Xiange Zheng, Karl Sohlberg

*Drexel University, Philadelphia, Pennysylvania, USA*

## CONTENTS

## 1. INTRODUCTION

Nanotechnology promises engineered devices constructed from just one or a few molecules, a technology with a potentially staggering impact. Applications are envisioned in medicine, molecular electronics based information processing systems, and information gathering and monitoring for defense, space science, and other extreme environments. Richard Feynman first speculated about the possibility of making machines from molecules in his historic address on December 29, 1959 entitled, "There's Plenty of Room at the Bottom," where he challenged all to try to maneuver matter one atom at a time [1]. Beginning in the early 1980s, K. Drexler was one of the first to bring the idea of nanodevices to public attention with his publications, which contained foresight into the future of nanotechnology [2, 3]. Since then our abilities to design and construct artificial molecular machines have been aided by a number of major breakthroughs in physics, chemistry, and biology.

Molecular analogs to macroscopic mechanical devices are currently being discovered at a remarkable pace. These molecules have all the essential features of macroscopic devices but with individual molecules serving as the components. In all probability, simple molecular devices will eventually be combined to form molecular and nanosystems that will resemble macroscopic machines. Broken down into the key features, a macroscopic machine consists of a power source (fuel) and work of a repetitive and often cyclic nature [4]. Molecular machines possess these same key features.

Currently there are two techniques being researched by which to construct such devices [5, 6]. The first and most popular of these methods is self-assembly. In self-assembly, the molecules move randomly and explore many possible orientations. Given sufficient time, a preferred arrangement will be adopted if it is more stable (the lowest energy conformation). Biological functions display the most sophisticated and effective examples of self-assembly [7]. The second method, positional assembly or template-directed assembly, is commonly found at the macroscopic level, but has yet to see widespread use for molecular and nanosystems. In positional assembly, some force keeps the parts/molecules positioned at or near a particular location. Deliberately moving the parts/molecules into close proximity with one another and linking them together achieves assembly. Recently it has been possible to construct a large range of molecular machines. These include abacuses, bearings, brakes, motors, rotors, ratchets, shuttles, sockets, and switches.

In systems where millions of molecular devices are utilized, the issue of heat dissipation will need to be taken into account [8, 9]. Knowing the amount of heat a single device emits will put a limit on the number of devices that could be combined on a substrate. By taking into consideration the thermal challenges of such systems, there will still be a considerable improvement over current technologies, but far below what could be achieved if considerations for heat dissipation did not need to be made [9].

In Section 2, realized examples of mechanical molecular devices are reviewed. In Section 3, we review theoretical and computational studies of both proposed and realized molecular and nanodevices. The focus is on molecular systems that have demonstrably "device like" character.

## 2. MOLECULAR ANALOGS OF MECHANICAL DEVICES

### 2.1. Molecular Switches

One class of molecules that has gained significant popularity over the past few years as a result of their ability to function as molecular shuttles is the rotaxanes and catenanes. These molecules are assemblies of two or more molecules that are mechanically linked but chemically independent and

can be formed by means of self-assembly [10]. Some rotaxanes and catenanes have been synthesized that serve as prototypes for artificial molecular machines because the relative motion of their components can be shuttled, hence evoking images of a nanoscale switch. Such devices are of considerable interest because they are thought to foreshadow the development of molecular-scale information processing systems [11]. A typical rotaxane system consists of a cyclic component threaded by a dumbbell shaped component (see Fig. 1). Rotaxanes are related to but topologically different from catenanes, which consist of two or more interlocked rings. If the macrocyclic component of a rotaxane (or catenane) can be induced to move from one initially favored "station" to a second "station" as a result of some external stimulus, then a very basic molecular switch has been produced. (Effectively the external stimulus is changing the preferential binding site.) This property, in which relative movement of their ring- and/or dumbbell-shaped components may be induced to switch between stable rest states with an external stimulus, endows the rotaxane (or catenane) with device-like character.

The existence of interlocked molecules was first described as early as 1912 by Willstatter [12]. However, due to the topologically complex structural features associated with rotaxanes and catenanes, their syntheses posed a significant challenge and only at the beginning of the 1960s were synthetic routes to such systems clearly stated by Frisch and Wasserman [12–16].

### 2.1.1. Rotaxanes

Several different schemes have now been reported for producing a rotaxane that undergoes shuttling action in response to an external stimulus. In 1991 one of the first functional molecular shuttles produced in reasonable yields was reported by Anelli and co-workers [11]. It is a [2] rotaxane containing a linear dumbbell-shaped component, possessing two $\pi$-electron rich hydroquinone rings separated by a polyether chain, and terminated by two bulky triisopropylsilyl groups as stoppers. A cyclic tetracationic cyclophane threaded onto the dumbbell component completes the system. The tetracationic cyclophane component shuttles back and forth between the two hydroquinone rings. This molecular shuttle was proposed as a prototype in designing more intricate systems in which different "stations" were inserted
onto the dumbbell component. These different "stations" would act to desymmetrize the system so that they could be addressed selectively by chemical, electrochemical, or photochemical means. Examples of more advanced rotaxane systems are described below.

Indeed both rotaxanes and catenanes can be designed and constructed with chemically, electrochemically, and/or photochemically active recognition sites introduced into one of their two interlocked components. Chemical controls, including for example systems whose switching properties are pH dependent, present a straightforward method for controlling molecular machines. However, such a system will require addition of fresh reactants or "fuel" to power the machine, which in turn will generate waste products that must be removed from the system [17]. This will undoubtedly cause limitations in the design of molecular machines based on such inputs. Electrochemical and photochemical inputs can "fuel" a molecular machine without the associated formation of waste as found in those machines that are chemically induced [17]. Photochemical means used for switching purposes are generally photoinduced redox reactions and photoisomerization, while electrochemically controlled systems make use of redox reactions.

***Chemically Induced Switching***  A chemically controllable molecular shuttle has been produced in which a [2] rotaxane is composed of a dibenzo[24]crown-[8] macrocycle and a dumbbell-shaped component that contains a dialkylammonium center and a 4,4′-bipyridinium unit [18]. Since the hydrogen bonding interactions between the macrocycle and the ammonium center are much stronger than the charge transfer interaction of the macrocycle with the bipyridinium unit, the stable conformation is that in which the macrocycle surrounds the ammonium station. Upon deprotonation of the system, displacement of the macrocycle to the bipyridinium unit is obtained where its ring becomes involved in weak donor/acceptor interactions. The system is shown schematically in Figure 2. The switching process is fully reversible and its mechanical movements can be induced by an acid/base stimulus.

Another acid-base controllable molecular shuttle in which the rotaxane bears a fluorescent and redox-active anthracene stopper unit in addition to a dialkylammonium center ($NH_2^+$) and a bipyridinium unit ($Bpym^{2+}$) has been reported by Ashton et al. [19]. Upon addition of an appropriate base, the $NH_2^+$ is deprotonated and the crown ether switches from the NH center to the $Bpym^{2+}$. Treatment with acid restores the $NH_2^+$ center and reverses the processes. Using the anthracene stopper, it is possible to monitor the switching process by means of electrochemical and photophysical

**Figure 1.** A schematic of a typical rotaxane system is shown above. In this system protonation/deprotonation of the ammonium station induces the shuttling action of the crown ether [18].

**Figure 2.** A schematic showing the relative positioning of the ring component with respect to the shaft component of a rotaxane as a result of its pH-dependency as described by Martinez-Diaz et al. [18].

techniques due to its absorption, luminescence, and redox properties.

A pH-switchable bistable [2] rotaxane that is kinetically controlled (therefore allowing the second state to be maintained after removal of the stimulus) has been reported by Lee et al. [20]. The [2] rotaxane consists of cucurbituril as the macrocycle, one protonated diaminobutane unit as the initial station, two pyridinium groups as linkers, two hexamethylene units as subsequent stations, and two terminal viologen groups. Previously all systems that had been reported to display switching properties were found to be in thermodynamic equilibrium. Therefore once the stimulus is removed, the system reverts back to its initial state. This system however has a high activation barrier and upon removal of the stimulus the reverse process is extremely slow, taking weeks to achieve the initial state of the system. Upon heating, however, the macrocycle shuttles back quickly and completely to its initial location. This feature is promising because in functional devices it may be impractical to maintain different chemical environments for each switched state. This type of system will allow the second state to be "locked in" and could be useful in designing "safeguarded" molecular switches [20].

***Electrochemically Induced Switching*** A rotaxane system described by Bissell et al. [21] has been shown to exhibit electrochemical switching. The dumbbell-shaped component of this system contains two recognition sites, one a benzidine and the other a biphenol unit. This system exhibits translation isomerism with the macrocycle located preferentially on the benzidine unit, the more $\pi$-electron rich station. However, electrochemical oxidation of the benzidine unit converts it to the monocationic radical state, and as a result of the repulsive electrostatic interactions, the macrocycle with its four formal positive charges moves to the biphenol unit. This redox system is completely reversible upon electrochemical reduction.

***Photochemically Induced Switching*** An example of a molecular shuttle shown to exhibit relative translation of the ring and shaft induced by photoexcitation with a laser pulse was reported by Brouwer et al. [22]. In this device, the stoppers on the two ends of the chain component are succinamide (*succ*) and 3,6-di-tert-butyl-1,8-naphthalimide (*ni*) units, respectively, which are separated by a $C_{12}$ alkyl spacer and serve as two potential H-bonding stations. The chain is encircled by a benzylic amide crown ether ring molecule named 1,4,7,14,20-hexaaza-2,6,15,19-tetraoxo-3,5,9,12,16,18,22,25-tetrabenzocyclohexacosane, which can be induced to change its position and shuttle between the *succ* and *ni* stations on the linear chain. The succinamide (*succ*) station on one end of the shaft component is an excellent macrocyclic ring binding site in the ground state. Meanwhile, naphathalimide on the other end is a poor H-bond acceptor [23] in the neutral ground state, and the rotaxane adopts the *succ*-co-conformation. The H-bond-accepting affinity [23] of naphathalimide is greatly enhanced when the shaft is reduced to the anionic state, which may be induced photochemically by a nanosecond laser pulse. It has been observed experimentally that after photoexcitation, the *ni* chromophone on the shaft undergoes an intersystem crossing to the triplet (T) state in high yield [22]. An electron donor can induce the formation of a contact radical ion pair by reduction of the triplet, which enables the shuttling of the macrocyclic ring component down the shaft from its original succinamide station to the reduced naphthalimide unit where ring binding is preferred in the reduced state.

Another photochemically induced switchable rotaxane system has been reported by Murakami et al. [24]. It consists of an $\alpha$-cyclodextrin macrocycle, an azobenzene chain molecule, and 2,4-dinitrobenzne units as stoppers. The macrocycle on this rotaxane systems moves between the azobenzene unit and a methylene spacer upon alternating photoirradiation with UV and visible light. The shuttle is forced to change position with respect to the shaft by conformational isomerization of the shaft.

### 2.1.2. Catenanes

Numerous schemes have also been reported in which catenanes undergo shuttling action in much the same manner as the rotaxanes. The first reported syntheses of catenanes, topologically fascinating molecules consisting of two or more interlocked rings, came in the 1960s [12]. During the subsequent three decades catenanes have received increasing attention. One of the first template directed synthesis of a positively charged [2] catenane was reported by Ashton et al. [25]. This [2] catenane demonstrated a highly efficient one-step template directed synthesis and dynamic $^1H$ NMR spectroscopic behavior.

Around the same time, terminology for these structures was evolving. A catenate is a transition metal complex whose organic backbone consists of interlocked coordinating rings [26]. A catenand is a demetalated catenate; this structure was identified and the name proposed by Dietrich-Buchecker et al. [27] when studying a technique of synthesis based on a template effect around a metal ion leading to a metallocatenane as an intermediate. The catenand obtained after demetalation of a catenate contains interlocked rings characteristic of a catenane.

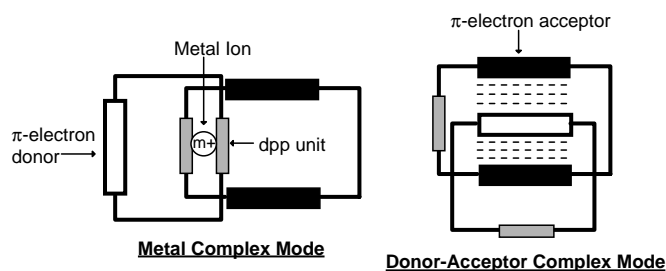
***Chemically Induced Switching*** A switchable hybrid [2] catenane in which two template concepts were combined has been reported by Amabilino et al. [28]. This has resulted in a molecular system whose properties are governed by either of the two template binding modes. In this case the combination of transition metal ion chelating units and $\pi$-electron donor-acceptor complexes was chosen. In this [2] catenate one ring contains a 2,9-diphenyl-1,10-phenanthroline (**dpp**) ligand and a 1,5-dixoynaphthalene unit and the other ring contains a **dpp** ligand and two bipyridinium units. This molecule possesses two different coordination sites: 1) coordination of Cu(I) by the two dpp ligands and 2) a donor-acceptor interaction between the 1,5-dioxynaphthalene unit and the two bipyridinium units (see Fig. 3). The coordination recognition site is stronger, and so the stable conformer is that in which the Cu(I) ion is complexed by the two **dpp** ligands. Removal of the Cu(I) ion however, forces the molecule to undergo a topological change in which it maximizes the noncovalent bonding interactions present in the demetalated system and affords the [2] catenand. Additionally the [2] catenand exhibits pH dependency. In the presence of acid, the formation of the protonated species occurs


**Figure 3.** A schematic of the two coordination sites in the [2] catenate/[2] catenand described by Amabilino et al. [28].

such that the H$^+$ ion is imbedded between the two **dpp** ligands, forcing a considerable change in the geometry of the molecule. Subsequent treatment with base regenerates the [2] catenand in which the donor-acceptor interactions dictate the relative positioning of the rings with respect to each other.

***Electrochemically Induced Switching*** One candidate for electrochemical switching is a [2] catenane in which a dissymmetric tetracationic cyclophane containing two different recognition sites (a bipyridinium unit and a trans-bis(pyridinium)ethylene unit) is interlocked with the symmetrical macrocyclic polyether ring, bis(p-phenylene)-34-crown-10 (**BPP34C10**) [29]. The bipyridinium unit resides inside the cavity of the **BPP34C10** component as a result of its high $\pi$-accepting ability. The first one-electron reduction occurs preferentially at the "inside" bipyridinium unit, yielding the radical cation, which is due to its much impaired $\pi$-accepting ability, undergoes circumrotation of the charged component through the **BBP34C10** ring, wherein the trans-bis(pyridinium) ethylene unit (the now better $\pi$-acceptor) is located inside the cavity of the crown ether. On oxidation, the species loses an electron and the circumrotation process is completed, returning the [2] catenane to its original geometry.

Another dissymmetric catenane in which the ring motions can also be driven by electrochemical means was reported by Livoreil et al. [30]. A copper catenate, a copper complex whose organic backbone is a [2] catenane and is able to adjust its coordination geometry to the oxidation state of the metal by changing the respective positions of its rings, was generated. The catenate consists of two different rings. The first rings is a 2,9-diphenyl-1,10-phenanthroline (dpp) unit. The second ring comprises a dpp moiety and a terdentate ligand, 2,2′:6′,2″-terpyridine (terpy). Both units are linked by three methylene groups. This catenate is able to adopt two geometries, each stabilizing preferentially a different oxidation state of the metal center. Oxidation or reduction generates a metastable complex, which rearranges to adopt the coordination mode best fitting the new oxidation state of the metal center. After oxidation of Cu$^I$N$_4$, the catenate undergoes a linkage isomerization, transforming the metastable complex Cu$^{II}$N$_4$ into the more favorable Cu$^{II}$N$_5$. Addition of hydrazine monohydrate or ascorbic acid triggers the reverse process, giving the starting complex, Cu$^I$N$_4$.

***Photochemically Induced Switching*** The co-conformational motion associated with the copper [2] catenate reported by Livoreil et al. [30] can also be induced

photochemically. Upon irradiation of a solution of the copper [2] catenate in MeCN in the presence of *p*-nitrobenzylbromide, the Cu$^I$-based chromophoric unit is excited to a metal-to-ligand charged transfer excited state. Electron transfer from the photoexcited copper [2] catenate with *p*-nitrobenzylbromide follows, which generates a pseudo-tetrahedral Cu$^{II}$ ion that forms a more stable pentacoordinated geometry. Upon addition of ascorbic acid, the pentacoordinated Cu$^{II}$ center is reduced to a tetracoordinated Cu$^I$ ion.

### 2.1.3. Related Molecular Structures

***Molecular Abacus*** An abacus is a manual computing device that consists of a frame holding parallel rods strung with movable beads, which serve as counters. When comparing this structure with that of a rotaxane, it is easy to see the correlation between the two. For this reason rotaxanes have begun to form the basis for molecular level abacuses. One example is provided by Ashton et al. [31] The [2] rotaxane is composed of a $\pi$-electron-donating macrocyclic polyether bis-*p*-phenylene-34-crown-10 and a dumbbell-shaped component that contains (1) a Ru$^{II}$ polypyridine complexes as one of its stoppers in the form of a photoactive unit, (2) a *p*-terphenyl-type ring system as a rigid spacer, (3) a 4,4′-bipyridinium unit and a 3,3′-dimethyl-4,4′-bipyridinium unit as $\pi$-electron accepting stations, and (4) a tetraarylmethane group as the second stopper. The ring component or "counter" can be induced by light excitation to move between two different recognition sites or "stations" on the dumbbell-shaped component.

A more complex molecular abacus is described by Shigekawa et al. [32] where an $\alpha$-CyD molecule on a polyrotaxane was able to be manipulated with an STM to move. It was possible for Shigekawa's group to initiate and terminate shuttle movement at a predetermined time, control the direction of the movement, and read the shuttle position. The movement was in a linear fashion along the dumbbell-shaped component of the polyrotaxane and performed without disturbing any of the other $\alpha$-CyDs that were present. Additionally they found it possible to move a pair of adjacent $\alpha$-CyDs simultaneously. The two $\alpha$-CyDs were reversibly manipulated while keeping their mutual positioning intact.

***Molecular Piston Cylinder*** A pseudorotaxane is essentially a rotaxane in which at least one of the terminal stoppers has been eliminated, making it possible to remove the macrocycle from the linear component. These systems may be viewed as molecular examples of a piston-cylinder since they undergo assembly and disassembly reminiscent of the movement of a piston in a cylinder (in which the macrocycle is the cylinder and the linear rod is the piston). An example was reported by Ashton et al. [33] who were able to incorporate a "light-fueled" motor into a pseudorotaxane and show that it behaves as a light-driven molecular machine in the form of a piston-cylinder through light-induced assembly and disassembly of the pseudorotaxane.

A similar system was described by Ishow et al. in which they report a molecular plug/socket in the form of a pseudorotaxane [34]. The molecular plug and socket system was generated using crown ethers that incorporate a binaphthyl

unit and a wire-like compound bearing an anthracenyl unit. The pH-dependency of the system controls the plug in/plug out motion of the system. The possibility of association (controlled by $H^+$ bonding between the ammonium unit and the crown ether oxygens) of these systems is strongly affected by the size of the crown ether and the bulkiness of the wire-like component.

***Synthetic Molecular Muscle*** Jimenez et al. [35] have found it possible to construct a unimolecular linear array capable of undergoing contraction and stretching. This molecule is composed of a rotaxane dimer. The stretching and contracting of the molecule is activated by a chemical stimulus. The molecular assembly was designed to mimic real muscles in which two filaments glide along one another. Both filaments move along one another but stay together as a result of the interlocked nature of the system. The doubly threaded compound reported can bind simultaneously to two metal centers, either in a four-coordinate or a five-coordinate geometry. The four-coordinate geometry corresponds to an extended state and the five-coordinate to a contracted state. From CPK model estimations, the length of the compound goes from 65 angstroms in the five-coordinate geometry to 83 angstroms in the four-coordinate geometry, a 128% change.

***Entropy-Driven Molecules*** Hanke and Metzler [36] have proposed a new type of mechanical molecule based on systems of similar topological nature to rotaxanes and catenanes. Typically, in molecules including rotaxanes and catenanes the Gibbs free energy, $F$,

$$F = U - TS \tag{1}$$

is minimized by variations in $U$, the internal energy. The proposed molecules rely on the minimization of the Gibbs free energy by variations in the entropy, $S$, while the energies and chemical bonds (internal energy $U$) are left unchanged. The entropy functional units can be specifically controlled by external parameters such as temperature, light, or electromagnetic fields. Functional behavior such as controlled transition from linear chain to ring polymer, swelling/de-swelling, switching, and molecular motion could be achieved. One such example provided describes a polymer ring along which a number of slip links are placed. Within each of the fringe loops, additional sliding rings are placed. If the sliding rings are immobile, the central loop consumes almost the entire length of the polymer. However, if the sliding rings are free to move, large fringe loops are entropically favored and the central loop will be drastically smaller.
## 2.2. Molecular Bearings

Bearings are an essential component in many macroscopic machines and are expected to hold equal importance in many molecular machines and devices. However, constructing a molecular bearing has proven difficult [37]. While friction in the conventional sense is not a problem it may still be the case that the bearing has certain preferred locations as a result of variations in the energy of the system upon rotation of the shaft with respect to the sleeve. Ultimately this could cause the bearing to stick in certain preferred positions determined by the lowest energy conformation of the system. Merkle [37] has proven theoretically, however, that bearings with short periods (A short period is created if the shaft and sleeve are made with $m$-fold and $n$-fold symmetry, respectively, by selecting $m$ and $n$ so that the greatest common divisor of $m$ and $n$ is small.) will usually have small barriers separating one minimum from the next, and that this can be achieved by paying attention to symmetries of the shaft and sleeve (see Fig. 4). Molecular mechanics models of such bearings have shown that potential energy as a function of rotational position is very nearly flat. Therefore, the barriers of rotation will be small, thereby reducing any "stickiness" in the system.

More recently the Gimzewski et al. have demonstrated how rotor molecules surrounded by molecules that form supramolecular bearings could be constructed [38]. This was achieved by depositing hexa-*tert*-butyl decacyclene molecules on copper surfaces under ultra-high vacuum. This molecule has a structure that is twisted into the shape of a propeller with six blades because of steric interactions among its hydrogen atoms. When coverage of the copper surface is just short of a monolayer, some of these molecules can function as rotors if a loosely packed collar of identical molecules that act as a supramolecular bearing surrounds them. Interaction of the rotor molecule with its bearing causes rotation, and the driving force is the thermal energy in the system. Manipulating the rotor with the tip of a scanning tunneling microscope can induce rotation.

## 2.3. Molecular Brakes

Another fundamental component of macroscopic machine is the brake. The automobile provides an excellent example in which brakes are essential components of the machine. They could well be equally critical in molecular machines. Brakes are designed to halt or control the speed of rotary motion. Kelly et al. reported a molecular analog to the brake [39]. The system is constructed of a triptycene wheel and a brake as seen in Figure 5. Triptycene is a rigid molecular unit with three blades composed of benzene rings and is reminiscent of a gear. Initial attempts to construct a molecular brake from such a molecule instead provided a system that acted more "like a playing card on a bicycle tire" [39]. However, it was found that upon addition of a metal (in this case $Hg^{2+}$), the brake is activated and the spinning of the wheel is

**Figure 4.** A schematic end-on view of a molecular bearing in which the shaft possesses 5-fold symmetry and the sleeve 15-fold symmetry.
**Figure 5.** A molecular analog to the brake constructed of a triptycene wheel, as reported by Kelly et al. [39].

**Figure 6.** A triptycenocrown ether, which constitutes a molecular gearing system that displays dynamic "rope-skipping" behavior [46]. The system has been synthesized with various chemical groups at the position marked X (O, S, NH, $CH_2$, $SiH_2$, $C_2H_2$).

halted. Treatment of the $Hg^{2+}$ complex with EDTA removes the $Hg^{2+}$ and releases the brake allowing the wheel to spin rapidly.

An alternative device was constructed in which the photochemical switching process of the donor-acceptor substituted helical alkene could be blocked completely by protonation of the N, N-dimethylamine donor unit [40]. Protonation of the amine group results in an acceptor-acceptor substituted lower half, and as a result the photochemical switching is blocked. Deprotonation restores the donor amine group, and the switching process is once again functional. The reversible protonation constitutes a brake effect, as by simple de(protonation) the on mode and off mode are addressed.

Yet another device that acts to control the speed of motion of a molecular rotor can also be considered a brake [41]. This device consists of a thioxanthene-based switch and a biaryl rotor. Photoisomerization from the *cis* conformation to the *trans* conformation moves the upper naphthalene unit away from the rotor, resulting in a decrease in steric hindrance and, one might expect, an increased propeller speed. The reverse was found, however, since in the *cis*-isomer the naphthalene unit easily bends away to allow passage of the rotor. In the case of the *trans*-isomer, the methyl substituents of the rotor interfere with the methylene groups of the upper part and therefore hinder the speed of the rotor. It was concluded from this study that the rate of motion of a rotor can be controlled by *cis-trans* isomerization.

## 2.4. Molecular Gearing Systems

Molecular gearing systems were among the first successful examples of rotary mechanical devices engineered and synthesized using conventional chemistry. The major efforts aimed at synthesizing molecular gears have been focused on triptycene derivatives. The use of triptycenes as molecular gears started during the 1970s with a significant body of the research being done by Mislow and Iwamura [42–44]. The simplest triptycene gears, however, were constructed by Oki [45] using two triptycene derivatives connected by an appropriate bridge.

More recent work has been done using triptycenes by Gakh et al. [46]. The simplest molecular systems that mimic bevel gears were constructed from two triptycene "gearing" fragments connected by an appropriate bridge. In other systems described, a crown ether bridge connects two ends of principle axis of the triptycene as seen in Figure 6. The "fan blades" of the triptycene gear pass through the ring of the
crown ether. The findings of this study indicate that not all synthesized triptycenocrown ethers display dynamic behavior, that is, the expected "rope-skipping" does not occur in all of the studied systems. This was often the case in systems with small crown ether bridges. It was anticipated that complexation of a guest by the crown ether would control the "rope-skipping" rotation [46], and indeed a small effect was observed for certain guests. Systems in which complexation would have greater control over rotation await further development.

### 2.4.1. Molecular Ratchets

Ratchets are devices that allow motion in only one direction. Generally they consist of three components: 1) the ratchet wheel, 2) the pawl, which acts to prevent rotation of the wheel in the wrong direction, and 3) the spring, which holds the pawl in place. Kelly et al. sought to translate these macroscopic properties of the ratchet to the molecular scale using triptycene as a wheel and helicenes as the pawl and spring components [47, 48]. The synthesis of triptycyl [4]helicene successfully incorporated the essential components of a simple ratchet into a single molecule (see Figure 5). It was demonstrated experimentally, however, that the molecular ratchet described rotates bidirectionally rather that unidirectionally. Rotation in both the clockwise and counter-clockwise direction requires the same amount of energy and therefore dictates an equal potential to rotate in either direction.

### 2.4.2. Molecular Rotors

Unidirectional motion was finally achieved by both Kelly et al. [49] and Koumura et al. [50] in another example of a molecular device, a molecular rotor. The system identified by Kelly et al. [49] is reminiscent of the unsuccessful molecular ratchet [47, 48] described by that same group in which the rate of rotation was controlled by a conformational change. The system consists of a three-blade triptycene and a [4]helicene connected by a single bond, and was found to exhibit unidirectional motion [49]. However when this system is thermally stimulated, rotation of the triptycene occurs in both the clockwise and anticlockwise directions to an equal extent. The unidirectional rotation results from the asymmetric skew of the helicene and the use of a monosubstituted triptycene, which results in non-identical energy surfaces for clockwise and counter-clockwise rotation.

The first system designed by Koumura et al. [51] is a rotor consisting of helical alkenes in which unidirectional rotation around a central carbon-carbon double bond occurs. The structure of the rotor is (3R,3′R)-(P,P)-*trans*-1,1′,2,2′,3,3′,4,4′-octahydro-3,3′-dimethyl-4,4′-biphenanthrylidene and consists of two identical halves connected by the central carbon-carbon double bond (see Fig. 7). Irradiation with ultraviolet light causes rotation about the central bond. The cycle may be regarded as four distinct states (at each of the isomerization steps) in an optical molecular switch, each achieved using the appropriate temperature and wavelength of light. If the appropriate temperature and wavelength are achieved, it is possible to induce a continuous unidirectional rotation.

More recently Koumura et al. [50] have reported a second-generation molecular rotor, which contains a chiral 2-methyl-2,3-dihydrothiopyran "upper half" and a thioxanthene "lower half." The upper naphthothiopyran unit has been found to undergo 360 degrees of rotation with respect to the lower portion of the system. At the appropriate wavelength and temperature, rotation is continuous and unidirectional. This rotor containing distinct upper and lower halves has been found to exhibit unidirectional rotation with the addition of a single stereogenic center.

Another example of rotary motion was reported by Bedard and Moore [52] in which they describe a molecular turnstile. The turnstile consists of a hexa(phenylacetylene) macrocyclic frame with a diethynylarene bridge. The bridging unit should exhibit rotation about its axis and act as the spindle of the turnstile. Hinderance to rotation about the spindle axis is almost entirely due to steric interactions between groups attached to the spindle and the macrocycle framework.

## 2.5. Molecular Piston

Components where internal cylinders are repeatedly moved back and forth inside the outer cylinders such as pistons or syringes also play an important role in macroscopic machines. Yu et al. [53] have succeeded in creating an equivalent molecular system consisting of multiwalled carbon nanotubes (MWCNTs) as seen in Figure 8. Both a stick-slip motion and a smooth pullout motion were observed in both of the MWCNTs studied. The data and analysis suggest that theoretical modeling will shed further light on the systems. The studies reported were the first to observe the sliding of nested shells in MWCNTs.

## 2.6. Molecular Barrow

A molecular barrow consisting of two front wheels, two rear legs, and a central board to work on a Cu(100) surface has been reported by Joachim et al. [54]. The barrow

**Figure 8.** Multiwalled carbon nanotubes (MWCNTs) exhibit movement that is similar to a bearing or piston/cylinder system.

is specifically designed to be guided by the tip of an STM and therefore to act as an individual nanoscale molecular machine. A tetracene unit was selected as the molecular board, and triptycene molecules were used for the two front wheels with a triple bond per wheel to ensure structural stability of the front axle. The rear legs are *tert*-butyl phenyl groups, which display efficiency for STM manipulation. All the pieces of the molecular equipment are covalently bonded together, resulting in a single molecule as seen in Figure 9. Unfortunately the wheels do not rotate and instead slide along the surface upon STM manipulation. One reason is that the Cu(100) surface corrugation is not large enough for the wings of wheels to find some friction to engage their rotation. A new structure was proposed in which there were two ratchet groups on the central board; however, the task remains to synthesize the proposed structure and manipulate it with STM. Uses for this molecular

**Figure 7.** A molecular rotor designed by Kourmura et al. [50].

**Figure 9.** A molecular barrow as reported by Joachim et al. [54].

machine could include the reconstruction of an atomic surface or the building of an atomic wire.

## 2.7. Molecular Motors

Recently, attempts at designing the first molecular motor have been made by Kelly et al. [55, 56]. The task is still incomplete, but the group reports that progress has been made. The motor is based on a molecular ratchet that the group reported previously (see Figure 5) [47–49]. The motor would work by trapping the molecule in an excited state, at which point it has a new "low energy" position closer in energy to the peak of the potential energy surface (see Fig. 10). Random thermal energy will eventually elevate the molecule from the new "low energy" position to the peak, which it can descend on the other side corresponding to unidirectional rotation. Trapping the molecule in the excited state is achieved by a 60 degree rotation followed by urethane formation that traps molecule in an energetically excited conformation around the triptycene/helicene bond. The next step will be to achieve repeated rotation controlled selectively at the appropriate time. Much work remains to be done before this and similar systems rival that of their biological and mechanical counterparts.

# 3. THEORETICAL STUDIES OF MECHANICAL MOLECULES AND NANO-DEVICES

Needed for the large-scale commercialization of nanomachines is a process equivalent to design engineering. Toward this end, there has been an increasing effort to identify simulation techniques for molecular and nanodevices. Molecular modeling is desirable in order to circumvent the need for time-consuming and expensive fabrication of numerous prototype systems. It is expected to provide a shortcut to functional molecular devices by enabling the screening of proposed designs and modifications based on predicated performance.

There are several technical challenges that must be met in order for a theoretical/computational treatment of a molecular or nanosystem to be successful. The most important concern is that the method gives reliable information. While the quantitative accuracy may vary, the method must correctly predict the fundamental aspects of the system. The second problem is that the method must be sufficiently efficient to allow a reasonable number of prospective designs

**Figure 10.** Upon formation of urethane there is an increase in the periodicity of hindered rotation, and as a result the molecule is trapped in an excited state affording a new "low energy" position that is now higher in energy.

to be screened within a reasonable time frame. While "reasonable" carries significant latitude, it must be acknowledged that if the time required is too long, or the required computational facilities too expensive, the modeling process will not serve as a useful design tool. Finally, perhaps the greatest challenge is that the method accommodates the wide variety of chemical and physical properties at play in nanosystems.

In the theoretical description of molecular devices, five key issues are identified:

1. Molecular device conformational isomerism
2. Molecular recognition
3. Skeletal vibrations and oscillations
4. Multicomponent dynamics
5. Manifestations of quantum mechanics

All five areas have been targeted in theoretical and computational studies. These studies often offer insight that was previously unknown and can be used to design more powerful and useful nanodevices.

## 3.1. Applications of Methods and Techniques

There exist three broad categories of theoretical methods for investigating static molecular properties. In approximate order of increasing complexity, they are the molecular mechanics (MM) methods, semi-empirical methods, and *ab initio* methods.

While MM methods are fast and readily allow energy minimizations and searching through large configurational spaces, they typically have some important limitations. For example, MM methods incorporate electronic structure effects only *implicitly* through empirical parameters. It is becoming increasingly evident that simultaneous simulation of mechanical and electronic properties is critical in molecular device modeling [57, 58]. At the other extreme, *ab initio* methods incorporate electronic structure effects *explicitly* and can in principle provide sufficient accuracy, but in practice extensive computational resources are required to treat even the smallest systems [59, 60]. Semi-empirical (SE) electronic structure methodology represents a compromise between these two extremes. SE methods treat only the valence electrons explicitly, and parameterize the computation of certain difficult-to-evaluate integrals for greatly increased computational efficiency. Techniques from all three categories have found application in the theoretical and computational description of molecular devices, with different techniques being most applicable to different key issues.

### 3.1.1. Molecular Device Conformational Isomerism

In a macroscopic machine there are typically two or more stable rest states [61]. For example, a valve may be open or shut, and a selector switch may take any of several positions. The analogous states of a molecular device are stable molecular conformations. The ability to design a molecular device entails the ability to predict these stable conformations.

Grabuleda and Jaime [62] have applied molecular mechanics methods to model the switching processes observed in

[2] rotaxanes. The MM3 and MM3* force fields were chosen, which they noted model nonbonded interactions reasonably well. The molecular mechanics studies on the series of rotaxanes chosen show that electrostatic and van der Waals terms are the major factors controlling the energy minima. This conclusion is probably generally true for large macrocycles containing highly electronegative atoms [63]. The simulation of the behavior of the rotaxanes as molecular devices at thermal equilibrium using the MM3 force field agrees with the experimental results for the preferred location of the translational isomers only when the dielectric constant has been changed to simulate solvent effects. Complementary computations were carried out using the MM3* force field, which showed less reliable and sometimes wrong behavior in the prediction of stability between isomers [62].

Calculations and statistical analyses of X-ray crystal structures were carried out by Biscarini et al. [64] on mechanically interlocked molecules, including rotaxanes and catenanes. The MM3 model [65–67] was used (as implemented in the TINKER package). They reported that they were able to reproduce experimentally determined rotational barriers and steric energies in these types of interlocked molecules [64].

Ceroni et al. [68] reported a comparative investigation of the electrochemistry of a benzylic amide [2] catenane and its topologically trivial subcomponents. They proposed that the redox behavior of the catenane can be understood in terms of the electrochemistry of smaller molecular fragments and simple molecular orbital considerations. Semiempirical quantum chemical (MNDO) calculations were performed on both neutral and doubly charged catenane species, and analyzed with electrochemical data from experiments. The electrochemical study and theoretical considerations suggest that the reductive behavior of the catenane is governed predominantly by the amide carbonyl groups. The quantum chemical calculations and the electrochemical behavior suggest that an electrochemically induced reaction in the catenane connects and disconnects the two interlocked macrocycles. The formation of a C—C bond between two reduced carbonyl groups, which arises from the close proximity brought on by macrocyclic ring rotation of the catenane, prevents further macrocyclic ring circumrotation. This could provide a useful means of switching "on" and "off" the dynamics of such interlocked macrocycles.

A computational investigation on several unsymmetrical [2] catenanes was carried out by Raymo et al. [69] with empirical force field and *ab initio* quantum mechanical calculations, for the purpose of understanding the factors governing the equilibrium proportions of the translational isomers and the nature of the $\pi$-$\pi$ stacking interactions associated with these systems. Monte Carlo conformational searches [70] were carried out individually on each of those catenane complexes and their separate components, which were constructed with the program Macromodel 5.0 [71] and energy minimized with the AMBER force field [72] and the GB/SA solvation model for $H_2O$, as implemented in Macromodel 5.0. Single point *ab initio* calculations were performed in vacuum at the HF/6-31G** level using the program Spartan 4.1 [73] to determine the electrostatic potential [74], (*Ep*), calculated on the surface of the aromatic units and the energies of the highest occupied molecular orbitals

(HOMO), $E_{HOMO}$. In their *ab initio* single point calculations [69], the tetracationic cyclophane component was removed from the global minima of the complexes obtained from the Monte Carlo conformational searches, and the polyether substituents attached to the aromatic units of the guests were replaced by methoxy groups without modifying the dihedral angles around the Ar—O bonds. The factors governing the translational isomerism are reported to be (i) the differences between the solvation energies of the two translational isomers and (ii) the differences between the binding energies of the corresponding supramolecular complexes, which are controlled by electrostatic interactions. The relative populations of the translational isomers observed in solution presumably arise from a competition between these two factors.

Results reported by Kelly et al. [48] for a proposed "molecular ratchet" and studies of conformational isomerism in bacteriorhodopsin, a potential candidate for protein-based molecular memory [75], suggest that semi-empirical electronic structure methods are a suitable choice for investigating molecular device systems.

As previously discussed, Murakami et al. have synthesized and characterized a novel two-component functional nanosystem, a light-driven molecular shuttle [24]. For example, Sohlberg et al. carried out a semi-empirical investigation [76] of the light-driven molecular shuttle of Murakami et al. [24]. The results of the semi-empirical calculations agree well with the experimental results as obtained by Murakami et al. [24]. As an isolated molecule the rotaxane shaft shows two-fold symmetry, but in both rotaxane conformers the symmetry is broken. The loss of symmetry upon inclusion into the cyclodextrin was also found experimentally [24]. The *cis* conformer was found to be energetically more stable, in accord with the experimental findings of Murakami et al. [24] who report a 2:1 preponderance of the *cis* conformer (67% vs. 33%) at 278 K. In the rotaxane *trans* conformer, the shaft is very nearly centered in the cyclodextrin cavity, as Murakami et al. [24] inferred from induced circular dichroism spectra. In the *cis* conformer, the shaft is off-center. This is presumably the source of the shuttling action described by Murakami et al. [24]. Additionally the *cis* conformer of the rotaxane structure displays a kink in the shaft, and therefore the conformational isomerism from *trans* to *cis* (or vice versa) involves significant structural transformation. Finally it was found that the barrier to conformational isomerization is $\geq 11$ kcal/mol. The significant structural transformation and large energy barrier account for the observed very slow rate of isomerization at room temperature [24].

More recently Frankfort and Sohlberg have reported semi-empirical electronic structure calculations for a switchable rotaxane that was demonstrated experimentally by Martinez-Diaz et al. [18] (reviewed above) and have shown that these calculations capture the essential "device-like" character of the system [77]. It has been established experimentally that the mobile component of this rotaxane system, DB24C8, resides initially on the dialkylammonium station and that it is possible to deprotonate the $NH_2^+$ center with base and "drive" the ring to the bipyridinium station [18]. AM1 semi-empirical calculations were able to replicate this feature [77]. Unlike some other methods, AM1 has

been found to be qualitatively acceptable for intermolecular hydrogen bonding [78], the dominant interaction between the macrocycle and the shaft in this rotaxane.

A starting structure of the rotaxane molecule was constructed from its principle subcomponents [77]. There are three subcomponent structures: the ring, shaft, and stopper. The ring is a crown-ether, dibenzo [24] crown-8; the shaft contains a dialkylammonium center, a stopper (3,5-di-tert-butylbenzyl), and a bipyridinium unit; and the stopper is 3,5-di-tert-butylbenzyl bromide. Low energy conformations were identified for each subcomponent and optimized using the AM1 semi-empirical method. The rotaxane was then assembled from the optimized subcomponents by computationally mimicking the $S_N2$ mechanism by which it is synthesized. The computations showed that internal energy of the system decreases during construction. Given that association of the shaft and macrocycle is most probably entropically unfavorable, an accompanying decrease in internal energy is presumably necessary for a practical synthetic mechanism.

After construction, the shuttling action of the [2] rotaxane was tracked by correlating the energy of the system to the position of the ring in both the protonated and *de*protonated states [77]. For both the protonated and *de*protonated species, 95 separate trial structures of the rotaxane were fully optimized at the AM1 level of theory. To generate these trial structures, the initial rotaxane structure (from the $S_N2$-mimicking construction) was modified by translating and rotating the ring about the shaft. For the fully assembled rotaxane in the protonated state, the heavily dominant structure places the ring around the dialkylammonium station. This structure accounts for 64% of the total population at 300 K; the second and third lowest energy structures constitute essentially all of the remaining 36%. The most highly populated structure is representative of all three since they are essentially the same, the only difference being slight translation of the macrocycle around the dialkylammonium center. Upon *de*protonation the ring is driven to the opposite side of the shaft where the bipyridinium station is located. The calculations identify three deprotonated structures that compose 86% of the population at 300 K. In all of these structures the ring is oriented asymmetrically around the bipyridinium station. The bipyridinium station contains a nitrogen atom on either end. The macrocycle associates with either of these two nitrogen atoms rather than symmetrically positioned between the two. This asymmetric positioning around the bipyridinium station in the *de*protonated state is in agreement with the experimental results based on proton NMR [18]. As shown by the energetic data for the structures, the addition of the proton to the dibenzylamine station is energetically favorable, which is also in accordance with experimental results. The calculations further show that relatively little structural change in the shaft accompanies the shuttling action. In agreement with experimental findings [18], the semi-empirical AM1 calculations predict that the DB24C8 ring resides initially on the $NH_2^+$, and upon *de*protonation with a base, the preference of the ring location changes, at which point it shuttles to the bipyridinium station. Another aspect of these calculations was an indication that once the shaft was *de*protonated the ring could not be made to approach the NH center closer than approximately 4 angstroms. Trial structures with ring-NH separations shorter than this distance either optimized to structures with the ring pushed beyond 4 angstroms or failed to converge entirely. This characteristic of the system suggests that the shuttling action performed by the ring is relatively strong. Such calculations may be useful for *a priori* predictions of the effect of proposed structural modifications on the shuttling action and therefore serve as a screening tool for selection of future synthetic targets [77].

Zheng and Sohlberg [79] have demonstrated, on an experimentally realized example, a procedure for modeling a photo-induced, redox-switchable, rotaxane-based molecular device that captures the features critical to its device-like character. The system consists of a benzylic amide macrocycle mechanically locked onto a thread featuring two potential hydrogen bonding stations, a succinamide (*succ*) site and a 3,6-di-tert-butyl-1,8-naphthalimide (*ni*) unit separated by a $C_{12}$ alkyl spacer. The system (previously described in detail) exhibits extremely fast and fully reversible shuttling motion.

The computational procedure includes conformational searching over the full torsional space of the rotaxane. This is followed by single-point semi-empirical calculations for all co-conformations in their neutral singlet, triplet, and anionic doublet states, and statistical analysis to correlate the structural features with energy in each state. The conformational searching was performed based on all torsional bonds of the two component molecules and generated more than $10^4$ co-conformations. The observed correlation was checked by repeating the analysis after full geometry optimizations on a subset of co-conformations ($\sim$1%). The overall procedure accurately captures the structural and switching characteristics of the physical system.

Based on calculations of single point energy and radius of gyration for 10,118 rotaxane structures, it was found that co-conformations with ring binding at the *succ* site predominate in the low energy regime for singlet and triplet species, with preference for the shaft component being extended [79]. Doublet species prefer to take on co-conformations with ring binding at the *ni* site in low energy structures, with coiled and extended shaft conformations being energetically. Zheng and Sohlberg [79] obtained effectively the same results by geometrical optimizations of a subset of co-conformations. These results are in excellent agreement with previous experimental observations [22]. Therefore, they proposed that the structure versus energy profile produced in the less expensive way, by using systematic conformational searching followed by semi-empirical single point energy calculations and correlating the structural features to energy, is consistent with what would be obtained if each structure were fully optimized. They suggest that instead of carrying out full structural optimizations at the semi-empirical level for each trial structure, the use of single point calculations is sufficient to obtain the profile of structural features versus energy, as long as the trial structures generated from the systematic conformational search are "chemically reasonable."

The systems described above provide strong evidence that semi-empirical calculations are capable of predictions of molecular device bistability that are consistent with measured properties and can provide considerable insight into functional nanosystems.

### 3.1.2. Molecular Recognition

Molecular recognition is a key issue in successful molecular device architecture [61]. Molecular recognition directs the self-assembly [7, 80] from the individual device components and subcomponents. Obviously, one critical key to molecular device design is a modeling tool that properly predicts molecular recognition.

In simple terms, molecular recognition is highly specific intermolecular interactions. Molecular recognition technology has a history of successful applications for ion separations [81–85], starting from the first reports of cation [86] and anion [87] inclusion compounds. This technology has led to the development of commercial ion separation systems [88]. Molecular recognition for the self-assembly of molecular device components is obviously more complicated than ion recognition. Nevertheless, owing to the availability of extensive experimental data, recognition serves as an excellent testing ground for molecular recognition modeling tools. Sohlberg and Tarbet have shown that when used to compute the energetics of certain ion exchange reactions, semi-empirical electronic structure methods reliably predict selectivites in the binding affinity of numerous anion receptors for atomic anions [89].

In 1994 Ricketts et al. [90] reported one of the first attempts at modeling interlocked molecules using molecular mechanics. They argued that the time would come when structural complexity and size would render current analysis techniques such as $^1$H NMR and X-ray crystallography less effective and more difficult to apply. They proposed a technique that uses molecular mechanics methods together with semi-empirical molecular orbital calculations. Ricketts et al. were able to predict structures of inclusion complexes in agreement with those obtained using X-ray crystallographic methods [90]. Noncovalent bonding interactions were reproduced using this technique and binding energies were found to follow the same trend as those determined experimentally. This is a common theme in the theoretical and computational description of molecular and nanodevices. The salient features are captured in trends, so computations of qualitative reliability are of considerable value.

Raymo et al. [91] have also used a molecular mechanics technique in order to study a system of interlocked molecules. These calculations were motivated by the study of a slippage approach to self-assembly in a series of [n] rotaxanes, each consisting of a bipyridinium-based backbone, encircled by one or more dioxyarene-based macrocyclic components. Systematic variations in the $R$ group attached to one of the phenyl rings of the tetraarylmethane-based stopper was found to greatly affect the yields. When certain $R$ groups are used no rotaxane was isolated leading to the observed "all-or-nothing" substituents effect. A computational study was undertaken in order to explain this substituents effect. The study revealed two main energy barriers for the slipping-off of the macrocycle over the stoppers. The trend in calculated energy barriers was in good agreement with experimental yields of the corresponding rotaxanes and the abrupt substituent effect was found to be a result of steric hindrance. This is an excellent example of theory and computation yielding qualitative trends that lead to insight that allows for targeted synthesis, accelerating the development process.

Due to the extensive computational resources needed to treat even the smallest systems using *ab initio* techniques, few studies of molecular devices have been undertaken in which *ab initio* is the primary means computation. Dobrowolski and Mazurek [92] reported *ab initio* calculations of the qualitative theoretical $^{13}$C NMR chemical shifts ($\delta$) of model carbyne catenanes and knots including $C_{10}C_{30}$ and $C_{20}C_{30}$ (Hopf links). They found that the chemical shift ($\delta$) tends to alternate along the catenane or a knot branch, and the $\delta$ fluctuation is associated with the redistribution of $C\equiv C$ triple bond $\pi$ electrons, which arises from the repulsion between catenane components or knot branches. Repulsion polarizes the $\pi$ electrons so that a carbon atom located closer to the perturbation is deshielded and one placed further away is more shielded.

One study performed by Raymo et al. [93] investigated the magnitude of [C—H···O] hydrogen bonding, which is typically the dominant intercomponent interaction. The investigations were carried out on complexes containing the following components: N-methylpyridinium cation, dimethyl ether, and the dimethyl phosphate anion. The quantum mechanical investigation studies the interactions between charged and uncharged systems, in which the main non-bonded contacts involve [C—H] bonds on electron-deficient species and oxygen atoms on electron-rich species. The results provide quantitative measures of the large stabilization energies that arise from [C—H···O] contacts in charged systems. These attractions are responsible for the self-assembly of bipyridinium based catenanes and rotaxanes.

Pioneering investigations of the mechanisms by which mechanically interlocked components move with respect to each other in benzylic amide catenanes, have been reported by Leigh et al. [94]. It was reported that the interlocked macrocycle dynamics are governed by a delicate balance of steric effects, intermacrocyclic arrays of hydrogen bonds, $\pi$-$\pi$ stacking, and "T herringbone-type interactions." T herringbone-type interactions are phenyl-phenyl interactions in the geometry of a distorted "T." It was found that a cascade of hydrogen-bond ruptures and formations occur during circumrotation and that these are accompanied by a series of cooperative conformational and co-conformational rearrangements that help to stabilize the energy of the molecule. The polarity of the environment was also reported to play a role in determining the interring dynamics.

### 3.1.3. Skeletal Vibrations

Previous simulations of the behavior of nanocomponents have revealed one common theme: the rigidity of a component is key to its proper performance. For example, Tuzun et al. simulated the flow of rare gas atoms inside carbon nanotubes [95] and found that the rigidity of the tube has a profound effect on the fluid flow. The performance of nanobearings has also been shown to depend critically on their rigidity [96]. Excessively large vibrational motion imposes drag on the rotational motion. Nanogears exhibit similar characteristics [97]. Clearly, successful nanomachine engineering will depend on the ability to reliably anticipate vibrational properties [98].

In the just-mentioned studies [95–97], and indeed in the vast majority of nanosystem simulations to date, the vibrational properties were computed with fully atomistic

numerical classical trajectories, which follow the molecular dynamics [99]. Molecular Dynamics (MD) methods solve Newton's equation of motion for some or all of the atoms in the system, typically based on an empirical functional form of the interatomic potential energy function. The method generates a series of time-correlated points from a suitable starting set of coordinates and velocities by a series of finite time steps [100]. Since small time steps must be used for integrating Newton's equation, (Typically a time step one order of magnitude smaller than the period of the highest frequency vibrational mode of the system is required for good energy conservation in the numerical determination of the classical trajectory.) considerable computer time is required for the simulation of a short period of molecular motion. In spite of the steady geometric increase in computer speeds over time, routine analysis of the dynamics of nanosystems by fully atomistic numerical classical trajectories is impractical. Admittedly, simulations of systems containing thousands of atoms are common, and even one million atom systems are now accessible, but such simulations are computationally demanding. Large-scale simulations have their place in fundamental research and in detailed final design work, but clearly the fully atomistic numerical classical trajectory is not an ideal design tool. In addition to the cost issue, they also ignore possible quantum effects.

An alternate approach, which focuses on the overall mechanical behavior of the structure and not on local details dependent on just a few atoms, is to employ continuum methods. Because the dynamical behavior of nanomachines will be governed predominantly by the gross movements of their components, it seems reasonable to assume that reliable predictions about the performance of nanosystems might be achieved through the uses of equations from the theory of elastic solids. Continuum methods have been successfully applied to numerous modes of nanotubes, including longitudinal stretching, circumferential breathing, torsional twisting, and transverse flexing [101]. Extensions to damped systems [102, 103] and systems with size dependent elastic moduli [104, 105] have also been reported. Popov et al. [106] have shown how to accurately estimate the elastic moduli through the application of a lattice-dynamical model.

### 3.1.4. Multicomponent Dynamics

Another important aspect of the design of a complex multi-component molecular device is the prediction of its dynamical behavior. Molecular device dynamics is most often studied with MD methods.

Another application of MD techniques is to search for low energy configurations of the system. Based on the ergodic hypothesis, if one assumes that the system can be modeled as a set of oscillators of incommensurate frequencies, a dynamical trajectory will eventually (given sufficient time) sample all of the energetically accessible configuration space. One problem with this method is that in order to sample the whole potential energy surface, an impractically long simulation time is necessary. Typically only the local area around the starting point is sampled [107]. In the event of commensurate vibrational frequencies, resonances occur and the ergodic hypothesis breaks down. Another difficulty with MD

techniques is that they neglect to take into consideration the quantum mechanical aspects of the system, which are of fundamental importance [108, 109]. Despite these shortcomings, MD methods have been employed with considerable success in the study of molecular and nanodevices.

Several studies have been undertaken in which MD simulations are used. Grabuleda and Jaime [62] have performed MD simulations in conjunction with the MM calculations reported in their study of translational isomerism in [2] rotaxanes mentioned previously. The reason for this was to avoid certain limitations of the molecular mechanics simulations. As described in the previous paragraph, molecular dynamics simulations in theory allow more extensive sampling of the phase space. These MD computations show qualitative agreement with the MM computations in the estimation of the shuttling barrier. Additionally, the MD computations provided information regarding [C—H•••O] hydrogen-bonding interactions throughout the shuttling process.

Leigh et al. have demonstrated the application of inelastic neutron scattering (INS) spectroscopy in combination with MD simulations to investigate the dynamics of catenane systems [110]. Since INS depends on the vibrational dynamics, it is a valuable tool for the investigation of the dynamical properties of complicated molecular systems. The accurate simulation of INS spectra provides a description of the atomic motions. Leigh et al. [110] noted that owing to its very large incoherent scattering length, hydrogen dominates the INS response of organic molecules. Inelastic neutron scattering spectra is therefore able to monitor the amount of motion of the hydrogen atoms, which is a crucial aspect of benzylic amide catenanes since they form a number of inter-ring or intramolecular and intermolecular hydrogen bonds. Leigh et al. reported molecular dynamics (MD) simulations of two benzylic amide [2] catenanes [110] with a model that was successfully used before [111, 112]. The Tinker program [113–115] and the MM3 force field [65–67] were employed for the calculations.

Another such simulation was performed by Caciuffo et al. [116]. The simulations were based on calculation of the normal modes of the isolated catenane and therefore included neither anharmonic nor crystal effects. These studies demonstrated that the combination of INS spectroscopy and MD can be used to discriminate between different proposed structures in large interlocked molecular systems, and that this combination of techniques is particularly well suited to access the strength of intramolecular and intermolecular hydrogen bonds that are the crucial interactions that govern the dynamics of such systems.

Tuzun et al. [117] have described a molecular motor based on a nanobearing on which molecular dynamics were carried out to simulate the rotation of the sleeve about the shaft upon laser excitation. The shaft consists of concentric carbon nanotubes with positively and negatively charged species bonded to atoms on one end of the ring. It was found that when the laser field is applied, the shaft with the attached charges tends to crimp (or uncrimp). This laser-induced periodic motion, along with the electric field, propels the shaft over the rotational energy barrier. If the end of the shaft crimps too severely, however, frictional braking occurs. A wide range of operating parameters, such as

laser frequency and power, molecular bearing sizes, and the positions of the charges within the molecular bearing, were searched for stable unidirectional rotations of the inner bearing tube. For a single applied laser field under all investigated operating conditions, the bearing would rotate in one direction and then rotate in the opposite direction. Using two applied laser fields the duration of unidirectional rotation was increased, and an attempt to find the optimal set of operating parameters with a neutral net simulator was made. It was concluded from this study that the use of laser excitation on nanocomponents might be a practical method for introducing controlled motion into nanomachines.

Srivastava has reported similar results in which he investigated rotational dynamics of carbon nanotubes under a single applied laser field [118]. An intrinsic frequency of the nanotube oscillations was defined for a given laser field strength and location of charges in the body. If the laser field frequency is much less than the intrinsic frequency, of the nanotubes, the motor shows rotational oscillations in both directions. When the laser field frequency is of the same order of magnitude as the intrinsic frequency, a quasiresonance between the nanotube oscillations and the laser field oscillations is present. If the phases of the two oscillations are also properly matched, unidirectional rotation of the nanotubes is possible.

Vacek and Michl describe a computer simulation of molecular propellers mounted on a square grid using molecular dynamics methods [119]. The propellers consist of a chiral complex of Re(I) with two phenanthroline-type ligands providing two blade areas oriented at about 45 degrees to the propeller axis and at about 90 degrees to each other. The computational procedure consisted of geometry optimization of a suitable molecular structure and subsequently a series of MD calculations on the grid-propeller combination in a stream of gas approaching the grid perpendicularly from the side opposite to that on which the propeller was mounted. Constraints were introduced in order to prevent the stream of gas from sweeping the propeller downstream. All of the runs showed one of two classes of behavior. Immediately after the gas flow was turned on, the propeller suffered a period of confused motion, vibrating and rotating randomly. After a period of picoseconds it either settled into a smooth rotational motion or it continued the initial random behavior. Inspection of the propeller shape during the simulation revealed considerable bending of the axle, acting more as a pendulum than a propeller, this lack of rigidity being the most obvious weakness of the system. As a result of the simulations conducted, it was found that there is a region of gas flow parameters for which the propellers will work in the sense of producing a fairly regular motion in the steady state (achieved after approximately 20–50 ps). From this study, a more stable propeller can be proposed in which the axle is fixed at both ends in order to prevent the pendulum-like motion. This is an excellent example of the type of iterative refinement of design that can be facilitated with theoretical and computational simulations.

More recently, Vacek and Michl carried out a similar study in which a grid-mounted dipolar rotor is mounted on a square grid and driven in vacuum by a rotating electric field [120]. Prior to simulation, the molecular structures were optimized. Initial velocities were assigned, and various starting geometries and velocity distributions were used in order to widely sample the operational envelope of the system. They anticipated five regimes of behavior (synchronous, asynchronous, random driven, random thermal, and hindered rotor) dictated by the relative importance of 1) random thermal forces described by $kT$, 2) the strength of maximum rotor-field interaction, 3) the friction constant $\eta$ that describes the break-off drag torque, and 4) the rotational barrier height $W$. Four of the five regimes were studied. The MD simulations provided a detailed view of the friction and thermal motion on the rotor.

In addition to rotors, several nanoscale ratcheting mechanisms have been proposed [48, 121–123], and the development of nanomachines incorporating such elements will obviously require design models capable of describing their dynamical behavior.

By analogy to macroscopic systems, it can be intuited that the dynamical performance of nanomachines will be governed predominantly by the gross movements of their components, and not by the details of the motion of the individual atoms. This observation suggests that accurate predictions about the performance of nanosystems can be achieved through the use of the rigid body approximation. The rigid body approximation has been tested on a prototypical nanosystem [124].

A nanobearing might consist of a pair of nested carbon nanotubes [37] with the outer tube (sleeve) held in place but the inner tube (shaft) held in position by the assemblage of the nanomachine only in the longitudinal ($z$) direction. In this configuration, the shaft is free to translate and rotate in the $x$-$y$ plane, but is restricted to maintain its $z$-position. As a prototype of such a system, a rigorously planar model was considered. It consists of a single atomic layer (slice perpendicular to the $z$-axis) from such a pair of nested nanotubes. This model, while synthetically unachievable, bears striking similarities to actual molecular rotors [38] and contains the essentials of the dynamics of a nanobearing. The two components (the shaft and the sleeve) are treated as rigid bodies. The configuration of the system is completely described with three independent variables: the $x$ and $y$ positions of the center of mass (COM) of the shaft, and the angular orientation of the shaft in the $x$-$y$ plane, $\phi$. It was found that for certain initial conditions, the dynamics of this model is quasiperiodic, but for other initial conditions the motion is chaotic. For optimum performance it is desirable to operate the bearing in the quasi-periodic regime because therein it will rotate without dissipating rotational kinetic energy into other modes over time as intimated by Feynman [1] (super-rotation). It can be seen that in order to ensure stable quasiperiodic dynamics, the bulk of the total system energy must be tied up in spin of the shaft. This is exactly the sort of insight needed for successful nanodevice design: How do gross movements of the components affect system performance?

In a rigid body simulation, it is necessary to specify the orientation of the body as well as its position. The specification of the location of a rigid body in space requires three coordinates. The specification of the orientation of that body requires another three parameters. In a typical analytical representation of the orientation of a rigid body, these three orientation parameters are typically taken to be the Euler angles [125]. A dynamical simulation of the motion of the

rigid body then requires solving the equations of motion not only for the coordinates of the center of mass of the body, but also those for the Euler angles. Unfortunately, the equations of motion for the Euler angles are inappropriate for use in numerical simulations because they become singular for certain orientations of the body. A solution to this problem is found in the use of the quaternion parameters to specify the orientation of the body [126]. The quaternion parameters contain just one redundant variable and have the advantage that the equations of motion expressed in quaternions are everywhere nonsingular [127]. This formulation of the dynamical equations of motion has been successfully employed in several rigid body simulations of nanosystems [124, 128].

### 3.1.5. Quantum Mechanical Considerations in Nanosystem Dynamics

In the prototype molecular bearing model just reviewed [124], the motion involves three independent degrees of freedom that are not analytically separable. In cases of high spin (of the shaft), however, the spin of the bearing shaft is essentially decoupled from the motion of its center of mass. The quantum state of the spin of the bearing shaft can then be given, to an excellent approximation, by applying the quantum condition for a rigid rotor. For a rotor of momenta of inertia, $I_s$, the allowed quantum eigenenergies are given by

$$E_s = S(S+1)/2I_s \tag{2}$$

where $S$ is a non-negative integer, the quantum number corresponding to the spin of the bearing shaft, and $E_s$ is the energy in spin.

The two remaining modes are due to the motion of the center of mass (COM) and correspond approximately to vibration in the radial displacement of the COM from its equilibrium position, and precession of the COM about this equilibrium. There is a radial coordinate $r = (x^2 + y^2)^{1/2}$ corresponding to the vibrational motion and an angular coordinate $\theta = \tan^{-1}(y/x)$ corresponding to the precession. The angular momentum conjugate to the precession coordinate $\theta$ can be quantized with the semiclassical methods.

The above analysis can provide insights available only when quantum mechanical considerations are taken into account. For example, from the analysis it can be seen that in the general case the level spacing of the spin eigenstates will be different from that of the precessional eigenstates. This means that there will be very low propensity for quantum transitions involving the exchange of angular momentum between the spin and precessional modes. A transition, which conserves total energy, will not conserve total angular momentum and vice versa. Any quantum transition will as a necessity involve yet an additional mode to maintain energy conservation. Simultaneous multistate and multiquantum transitions are typically low probability events.

Leigh et al. reported a low-dimensional quantum-mechanical modeling description of circumrotation in benzylic amide [2] catenanes [129]. They found that by appropriate fitting of parameters in the analytic potential form to match the symmetry and energy properties of the system, they were able to reproduce rate constants and barriers similar to those determined by temperature-dependent nuclear magnetic resonance experiments. The calculation of the rates of circumrotation was accomplished by employing transition state theory (TST) in the harmonic approximation. Related low-dimensional quantum-mechanical modeling of molecular shuttling in a rotaxane has also been reported by Leigh et al. [130]. A one-dimensional quartic potential is used to describe the variation in potential with shuttle movement along the shaft of a rotaxane. This is a double-well potential, each well corresponding to one of two ring-binding stations on the shaft separated by a potential barrier. The coefficients on the quadratic and quartic terms in the potential are adjusted to reproduce the observed shuttling rate at 298 K. The model yields considerable insight into the contributions of quantum effects to the shuttling dynamics. For example, it is found that energies slightly in excess of the barrier correspond to a high quantum number eigenstate, which implies that the probability distribution approaches the classical limit. This means that at these energies the shuttle may be found with greatest probability in the vicinity of the barrier, settling into one of the ring-binding stations with high probability only at energies far below that of the barrier.

Quantum mechanical effects are also manifest in electronic degrees of freedom. Brouwer et al. [131] suggest that for materials science applications, the properties of interest to catenanes are likely to be electronic and vibro-electronic. Such properties require a theoretical model that explicitly includes electronic degrees of freedom. They reported a study of the electronic states of a benzylic amide [2] catenane through a combination of experimental and theoretical techniques. Semiempirical quantum chemical calculations were carried out with the CNDO/S method [132, 133] and showed partial delocalization of the electronic states over the many chromophores of the catenane.

Manifestations of the quantum mechanical nature of matter are quite important in nanosystems [109, 124]. Semiempirical techniques may be used effectively for electronic properties, being sufficiently efficient for application to quite large molecular systems, while still retaining an explicit description of the (valence) electronic degrees of freedom. The application of semiclassical methods to nanosystems can provide key insights into dynamical properties [124].

## 4. CONCLUSIONS

The past decade has seen rapid advances in the field of mechanical molecular and nanodevices. A wide array of devices, based on diverse chemistry, has now been reported. Most successful synthetic schemes have employed self-assembly, with relatively few using positional assembly. The former is almost certainly more practical for mass production, given that self-assembly can be carried out in mole quantities.

The theoretical and computational description of mechanical molecular devices has seen successful application for techniques from four broad classes of methods: molecular mechanics, semi-empirical quantum mechanics, *ab initio* quantum mechanics, and molecular dynamics. Examples

of theory-directed synthesis and theory-accelerated design refinement are starting to emerge.

## GLOSSARY

**Carbon nanotubes** A cylindrical arrangement of carbon atoms with a diameter in the nanometer range. Often described as a sheet of graphite rolled up and joined along opposite edges.

**Catenane** An assembly of two or more ring molecules that are chemically independent, but mechanically linked, as in interlocked rings.

**Molecular device** A molecule or an assembly of a few molecules that can be made to carry out a specific task by responding to an external stimulus. Molecular devices may perform electrical or mechanical tasks (or both).

**Molecular machine** A machine, the principle components of which are individual molecules.

**Multiwalled carbon nanotube** Nested carbon nanotubes.

**Nanodevice** A machine or circuit with characteristic length in the nanometer range.

**Pseudorotaxane** A *rotaxane* that lacks one or both bulky terminal groups and therefore may spontaneously unthread.

**Rotaxane** An assembly of two or more chemically independent molecules in which a long chain molecule is encircled by one or more rings. The chain component is terminated on both ends with bulky functional groups to prevent unthreading of the ring(s).

**Self-assembly** The spontaneous organization of molecules into a complex structure.

**Template-directed assembly** Deliberately moving device components (molecules) into close proximity with one another and linking them together to achieve assembly.

## 1. INTRODUCTION

In Lilliput, Gulliver noted that "there are some laws and customs in this Empire very peculiar" [1], an observation which might apply to nanophased materials too. Nanophased materials behave indeed differently from their macroscopic counterparts because their characteristic sizes are smaller than the characteristic length scales of physical phenomena occurring in bulk materials. Hereafter, we shall focus on consolidated nanomaterials or on powdered materials, named "nanostructured materials" (NSMs) [2, 3], whose particle sizes are large as compared to the mean crystallite size which is required to be lower than 100 nm, a conventional limit usual for structural materials. Materials whose grain size ranges between 100 nm and 1 $\mu$m are commonly named ultrafine grained materials.

Nanostructured materials are bulk solids with a nanometer-scale microstructure "in which the chemical composition, the atomic arrangement and/or the size of the building blocks (e.g. crystallites) forming the solid vary on a length scale of a few nanometers throughout the bulk" [2]. Nanostructured materials have then a significant fraction of atoms residing in defect environments (grain boundaries, interfaces, interphases, triple junctions). The volume fraction associated with grain boundaries is for instance $\sim$20% for a grain boundary thickness of $\sim$0.7 nm [4] and a grain size of 10 nm. Metastable nanostructured and ultrafine grained materials are produced by a large variety of methods. In this chapter, we shall concentrate on processes based on the deformation behavior of materials, more particularly on high-energy ball-milling [5–14], notable methods being the processing of bulk materials using severe plastic deformation methods [15] and the codeformation of multilayers by cold-rolling [16–20] which consists of successive rolling and folding steps. We finally mention mechanofusion, a process used for producing coated powders in specially designed mills [21].

Sophisticated methods most often spring to mind when thinking of means of mixing and combining elements in the solid state down to the atomic scale at moderate temperatures. Surprisingly, milling, a technique which was and still is mainly used for reducing the sizes of particles of various materials, is a possible method for this purpose. High-energy ball-milling offers indeed supplementary degrees of freedom in the choice of possible routes for synthesizing new materials and appears further as an attractive method of synthesis in view of its potential for large scale production. For a period of about 30 years, milling has indeed been a method of synthesis of advanced materials. Mechanical alloying (MA) [5–14], which is basically a dry and high-energy milling process, is a powerful technique for synthesizing all kinds of materials from initial mixtures made of powders with different chemical compositions: extended solid solutions,

alloys of immiscible elements, synthesis of alloys made from elements with widely different melting points, quasicrystals, amorphous phases, all sorts of compounds and composites. Moreover, it is amusing that the repeated fracturing and rewelding processes of powder particles, which occur in a mill, mix elements in a way reminiscent of chaotic transformations of the "baker" type. The synthesized materials, often with nonequilibrium structures, include, among others, crystalline materials with nanometer-sized grains, with a typical average size of ca. 10 nm. Besides materials synthesis, high-energy ball-milling is a way of modifying the conditions in which chemical reactions usually take place either by changing the reactivity of as-milled solids (mechanical activation [10–14]—increase of reaction rates, lowering of reaction temperatures of ground powders)—or by inducing chemical reactions during milling (mechanochemistry [10–14]). It is, furthermore, a way of inducing phase transformations in starting powders whose particles have all the same chemical composition: amorphization or polymorphic transformations of compounds, disordering of ordered alloys [12–14], etc., Mechanical alloying and grinding of materials are complex processes which depend on many factors, for instance on physical and chemical parameters such as the precise dynamical conditions, temperature, nature of the grinding atmosphere, chemical composition of the powder mixtures, chemical nature of the grinding tools, etc. This may partly explain why the theoretical problem of predicting nonequilibrium phase transitions under milling is still in debate.

High-energy ball-milling, which has been described in broad outline, is the central theme of this chapter. Its interest stems from a fortunate combination of technical simplicity and of complexity both of phenomena occurring during grinding and of mechanosynthesized materials. A fair and exhaustive review of all published contributions to the field of mechanical alloying and of mechanical milling would require thousands of pages (more than three papers are now published every day) and would discourage even those used to tackle frightening creatures. We decided thus to select topics which appear important in our eyes, to a large extent based on our own results, and to refer readers to networks, databases, journals, and complementary review papers devoted to mechanical alloying for more information [22–35]. By that choice, we run the risk not to "render unto Caesar that which is Caesar's" as it is further often difficult to find who is Caesar and what is really "that which is Caesar's," the literature sometimes being misleading on who did what first. Some 19th century papers on mechanochemistry have for instance been dug up only recently by Takacs (private communication). Further, many Russian (and some French, Japanese, etc.) papers on mechanical alloying and on mechanical grinding written in the 1960s and 1970s were (some probably are still) ignored, among others because the journals in which they were published were (and are) not very accessible. We apologize in advance to the authors who might think that they have not been given the credit they deserve for their work.

This chapter first describes some general characteristics and some applications of high-energy ball-milling. After having evoked some basic features of high-energy ball-milling

(Section 2), we shall present a few selected examples to illustrate the flexible use of these means of mechanochemical synthesis, in short mechanosynthesis, to transform and to synthesize materials, notably nanophased materials.

Phase transformations induced by milling in oxides (Section 3), mechanically activated annealing of transition metal silicides, mechanically activated self-heat-sustaining reactions (MASHS) of intermetallic compounds (FeAl, $NbAl_3$, $FeSi_2$, $MoSi_2$, $Cu_3Si$) (Section 4), and the synthesis route from mechanosynthesized powders to consolidated alumina–(Fe,Ti) composites (Section 5) will be discussed. Some investigations aimed at understanding the physical mechanisms at work during mechanosynthesis, particularly in systems for which thermal and mechanical energy compete, are finally considered in Section 6 (order–disorder) and in Section 7 (unmixing–mixing) respectively.

As mentioned, the main purposes of this chapter were to focus on particular features of mechanosynthesis/mechanical activation and to point out the strong advantages of such powder processings in terms of very versatile powder processings. Some formerly published reviews will kindly complete the given text [22–35]. Up to date references may also be found on the website of the Réseau Français de Mécanosynthèse [36].

## 2. TYPICAL INGREDIENTS OF HIGH-ENERGY BALL-MILLING

### 2.1. Milling Equipment and Experimental Conditions

Experiments are performed in various types of high-energy mills including for instance attrition mills (milling results from the stirring action of a rotating impeller with arms, horizontal in Fig. 1, which produces a relative movement between balls and powders), planetary mills, and vibratory mills [37] (Fig. 1).

### 2.1.1. Various Milling Machines

Planetary mills, for example, Fritsch commercial mills P5 or P7, or mills G5 and G7 designed by Gaffet et al. [37] (in which the rotation speeds of the vials $\omega$ and of the disc $\Omega$ can be varied independently; mill G5 is now sold by Fristch under the name "vario planetary mill P4"), vibratory mills

**Figure 1.** Various types of mills.

(e.g., Spex 8000), and mills with control by an external magnetic field (designed by Calka and Radlinski [38]) are the most widely used in laboratories.

In a planetary ball mill (Fig. 1a), a rotating disc bears vials which rotate in opposite directions. Both rotation speeds are of the order of some hundreds rpm (the maximum rotation speeds $\omega_m$ and $\Omega_m$ are 1000 rpm for the mills G5 and G7).

In a vibratory mill like the Spex 8000 mill, the vial is shaken at a frequency of $\sim$20 Hz in three orthogonal directions. The impact speed of balls is of the order of some m/s [39] and shock frequencies are about some hundreds of Hz.

### 2.1.2. Milling Media

Powders of the materials to be ground are introduced in the required proportions in a vial together with balls. Surface-active organic agents may be added to the powders to optimize the balance between welding and fracturing (see next section). They may give rise to a detrimental contamination of the ground powders by carbon.

The vial is generally sealed in a glovebox in various atmospheres (argon, nitrogen, air, etc.) or in vacuum. Nitrogen may, however, react with ground powders to form interstitial solid solutions or nitrides. Balls and vials are usually made of hardened steel, tungsten carbide, zirconia, etc.

Besides the previous experimental conditions, other important experimental parameters include the number of balls which depends on the mill and on the vial volume, the powder to ball mass ratio which is typically of the order of 1/5 to 1/50, the minimum time which is needed to reach a final stationary state, and the milling temperature which may be for instance conveniently varied in some vibratory mills [39–41].

The milling duration depends among others on the type of mill used, milling intensity, which sets for instance the rotation speeds $\omega$ and $\Omega$ in a planetary mill, milling mode (friction or direct shock), and milling temperature. It amounts typically to some tens of hours for most high-energy ball mills. Le Brun et al. [42] have modeled the MA process in planetary mills as a function of $\omega/\Omega$. They conclude that most commercial mills operate in a mode which involves friction on the inner wall of the vial and not impact.

## 2.2. Process Description

Figure 2 compares the typical average powers, in eV/at.s., involved in various processes applied to solid materials (the actual distribution of the injected power among atoms would have to be considered for more detailed comparisons) [37]. Ball-milling is seen to cover a convenient range of injected powers.

In the MA process of ductile powder mixtures of A and B, particles are trapped between colliding balls or between ball and vial and are subjected to a severe plastic deformation, which exceeds their mechanical strength, accompanied by a temperature rise. During collisions, powder particles are subjected to high stresses (of the order of 200 MPa for steel balls in a Spex mill) for times of the order of milliseconds [43]. The waiting period between such efficient trapping events is typically of the order of tens to hundreds of seconds [44, 45]. Particles are repeatedly flattened, fractured, and welded. Fracture and welding are the two basic events which produce a permanent exchange of matter

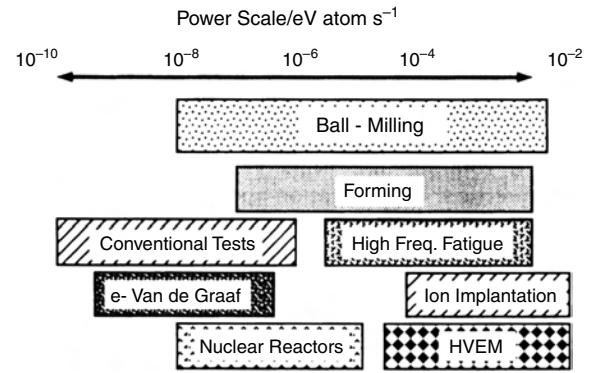

**Figure 2.** Typical average injected powers (expressed, in eV/at) for various processes.

between particles and ensure mixing of the various elements of ground powders.

A layered structure of A and B is thus formed and progressively refined and convoluted. Five typical stages of evolution of ductile powder mixtures are shown in Figure 3. A balance between coalescence and fragmentation is achieved during MA which leads to a rather stable average particle size. The mixture of constituents finally becomes homogeneous and the elements are mixed on an atomic scale.

In the case of brittle materials [46] the temperature rise of the powder surface plays a major role and thermal activation is required for MA to occur. In the latter case, a granular-type microstructure is observed. The temperature rise $\Delta T$ of metallic powders during MA is believed to be less than 300 K [46].

Mechanical alloying of mixtures of powders of pure elements or of powders of already partially combined elements has to be distinguished from grinding of materials whose chemical composition remains the same during milling but whose structure is expected to evolve. They may lead to distinct end products whose nature depends on the various parameters of such synthesis and transformation processes (i.e., as previously mentioned, the powder to ball mass ratio, the milling duration, the milling temperature).

Kinematic analyses have considered average shock energies, average shock frequencies [47], or ball momenta [41] to define dynamical parameters characterizing a milling

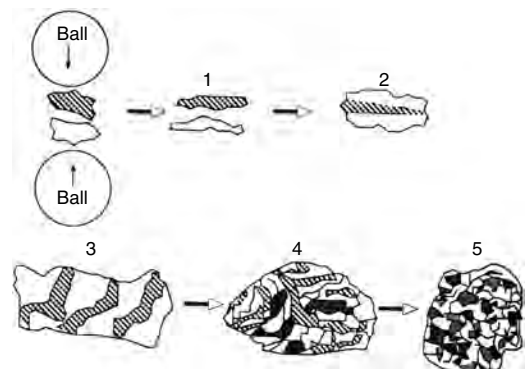

**Figure 3.** Steps of powder evolution during mechanical alloying.

experiment which are expected to be relevant for most mills. They lead to the definition of dynamical phase diagrams which describe, for a given milling temperature, the various phases which may be expected to form from an initial powder mixture according to the milling conditions.

## 2.3. Milling Machine Modelling

Various methods have been used to model the motion of balls inside mills, including analytical ones or a discrete element method [48]. They will be discussed in the next sections.

### 2.3.1. Planetary Milling Machines

From an historical point of view, the work of Joisel [49] is worth being mentioned as the first attempt (to the best of our knowledge) to study the shock kinematics of a "satellite milling machine," named in French "Broyeur à Satellites," and to design a "broyeur à satellites" working in a continuous way. Considering milling as a suitable way to comminute powders, the work was focused on the determination of the milling parameters which optimize shock energy. Fifty years ago, computers were not in current use as they are today. The various parameters were therefore determined geometrically and the theoretical predictions were checked experimentally using a specifically designed planetary mill. The specific powder area was measured as a function of the milling parameters.

Some industrial developments of such a mill can be found in a paper of Bradley et al. [50]. This paper reported some industrial developments related to a centrifugal mill. Such a three-tube vertically operated centrifugal mill was installed at Durban Roodepoort Deep in 1971. The weight of the mill rotor assembly, containing three satellite tubes, was 0.7 tons. The total ball charge was approximately of 70 kg. At 11 Hz, the apparatus drew 150 kW, equivalent to a very high power density in the mill of 2 MW per ton of balls.

The main aspect in terms of industrial development was the fact that the results of tests to date suggested that for mill powers up to 500 kW, it should be possible to construct a mill having a mass about one-tenth that of an equivalent convential mill (i.e., horizontal ball mill).

In such a centrifugal mill, it is shown that the power drawn is given approximatively by

$$\text{Power} \propto D^3 \times L \times G \times N^3 |R|$$

where $D$ is the inside tube diameter, $L$ is the inside tube length, $G$ is the gyration diameter, $N$ is the speed of rotation of the assembly, and $|R|$ is the absolute value of sun to planetary gear ratio.

**Ball Kinematics**   Many works have aimed to study the trajectories and the impact velocities of grinding bodies in planetary mills.

**Influence of the Ratio of the Planetary Wheel Speed to the Satellite Speed**   Schilz et al. [51, 52] have shown that the crucial role in milling performance is played, from a macroscopical point of view, by the geometry of the mill and by the ratio of the angular velocities of the planetary and

of the system wheel. Indeed, under the assumption of single particle movements, the trajectories and thus the impact energies of mass particles depend only on the ratio of planetary and system wheel radii and on the ratio of their angular velocities. In the case of the brittle–brittle Si–Ge system, the frequency ratio has to be set to achieve the maximum normal impact energy (i.e., to a value of $-2.5$), whereas for the ductile–brittle $Mg_2Si$ system, a higher frequency ratio is desirable. One related observation of the solid state mechanism which is mentioned by Schilz et al. is the fact that the alloy formation occurs via solid-state diffusion for the Si–Ge system whereas in the case of $Mg_2Si$ or $Mg_2(Si,Sn)$, alloying occurs on the surfaces of Mg particles.

For the ductile–brittle Mg–Si system [53], the efficiency of the planetary ball mill was found to be mostly influenced by the ratio of the angular velocity of the planetary wheel to that of the system wheel and the amount of load. It was demonstrated that a ratio of angular velocities of at least 3 (i.e., $\omega/\Omega$ is necessary to compensate the reduction of efficiency due to slip. Such a ratio has been found to lead to a separation of the milling balls from the vial wall and to a higher energy transfer into the powder.

The effect of rotational direction and rotation-to-revolution speed ratio in planetary ball milling has been studied by Mio et al. [54].

The discrete element method was used to calculate the effects on the specific impact energy of balls, of the rotational direction of a pot in a planetary ball mill, and of the rotation speed to the rotation speed of the disc.

The main conclusions of this work can be summarized as follows: The rotation of the satellites and of the disc in opposite directions rather than in the same direction can enhance the impact energy of balls up to large energies.

Specific attention has been paid to the *in-situ* study of the mechanically injected power during mechanosynthesis [55]. Magini et al. [55] have, for instance, clearly shown that the power consumption due to the milling action can be revealed by suitable electrical power measurements. In the case of single path cumulative reaction, the only factor governing the progress of the reaction is thus found to be the energy consumption during milling. Modifiyng the milling parameters but absorbing the same energy will lead to the same end product.

- The specific impact energy of balls increases with an increasing rotation-to-revolution speed ratio, but it falls about the critical speed ratio due to rolling motion.
- It is important to keep the milling conditions at the critical speed ratio for effective milling. The critical speed ratio can be estimated according to

$$r_c = ((R/l_c) - 1)^{-1/2}$$

where with $l_c$ is the distance from the rotating shaft to the centroïd of the ball that contacts with the mill wall, $R$ is the revolution radius, and $r_c =$ ratio of rotation-to-revolution speeds.

Based on the work undertaken by Mishra [56] studying the ball charge dynamics in a planetary mill, the coefficient of friction has been found to play an important role in the analysis of the charge. It is shown that the charge tends to

loosen when the coefficient of friction is high. Also, there is an increase in high-energy impacts with an increase in the coefficient of friction.

Based on a kinematic modeling of the planetary ball mill developed by Abdellaoui and Gaffet [47, 57], the kinematic equations giving the velocity and the acceleration of a ball in the vial have been determined. Theoretical and experimental dynamical phase diagrams for ball-milled $Ni_{10}Zr_7$ were obtained and comparisons of the calculated to some experimental results show that neither the shock energy nor the shock frequency, separately taken into account, governs the end product but only the injected shock power is responsible for the ball-milled end product.

***Effect of Filled Vial Fraction*** Based on computer simulation analyses of the milling process in a planetary ball mill carried out by by Shelekhov et al. [58], the nature of ball motion in a vial of a planetary ball mill was concluded to depend strongly on the filled fraction. When it reaches 55%, a transition takes place from a motion of balls in aggregation to the effect of their spread on the vial wall. This effect is accompanied by an abrupt decay of energy dissipation and temperature.

An increase of the ball size at a given filled fraction in most cases results in an increase of energy dissipation and temperature. By varying the filling factor, it is possible to modify the character of action on the materials from abrasion to shock strain.

### 2.3.2. Vibratory Milling Machine (*Shaker*)

Shulin et al. have focused attention on the impact dynamics of a vibration rod mill [59]. A mathematical model of the vibration system is determined by the principal and subharmonic impacts of the grinding media which consist of balls or of rods made of various materials. An impact acts on the system not only as an excitation, but also as damping. The changing rate of the impact mass is proportional to the exciting frequency.

### 2.3.3. Tumbling Milling Machine

Several works have been devoted to the determination of the motions of balls or barrels in tumbling milling machines [60–62].

Considering the work of Raasch [60], if the grinding bodies are small in comparison to the mill shell diameter, it is reasonable to consider their motion as that of point masses. Such a point mass $P$ is subjected to two forces, a gravity force $Fg$,

$$Fg = mg$$

and a centrifugal force $Fc$,

$$Fc = mR\omega^2$$

where $R$ is the mill shell radius and $\omega$ is its rotation speed.

At the point of projection (defined by an angle so-called hereafter $\alpha_0$), the radial component corresponding to the sum of the two forces has to be equal to zero. That is,

$$mR\omega^2 - mg \cos \alpha_0 = 0$$

leading to

$$\cos \alpha_0 = R\omega^2/g$$

As mentioned by Raasch, for grinding bodies located on different radii $R$, different angles of projection $\alpha_0$ are obtained. The locus of the points is a semicircle of diameter

$$y_c = g/\omega^2$$

that is, a semicircle, which is known as the Davis circle.

Considering such a circle, a critical value of the speed rotation, $\omega_c$, is reached when the outermost layer of grinding bodies is no longer projected. For example, with

$$R = D/2 \quad \text{and} \quad \alpha_0 = 0$$

it gives

$$\omega_c = (2g/D)^{-1/2}$$

As discussed by Raasch [60], it should be stressed that a precise theory of the grinding body motion in a conventional ball mill does not exist. The simplest theory is suitable to describe such motion when the mill filling is cataracting (i.e., in the case of moderate fractional mill fillings and relatively high rotation speed). In the case of larger fractional fillings and lower speeds, the mill filling is essentially rolling in itself. Such a behavior cannot be described by any of the existing theories, as claimed by Raasch [60].

It has been shown experimentally that the grinding effect of a conventional ball mill in dry milling of hard products is greatest if the ratio of rotational speed $n$ to its critical value $n_k$ is chosen as approximately $n/n_k = 0.76$, corresponding to an angle of projection $\alpha_0 = 54.7°$ for the outermost layer of grinding bodies.

A method for simulating the three-dimensional motion of balls under the presence of a powder in a tumbling ball mill has been developed by Kano et al. [63]. The method is based on the particle element method and a coefficient of friction of colliding balls is the key to simulate the motion under powder filling. Such a model has been applied to four kinds of samples (i.e., glass beads, silica, aluminum hydroxide, and kaolinite powders).

Based on video recorder observations of the movement of the balls without and with powders, the actual movement of the grinding media has been found to depend on the kind of sample. The variation of the movements can be calculated by the given method by choosing a suitable coefficient of friction for each sample. The one for kaolinite (the largest one) has been found to be four times larger than that in grinding without powder.

The notion of critical rotation speed for ball-milling using a tumbling machine has been considered by Watanabe [64].

Based on some previous observations made in 1957 by Rose and Sullivan, the following events may be observed as the rotation speed increases: distinct avalanche, continuous avalanche, cascading motion, cataracting motion, and centrifugal motion. In this final stage, the outermost layer balls are placed stationarily with respect to the inner wall of the vial, the corresponding rotation speed being called the critical rotation speed.

Based on the results of the discussed work, it has been shown that the critical rotation speed significantly depends on ball-containing fraction in jars and approaches a value asymptotically as the ball-containing fraction approaches one. This asymptotic value is equal to the traditional critical rotation speed. The effect of individual rotation of the ball of the jar is significantly small to centrifugal motion.

## 2.4. Effective Mechanical Energy Transfer/Shock Events

In the earliest 1990s, Maurice and Courtney reported on the physics of mechanical alloying [65]. Based on their idea, the mechanical alloying process has been modeled on the basis of a perturbed Hertzian impact. The powder particles are presumed to only mildly alter the elastic collision between the grinding media.

Specific aspects of the developed model [66] (consider a porous powder cylinder impacted between colliding work-pieces having a relative collision velocity) depend on the choice of the milling machine. The cylinder radius and the duration of impact are defined by the Hertzian impact theory. Two milling machines have been considered, a Spex milll and an attritor.

In the case of the attritor, the average ball velocity has been estimated to be 2/3 the maximum velocity (i.e., 0.53 m/s). For the Spex shaker mill, the value of the ball speed has been determined as being equal to 3.9 m/s. The ball speed for a horizontal ball mill has been given as ranging from 4.4 to 6.3 m/s for commercial drums varying from 1 to 2 m in diameter.

Ten years later, from the analysis by Chattopadhyay et al. [67], it emerges that the role of velocity components of the ball at the instant of its impact on the vial wall warrants proper consideration, because the tangential force determines the lower bound of the vial-to-disc speed ratio conducive for effective transfer of impact energy to the powder charge in the mill. A comparison of the experimental results of grain size reduction during milling of an elemental Fe and Cu all powder mixture with the similar predictions of the given analysis demonstrates that elastic properties of the balls and vials play an important role in determining the rate of structural refinement during ball-milling.

Szymanski and Labaye [68] have investigated the energy dissipation in the dynamics of a bouncing ball based on a one-dimensional model consisting of a rigid wall, a vibrating plate, and an object moving horizontally between the wall and the plate. The dynamics of such a model has been studied on both numerical and experimental approaches. Three types of behaviors have been observed:

(1) high energy periodic modes which exhibit period doubling routes to chaotic solutions with nearly unchanged energy characteristics,
(2) short period chattering and locking in which a small amount of energy is dissipated,
(3) chaotic or long-period modes.

The first type is called resonant, the others nonresonant. A remarkable gain of shock power is observed in the simulation as well as in the experimental approach when the system enters into a resonant mode.

A nanocomposite mechanical approach has been proposed by Rahouadj and Gaffet [69] to investigate the shock transfer. Such a model is based on the nanostructural aspect of the ball-milled materials and therefore on the transfer of a macroscopic mechanical power (induced by the milling ball) to the materials exhibiting nanometer size structures.

The latter are assumed to consist of rheological assemblies (serial and parallel features). Such a mechanical approach based on the cyclic loading response allows one to understand the effective saturation of the phase transition which may be introduced by mechanical alloying or ball milling.

The main results are as follows:

(1) The energy which is dissipated at each shock drastically decreases as a function of the number of shocks. By assuming that the microstructural transformation $M \Rightarrow nM$ depends on this transfered mechanical energy, the probability of transformation has been found to become maximum during the first shocks.
(2) The parallel model reveals a qualitative occurrence of internal stresses from the first shocks. The amplitude of theses stresses tends to decrease as a function of the number of shocks.

The investigation of the effect of powder on the impact characteristics between a ball and a plate using free falling experiments has been developed by Huang et al. [70]. Based on the results of such a study of the effects of milling conditions, including impact velocity, ball size, and powder thickness, on the coefficient of restitution and impact force, it is noted that the powder has a significant influence on the impact process due to its porous structure. Such an effect has been demonstrated using a modified Kelvin model. When the powder thickness is increased, the buffer effect of the powder is enhanced, thus resulting in a decrease of the magnitude of the impact force and an increase of the impact duration.

The second main point of this work has been to show that the impact force is a relevant parameter for characterizing the impact event due to its sensitivity to the milling conditions.

Another interesting feature occurring during milling is fracturing which may occur at contact surfaces subjected to normal and tangential loads. Such a feature has been investigated by Shah and Wong [71].

The partial-slip situation increases both tensile and shear stresses even though the contact is subject to the same forces and shows the importance of the friction coefficient at the contact. During unloading of the tangential force, the location of maximum tensile stress moves away from the trailing edge toward the center and may be responsible for surface damage during cyclic loading. The critical fracture load required for the development of a hertzian crack system is reduced significantly by the tangential load application. The spacing, which is the inverse of surface fracture density, reduces with applied loads and also with friction coefficient.

Some other investigations have been performed to study the energy transfer. Local modeling of a collision event, coupled with a classical thermodynamic assessment of the $Fe_2O_3$–$Fe_3O_4$ system, was used by Zdujic et al. [72] to rationalize the experimental results. It is proposed that

the mechanochemical reactions proceed at the moment of impact by a process of energization and freezing of highly localized sites of a short lifetime. Excitation on a time scale of $10^{-5}$ s corresponds to a temperature rise of the order $(1–2) \times 10^3$ K. Decay of the excited state occurs rapidly at a mean cooling rate higher than $10^6$ K/s.

### 2.4.1. Milling Induced Vial Heating (Milling Temperature)

In the case of experimental work performed by Xu et al. [73] studying the deformation-assisted decomposition of an unstable $Fe_{50}Cu_{50}$ solid solution during low energy ball-milling, the experimental results are interpreted in terms of an effective-temperature model which has been adapted from former models applied to irradiated alloys.

The Fe–Cu system has been selected as a model alloy to examine the transformation kinetics and steady state during ball-milling.

The precipitation kinetics has been determined to be significantly enhanced by milling-induced deformation, despite the reduced driving force due to the homogenizing effect of the deformation.

In contrast to irradiated materials, the ballistic interdiffusion coefficient has been found to be strongly dependent on microstructure in the case of ball-milled materials. Such a behavior results in a time dependent effective temperature, leading to a nonmonotonic decomposition behavior.

The ball temperatures during mechanical alloying in planetary mills have been investigated by Kwon et al. [74]. The temperature rise during milling is mainly due to ball-to-ball, ball-to-powder, ball-to-vial wall collisions, and frictions. An implementation to take into account is the exothermic contribution of the reaction involving the component powders which have been introduced in the vials.

The influence of the ball temperature on the MA process was demonstrated in the case of the $Mg_{67}Ni_{33}$ and $Ni_{50}Al_{50}$ powder blends. Based on a calorimetric technique, the temperature of balls has been estimated during mechanical alloying in a planetary ball mill. The major comment from Kwon et al. is that the temperature distribution during mechanical alloying is more complicated than a simple overall temperature in the vial and local temperatures due to the collisions. An essential difference has been found between the ball temperature and the vial wall one, except for cryomilling. The ball temperatures have been found to increase with increasing milling power and ball diameter. A decrease has been observed when increasing the total surface of the balls, heat conductivity, and gas pressure in the vials. A specific high temperature rise up to 600 °C has been determined in the case in which compact milled powder layers are formed on the ball surface and on the vial wall. In the case of free powders, a decrease of the ball temperature has been observed.

### 2.5. Particle Evolution during Milling/Macroscopic Model

A model, based on the modified isoconcentration contour migration, has been developed by Pabi et al. [75] to predict the kinetics of diffusive intermixing in a mechanically alloyed binary miscible system. The as-discussed model takes into account the variation of the diffusion coefficient with composition, and an interface shift induced both by the species interdiffusion and the mechanical deformation. Based on a comparison with the experimental investigation of the ball-milling induced behavior for the Cu–Ni and Cu–Zn systems, it has been shown that the effective mass transport which is operative during mechanical alloying reaches a rate intermediate between that for volume and grain boundary diffusion.

The use of an effective temperature, $T_{eff}$, for such a diffusive alloying is proposed. $T_{eff}$ has been found not to depend on the localized temperature rise at the point of ball-to-powder impact but rather on the alloy composition, being related to the liquidus of the studied mechanically alloyed systems.

To determine the correlation of size reduction rate of inorganic materials with impact energy of balls in planetary ball-milling, room-temperature planetary ball-milling of four kinds of powder materials has been selected based on the grindabililty (i.e., talc, gibbsite, limestone, and quartz).

It has been found by Kano et al. [76] that the size reduction rate ($K_p$) of each material is proportional to the specific impact energy of the balls.

The specific impact energy is defined as

$$E_w = (n^* \times m \times v_r^{*2})/(2 \times W)$$

where $n^*$ is the number of collisions of a ball against another ball or vial wall per second, $V_r$ is the relative speed of the balls, and $W$ is the weight of powder put in the vial.

$K_p$ is expressed by $AE_w$, where $A$ is a proportional constant, inversely proportional to net work index, which is calculated by substituting $E_w$ instead of the required energy in Bond's equation.

Several empirical energy laws on communition have been proposed and one of them is known to be the third theory proposed by Bond [77], given by

$$W_b = 10W_i\big(1/P_{80}^{1/2} - 1/F_{80}^{1/2}\big)$$

where $P_{80}$ and $F_{80}$ are the 80% product and feed size respectively. $W_b$ is the energy required to reduce the particle size from $F_{80}$ to $P_{80}$ and $W_i$ is the work index.

Many papers have described the particle size distribution of powder during mechanical alloying and communition [78, 79]. Harris et al. [80] compared different models of mechanical alloying.

Five potential models describing the particle size distribution of powder during the mechanical alloying process were analyzed. Such models are based on Smoluchowski's coagulation–fragmentation equations and use a range of size dependent aggregation and fragmentation rates.

The first model (model 1) is the simplest one, having no size dependence. The aggregation and fragmentation rates are constant. As mentioned by Harris et al. [80], such a model is very similar to the one previously developed by Aikin and Courtney [81].

Models 2 and 5 generalize model 1, using aggregation rates that are size dependent while maintaining a size-independent fragmentation rate. In model 2, the aggregation rate is proportional to the sum of the sizes of particles or

equivalently the size of the agglomerate formed. In model 5, the rate is supposed to depend on the product of the sizes of the particles before combination.

Models 3 and 4 also use size-dependent aggregation rates, but introduce size-dependent fragmentation as well.

The rates used in models 2 and 3 increase more slowly with size, suggesting that smaller particles will aggregate more readily than larger ones when involved in collision.

Models 4 and 5 are unsuccessful because they predict that some proportion of the material will form infinitely large particles early in the process. Such models are better suited for materials that aggregate readily during milling.

A discrete event molecular dynamics simulation engine was developed to investigate the collision rate and energy transfer of shaker ball mills [82]. The input parameters of the model include geometry of the cylinder, filling ratios, and ball characteristics. It has been shown that the end product distribution of the particle radius is almost independent of the initial particle radius (i.e., the milling rate is significantly higher for larger particles). It has also been observed that the milling rate is independent of the amount of materials put into the mill.

Based on a nonlinear elastoplastic model for collisions between solid particles, the average impact duration, force, geometry, the normal and tangential velocities, and normal and tangential stresses have been calculated [83, 84].

Such results of the given approach were used to determine the $t - p\, T$ conditions of mechanochemical processes in grinding machines (pressure and temperature pulses in the contact area of particles). The results of their investigations show that the physicochemical effect of mechanochemical reactors is due to brief pressure ($10^9$–$10^{10}$ Pa) and temperature pulses. The largest temperature pulses (up to $10^3$ K) are associated with dry friction. For micronic particles, the characteristic length and time of the process are $10^{-8}$ m and $10^{-8}$ to $10^{-9}$ s.

In some work performed by Gonzalez et al. [85], the particle size has been found to not depend on intensity but on milling time for all the investigated mill configuration conditions. The elastic and plastic energies are exponentially dependent on the impact frequency and this has a marked effect on the efficiency of alloy formation. In addition, the change of the milling frequency has been found to allow a control of the time for alloy formation in the case of the Fe–Al system, ball-milled using a Spex machine.

## 2.6. Local Effect/Microscopic Model

In a recent paper, Tian and Atzmon have studied the kinetics of microstructure evolution in nanocrystalline Fe powder during mechanical milling [86]. A phenomenological model has been proposed based on the assumption of simultaneous grain refinement and grain growth. The weak temperature dependence of the grain-growth term is consistent with nonequilibrium vacancy production. Based on the results of such an approach, it has been shown that the efficiency for refinement and vacancy production decreases with increasing vibration amplitude.

Nevertheless, the main conclusion of the aforementioned paper is that the detailed mechanisms of grain refinement and growth need to be explored to better understand the formation of nanocrystalline materials during ball milling. In the next, selected contributions will be discussed.

The model developed by Schwarz [87] is based on dislocation kinetics and the diffusion of solutes along the dislocation cores. Such a developed model is based on jerky dislocation kinetics (i.e., short gliding times separated by long waiting times) and solute diffusion along dislocation cores during the waiting times.

During MA, the dislocations act as solute-pumping stations which introduce solutes into crystalline lattices even in the presence of a chemical energy barrier. In response, the solutes diffuse into the dislocation cores and populate the cores forming linear solute chains. When the dislocations are mechanically forced to move, they leave behind rows of substitutional solutes in an otherwise perfect lattice. Therefore, the lattice is locally left in a state of high supersaturation. Such a mechanism is named dislocation solute pumping.

As discussed by Pochet et al. [88], two main features have been investigated: atomistic scale modeling of coherent phase transformation and evidence of milling enhanced precipitation. Atomistic modeling reveals unique features of the microstructure in crystallites under milling: depending on the conditions of the latter, stationary microstructures are stabilized, at variance with thermal equilibrium. These microstructures are characterized by a stationary coherency length. In the case of a positive heat of mixing, the latter length has been found to continuously evolve with the shear frequency and temperature.

In the ordering case, the amount and geometry of the chemical disorder introduced by each shearing event, as well as the number of injected vacancies, are found to have important consequences on phase stability in such dynamical systems. Dynamical transitions between microstructures are observed rather than transition between phases. Such an atomistic model has been applied to the Ni–Ge system.

Pochet et al. [89] have explained that phase transformation under ball-milling can be addressed from the theoritical point of view, as transitions between stationary states of a driven alloy: shear induces some sort of disorder which is annealed by thermal diffusion, between two shearing events. This type of problem has been modeled in great detail in the context of irradiation effects on phase stability of alloys.

Depending on the milling temperature and intensity, it has been found in the case of the Fe–Al system that the crystallites are either in an ordered state with the B2 structure or disordered as body-centered cubic (bcc) solid solution (A2). In the ordered state, the degree of order has been observed to reach a steady state value, depending in a reversible way on both the temperature and the milling intensity: the higher the intensity or lower the temperature, the lower the steady degree of order.

As predicted by their model, the order–disorder transition which is of second order at equilibrium can become of first order under appropriate milling conditions.

Such a driven alloy theory has also been used for the precipitation–dissolution reaction under ball-milling. From atomistic Monte Carlo simulations, it is noted that stationary mesoscopic microstructures can be stabilized and that their characteristic length scales can be adjusted by tuning the milling conditions.

In a complementary work, Wu et al. [90] have studied the forced mixing and nanoscale decomposition in ball-milled Cu–Ag characterized by atom probe field ion microscopy (APFIM). Statistical analyses of the atom probe field ion microscopy yield the degree of mixing induced by ball-milling in the Ag–Cu system (equiatomic composition). Atomic composition has been determined as a function of the length scale. These results have been compared with the ones obtained from kinetic Monte Carlo simulations. The model one is a kinetic Monte Carlo algorithm with competing dynamics. In these simulations, thermally activated vacancy migration promotes phase separation of an $A_{50}B_{50}$ binary alloy, which consists of immiscible elements distributed on a face-centered cubic (fcc) rigid lattice, whereas shears, produced at a controlled frequency along randomly selected glide systems of the fcc lattice, homogenize the composition field.

The experimental investigations provide direct confirmation of the near random mixing obtained for the 85 K milling and of the nanoscale decomposition for the 453 K milling. APFIM also evidences the presence of long-range composition heterogeneities, at scales larger than 10 nm, for all the studied temperatures (i.e., 85, 315, and 453 K). A comparison of the observed features has been found to stress the merits of such simulations but also their limitations.

Based on a different approach, Badmos and Bhadeshia [91] have investigated the evolution of solutions by the way of a thermodynamic analysis of mechanical alloying.

To analyze the various mechanisms occurring during the mechanical alloying process, the purpose of the work is to examine the way in which a solution is created by continuously refining a mixture of powder particles composed of pure elements, from a purely thermodynamic point of view.

Based on the results of such a model, it is predicted that solution formation by mechanical alloying of solid components cannot occur unless there is a gain in coherency as the particles become small. In complement, the formation of a metastable state prior to the achievement of full solution may be achieved when the component atoms prefer like neighbors.

Strain-induced structural changes and chemical reactions have been investigated from thermomechanical and kinetic models by Levitas et al. [92]. Strain induced chemical reactions are experimentally observed in shear bands for both Ti–Si and Nb–Si mixtures. One of the aims of the discussed paper is to find, theoretically, whether there are possible macroscopic mechanisms of intensification of the observed chemical reactions due to plastic shear in the solid state.

The class of structural change (SC) without stable local temperature state is treated. The SCs are considered as a process of variation of the transformation deformation gradient in an infinitesimal final volume from the initial to final value which is accompanied by a jump in all thermomechanical properties. The kinetics of a thermal SC can be described in terms of applied stresses, deformations, and temperature, rather than real time. A thermodynamically consistent kinetic theory of thermally activated SC is suggested. A specific approach has been developed considering the time of structural change in some transforming volume instead of known approaches describing kinetics in terms of rate of phase volume fraction change. The former is consistent with

the standard method of nonequilibrium thermodynamics which relates conjugate force and rate in the expression for dissipation rate. The discussed model leads to the threshold-type generalizaton of Arrhenius-type kinetics in which the actual activation energy includes the driving force, dissipative threshold, and surface energy. By introducing such an effective temperature, it has been taken into account that temperature can vary significantly during SC.

Some years ago, Gilman [93] suggested that elastic shear strain can accelerate the chemical reactions by lowering the highest occupied bonding molecular orbital/lowest unoccupied antibonding molecular orbital energy gap.

Another major effect of energy/power threshold is the capability to initiate self-propagating high temperature synthesis during milling. Attention has been paid the synthesis and formation mechanisms of molybdenum silicide by mechanical alloying [94].

The milling energy was calculated using a collision model and the milling energy maps were attained. Results showed that when the effective extensive factory is above 1.06 J/g s, the formation mechanism of $MoSi_2$ by mechanical alloying is a self-propagating high-temperature synthesis one. Otherwise, when it is below 0.917 J/g s, the formation mechanism of $MoSi_2$ is a diffusion solution.

# 3. GRINDING OF ELEMENTAL POWDERS

## 3.1. Introduction

Ball-milling of elemental powders has been thoroughly investigated in various conditions of energy transfer to identify the mechanisms by which materials deform to produce nanometer-sized grains, characterize the intergranular and intragranular defects of nanograined ground powders, and measure the resulting changes in properties with respect to those of coarse-grained elements, for instance mechanical, magnetic, hydrogen storage capacity [95–126]. Notable examples are bcc metals (Cr, Fe, Nb, Mo, W), fcc metals (Al, Ni, Cu, Rh, Pd, Ag, Ir), hexagonal close-packed metals (Mg, Ti, Co, Zn, Zr, Ru, Hf) [95–136], semiconductors Si, Ge, and graphite [137–146].

In most cases, the crystallographic structure of the starting element remains unchanged when grain size decreases down to an average size $d$ of ca. 10 nm, the typical size reached in classical high-energy laboratory mills. Phase transformations may, however, take place; for instance bcc Nb has been reported to be transformed into fcc Nb [130] while Si, Ge, Se, and graphite are partially or totally amorphized [137–146]. To establish the very nature of the observed structural transformations, it is, however, essential to analyze the possible consequences of the unavoidable contamination of ground elements. During milling, impurities may indeed be incorporated in the starting elements from solids constituting the milling tools (ex: hardened steel, tungsten carbide, zirconia, etc.), from gazes of the milling atmosphere (argon, nitrogen, hydrogen, air, etc.), or from elements physi- or chemisorbed on starting powder particles. Contamination may further occur during air exposure of as-milled powders. For instance, the uptake of argon, oxygen, nitrogen, and iron and their consequences on the formation

of disordered phases at grain boundaries or on the formation of nitrides has been been followed during milling of molybdenum in various atmospheres [136]. Finally, mechanical characteristics of powders may change significantly during milling because of the grain size decrease (Hall–Petch relation for example). The flow stress of ground and consolidated Fe powders with a grain size of $\sim$80 nm is for instance about twice that of coarse-grained Fe at strain rates of $\sim$$10^3$–$10^4$/s [147] which are typical of the compression rates of particles trapped during milling between colliding bodies. More importantly, such changes cause a decrease of the energy transferred from balls to powders [148].

## 3.2. Grain Size Reduction

Ball-milled crystalline materials have grain sizes generally in the range from $\sim$5 to $\sim$30 nm. Most often, for instance in metallic materials, the average size of as-milled powder particles is, however, not in the nm range but typically micronic or submicronic as a result of a steady-state equilibrium between fracture and welding. Every powder particle includes many nanograins, $\sim$$10^6$ grains/$(\mu m)^3$, and may thus be considered as a textureless polycrystal with a large density of grain boundaries. Brittle or ductile elements may, however, exhibit particle size distributions which are shifted significantly downward or upward respectively. Such shifts reflect the modifications of the aforementioned steady-state equilibrium. A predominance of cold-welding over fracture results for instance in the formation of millimeter-sized hollow particles, up to 10 mm in diameter, which contain themselves smaller particles (Russian Doll effect) when "grinding" a copper powder with a micronic average particle size [100]. Milling particles of Al and of Zn with a starting size of 50 $\mu$m similarly yields millimeter-sized particles [133].

At high strain rates, the deformation of the starting coarse-grained particles is localized in shear bands which contain a high density of dislocations. The subsequent recombination of dislocations to form a nanosized cellular structure with small-angle grain boundaries, which are in turn replaced by higher angle grain boundaries through grain rotation, is a proposed scenario for the development of a nanocrystalline microstructure [101, 102, 107]. The fragmentation and the reorientation of crystal volumes at the nanometer level may occur through the generation and interaction of partial wedge disclinations which have been observed in ball-milled bcc Fe by high-resolution transmission electron microscopy [127]. In fcc Cu, twinning is the preferred mode of deformation when the average grain size becomes smaller than some critical value [117]. The crystallite size of ball-milled metals decreases rapidly with milling time but reaches a saturation value with prolonged grinding. A balance between the defect structure produced by plastic deformation and its rate of recovery by thermal processes explains the latter. A phenomenological model based on the assumption of simultaneous grain refinement and grain growth was for instance applied to low-energy ball-milling of Fe, evidencing further the role of nonequilibrium vacancy production [114]. Oscillatory variation of the hardness with milling time is observed in cryomilled nanocrystalline Zn [134]. Large variations in the dislocation density and grain-size distribution occur during cryomilling as a result of recrystallization which takes place in larger grains when the dislocation density due to strain-hardening reaches a critical level. Similarly, the reduction of grain size of ball-milled Mg down to 42 nm occurs by twinning and retwinning within the grains developing subgrain boundaries. The relatively large minimum grain size obtained for ground Mg as compared to other metals and the associated low internal strain value are due to the occurrence of recovery processes during milling of this low melting temperature metal [135].

The stationary grain size reached during milling, from $\sim$25 nm for Al and Ag to $\sim$6 nm for Pd, scales inversely with the melting temperature when the latter is below $\sim$1800 K [98, 107]. For higher melting temperatures, it appears that $d$(fcc) $< d$(bcc) $< d$(hcp) independently of the mill energy [107]. The grain size is most often derived from X-ray diffraction patterns whose line broadening further yields strain values which depend on $d$ and have typical values of some 0.1%.

## 3.3. Defects

### 3.3.1. Grain Boundaries

Nanostructured materials (NSMs) have a significant fraction of atoms residing in defect environments. The volume fraction associated with grain boundaries (GBs) is for instance $\sim$20% for a grain boundary thickness of $\sim$0.7 nm, as found from computer-generated $n$-Ni [149], and a grain size of 10 nm. For grain sizes less than $\sim$10 nm, the volume fraction of triple junctions becomes significant and may influence some properties, for instance the mechanical properties. The understanding of the structure of grain boundaries and of the nature of intragranular defects in nanostructured materials benefits from high-resolution electron microscopy experiments and from computer simulations. Molecular dynamics is currently used for investigating the nature of grain boundaries in nanostructured materials which is still in dispute between the defenders of amorphous models [150, 151] and those who conclude that they are similar to grain boundaries of coarse-grained materials [152, 153].

From transmission electron microscopy (TEM) observations, Li et al. [117] conclude that most grain boundaries in NSMs prepared by nanocrystallization of amorphous alloys, inert-gas condensation, *in-situ* consolidation, and mechanical alloying are similar to grain boundaries in coarse-grained materials. Grain boundaries with a disordered structure are frequently observed in samples prepared by the last two methods [117]. The structure of grain boundaries might, however, change when thinning samples for TEM observations [153]. Measurements of bulk properties are thus of great interest to provide additional information on interface structure. The self-diffusivity of consolidated $n$-Fe and of $n$-Pd is for instance measured to be close to that expected for conventional grain boundary diffusion from the extrapolation of high-temperature data ($\sim$$10^{-20}$ m$^2$/s for $n$-Fe with $d \sim 20$ nm at 500 K) [154]. Kolobov et al. [155] investigated recently the diffusion of copper deposited on the surface of coarse-grained cg-Ni ($d \sim 20$ $\mu$m), of ultrafine uf-Ni ($d = 300$ nm) prepared by equal channel angular extrusion, and on the surface of $n$-Ni prepared by electrodeposition ($d = 30$ nm). The Cu diffusivity, which is $4.3 \times 10^{-19}$, $9.6 \times 10^{-15}$, and $3.8 \times 10^{-17}$ m$^2$/s for cg-Ni, uf-Ni, and $n$-Ni at 423 K, is not found

to be faster for the smallest grain size. The higher diffusivity in $n$-Ni than in $gc$-Ni is attributed to triple junctions. Copper diffusion is concluded to be primarily determined by the GB structure and not by the volume fraction of interfaces. Not surprisingly, the "structure" of grain boundaries in a given NSM depends on the nonequilibrium method used to synthesize it and in turn influences its properties. Significant changes of strength and of ductility occur for instance when going from electrodeposited $n$-Cu with low-angle grain boundaries to $n$-Cu with high-angle ones, both with $d \sim$ 20 nm [156, 157]. The formation of a work-hardened layer along the grain boundaries, which is expected to depend on the GB structure, modifies the mechanical characteristics of NSMs [158]. A phenomenological model which represents then NSMs as composite materials exhibits an inverse Hall–Petch behavior [159] and a trend to strain localization with a limited ductility when $d$ decreases [158]. High-energy GB configurations, with their associated high densities of GB defects and dislocations, are argued to induce large microstrains in their vicinity [160]. An overall microstrain release occurs without grain growth by annealing of $n$-Cu synthesized by magnetron sputtering and reflects changes of the GB microstructure. It is accompanied by a decrease of the linear thermal expansion coefficient $\alpha$ from 16.6(2) $10^{-6}$ to 15.0(2) $10^{-6}$ K$^{-1}$ (80 K $\leq T \leq$ 290 K) when the strain decreases from 0.24% to 0.14% [160]. A similar decrease of $\alpha$, associated with GB relaxation, was found during milling of Fe [126]. Finally, an enhanced thermal stability of NSMs has been predicted theoretically as a consequence of the redistribution of the excess volume of grain boundaries during grain growth [161] and has been verified quantitatively for ball-milled $n$-Fe between 750 K and 960 K [162].

### 3.3.2. Intragranular Defects

Recent TEM observations led to the conclusion that grains of NSMs prepared by the *in-situ* inert gas condensation and consolidation method or by nanocrystallization of bulk amorphous alloys are defect-free while grains of mechanically alloyed NSMs contain dislocations in their interior or at the GBs and twins [117]. The density of dislocations is $\sim 5 \times 10^{15}$ m$^{-2}$ in $n$-Cu (cfc) with $d$ between $\sim$15 nm and $\sim$30 nm, $\sim 5 \times 10^{15}$ m$^{-2}$ in milled $n$-Ti (hcp) with $d \sim 9 \pm 3$ nm and $\sim 10^{16}$ m$^{-2}$ for milled $n$-Fe (bcc) with $d = 8$ nm, that is $\sim$1 dislocation with a length of $\sim$10 nm per grain [126, 131]. These dislocation segments are in any case too short to be glissile and to be involved in plastic deformation. Nanovoids are observed by TEM in local regions of various NSMs [117]. Pores are often considered as major artifacts from two-step synthesis methods which involve a final consolidation stage to prepare bulk samples from powders in order to reach the highest possible density while avoiding a significant coarsening of nanosized grains [163]. The free volume in $n$-Ni, synthesized by different techniques, inert gas condensation (two steps), electrodeposition, and high-pressure torsion (one step), has been very recently studied by TEM and positron lifetime spectroscopy [164]. Experimental results show the presence of nanovoids of 12–25 vacancies which can be located inside the grains, in the GBs, or in the triple junctions. Even in the fully dense samples, 1–2 nm sized pores as well as smaller nanovoids were observed suggesting

that these nanovoids are actually intrinsic defects of nanostructured materials [164].

The enthalpy stored in a ball-milled metal, with its high density of grain boundaries and intragranular defects, is a large fraction, typically $\sim$20%, of the enthalpy of melting which is not achieved in materials processed with conventional cold working methods [95, 98, 106, 107, 111]. The stored elastic energy associated with disclination defects has recently been suggested to be partly responsible for the high enthalpy found for ball-milled Fe (15% of the enthalpy of melting [95]) [127]. Finally, the stored enthalpy was found to decrease during milling of Fe because of a GB relaxation process taking place during the stage of the steady-state grain size [126].

## 3.4. Grinding of Transition Metals, Notably of Fe

### 3.4.1. Experimental Results and Difficulties

Besides its theoretical and applied importance either as a metal or in combination with all kinds of elements to form alloys and compounds, iron is further an almost unavoidable element in ball-milled materials when they are ground with steel tools. All these reasons explain that milling of elemental iron has been and is still of widespread interest [95, 103, 106, 108–115, 117–126]. The difference in the interfacial energies of $\alpha$-Fe and of $\gamma$-Fe might favor fcc $n$-Fe over bcc $n$-Fe at room temperature when the grain size is sufficiently small [128]. A bcc $\to$ fcc transformation was recently reported to occur in ground elemental Nb when $d$ becomes smaller than 10 nm [130]. A significant amount of contamination by C, N, and Fe was, however, found. These elements were assumed to remain mostly dissolved in the final fcc Nb phase [130]. It would be worth examining if such solute elements may influence the fcc $\to$ bcc transformation.

Because of its interest in cemented carbides, the cobalt cubic to hexagonal transformation produced by wet milling of WC and Co was studied by Kimmel [165]. The extent of the transformation was reported to depend on both milling intensity and initial carbide particle size. The allotropic transformation induced by dry ball-milling of cobalt was also investigated [166–170]. After milling for a few hours, Cardellini and Mazzone [166] observed that the hcp phase transforms to a disordered phase composed of an essentially random stacking of close-packed planes. They further concluded that prolonged milling does not affect the stability of this phase up to the point where iron contamination induces the transition to the fcc structure. As emphasized by Mazzone [167], the progressive contamination arising from the steel milling tools can result in a stabilization of the fcc phase for iron concentrations of only a few at% as shown by the equilibrium Fe–Co phase diagram. The allotropic transformation of hcp Co to fcc Co, which occurs in all cases by heating the ground powders at sufficiently high temperatures, seems to be related to the amount of disorder present in the stacking sequence of close-packed planes. A similar study was later performed by Huang et al. [168–170] whose results were reported to be in broad agreement with those of Cardellini and Mazzone. Besides contamination effects, they stressed the importance of the milling intensity which

controls the rate and level at which defects accumulate. Sort et al. [171] have shown similarly that a large amount of stacking faults is accumulated in cobalt during ball-milling. They did not obtain a pure fcc phase, even after increasing the milling time and/or the milling intensity. The final state was concluded to resemble a random hcp–fcc stacking sequence rather than two well separated phases.

Similarly, the characterization of the contamination of iron during ball-milling is essential to reach firm conclusions about the occurrence of phase transformation as iron is easily combined during milling and/or during subsequent exposure to air [111] or/and annealing with many elements, notably with oxygen, carbon, and nitrogen. The possible formation of a magnetically ordered fcc Fe phase in milled and annealed $\alpha$-Fe [108] is indeed the subject of much controversy [117, 118] among other things because its reported transition temperature (about 500 K) and hyperfine magnetic field (21 T at room temperature) are very close to those of easily formed cementite $Fe_3C$ (485 K and 20.8 T, respectively). Classical fcc $\gamma$-Fe has a complex antiferromagnetic structure with a transition temperature at about 67 K but its magnetic properties can be drastically different according to its lattice parameter [123]. The determination of the isomer shift of the discussed phase would certainly be of great help to distinguish between these two phases. The use of zirconia milling tools, without magnetic contaminants and without risks of carbide formation at grain boundaries, might be of further interest in such studies.

The inclusion of nitrogen in Fe by enhanced diffusion along GBs during ball-milling or during subsequent exposure to air must be further considered. It was, for instance, responsible for the formation of $Fe_4N$ during heating of $n$-Fe ball-milled in vacuum [111]. When milling Fe powders in nitrogen with a Szegvari-type attrition mill, infused nitrogen is located at GBs and in layers along GBs transforming the bcc lattice to a body-centered-tetragonal (bct) lattice [110, 116]. As the concentration of interstitial nitrogen increases, this outer bct shell of grains forces the inner bcc phase to expand [116]. Milling of iron in nitrogen with a Uni-Ball-Mill was concluded from X-ray diffraction patterns to result in a bcc phase containing ~4 at% N. Further, $^{57}$Fe Mössbauer spectra show evidence of significant contributions from Fe atoms perturbed by N atoms in contrast with spectra recorded for Fe milled in vacuum or in helium [105]. Milling Fe in a continuous flow of nitrogen produces even iron nitrides with significantly higher nitrogen contents (up to $Fe_2N$) [172].

Finally, a nanostructured surface layer of a thickness of ~15 $\mu$m was formed on a Fe plate by means of "surface mechanical attrition," a technique which is a combination of milling and of shot peening in which the bulk Fe sample is simply part of a wall of the vial [129]. High strains with a high strain rate are both found to be necessary for the formation of nanocrystallites during plastic deformation of the iron plate.

### 3.4.2. Some Properties of Ground Metals

High-pressure X-ray diffraction experiments were recently performed to obtain the equation of state of $n$-Fe ($d = 10$ nm) up to 46 GPa [125]. Nanocrystalline bcc Fe

transforms into $\varepsilon$-Fe when compressed to 10.9 GPa while $\varepsilon$-Fe transforms back to bcc Fe at a pressure lower than 7.6 GPa, both transformations taking likely place at lower pressures than the corresponding transformations in coarse-grained Fe. Chen et al. [125] conclude that the equations of state do not differ within experimental uncertainty for $n$-Fe and for cg-Fe.

Bulk moduli and Young's moduli of ground nanocrystalline metals (Fe, Cu, Ni) were measured to be the same as those of coarse-grained metals for grain sizes larger than ~10 nm [104, 115]. A Young's modulus decrease of ~5% when compared with that of cg-Fe is measured for ground $n$-Fe with $d = 7$ nm [104]. Molecular dynamics simulations yield similar conclusions for Young's moduli of $n$-Ni and of $n$-Cu with $d > \sim$10 nm. Young's modulus is found to decrease when $d$ decreases below ~5 nm, being for instance reduced by about 25% of the bulk value for $d = 3.4$ nm in $n$-Ni [173, 174]. An opposite variation, namely an increasing bulk modulus with a decreasing grain size, was, however, measured for ground $n$-Ni [115]. The vibrational densities of states (VDOS) have also been determined for $n$-Fe and $n$-Ni with $d$ around 15 nm [120, 121]. In comparison with reference coarse-grained samples measured in the same conditions, the nanocrystalline specimens exhibit a slight increase in the population of low-frequency modes and a distinct broadening of the transverse and longitudinal phonon peaks. The former feature has been related to the presence of interface modes and the latter to reduced phonon lifetimes due to the nanometer scale of crystallites. The VDOSs of bulk $n$-Ni and $n$-Cu model samples, with $d$ between 5 and 12 nm, were calculated recently from molecular-dynamics simulations [175]. The density of states is shown to be enhanced at low and high phonon energies, with a power-law behavior of the low-frequency grain-boundary VDOS possibly due to a reduced dimensionality effect. The enhancement of the VDOS at low and high energies, which increases with decreasing grain size, is found to be mainly caused by the high number of grain-boundary atoms [175].

Recent investigations [122, 124] failed to detect changes of Mössbauer spectra and room-temperature magnetic properties when ball-milling Fe down to grain sizes of ~10 nm. A similar result was found for $n$-Ni [103]. The low-temperature magnetic behavior of ball-milled $n$-Fe has been investigated recently [112]. A transition from a high-temperature ferromagnetic state to a low-temperature disordered regime was attributed to structurally disordered GBs.

## 3.5. Amorphization of Elements Si, Ge, Se, C

### 3.5.1. Si, Ge, Ge–Si Amorphization Induced by Milling

The crystal to amorphous phase transformation depends on the ability of the crystalline phase formed by mechanical alloying or mechanical milling to sustain or not a nanostructured state. In other words, the grain size of systems which possibly amorphize are expected to be close to a critical germination size. A transformation from a crystalline phase to an amorphous phase was first reported to

occur for various elements or alloys with a diamond-type cubic structure such as Si [137], Ge [176], GeSi [177], and GaAs [178].

Mechanical milling (Si, Ge, GaAs) and/or mechanical alloying (GeSi) leads to a refinement of the grain size. Two critical grain sizes are found experimentally: the first, $d_1$ (in the range of 20 to 30 nm for ball-milled silicon or germanium), is the grain size below which the lattice expands significantly (up to 0.2% and 0.4% in the case of ball-milled silicon and germanium respectively) and the second, $d_2$ (8 and 4 nm for Si and Ge respectively), $d_2 < d_1$, is the grain size below which the crytal to amorphous phase transition takes place. The size $d_1$ has been proposed to be the size below which the surface energy becomes larger than that of the volume. Lattice expansion is a way to compensate for this energy difference while keeping constant the total number of atoms (isolated grain hypothesis). Such a mechanism cannot be effective at any size smaller than $d_1$ and a new mechanism, namely a crystal to amorphous phase transformation, must operate below a second critical value $d_2$. The problem which remains open is that of the refinement mechanism that allows crystals to decrease so strongly in size.

Gaffet and Harmelin [137], following a suggestion of Swain (CSIRO, Sidney, Australia), proposed a mechanism to explain the Si amorphization,

$$\text{Si(I)} \underset{\text{under shock}}{\Longrightarrow} \text{Si(II)} \underset{\text{after shock}}{\Longrightarrow} \text{Si(III)} \Longrightarrow \text{refinement}$$

with Si(I), Si(II), and Si(III) exhibiting different structures, namely the diamond cubic (initial state), $\beta$-Sn, and bcc structures respectively. Such Si(II) and Si(III) structures are indeed observed in high-pressure experiments. The Si(I) → Si(II) phase transition occurs when silicon is compressed during mechanical shocks up to 11.3 GPa, leading to a relative volume decrease of 22%. During pressure release, Si(II) transforms into Si(III) at 7.5 GPa. The Si(III) volume per atom is equal to 92% of that of Si(I). The volume increase from Si(II) to Si(III) induces mechanical strains, leading to a breakage of the material and thus to grain refinement.

Further works performed in particular by Shen et al. have confirmed the crystal to amorphous phase transition induced by ball-milling [138, 179]. Two amorphous phase and nanocrystalline Si were produced by ball-milling of polycrystalline elemental Si. The nanocrystalline component contains some defects such as dislocations, twins, and stacking faults which are typical defects of conventional coarse-grained polycrystalline materials. The estimated volumic fraction of amorphous Si is about 15% while the average size of nanocrystalline grains is about 8 nm. Oxygen-free amorphous elemental Si can be obtained by ball-milling. The distribution of amorphous Si and the size of nanosized Si crystallites is heterogeneous in the milled powder. The amorphous Si is concentrated near the surface of milled particles while the grain size of nanocrystalline Si ranges from 3 to 20 nm. Two possible amorphization mechanisms (i.e., pressure-induced amorphization and crystallite-refinement-induced amorphization) are proposed for the amorphization of Si induced by ball-milling.

Such an amorphization of silicon induced by mechanical treatment has recently been investigated by Strelestkii et al. [180, 181]. The mechanical treatment of silicon in an inert atmosphere is accompanied by the formation of two populations (coarse and fine) of nanoparticles along with the formation of an amorphous phase. It may be concluded that the decrease of grain size below the critical value of about 4 nm is accompanied by the amorphization of silicon. The amount of amorphous phase for the maximum injected energy (500 kJ/g) exceeds 40%.

Particular attention has been paid to the cathodoluminescence of mechanically milled silicon [182]. Nanocrystalline silicon has been produced by ball-milling of silicon single crystals. The milled powder shows cathodoluminescence in the visible and near-infrared ranges. The main visible band appears at about 1.61–1.64 eV and is attributed to the presence of nanocrystals. An intense infrared band, which is not systematically observed in nanocrystalline silicon structures, appears in milled silicon at the same energy (0.8 eV) as the well-known dislocation luminescence band of silicon. It is suggested that this emission arises from the high density of extended defects generated during the milling treatment.

### 3.5.2. Se, Ge–Se Amorphization Induced by Ball-Milling

Experiments show evidence that mechanical attrition can induce complete crystallization of an amorphous solid and complete amorphization of a nanocrystalline phase as shown in the case of Se [142]. The induced MA phase transformation has been found to be closely related to the initial microstructure of the processed materials. Depending on the starting materials, MA may either (i) raise the excess energy of the milled sample by accumulating various microdefects or (ii) lower the total excess energy by activating a phase transformation to a more stable state (such as crystallization).

Some calorimetric experiments [140] have shown that during cryogenic temperature milling, amorphization is faster than at ambient temperature. The experimental results have been interpreted as a crystal to amorphous phase transition driven by defects created by frequent mechanical deformation.

X-ray diffraction investigations and thermal analyses have revealed that the amorphization onset corresponds to a critical size and a drop in microstrain [143]. During the major amorphization process, the remaining crystallite size remains unchanged with a constant lattice expansion. The amorphization kinetic was explained in terms of a crystallite destabilization model rather than by the classical shell kinetic model.

The interpretation of the latter authors has been questioned by Caro and Van Swygenhoven from computer simulations [149]. For these amorphous Se-annealed samples, a correct account of GB area and energy balance in the nanocrystalline phase yields a grain boundary width of 2.5 nm and a grain boundary energy of 0.4 J/m$^2$. The GB width is significantly larger than in simulated nanocrystalline nickel. A description which does not correctly take into

account the finite width of the GB leads thus to an apparent decrease of the GB energy with decreasing grain size.

Nasu et al. [183] analyzed the structure of amorphous Ge–Se prepared by mechanical milling. The amorphization process and the short-range-order structure of amorphous $GeSe_2$, $Ge_3Se_4$, and $Ge_4Se_5$ prepared by mechanical milling was investigated. $GeSe_2$ becomes amorphous in a shorter milling time. A much longer time is needed to amorphize Ge-enriched alloys such as $Ge_4Se_5$. Amorphous $GeSe_2$ and $Ge_3Se_2$ prepared by mechanical milling exhibit a local order similar to the corresponding amorphous phases prepared by liquid quenching, that is, the covalent 4(Ge)–2(Se) folded structure. The amorphous $Ge_4Se_5$ (which cannot be obtained by liquid quenching) also has the 4–2 folded structure, although its composition is nearer to GeSe.

Such a crystalline–amorphous transition of Ge–Se alloys by mechanical grinding has been also investigated by Tani et al. [184]. The mechanisms for amorphization of Se are suggested to be based on the distortion between helical chains connected by van der Waals forces. Monoclinic $GeSe_2$ is amorphized by disordering between the connected tetrahedra. The tetrahedral unit of $GeSe_2$ by mechanical grinding is distorted with wide distributions. $GeSe_2$ is completely amorphized after 4 hours of grinding, and Se after 30 hours for the given milling conditions. The difference has been considered an indication that disordering between the connected tetrahedral units in monoclinic $GeSe_2$ is induced more easily than it is between chains in trigonal Se.

### 3.5.3. Graphite Amorphization Induced by Ball-Milling

Huang investigated by high resolution TEM and electron energy loss spectroscopy the defect structure and the amorphous-like graphite induced by ball milling [185]. The deformation structures and the amorphization kinetics of graphite were clearly revealed in that way. Basal plane stacking disorder, cleavage, delamination cracks, misorientation bands, and low angle (0002) twist boundaries are observed. The basal plane stacking disorder is probably produced by a simultaneous shearing. Other defects such as a number of half Frank loops or interstitial loops, and bending and buckling of the basal planes, are also observed. Frequent shearing of (0002) planes acting in parallel with the increase of the Frank loop density finally leads to the breakage of the hexagonal network at a very fine scale until an amorphous-like structure results. The amorphous-like phase comprises highly curled flakes with $L_a$ less than 5 nm and $L_c$ less than 2 nm and it exhibits an $sp^2$ hybridization. The amorphization kinetics has been found to correspond to a defect-controlled process.

Welham and Williams have also studied extended milling of graphite and activated carbon [186]. Graphite and activated carbon were ball-milled under vacuum for up to 1000 hours. The graphite became amorphous, with no evidence of recrystallization after heating up to 1200 °C. There was little change in the structure of the activated carbon. Heating the two milled samples under argon showed that they absorbed substantial gas amounts, over 30% of their mass in some cases. The onset temperature of oxidation of graphite and activated carbon is decreased by ball-milling for extended times. The greatest decrease in ignition temperature for graphite was concomitant with the largest increase in noncrystalline carbon indicating the role of disordered carbon in enhancing the oxidation. Indeed, graphite milled for 1000 hours showed reactivity similar to that of activated carbon.

The structural disorder and phase transformation produced by ball-milling in graphite was also investigated by Shen et al. [144]. It was shown that nanocrystalline graphite with a crystallite size of about 2 nm is formed after 8 hours of ball-milling. Further milling produces a mixture of nanocrystalline and amorphous phases. Relatively large structural disorder is induced in the ball-milled graphite as revealed by X-ray diffraction (XRD) and Raman scattering experiments. Furthermore, the nanocrystalline graphite is relatively stable when compared with some nanocrystalline metals.

Salver-Disma et al. have performed transmission electron microscopy studies of carbon materials prepared by mechanical milling [187]. Mechanical grinding has been observed to generate an increasing amount of disordered carbon at a rate depending on the type of grinding mode used (shear- or shock-type modes). When the shock-type grinding is used, the triperiodic structure and the lamellar microtexture of graphite completely break down to give microporous and turbostratic carbons made of misoriented basic structural units. Graphite grinding permits the elaboration of disordered carbons. The involved mechanism differs from a simple reverse graphitization, since not only the structure but also the microtexture is strongly modified by the grinding. After heat treatment at 2800 °C, the graphite organization is not recovered, and a mesoporous turbostatic carbon is mainly obtained. Shear grinding has been found to be less effective since remnants of graphitic carbon are still present within the disordered carbon.
In order to achieve lithium intercalation, such a milling process has been performed in graphite and soft carbons [188, 189]. The effects of mechanical grinding on the morphology and electrochemical performance of graphite and soft carbon powders with respect to lithium insertion were studied. The morphology of the milled graphite powders was found to depend strongly upon the nature of the interactions (i.e., impact or shear shock modes) generated by two kinds of mixer mills used. For the same milling time, crystallite size was smallest and the density of defects highest for graphitic powders that were ball-milled using impact interactions. For each grinding mode (shear of impact shock modes), the resulting ball-milled carboneceous powders were found to be totally independent of the nature of the precursor used (graphite, carbon, coke) and/or of its morphology (layers, microbeads, and fibers).

In complement, the effect of liquid media during milling of graphite has been investigated by Janot and Guerard [190]. Ball-milling of graphite in the presence of a liquid leads to very thin, well-crystallized, and anisometric particles. In the presence of water, the graphite particles are covered by gamma $Fe_2O_3$ (maghemite) formed by the oxidation of the ferrous alloy coming from the milling tools. In the presence of $n$-dodecane, well-crystallized and highly

anisotropic particles of graphite can be synthesized, exhibiting promising features as anodic materials for lithium-ion batteries.

## 3.6. Elemental Nanoparticles Dispersed in a Matrix

We describe finally two uses of ball-milling which do not involve a unique element right from the start but end up with a nanosized dispersion of an element inside a matrix. Attractive nanograined metals are indeed also obtained from chemical reactions which take place between ground reactants at temperatures and at rates at which they would normally not occur. Some reactions, for instance the mechanochemical reduction of $SmCl_3$,

$$SmCl_3 + 3Na \rightarrow Sm + 3NaCl$$

which would never occur at elevated temperatures due to unfavorable thermodynamical conditions, are even rendered possible. Mechanochemical reactions may thus be put to work to prepare dispersions of nanometric elemental particles ($\sim$10 nm and smaller) within matrices, for instance within sodium chloride [191–196] which is dissolved afterward and within alumina [197, 198]. Redox or displacement reactions like

$$\text{oxide or chloride of } A + B \rightarrow \text{oxide or chloride of } B + A$$

(for instance, A = Ti, V, Cr, Fe, Ni, Cu, Zn, Zr, Ta, Gd, Er, Sm, B = Na, Mg, Al, Si, Ca, Ti, Ni) have been used recently to prepare ultrafine magnetic metal powders with promising applications (recording media, ferrofluids, nanocomposite magnets), quantum dots, cermets, etc. Ball-milling of Al-10 wt% M blends made up of pure immiscible elements M and Al (M = In, Sn, Bi, Cd, Pb) has been used to disperse elemental nanoparticles of M in an Al matrix to investigate the size dependence of their melting temperatures [199–201]. The particle size was controlled simply by varying the milling time. Both the melting point $T_m(d)$ and the latent heat of fusion decrease linearly with $1/d$ [199]. For nanoparticles embedded in a matrix, the melting behavior is controlled not only by the particle size but also by the nature of particle/matrix interfaces. In the case of M = In, for instance, the semicoherent In/Al interfaces formed in melt-spun samples are associated with superheating of particles whose melting temperature increases with $1/d$ [$T_m(\infty) - T_m(10 \text{ nm}) \sim -27$ K]. By contrast, the melting temperature decreases with $1/d$ for the incoherent In/Al interfaces formed during ball-milling [$T_m(\infty) - T_m(10 \text{ nm}) \sim +23$ K] [201].

To conclude, ball-milling is a simple technique of preparation of nanograined elements. The follow-up of ground elements tells much about the physics of ball-milling. Once characterized with care, ground crystalline elements allow further investigation of the size dependence of all kinds of properties. Some properties are found to be largely determined by the actual grain size distributions of NSMs and not by their sole mean size $d$ which may sometimes constitute just a rough representation of a broad distribution. Such distributions may then be tailored to improve the properties of NSMs by combining the advantages of nanograined materials with those of coarse-grained materials. Most NSMs are often extremely hard and brittle, for instance with a low tensile ductility at room temperature with an elongation to failure less than 5% in the absence of strain hardening. A thermomechanical treatment that results in a bimodal grain size distribution, with micrometer-sized grains embedded inside a matrix of nanocrystalline and ultrafine grains ($d < 300$ nm), was applied to copper [202]. This heterogeneous microstructure of copper imparts both high strength and high tensile ductility (a yield strength of about 350 MPa and an overall uniform elongation of $\sim$30% are measured at room temperature). To toughen nanostructured materials, microstructures combining both nanometer sized phases and micrometer sized ductile crystalline phases were recently engineered [203]. An *in-situ*-formed nanostructured matrix/ductile dendritic phase composite microstructure was prepared in Ti-base alloys (ex: $Ti_{60}Cu_{14}Ni_{12}Sn_4Ta_{10}$) by using well-controlled solidification conditions [203]. Deformation occurs partially through dislocation movement in dendrites and partially through a shear-banding mechanism in the nanostructured matrix. The dendrites act as obstacles to the propagation of shear bands by isolating them in small, discrete interdendritic regions. In a compression test at room temperature, the $Ti_{60}Cu_{14}Ni_{12}Sn_4Ta_{10}$ composite exhibits a yield strength of 1.3 GPa, an ultimate stress of 2.4 GPa, and a 14.5% plastic strain [203].

## 4. MECHANICAL ACTIVATION

### 4.1. Mechanical Activation of Self-Heat-Sustaining Reaction

#### 4.1.1. Nanostructured Porous Materials Synthesis

Combustion synthesis or self-heat-sustaining (SHS) reactions provides a suitable method for producing advanced materials, such as ceramics, composites, and intermetallics. The SHS process offers advantages with respect to process economy and simplicity. The basis of such a synthesis method relies on the ability of highly exothermic reactions to be self-sustaining and therefore energetically efficient.

If a very exothermic reaction between solids or solid and liquid reactants is locally initiated, it may generate enough heat to ensure the propagation of a transformation front leading to an end product involving all the initial amounts of the elemental components. Such a process is characterized by a fast moving combustion front (1–100 mm/s) and a self-generating heat which leads to a sharp increase of temperature, sometimes up to several thousands of K/s. The temperature reached inside the reaction front has been found to be effective to volatilize low boiling point impurities, helping by the way to produce purer end products than those obtained by some more conventional techniques.

Furthermore, if the temperature variation after the end product formation is kept under control, no chemical macrosegregation occurs.

The new version of the SHS process introducing a first mechanically activation step (before the ignition of the SHS reaction), that is, the so-called MASHS process, was first proposed by Gaffet in 1995 for the synthesis of the nanocrystalline FeAl compound [201].

Such a MASHS process has been successfully used to obtain various nanocrystalline compounds such as FeAl [202–206], $MoSi_2$ [207, 208], $FeSi_2$ [209, 210], $Cu_3Si$ [211–213], and $NbAl_3$ [214–217].

Such a mechanical activation effect on the combustion synthesis of $NbAl_3$ has been recently investigated by Neto and da Rocha [218]. As milling time is increased, the ignition temperature is decreased to temperatures below the melting point of aluminum, going from 850 to 500 °C. Also a variation in the reaction evolution is observed, changing from two stage to single stage reaction.

Uenishi et al. [219] have succeeded in the synthesis of nanostructured titanium aluminides and their composites formed by combustion synthesis of mechanically alloyed powders. Application of MA and $TiB_2$ addition was confirmed to be effective for the suppression of grain growth as well as for the nanostructure synthesis caused by the subsequent heat treatment, but it made the sintering conditions harder for full densification.

Such a combustion synthesis of ball-milled powders has been applied to the fabrication of a thick intermetallic compound $Al_3Ti$ layer on metal substrate [220]. A thick intermetallic compound $Al_3Ti$ layer was formed on a Cu or Ti substrate by a coating process involving combustion synthesis of a ball-milled Al–Ti powder mixture. This layer has almost the same wear property and hardness as that of a cast $Al_3Ti$.

The influence of premechanical alloying on the self-propagating high temperature synthesis has been investigated in the case of difficult to initiate reactions, that is, $Ni_3Si$ [221]. Self-propagating high temperature synthesis of $Ni_3Si$ is difficult, if not totally impossible, without mechanical alloying. The propagation rate of the reaction is influenced by MA. The ignition became easier as the reactivity increased due to MA. Increasing reactivity lowered the threshold temperature where reaction starts and therefore decreased the need for preheating.

The combustion synthesis of mechanically activated powders in the Ti–Si system has been found to be strongly modified [222]. Reactivity in the system Ti–Si was investigated as a function of milling. The reduction of the particle size as a consequence of the milling process has been found to stabilize the combustion propagation for the Ti:Si $= 1:2$ composition and to increase the front temperature and velocity for the Ti:Si $= 5:3$ composition. These compositions were found to produce single phases. Two different steps are proposed for the interaction: solid state interaction at the reaction front followed by the solid–liquid homogeneization step in the postfront region. The first step has been observed to be influenced by milling, while the second shows no such dependence.

The combustion synthesis of an alpha′ AlFeSi intermetallic has been investigated by Murali et al. [223]. The speed of ball-milling has been found to be an important parameter in the combustion synthesis of intermetallics from elemental powders. Synthesis of a monophase alpha′ from

its stoichiometric mixture is possible when ball-milled at 22 rpm. At higher milling speeds (100, 200, 380 rpm), synthesis is incomplete.

### 4.1.2. MASHS Process in-situ Study

In order to control the SHS as well as MASHS and MAFA-PAS (see Section 4.2.1) reactions, a better understanding of the initial conditions controlling the ignition step is requested, since the initial conditions are the easiest ones, if not the only parameters allowing control of the reaction.

Many different characterizations have been used in order to obtain such information. Until recently, it has been difficult to investigate these reactions by conventional techniques due to the high temperatures involved and the fast rates of combustion. Conventional techniques do not permit the study of the intimate mechanisms which are involved during such exothermic reactions, such as the role of the liquid formation and the existence of transitory phase and other parameters which may induce changes of the texture or nature of the end product.

Recently, real time *in-situ* investigations of structural change and chemical dynamics occurring in the combustion area have been made possible by the use of synchrotron radiation. Our group consortium involving several laboratories from Dijon (UMR 5613 CNRS, Univ. Bourgogne, F. Bernard), Belfort (UMR 5060 CNRS, UTBM), Villetaneuse (LIMHP, D. Vrel), and Orsay (LURE, M. Gailhanou, D. Thiaudière) have developed a specific tool suitable to study the SHS reaction by time resolved X-ray diffraction coupled to 2D surface temperature recording with an infrared camera, under synchrotron radiation flux (see Figs. 3 and 4) [224, 225].

**Figure 4.** Synchrotron TRXRD apparatus for *in-situ* MASHS characterization: (1) X-ray fast detector (using 80° two theta), (2) reaction chamber under controlled He atmosphere, (3) vertical heating elements, (4) Mylar window, (5) synchrotron radiation, (6) infrared camera, (7) video camera, (8) sample ($1.5 \times 1 \times 0.5$ cm$^3$), (9) horizontal heating elements.

## 4.2. Mechanical Activation of Sintering Processes

Full attention has been paid to the synthesis of dense nanometric $MoSi_2$ through mechanical and field activation. To achieve such an objective, mechanically activated powder metallurgy processing has been developed.

### 4.2.1. Mechanically Activated Field Activated Pressure Assisted Synthesis (Nanostructured Fully Dense Homogeneous Materials)

Some years ago, the simultaneous effect of an electrical field combined with an applied pressure during the combustion was found by Munir (Univ. Davis, California, USA) as a suitable method to produce dense intermetallics compounds in a one-step process.

Such a process has been called field-activated pressure assisted synthesis (FAPAS) (see Fig. 5).

The application of the FAPAS process to mechanically activated powders has been found to be a new way to produce dense nanostructured materials (the so-called MAFAPAS process) [226]. The feasibility of this new approach for the simultaneous synthesis and densification of nanomaterials has been successfully demonstrated for the synthesis of FeAl [227], $MoSi_2$ [228], and $NbAl_3$ [229] compounds.

This new process combining electric field activation and the imposition of pressure from mechanically activated powder mixtures is demonstrated as a means to simultaneously synthesize and densify nanostructured materials in one step.

The mechanically activated powder mixtures were first cold compacted into well-adjusted cylindrical graphite dies using a uniaxial charge (from 0 to 200 MPa). The relative density of the green samples ranged from 50 to 65%. The graphite die containing the cold compacted mixture was placed inside the FAPAS reaction chamber, evacuated, and back-filled with argon (quality U) to minimize oxidation phenomena.

Then, mechanically activated reactant powders were subjected to a uniaxial pressure (0–110 MPa) while a high level electric current (0–1750 A) is passed through the die (see Fig. 6 for typical experiment set). Under these conditions, a reaction is initiated and completed within a

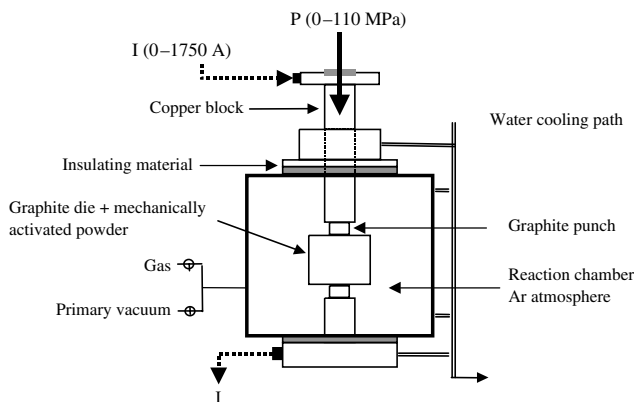

**Figure 5.** The FAPAS apparatus.

**Figure 6.** Typical combination of current intensity and uniaxial pressure during a FAPAS synthesis. The induced temperature is also shown.

short period of time (2–6 min). Temperature was measured on the external surface of the die by means of a K-type thermocouple.

The densified MAFAPAS end-products specimens were disks of 20 mm in diameter and about 2 to 5 mm height.

The relative density evaluated by weight and geometric measurements, the crystallite size determined from X-ray line profile analysis, and chemical composition are presented in Table 1.

The various tested end products were found to be nanocrystalline compounds corresponding to the expected phases with little or absolutely no secondary phases.

### 4.2.2. Mechanically Activated Spark Plasma Sintering Monolithic Compounds

In a work by Orru et al. [230], powders of Mo and Si, milled separately or co-milled in a planetary ball mill, were reacted in a spark plasma synthesis (SPS) apparatus under different electric current conditions. Milled powders reacted faster and required less current than unmilled powders. Mixtures of powders which were milled separatedly (to nanometric size) have been found to lead to the formation of micrometric alpha $MoSi_2$. Similar results were obtained for samples co-milled to produce nanometric reactants which did not contain detectable amounts of the end product phase. When products were formed during milling, they contain both the alpha and beta $MoSi_2$ phases. The product after the SPS reaction was nanometric $MoSi_2$ with a crystallite size of 140 nm.

In complement of the reported work, the effect of phase transformation during high energy milling on field activated synthesis of dense $MoSi_2$ has been investigated by Sannia et al. [231]. The effect of mechanical activation through high-energy ball-milling of reactant powders on the subsequent synthesis of $MoSi_2$ by field activation was investigated. The initiation of the synthesis reaction required a

**Table 1.** Relative density, crystallite size, and phases obtained in each system.

| System | Density | Size | Phases |
|---|---|---|---|
| Fe/Al [227] | 98 to 99.5% | 32–90 nm | $Fe_{0.515}Al_{0.485}$ |
| Nb/3Al [229] | 85–96% | 57–150 nm | $NbAl_3$, $Al_2O_3$ |
| Mo/2Si [228] | 82 to 93% | 58–75 nm | $MoSi_2$ |

threshold power level (equivalent to the level of the current, according to the authors), with the threshold decreasing with increased milling time. However, the initiation time increased when milling resulted in the formation of a significant amount of the product phase, with the increase being markedly significant at low power levels.

The characterizations of NiAl intermetallic produced by mechanical alloying and consolidated by spark plasma sintering have been realized by Coreno-Alonso et al. [232]. Elemental powder mixtures were milled for times shorter than those required for the formation of the NiAl intermetallic, then subsequently hot consolidated by spark plasma sintering. Such a fabrication process has been demonstrated to produce consolidated nanocrystalline NiAl specimens having densification levels up to 91–93% and maximum microhardness values of about 609–661 VHN.

***Nanocomposites*** The synthesis of Cu dispersed $Al_2O_3$ nanocomposites by high-energy ball-milling and pulsed electric current sintering was studied by Kim et al. [233]. The nanocomposite powders with crystallite size of about 25 nm were successfully synthesized by a high-energy ball-milling process. The composites sintered at 1250 °C for 5 min showed a relative density above 97% and enhanced fracture toughness of 4.51 MPa $m^{1/2}$.

Microstructural observation of the sintered composites revealed that the nanosized Cu particles were uniformly distributed and situated on the grain boundaries of $Al_2O_3$ matrix.

Dense nanocrystalline $TiB_2$–$TiC$ composites have been formed by field activaton from high-energy ball-milled reactants [234]. Elemental powders (Ti,C,B) were milled in a planetary mill to produce nanometric powders without product formation. No significant amount of any of the two product phases was found to be formed until after 3 hours of milling. The as-milled powders were reacted under the influence of a high current (ac current 1800 A) and a uniaxial pressure (30 MPa, 3 min). Dense (up to 98.6%) nanocomposites were formed. The crystallite sizes of $TiB_2$ and $TiC$ in the dense composite formed from powders milled for 10 h were 71.4 and 62.5 nm, respectively. The microhardness of this composite was 20.6 GPa.

El-Eskandarany et al. [235] have succeeded in the synthesis of nanocomposite WC/MgO powders by mechanical solid state reduction and subsequent plasma-activated sintering. A mixture of elemental Mg, $WO_3$, and C powders is milled under an argon gas atmosphere at room temperature, using high-energy ball-milling. A nanocomposite powder of WC/MgO (17.6 at% MgO) was obtained after milling. Plasma-activated sintering was applied to consolidate this end product into a fully dense bulk sample. The consolidation step does not lead to extensive grain growth and the compact sample consists of nanoscale grains of MgO (2.5 nm in diameter) embedded into the matrix of WC. This as-fabricated nanocomposite combines high values of hardness (about 15 GPa) and fracture toughness (14 MPa $m^{1/2}$).

***Composites*** In order to produce alumina–Cr and –Nb composites, attrition-milled Nb–50 vol% $Al_2O_3$ and Cr–50 vol% $Al_2O_3$ have been densified from 1310 to 1450 °C in about 10 min using the SPS process applying 45 MPa of pressure [236]. The milling intensity as conducted on the

metal–$Al_2O_3$ powders has been found to play a fundamental role determining not only the degree of densification but also the final nature of the composites thus processed. The longer milling time has been found to lead to a material exhibiting a finer microstructure. The maximum fracture strength developed in these composites has been achieved at 1380 °C sintering, reaching 825 MPa for the Nb–$Al_2O_3$ materials.

Murakami et al. [237] have studied the microstructure, the mechanical properties, and the oxidation behavior of powder compacts of the Nb–Si–B system prepared by spark plasma sintering. The microstructure, mechanical properties, and oxidation resistance of spark-plasma sintered compacts with eight different compositions in the $Nb_5Si_3$–$NbB_2$–$NbSi_2$ triangle were investigated. Compacts were prepared via three different routes, that is, (i) blending elemental powders in a rotational ball mill and sintering blended powders, (ii) mechanically alloying elemental powders and sintering mechanically alloyed powders, and (iii) presintering blended elemental powders, milling presintered compacts, and sintering presintered and milled powders. The most homogeneous and the least oxygen contamined compacts were obtained via the third route.

### 4.2.3. Mechanically Activated Sintering

The influence of milling process on sintering zirconia alloys has been studied by Farne et al. [238]. Innovative milling processes such as mechanofusion (MF) and MA were introduced on powder prepared from traditional oxides and from pyrolytic precursors. All the sintered products appeared largely porous, above all the samples prepared by MF processing. These products seem to exhibit promising features for the all cases where a high surface area can be requested (i.e., gas sensors).

The dilatometric analysis on the sintering behavior of nanocrystalline W–Cu prepared by mechanical alloying has been investigated by Ryu et al. [239]. Dilatometry showed that the shrinkage behavior of nanocrystalline mechanically alloyed W–30 wt% Cu powder was quite different from that of simple mixed powder with coarse grains. The shrinkage of simple mixed W–Cu powder increased steeply at the Cu melting point. Nanocrystalline powders have been shown to exhibit a shrinkage behavior in two stages, which was strongly dependent on the heating rate, and the temperature at which the sintering shrinkage started to be accelerated was considerably below the Cu melting point due to the enhanced densification in solid phase. Such a feature was attributed to the coupling effect of the sintering occuring inside individual powders and the sintering between powder particles.

## 4.3. Mechanical Activation of Annealing-Induced Reactions

### 4.3.1. Metallic Compound Formation

In the case of silicide synthesis by direct mechanical alloying, it has to be noticed that a high contamination is detected. Some ways to solve such a problem may be found by the addition of a solvent. In the early 1990s, an alternative to this problem has been proposed by Gaffet et al. [240–243],

the so-called mechanically activated annealing processing (M2AP, called in French "Elaboration par Recuit Activé Mécaniquement" or ERAM).

Such a solid state method, combining short duration mechanical alloying and low temperature annealing, has been successfully applied to the synthesis of $FeSi_2$ [240, 241], $MoSi_2$ [242], and $WSi_2$ [243]. Starting from a mixture of elemental powders, the first M2AP step corresponding to the short duration mechanical alloying leads to the formation of micrometer powders in which nanoscale 3D polyinterfaces of the elemental components have been formed. The true solid-state reaction leading to the end product phases occurred during the annealing. The effect of the milling conditions on the grain sizes as well as the residual stresses has been reported to modify the phase transformation kinetics induced by low temperature isothermal annealing starting from pre-short-duration mechanically alloyed elementary components.

Therefore, according to such experimental results, M2AP is a very suitable powder metallurgy process allowing the direct driving of the solid-state reaction occurring for example during the reactive sintering process.

More than that, M2AP has been found to be a very suitable method to produce nanocrystalline $MoSi_2$ phase. Indeed, the first mechanical M2AP step leads to an activation of the three-dimensional elementary distribution which reacts 400 °C below the temperature of the classical processes (i.e., 800 instead of 1200 °C).

$Mg_2Si$ (as a negative electrode material for lithium-ion batteries) was synthesized [244] by mechanically activated annealing and evaluated as a negative electrode materials. Such an annealing processing was achieved at 600 °C and the structural investigation has been found to prove that the silicon is the host phase for alloy formation.

In the case of solid-state reactions in nanometer scaled diffusion couples prepared using high-energy ball-milling, it has been shown by Zhang and Ying [245] that when the size of the diffusion couples is reduced and the atomic diffusivity is enhanced through prolonged milling, the temperatures for activating the solid-state reactions decrease significantly. It has been noticed that in the case of the Al–Ti and Cu–Al systems, the phases which have been formed during heating the mechanically prepared nanometer scaled diffusion couples are the same as those formed during mechanical alloying and during low-temperature annealing of multilayer thin films prepared by using sputtering.

### 4.3.2. Ceramic Phase Formation

Ren et al. have studied the preparation of nanostructured TiN powder via an integrated mechanical and thermal activation [246]. $TiO_2$ and graphite are used as starting materials and the carbothermic reduction and the simultaneous nitriding reaction are enhanced by high-energy milling prior to reactions. It is found that under the same nitridation condition, 100% TiN is formed for $TiO_2$ and graphite powder mixtures with high-energy milling, whereas no TiN is obtained for powder mixtures without milling.

Based on the same approach, the synthesis of nanostructured TiC via carbothermic reduction enhanced by mechanical activation has been achieved by Ren et al. [247].

The set of experiments has demonstrated that carbothermic reduction of $TiO_2$ by graphite from TiC can be greatly enhanced by mechanical activation. In comparison with the current industrial carbothermic reduction, temperatures for a complete reduction of $TiO_2$ to TiC have been reduced by 500 °C and at the same time, the reduction time shortened to 1–2 hours by high-energy milling the reactants for 2 hours at ambient temperature. TiC powder formed through mechanically activated synthesis is submicrometer sized with nanostructures.

The solid state synthesis of strontium oxoferrates from the mechanically activated system $SrCO_3$–$Fe_2O_3$ has been investigated by Berbenni and Marini [248]. The starting chemicals $SrCO_3$ and $Fe_2O_3$ have been dry milled in a high-energy planetary milling machine. It has been found that the $SrFe_{12}O_{19}$ phase is produced from mechanically activated mixture at temperatures lower (800 °C) than in the conventional solid state route.

The mechanical activation conditions of the $Fe_2O_3$ and $V_2O_3$ mixture powders in order to obtain a nanometric vanadium spinel ferrite have been studied by Nivoix et al. [249]. Co milling of iron and vanadium oxides allows one to obtain an intimate oxide mixture at a nanoscale, similar to coprecipitates elaborated by soft chemistry. Reduction of such a mixture in the same temperature and oxygen partial pressure conditions (500 °C and $10^{-25}$ Pa) as the soft chemistry products lead to a nanometric vanadium ferrite with the only spinel phase.

The kinetics of the thermal decomposition of mechanically activated pyrite and nonactivated pyrite was studied by Hu et al. [250] using the Friedman method. It is found that the mechanical activation of the original materials brings about a change in the surface structure of pyrite, which results in activated pyrite's transformation into metastable pyrite in the course of mechanical activation. The metastable pyrite is more liable undergo to thermal decomposition than nonactivated pyrite.

Various works have paid attention to the synthesis of Ba-based compounds. The effect of mechanical milling on the solid state reactions in the barium oxalate–iron (III) oxide system has been studied by Berbenni et al. [251]. The effect of mechanical activation on the formation of barium hexaferrite ($BaFe_{12}O_{19}$) from barium oxalate and hematite has been investigated. Thermogravimetric analysis shows that mechanical activation of $BaC_2O_4$–$6Fe_2O_3$ mixtures results in the mass loss being complete at about 600 °C, that is, well below the temperature where $BaCO_3$ (the more common barium precursor) spontaneous decomposition is complete ($T > 850$ °C). Such a noticeable temperature lowering is a consequence of the high-energy milling enhancing the formation of $BaFe_2O_4$.

A ternary mixture $BaCO_3$–$Al_2O_3$–$SiO_2$ was mechanically activated for different lengths of time [252]. The obtained data show that reaction rate increases with prolonged activation time, under the same conditions of thermal treatment ranging from 750 to 1200 °C. Formation of hexacelsian via a series of solid state reactions involving Ba silicates was favored with increasing activation time. Direct formation of monoclinic celsian has been found to be retarded with prolonged activation.

BaAl$_2$O$_4$/aluminum bearing composites have been synthesized [253] via the low temperature oxidation of Ba–Al precursors. Ba–Al powder mixtures were prepared via high-energy vibratory milling, then unixially pressed into bar-shaped samples which were then exposed to heat treatment in pure flowing oxygen at temperatures up to 640 °C. Oxidation at 300 °C resulted in the formation of barium peroxides (BaO$_2$). Heat treatment at 550 °C leads to the consumption of BaO$_2$ and of some aluminum to yield to BaAl$_2$O$_4$ and Al$_4$Ba. The oxidation of Al$_4$Ba at 640 °C has been found to produce additional BaAl$_2$O$_4$.

The fast synthesis of YBa$_2$Cu$_3$O$_z$ superconductor at low temperatures of its orthorhombic modification existence using mechanically activated and densified two-powder precursors has been investigated by Goodilin et al. [254]. Mechanically activated and densified two-powder precursors yield reproducibly an YBa$_2$Cu$_3$O$_z$ phase when using internal oxygenation of soft chemistry produced Cu$_2$O by YBa$_2$O$_{3.5}$ (containing BaO$_2$) in their mixture (Y:Ba:Cu = 1:2:3) mechanically activated in a planetary mill and warmly compacted at 250 °C into a dense pellet.

A "mild" mechanochemical synthesis based on mechanical activation of highly reactive compounds in the grinders (solid acids and bases, hydrated oxides, acidic or basic salts, crystallohydrates) has been used for the preparation of cordierite [255]. Mechanical activation accelerates the mixing and mass transfer processes at an atomic level. Sometimes, this treatment suffices to complete thermodynamically favorable reactions. However, in the majority of cases, the amorphous phases are formed and a subsequent thermal treatment is necessary at temperatures which are 200–300 °C lower than that of common thermal synthesis.

### 4.3.3. Nanotubes/Nano"cage" Synthesis

Mechanically activated solid state reaction has been found to be a suitable method for the production of carbon and boron nitride nanotubes [256]. Both carbon and boron nitride nanotubes have been produced by first ball-milling of graphite and boron nitride powders at room temperature and then by isothermal annealing at temperatures less than 1500 °C. Ball milling has been found to create the nuclei for nanotubes and the subsequent isothermal annealing is responsible for nanotube growth.

The investigation [257] of morphological and structural changes during high-energy ball-milling and thermal annealing of the mixtures soot–iron and soot–nickel demonstrated that the activation is accompanied by the formation of nanosized metal particles (10–50 nm) distributed over the amorphous carbon matrix. Prolonged mechanical activation of the amorphous soot iron has been found to lead to the formation of nanosized cementite Fe$_3$C compound. Morphological characteristics of the annealed, mechanically activated soot–metal samples depend on the time of the mechanical activation step. Annealing after short-time mechanical activation has been demonstrated to cause a crystallization of the amorphous carbon as onionlike graphite–metal structures. Annealing of the soot–metal samples after mechanical treatment for more than 5 min leads to the formation of metal nanoparticles (40–50 nm) encapsulated by graphite. The longer the preliminary mechanical activation, the smaller the size of encapsulated particles.

## 5. MECHANOCHEMISTRY

Mechanochemical processing is broadly the use of mechanical energy to cause reactions, which normally require elevated temperatures, to occur at ambient temperatures. For example reduction reactions which are normally carried out at temperatures close to 1000 °C can be achieved at ambient temperatures through the mechanochemical process [258, 259].

Normally the reaction products formed by the process are ultrafine powders with a wide distribution of particle size ranging from a few nanometers to micrometers [260].

In a paper entitled "Recent development of materials design through a mechanochemical route," Senna [261] wrote a critical overview of the principle and practice of modern mechanochemical processes for the preparation and design of high-value-added materials. The importance of the low coordination states and effects of symmetry disturbance of crystal and ligand fields are emphasized. Several successful examples of applications are displayed, such as inorganic complexes for electronic and construction materials, bioceramic materials, and metal organic coordination compounds.

Starting from the binary system, Ca(OH)$_2$–SiO$_2$, it was shown that a proton from a surface silanol group transfers to an OH group of Ca(OH)$_2$, a so-called mechanochemical dehydration, leaving a bridging bond, Ca–O–Si [262]. Similar reactions lead to heterobridging bonds or heterometaloxane bonds when two dissimilar metal atoms, Me(I) and Me(II), are connected by an oxygen atom serving as a hinge. Several conditions must be associated for such a reaction mechanism to occur. One is the state of the low coordination number of atoms. The coordination number of Ca in Ca(OH)$_2$ is equal to 6 in the crystal bulk but it may decrease to 5, 4, or even 3, not only for atoms located on surfaces (edge or corner atoms) but, more importantly, due to various lattice defects. The second condition, not less important, is the loss of crystal field symmetry.

Knowing that bridging bond formation is a consequence of a redox reaction between two metal oxides or hydroxides, it has been applied to complex oxide syntheses such as that of perovskite compounds Pb(Mg$_{1/3}$Nb$_{2/3}$)O$_3$. The same principle has been applied to complex oxides other than perovskites, for example, the formation of MgTiO$_3$ starting from Mg(OH)$_2$ and TiO$_2$·H$_2$O hydrogel [263, 264] or of Sr$_{0.6}$FeO$_4$ from Sr(OH)$_2$ and alpha-FeOOH.

Another field of successful applications is the synthesis of rapid hardening agents for cement which are necessary for emergency construction and for shortening construction time. It has been realised via a mechanochemical activation. When Al(OH)$_3$ was milled by an agitation mill and subsequently mixed with Ca(OH)$_2$ in equimolar proportions, the mixture served as an excellent hardener [265].

## 5.1. Formation of Ultrafine Oxide Nanoparticles

Various ultrafine particles have been reported to be prepared by a combination of mechanochemical and thermal processes. Several examples are described.

One is the synthesis of pure $ZrO_2$ by mechanochemical reaction of $ZrCl_4$ with MgO, as given by $ZrCl_4 + 2MgO \rightarrow ZrO_2 + 2MgCl_2$. The degree of interparticle agglomeration was found to be significantly reduced by postmilling heat treatments and also by the use of alcohol wash solvents [266].

The solid-state reduction of haematite (alpha-$Fe_2O_3$) with carbon mainly to nanocrystalline wüstite by room-temperature dry ball-milling was investigated by Matteazzi and Le Caër [267]. In addition to wüstite, a small amount of nanocrystalline magnetite is also formed, possibly by a disproportionation reaction of wüstite.

In some cases, the chemical reaction has been found to not occur during milling but during a postmilling annealing step. The formation of alumina via the reaction

$$2AlCl_3 + 3CaO \rightarrow Al_2O_3 + CaCl_2$$
does not occur during mechanical milling. Annealing at 150–200 °C leads to the formation of $AlCaCl_5$. $CaCl_2$ was found to form by annealing at temperatures higher than 300 °C, indicating the formation of alumina. After washing to remove the chloride, the samples were found to consist of gamma alumina nanoparticles (10–20 nm). This phase, which is metastable at room temperature, transforms into alpha alumina during annealing at 1250 °C [268].

Such a feature is also the case for the mechanochemical synthesis of ultrafine $ZrO_2$ powders [269].

They are obtained by a subsequent annealing of ground powders at 300–400 °C, according to the expected milling induced reaction

$$ZrCl_4 + 2CaO \rightarrow ZrO_2 + 2CaCl_2 \qquad (\Delta G = -440 \text{ kJ})$$
In fact, the absence of diffraction peaks for the $ZrCl_4$ phase just after milling suggests that amorphization occurs during milling, leading to an embedding of separated CaO crystallites in an amorphous $ZrCl_4$ matrix. After annealing, the $ZrO_2$ nanophase is dispersed in a $CaCl_2$ matrix which can then be dissolved in methanol.

The same behavior is observed in the case of hematite powders synthesized by mechanochemical processing [270] according to the following chemical reactions:
$$2FeCl_3 + 3CaO \rightarrow Fe_2O_3 + 3CaCl_2 \quad (\Delta G = -508 \text{ kJ})$$
$$2FeCl_3 + 3Ca(OH)_2 \rightarrow Fe_2O_3 + 3CaCl_2$$
$$+ 3H_2O \quad (\Delta G = -341 \text{ kJ})$$
The diffraction pattern for the as-milled powder indicates that CaO remained unreacted during milling. Annealing at 50 and 100 °C did not result in any changes of the as-milled mixture. After annealing at 150 °C, X-ray diffraction peaks associated with the $CaCl_2$ and $Fe_2O_3$ phases were observed indicating that the reaction has occurred. A methanol washing was used to remove the $CaCl_2$ phase. The $Fe_2O_3$ powder exhibits particle sizes ranging from 100 to 500 nm. Dilution of the starting materials with $CaCl_2$ resulted in the reduction of the $Fe_2O_3$ particle size down to 10–30 nm.

Milling of a starting mixture which contains $Ca(OH)_2$ results in the formation of FeOOH. Annealing at temperatures below 150 °C did not lead to any significant changes in the XRD patterns. Annealings above 200 °C are needed to form crystalline $CaCl_2$ and hematite $Fe_2O_3$, due to dehydration of FeOOH. The hematite particle size ranges between 20 and 50 nm.

The synthesis of ultrafine (Sn, Zn, Ce) oxides by mechanochemical reaction and subsequent calcinations was studied [271]. A simple washing process has been found to remove the by-product phase, resulting in the production of nanopowders of $SnO_2$, ZnO, and $CeO_2$ with mean particle size of 40, 28, and 10 nm, respectively:

$$SnCl_2 + Ca(OH)_2$$
$$\rightarrow SnO + CaCl_2 + H_2O \qquad (\Delta G = -59 \text{ kJ})$$
$$ZnCl_2 + Na_2CO_3 + 8.6NaCl$$
$$\rightarrow ZnO + 10.6NaCl + CO_2(\text{gaz}) \qquad (\Delta G = -80 \text{ kJ})$$
$$CeCl_3 + 3NaOH$$
$$\rightarrow Ce(OH)_3 + 3NaCl \qquad (\Delta G = -345 \text{ kJ})$$
To prevent the occurrence of a combustion reaction, 12 moles of NaCl diluent were added to the starting mixture yielding the reaction

$$CeCl_3 + 3NaOH + 12NaCl \rightarrow Ce(OH)_3 + 15NaCl$$
which takes place progressively instead. In the cases of the $SnCl_2$ and $CeCl_3$ initial chlorides, such reactions lead to the hydroxide phase formation during milling. The removal of $H_2O$ and the final oxidation step occur on heating ground powders above 100 °C in air. With the $ZnCl_2/Na_2CO_3$ reaction, the $ZnCO_3$ phase is stable at room temperature and calcinations above 200 °C were required to form ZnO.
## 5.2. Formation of Ultrafine Metallic Nanoparticles

Mechanochemical synthesis has been successfully applied to the synthesis of ultrafine metallic powders.

### 5.2.1. Na Reducing Agent

Such a method has been applied to the production of ultrafine Fe powders [272].

The formation of Fe is due to the reduction of $FeCl_3$ by Na via the reaction

$$FeCl_3 + Na \rightarrow Fe + 3NaCl$$

An important requirement for the formation of nanoscale particles is that the volume fraction of the by-product phase has to be sufficient to prevent the particle agglomeration resulting in an increase of the crystallite size.

In the case of ultrafine Cu particles prepared by the mechanochemical process [273], the milling induced solid state displacement reaction is
$$CuCl_2 + 2Na \rightarrow Cu + 2NaCl$$
Depending on the reaction modes (continuous or combustion ones), two distinct morphologies of Cu particles have been observed; Cu particles with sizes uniformly distributed

in the range 20–50 nm are formed by a steady state reaction during mechanical milling, whereas larger particles were observed in the combustion reaction case.

McCormick et al. showed such an addition of Na to metal chlorides [274] to produce ultrafine Co and Ni particles, with particle sizes of 10–20 nm, according to the following reactions:

$$CoCl_2 + 2Na \rightarrow Co + 2NaCl \quad (\Delta G = -495 \text{ kJ})$$

$$NiCl_2 + 2Na \rightarrow Ni + 2NaCl \quad (\Delta G = -507 \text{ kJ})$$

The formation of ultrafine particles requires again the volume fraction of the metallic phase being formed to be small relative to that of the by-product phases and combustion during milling must be avoided to prevent particle coarsening.

### 5.2.2. Mg Reducing Agent

Instead of using Na as reactant, a solid state displacement reaction between $NiCl_2$ and Mg, induced by mechanical milling [275], was employed for the production of fine Ni powders. The end product was leached with dilute HCl to obtain the nickel powder with sizes ranging between about 10 to 500 nm. It has been observed that unlike the results on reduction reaction in ZnO/Ti and CuO/Fe systems, interruption during milling of $NiCl_2$/Mg prolongs the start of ignition. A critical combination of intimate mixing of the reactants with freshly formed surfaces, structural strains, and a milling induced temperature rise is necessary for the ignition to take place.

Such a Mg reactant chemical reaction has also been used for the reduction of tantalum chloride by magnesium during reaction milling [276]. The reaction used is

$$2TaCl_5 + 5Mg \rightarrow 2Ta + 5MgCl_2 \quad (\Delta G = -356 \text{ kcal})$$

The vial temperature, which was measured during milling, indicated that the *in-situ* mechanochemical reaction which has been found to occur is a combustion one. Crystalline Ta and $MgCl_2$ were identified immediately after the combustion (corresponding to an abrupt increase of the vial temperature) while further milling led to chloride amorphization. The ball mass has an important effect on the conditions required for combustion to occur.

A mechanochemical reduction of nickel oxide by graphite has been tested to produce ultrafine Ni [277]. Milling at ambient temperature did not result in the reduction of nickel oxide to nickel. However, milling significantly decreased the critical reaction temperature for the reduction, from 1350 K for the unmilled sample to 650 K for samples milled for 12 hours or longer. Reduction of NiO to Ni occurred during milling at elevated temperatures. The extent of the reaction during milling at elevated temperatures was dependent on the partial pressure of $CO_2$ in the sealed vial.

Ultrafine Mo particles can be produced as a result of the slow burning transition into detonation in the $MoS_2$–Mg mixture [see N. G. Danielian et al. *Mod. Phys. Lett. B* 5, 1301 (1991)] according to the following reaction:

$$MoS_2 + 2Mg \rightarrow 2MgS + Mo$$
The mechanical treatment of the reactant mixture results in a considerable decrease of the ignition temperature and in a strong increase of the burning speed.

To close this section about the description of the mechanochemical synthesis of ultrafine metallic particles, we notice that similar methods can be used to prepare nanostructured intermetallic compounds [278].

The basis for the synthesis of Ti–Al alloys is the coreduction reaction induced mechanically:

$$6TiCl_4 + 2AlCl_3 + 7CaH_2 + 8Mg \rightarrow 2Ti_3Al(H)$$
$$+ 7CaCl_2 + 8MgCl_2$$
The reaction product after leaching is $Ti_3Al(H)$ with hydrogen in interstitial sites of the $Ti_3Al$ structure. The use of $CaH_2$ as a reducing agent in the given example results in the formation of $Ti_3Al(H)$ which is more passive to oxidation than $Ti_3Al$.

Nanocrystalline TiC was synthesized by the displacement reaction

$$TiCl_4 + 2CaC_2 \rightarrow TiC + 2CaCl_2 + 3C$$
The reaction has also been modified to avoid the formation of free carbon, by the addition of Mg:

$$2TiCl_4 + CaC_2 + 3Mg \rightarrow 2TiC + CaCl_2 + 3MgCl_2$$
### 5.2.3. Si, Fe Reducing Agents

The mechanochemical synthesis of refined Ag and Zn composite powders starting from oxides using Si and Fe as reducing agents was reported by de la Torre et al. [279]. $Ag_2O$ and ZnO powders were reduced by a mechanochemical process using Si and Fe as reducing agents.
A number of advantages are conferred to the end products Ag–$SiO_2$, Ag–$Fe_2O_3$, Zn–$SiO_2$, and ZnO–$Fe_2O_3$ submicrometric composite products prepared in that way. The active oxides, with nanometer-sized tailored particles, are for instance homogeneously dispersed into the reduced metal matrix.

## 5.3. Formation of Semiconductor Nanoparticles

Mechanochemical synthesis has been applied to the large scale preparation of ultrafine Si nanoparticles by ball-milling [280]. Si nanoparticles were synthesized by ball-milling of mixtures of graphite and of $SiO_2$ powders followed by subsequent annealing at 150 °C.

## 5.4. Sulphide Reduction or Production

Mechanical milling [281] of $ZnCl_2$ and CaS mixtures resulted in the formation of 500 nm ZnS particles containing aggregates of 12 nm crystallites according to the following reactions:

$$ZnCl_2 + CaS \rightarrow ZnS + CaCl_2$$

$$ZnCl_2 + CaS + 3.6CaCl_2 \rightarrow ZnS + 4.6CaCl_2$$

$$ZnCl_2 + CaS + 8.2CaCl_2 \rightarrow ZnS + 9.2CaCl_2$$

The addition of 71 vol% $CaCl_2$ as a diluent to the reactants resulted in the formation of separated 16 nm particles of ZnS. Using mechanically alloyed CaS (10–50 nm particle size) enabled the synthesis of isolated ZnS particles 7–9 nm in size.

Such a method is claimed to be applicable for the production of nanoparticles of other II–VI semiconductors, of ternary II–VI semiconductors such as CdHgSe and CdSTe, or of heavily doped semiconductors such as Zn(Mn)S as well as that of metal sulphide compounds.

Solid-state room temperature reduction and exchange reactions of metal (M) sulphides (FeS, $WS_2$, $MoS_2$, $Cu_2S$, CoS, PbS, ZnS) [282] were driven by ball-milling of powder mixtures of a sulphide and of either a reductant (R = Al, Mn, Fe, Si) or an exchange compound (CaO).

Milling results in a complete reduction of the metal sulphide and in the formation of nanocomposites made of M and R sulphide. Exchange reactions with CaO show the formation of M oxide–CaS nanocomposites:

$$MS + R \rightarrow RS + M$$

$$MS + CaO \rightarrow CaS + MO$$
Iron sulphides were for instance reduced by aluminum, manganese, and silicon, copper sulphides by aluminum and iron, and cobalt, lead, and zinc sulphides by aluminum. Exchange reactions took place for iron, tungsten, and molybdenum sulphides.
## 5.5. Nanocomposite Formation

### 5.5.1. Magnetic Nanocomposites

Magnetic nanocomposites [283] of small iron particles embedded in nonmagnetic zinc oxide have been prepared by ball-milling (Spex machine) via *in-situ* displacement reactions:

$$Fe_3O_4 + 4Zn \rightarrow 3Fe + 4ZnO$$
The final particle size is about 9 nm as estimated from X-ray diffraction line broadening. The end product is a semi-hard magnetic material exhibiting a significant volume fraction of superparamagnetic Fe particles.

Solid-state room temperature exchange reactions of iron nitride, fluoride, and cementite $Fe_3C$ with silicon or aluminum, carbon, and chromium respectively were investigated [284] according to

$$(\text{iron nitride}) + Al \rightarrow AlN + Fe$$

$$(\text{iron nitride}) + Si \rightarrow Si_3N_4 + Fe$$

$$FeF_3 + C \rightarrow C \text{ fluoride } + \text{ Fe fluoride}$$

$$Fe_3C + Cr \rightarrow (Fe, Cr) \text{ carbide}$$

A partial transfer of nitrogen from iron nitride to aluminum and silicon, with the formation of aluminum and silicon nitrides, was evidenced. Partial transfer of fluorine was obtained too by reaction milling. A mixed, largely amorphous (Fe,Cr) C alloy was formed. The as-milled powders have small crystallite sizes (10–20 nm) and may

thus be considered as nanocomposites composed of AlN–$Fe_{2.5}N$–(FeAl) alloy, $Si_3N_4$–$Fe_{2.5}N$–(FeSi) alloy, $FeF_3$–$FeF_2$–$FeF_3(H_2O)_{0.33}$–$CF_n$–$(CF_{1.1})_n$ and (Fe,Cr)carbide–(Fe,Cr)C amorphous alloy.

### 5.5.2. Synthesis of Nanocermets (Oxide–Metal Nanocomposites)

Metal–matrix composites (MMCs) have been of interest for several decades. Several methods have been developed to incorporate large volume fractions of oxides, carbides, borides, and other particles into metallic matrices. The mechanical alloying technology has been used to produce strengthened MMCs with oxide dispersions and controlled fine microstructures. Derived from mechanical alloying, the mechanochemical process is suited for the formation of complex precursor oxides for advanced materials technology applications. Schaffer and McCormick [285] reported the direct synthesis of metallic Cu by milling mixtures made of its oxide and of various reducing elements such as Al, Ca, Ti, Mg, Mn, Fe, and Ni.

### 5.5.3. Alumina–Metal Nanocomposites

Nanometer sized alpha-$Al_2O_3$–M composites (M = Fe, V, Cr, Mn, Co, Ni, Cu, Zn, Nb, Mo, W, Si, Fe alloys) were synthesized by solid-state reduction reactions occurring during room-temperature ball-milling of mixtures of a metal oxide ($M_xO_y$) and aluminum ($Al_{2y/3}$) [286, 287].

The sizes of both alumina and metal crystallites obtained in that way are close to 10 nm for powders processed in a vibratory mill (24 hours). In a planetary mill, nanocrystalline phases have crystallite sizes about 2–3 times larger after milling for about one hour with a smaller powder-to-ball ratio.

Nanocomposite powders [(Fe or Fe–Cr alloy)/alpha alumina (75 and 85 vol%)] were prepared [288] by room temperature high-energy milling powder mixtures of haematite (and chromium oxide) with aluminum and alumina in a high-capacity mill according to the following reactions:

$$Fe_2O_3 + 2Al + 0.7 \text{ (or 2.1) } Al_2O_3$$
$$\rightarrow 1.7 \text{ (or 3.1)}Al_2O_3 + 2Fe$$

$$Fe_2O_3 + 0.16Cr_2O_3 + 2.32Al + 0.77 \text{ (or 2.49) } Al_2O_3$$
$$\rightarrow 1.93 \text{ (or 3.65) } Al_2O_3 + 2Fe + 0.32Cr$$

Both the metallic and ceramic phases have crystallite sizes smaller than 15 nm for all the investigated compositions. A spinel oxide, hercynite, $FeAl_2O_4$, is formed during the reduction reaction and is retained in small amounts in the final powders. In the Fe–Cr/$Al_2O_3$ composite, the metallic matrix has a lower Cr content than expected as a significant amount of Cr is dissolved in alumina.

The solid-state reduction of $Fe_2O_3$ (haematite) by ball-milling with Al or Mg has been investigated by Nasu et al. [289] according to the following equations:

$$Fe_2O_3 + 2Al \rightarrow 2Fe + Al_2O_3$$

$$Fe_2O_3 + 3Mg \rightarrow 2Fe + 3MgO$$
A partial substitution of Fe by Al in the alpha-Fe lattice has been revealed by Mössbauer analyses.

For the second reaction, the reduction of $Fe_2O_3$ results in the formation of alpha-Fe, MgO, and an unknown compound (presumably a wustite-like $Fe_{1-x}Mg_xO$ compound).

Takacs has studied the reduction of magnetite by aluminum by the way of a displacement reaction induced by mechanical alloying [290]. An explosive solid-state reaction occurs in a wide composition range as revealed by the sudden temperature rise of the grinding media. The reduction of $Fe_3O_4$ to Fe by metallic Al is consistent with the following reaction:

$$3Fe_3O_4 + 8Al \rightarrow 9Fe + 4Al_2O_3$$
Off–stoichiometry lengthens the incipient stage of the reaction and changes the reaction products. A slight reduction of the amount of Al results in the formation of hercynite, $FeAl_2O_4$, instead of $Al_2O_3$; an excess of Al suppresses the formation of the metastable gamma-$Al_2O_3$ phase and of $FeAl_2O_4$ and results in a disordered bcc alpha-FeAl solid solution and alpha-$Al_2O_3$.

Shengqi et al. have investigated the solid-state reaction of the Al/CuO couple by high-energy ball-milling [291]. A sole reduction occurs for an Al content of 20 wt%. When the amount of Al exceeds 20 wt%, along with the reduction leading to the formation of alumina, a synthesis reaction occurs simultaneously. As the amount of Al increases, the reaction products are $Cu_9Al_4$, $CuAl_2$, or a Al(Cu) solid solution, respectively.

### 5.5.4. Silica–Metal Nanocomposite Formation

The reduction induced by ball-milling of hematite ($Fe_2O_3$) by silicon takes place through the formation of intermediate phases containing divalent iron [292].

The phases are oxides (magnetite and wüstite) and silicates (fayalite and iron silicate glass). In the stoichiometric conditions, the reduction is not fully achieved leading to an end product consisting of alpha-Fe and divalent iron in a silicate glass. In the case of an $Fe_2O_3$ excess in the starting powder mixture, the final product is also composed of fayalite and magnetite.

On the basis of the intermediate compounds which were characterized by Mössbauer spectrometry, during the evolution of the reaction, the following steps have been proposed to describe the oxygen transfer:

(1)  $2Fe_2O_3 + Si \rightarrow 4FeO + SiO_2$
     $FeO + Fe_2O_3 \rightarrow Fe_3O_4$

(2)  $2FeO + SiO_2 \rightarrow Fe_2SiO_4$
     $xFeO + SiO_2 \rightarrow Fe_xSiO_{2+x}$
     $FeO + Si \rightarrow Fe + SiO_2$

(3)  $Fe_3O_4 + 2Si \rightarrow 3Fe + 2SiO_2$
     $Fe_xSiO_{2+x} + x/2 \rightarrow xFe + x/2SiO_2$

Corrias et al. have prepared Ni–silica, Cu–silica [293], and Fe–silica [294] nanocomposites by ball-milling according to the following reactions:

$$2NiO + Si \rightarrow 2Ni + SiO_2$$

$$2CuO + Si \rightarrow 2Cu + SiO_2$$
In the first reaction, oxygen is directly transferred from NiO to Si which is completely oxidized into silica, while the stoichiometric quantity of NiO is reduced to Ni. The sizes of the Ni crystallites are in the nanometer range. Similar milling processing conditions, which have applied to mixtures containing CuO, give rise to the formation of Cu(I) intermediate products.

### 5.5.5. Other Nanocomposite Formation

In a study of the dynamics of planetary ball mills, Dallimore and McCormick have investigated the CuO/Ni displacement reaction milling kinetic [295]. A two-dimensional, discrete element method software (so-called DEM simulation) has been developed to predict ball motion in a planetary ball mill. Various models have been assessed to simulate actual milling impacts. They have been used to study the relevant parameters of the kinetics of the CuO/Ni displacement reaction propagated under these conditions. It was concluded that the distribution of the impact energies does not significantly affect reaction propagation over the range of the investigated speeds.

The structural evolution of rod-milled $Cu_2O$ and Ti powders during mechanical solid-state reactions has been studied by El-Eskandarany [296]. Cuprous oxide is reduced to metallic copper by elemental titanium in such processing conditions. The end product is a mixture of nanocrystalline Cu and $TiO_2$ powders with an average crystallite size of 7 nm.
### 5.5.6. Reduction of Minerals: The Case of Ilmenite

The mechanochemical reactions of ilmenite with different additives have been investigated by several authors.

Chen et al. [297] have reported the reactions with Si and Ti. The results can be summarised as follows:

$$2FeTiO_3 + Si \rightarrow 2Fe + 2TiO_2 \text{ (nanocrystalline)}$$
$$+ SiO_2 \text{ (amorph.)}$$
$$(\Delta G = -76.3 \text{ kcal mol}^{-1})$$
$$2FeTiO_3 + Ti \rightarrow 2Fe + 3TiO_2$$
$$(\Delta G = -84.2 \text{ kcal mole}^{-1})$$

The reactions with Al and Zr differ from the previous ones as they result in the formation of a mixture of alpha-Fe and of a multinary amorphous phases. Therefore, ball-milling induces not only reduction/oxidation reactions but also new chemical reactions:

$$3FeTiO_3 + 2Al \rightarrow 3Fe + 3TiO_2 + Al_2O_3$$
$$(\Delta G = -185.5 \text{ kcal mole}^{-1})$$
$$2FeTiO_3 + Zr \rightarrow 2Fe + 2TiO_2 + ZrO_2$$
$$(\Delta G = -120.1 \text{ kcal mole}^{-1})$$

Mechanically induced chemical reactions between $FeTiO_3$ and Si [298] lead to the formation of elemental iron, $TiO_2$,

and metal silicides, depending on the Si content. The products are increasingly reduced as the molar ratio of silicon to ilmenite increases from 1:2 to 2:1. The reaction has been found to lead to the formation of $TiO_2$ and elemental iron. Further reduction of the $TiO_2$ to $Ti_nO_{2n-1}$ phases then occurred in parallel with iron silicide formation. The final stage is the reduction of the $Ti_nO_{2n-1}$ phase to titanium silicide. Under a high intensity impact, the reaction proceeds more rapidly than under low intensity impact.

Milling of a mixture of ilmenite and aluminum [299] leads to reaction within the mill forming $TiAl_3$, $Fe_4Al_{13}$, $Al_2O_3$. The same reaction occurs in unmilled powders after heating to a temperature higher than 850 °C for 1 h.

To increase the efficiency of the preceeding reduction process, the carbothermic reactions were extensively investigated [300].
The chemical reactions that occur during the reduction process can be conveniently separated into a solid-state reduction (typically from 860 to 1000 °C),

$$FeTiO_3 + C \rightarrow Fe + TiO_2 + CO \quad (gas)$$
a gaseous reduction (typically above 1000 °C),

$$FeTiO_3 + CO\ (g) \rightarrow TiO_2 + Fe + CO_2\ (g)$$
and a reduction of rutile (typically above 1200 °C),

$$3TiO_2 + CO\ (g) \rightarrow Ti_3O_5 + CO_2\ (g)$$

After ball-milling of a carbon–ilmenite mixture at room temperature, ilmenite was found to be reduced to rutile and alpha iron during subsequent low temperature annealing. The reduction temperature and the reduction kinetics for production of this intermediate reduction state ($TiO_2$) depend critically on the milling conditions:

(1) With increasing milling time, the reduction temperature decreases and the reaction rate increases.
(2) High milling intensity also leads to a lowering of the annealing temperature for the main reduction step to rutile.

A parametric study of the mechanically activated carbothermic reduction of ilmenite has been performed by Welham [301]. As reported by Welham, ilmenite ($FeTiO_3$) is the primary global source of titanium dioxide which is commonly used as a whitening agent in paper manufacture and as a pigment in paint manufacture:

$$FeTiO_3 + C \rightarrow Fe + TiO_2 + CO$$
$$C + CO_2 \rightarrow 2CO$$
$$FeTiO_3 + CO \rightarrow Fe + TiO_2 + CO_2$$
$$nTiO_2 + CO \rightarrow Ti_nO_{2n-1} + CO_2$$
The separation of iron from titanium has been enhanced by milling ilmenite and coal powder together prior to annealing. The subsequent solubility of iron was maximized when the fraction of the elemental iron after annealing was at a maximum. On the other hand, titanium solubility was minimized when rutile was the predominant titanium product.

The leaching step is much faster than conventional processing, primarily due to the much finer particle size. No elemental iron could be detected by X-ray diffraction after leaching. Leaching indicated that the reduction of rutile was detrimental to iron removal and led to increased titanium dissolution.

### 5.5.7. Reduction of Minerals: The Case of Bastnaesite

A nonthermal process for extracting rare earths from bastnaesite by means of mechanochemical treatment has been developed by Zhang and Saito [302]. Bastnaesite ($ReCO_3F$, Re = rare earths) is one of the most important resources containing rare earth elements such as La and Ce. There are several hydrometallurgical methods for extracting them from bastnaesite. They can be classified into two process methodologies: one is the acidic method using $H_2SO_4$ solution; the other the alkali method using NaOH. In the former, bastnaesite is dissolved in a concentrated acid solution which is heated to 473 K to form rare earth sulfates. Another method is the dissolution of bastnaesite in acid solution after roasting at 1073 K. In this case, the initial material is decomposed into oxide forms $Re_2O_3$. One of them, $Ce_2O_3$, is oxidized to $CeO_2$ which is hard to dissolve in the acid solution. Therefore acid leaching is used for separating soluble rare earths from $CeO_2$.

In contrast, several investigations using the alkali method have been reported. One is the decomposition of bastnaesite by a 45% NaOH solution heated at near the boiling point. Another involves the decomposition of minerals by a NaOH solution in an autoclave or by a molten NaOH medium. In any case, high temperature treatments are needed to extract the rare earths from bastnaesite. Therefore an alternative process operated at relatively low temperature and mild conditions would be desirable:

$$LaCO_3F + 3NaOH \rightarrow La(OH)_3 + Na_2CO_3 + NaF$$
Extraction of the rare earth elements such as La, Ce, Pr, Nd, Sm included in bastnaesite was attempted with NaOH powder using a planetary mill.

(1) Milling of the mixture composed of bastnaesite and NaOH powders permits the formation of rare earth hydroxides and Na compounds. The $Ce(OH)_3$ and $Pr(OH)_3$ so formed are changed into the respective oxides in the high oxidation state during and after the milling operation.
(2) The rare earth hydroxides/oxides can be separated from the Na compounds by washing with distilled water at room temperature. Most of the carbonates and 75% of the fluorides are removed from the milled mixture by the washing operation.
(3) The rare earth oxides are dissolved by either $H_2SO_4$ or HCl solutions at room temperature. Controlling the concentration of the $H_2SO_4$ solution is a key to the preferential extraction of La, Nd, Sm from Ce and Pr in the leaching stage. In addition, milling of the mixture composed of bastnaesite and NaOH powders plays a significant role in achieving a high yield of rare earth elements in the leaching of the washed sample.

# 6. ORDER–DISORDER TRANSFORMATIONS AND BALL-MILLING

## 6.1. Introduction

Order–disorder transformations, which have played a major role in the development of modern physical metallurgy, attract still a great deal of attention both for theoretical reasons and for their applications as high-temperature structural materials [303–307]. Further, recent potential applications of ordered alloys are based on peculiar combinations of magnetic, transport, and structural properties which are strongly dependent on chemical order (among others [308–311] and references therein). Notable examples are Heusler alloys such as $Co_2MnGe$, $Co_2MnSi$, or $Ni_2MnIn$ for spin-sensitive electronic devices which include magnetic memory and hard disk read-heads, or $Ni_2MnGa$ for actuators and sensors because giant deformations can be induced by an externally applied magnetic field to which the alloy responds much faster than to heating or cooling. Another notable ordered alloy is $Fe_{65}Co_{35}$, which has the largest room-temperature magnetization, but it is a soft magnet. A way to enhance the properties of permanent magnets is through "exchange coupling" between a hard material and a soft material with a large magnetization. Models show that the soft phase must have grains of about 10 nm diameter and that the hard phase too must have nanosized grains ([312] and references therein). An ideal exchange-coupled magnet, consisting of aligned grains of $Sm_2Fe_{17}N_3$ and of $Fe_{65}Co_{35}$, is expected to reach an energy product of about 125 MGOe [313]. For both applied and fundamental aspects, it is thus necessary to characterize and master the state of order of alloys, in particular for the more demanding class of nanostructured materials for which there are prospects of improved properties with respect to those of their classical counterparts and expectations of extended fields of applications.

Ordered intermetallics are usually found in rather narrow compositional ranges around simply expressed stoichiometric compositions which reflect the underlying existence of superlattices which are few in number. Reversibly ordered alloys have their critical ordering temperature $T_C$ which is lower than their melting temperature $T_m$ (examples are $L1_2$ $Cu_3Au$, $DO_3$ $Fe_3Al$, $DO_{19}$ $Ti_3Al$, $L1_0$ $CuAu$, B2 FeCo, B2 CuZn). By contrast, permanently ordered alloys have only a virtual ordering temperature $T_C$ as it is higher than $T_m$ (examples are $L1_2$ $Ni_3Al$, B2 NiAl, $L1_0$ TiAl) [303, 304]. Reversibly ordered alloys are the sole alloys which can in principle be retained in a disordered nonequilibrium state at temperatures lower than $T_C$ by a heat treatment followed by a quench. As discussed by Cahn [303, 304] thermal treatments of the latter alloys falls into three categories: (1) alloys which are easily disordered or ordered by slow cooling, (2) alloys in which the self-diffusivity is so high that disordering is difficult at normal quenching rates, and (3) alloys in which the self-diffusivity is so low that it is difficult to order them even by very slow cooling. Other methods may be used to drive order–disorder transformations, notably irradiation [35, 314]. As reviewed (and modeled) by Martin and Bellon [35], two contradictory processes compete under

irradiation for establishing a steady-state configuration, on the one hand a chemical disordering proportional to the irradiation flux, on the other hand a reordering promoted by thermally activated point defects at a rate proprotional to the product of their concentration, their jump frequency, and their temperature-dependent driving force for ordering. The eventual steady-state configurations achieved by such alloys depend on the "forcing" conditions. Dynamical equilibrium phase diagrams have been determined theoretically and experimentally [35].

Plastic deformation is also a means of changing the state of order of alloys which was and is still used to prepare and investigate structures far from equilibrium. The changes of magnetic properties of B2 $Fe_{1-x}Al_x$ $(0.30 \leq x \leq 0.40)$ alloys during compression testing were for instance studied recently [315]. A technique to plastically deform particles is simply ball-milling and the focus will be hereafter on its effect on order–disorder transformations. Earlier works are about the influence of grinding on the magnetic properties and on the hyperfine magnetic properties [nuclear magnetic resonance (NMR), Mössbauer spectroscopy] of B2 FeAl [316] and of $L2_1$ Heusler alloys $X_2MnY$ (X = Ni, Cu, Pd, Y = Al, In, Sn, Sb) [317, 318] (Fig. 7). The crushing of some Heusler alloys to prepare powdered samples was indeed observed to change drastically their magnetic properties, for instance reducing the saturation magnetization to about one-third of its value, increasing the NMR signal intensity, and generating satellite lines in $Pd_2MnSn$ [318, 319]. These investigations were thus motivated by the need to eliminate the defects produced by cold-work (dislocations, antiphase boundaries, atomic disorder) by annealing treatments. More recent studies of ball-milling of ordered alloys are still aimed at characterizing ground alloys with nanometer-sized grains and their reordering kinetics if disordered but the determination of steady states "under" milling has become central to that research field [35, 314].

The studies of ball-milled ordered alloys typically show a large accumulation of defects during milling which can drive phase transformations such as amorphization [320–322]. The reverse transformation, disordering a B2-ordered $Fe_{60}Al_{40}$ nanocrystalline alloy during high-energy ball-milling, has also been studied recently [323]. We shall first describe a study of mechanical milling of $X_2MnSn$ Heusler alloys to emphasize the possibility that thermally induced disorder differs from mechanically induced disorder. Then, we will describe an example of reordering of disordered nanocrystalline FeV alloys by low-temperature annealing.

**Figure 7.** The ordered structures: $L2_1$, $D0_3$, and B2, shown on an underlying lattice of eight bcc unit cells. In the $L2_1$ structure of $X_2MnSn$, the X atoms occupy the white sites, the Mn occupy the gray, and the Sn occupy the black.

## 6.2. Disordering of Ordered Alloys by Ball-Milling: The Example of X₂MnSn Heusler Alloys

Heusler alloys X$_2$YZ, more particularly X$_2$MnSn alloys in which Mn atoms carry a magnetic moment of more than 3 $\mu_B$, are excellent candidates for evidencing such behavior. Their structure is indeed reasonably simple (Fig. 7) and their magnetic (and hyperfine magnetic) properties are well documented (see [324–331] among others). The L2$_1$ structure may contain two types of antiphase boundaries (APBs) with fault vectors of $a/4\langle 111\rangle$ (B2 APBs) and $a/2\langle 100\rangle$ (L2$_1$ APBs) respectively, where $a$ is the lattice parameter [317, 318]. First and second nearest-neighbor Mn atoms are altered in the APBs with the formation of first nearest-neighbor Mn–Mn pairs in L2$_1$ APBs and of second nearest-neighbor Mn–Mn pairs in B2 APBs. As the magnetic properties are strongly dependent on the interactions between Mn atoms, a difference in the nature of thermal APBs and of APBs formed during plastic deformation may produce large magnetic differences between thermally and mechanically disordered alloys. The effect of cold work simply produced by crushing samples with a pestle in an agate mortar varies indeed considerably from one Heusler alloy to another [316–319]. A significant reduction of saturation magnetization, by about 60%, with cold work is for instance observed to occur in Pd$_2$MnSn [317–319] and is attributed to a high density of B2 antiphase boundaries created by plastic deformation [317, 318]. By contrast, crushing is supposed to bring about only L2$_1$ APBs in Pd$_2$MnSb because the reduction of magnetization is very small for that alloy [318]. The Heusler alloys Cu$_2$MnSn [332] and Cu$_2$MnAl [333] were found to be unstable when milled for short and for long times respectively.

The disorder induced thermally in Ni$_2$MnSn was compared to the disorder induced by ball-milling using neutron diffraction and [119]Sn Mössbauer spectrometry [332]. As-cast Ni$_2$MnSn alloys were annealed under low-pressure argon at a temperature $T_a$ ($T_a$ = 773, 973, 1023, 1073, 1173, 1273 K) for 1 month and were quenched into water. Samples were milled under an argon atmosphere in a Fritsch P7 planetary mill for different times from 0.5 to 20 h with different powder-to-ball weight ratios, $R$, from 1/15 to 1/50. The magnetic properties (Fig. 8) and the hyperfine magnetic field distributions $P(H)$, where $P(H)\Delta H$ is the fraction of [119]Sn atoms whose hyperfine magnetic field is between $H$ and $H + \Delta H$ (Fig. 9), of as-milled samples differ strongly from those of samples quenched from high temperatures. The Curie temperature $T_c$ decreases sligthly from 343(3) to 333(3) K when $T_a$ increases from 773 to 1073 K. The magnetization curves of all as-quenched samples are similar to those of Figure 8 (left). In contrast, Figure 8 (right) shows that drastic changes of the magnetic structure take place in ground samples. As-milled Ni$_2$MnSn, which remains of the L2$_1$ type with a tendency toward B2 type of order, has a disordered magnetic structure while as-quenched samples remain basically ferromagnetic [332]. Further, neutron diffraction patterns indicated that the disorder retained by quenching from $T_a$ is similar to the disorder measured by *in-situ* diffraction experiments at temperatures identical or

**Figure 8.** Magnetization curves at 5, 30, 50, 100, 150, 200, 250, 300 K (from top to bottom) of Ni$_2$MnSn quenched from 1273 K (left) and ground (right) (note the difference in scales).

close to $T_a$. High-temperature neutron diffraction measurements at 1080, 1180, and 1265 K show that the structure of Ni$_2$MnSn is still of the L2$_1$ type above 980 K and not of the B2 type as proposed in the literature [334]. Moreover, the lattice parameter of as-quenched samples decreases regularly from 0.6045(1) to 0.6015(2) nm for 973 K = $T_a$ = 1273 K while it is 0.6022 nm for the ground sample.

Figure 9 shows the [119]Sn Mössbauer spectra at 80 K of as-quenched samples and the associated hyperfine magnetic field distributions $P(H)$. The 119 Sn hyperfine magnetic field distributions of as-quenched samples at 80 K have two characteristics: a main peak near 90 kG, the sole contribution expected for a perfectly ordered alloy, and a broad

**Figure 9.** [119]Sn Mössbauer spectra at room temperature and at 80 K of Ni$_2$MnSn either quenched from $T_a$ or ground and hyperfine magnetic field distributions $P(H)$ associated with the spectra recorded at 80 K.

low-field tail (Fig. 9) [332]. The increase of the weight of the latter contribution with $T_a$ reflects the greater chemical disorder retained by quenching from higher $T_a$. This increase reflects the greater chemical disorder retained by quenching from higher $T_a$. The main peak of $P(H)$ remains at the same position for all $T_a$. In contrast, spectra from the as-milled samples differ strongly from those of as-quenched samples with broad, almost featureless, field distributions without a main peak near 90 kG. The mean field at 5 K was found to be reduced from 92 kG for perfect order to 69 kG for $T_a = 1273$ K and to 55 kG for ground samples milled long enough to be in a steady state. Hyperfine properties show thus that the magnetic disorder in ground samples differs from the magnetic disorder in as-quenched samples in agreement with magnetic measurements. These results suggest that in the as-milled samples there is a broad distribution in both magnitudes of Mn moments and angles between them. Changes of magnetic (and hyperfine magnetic) properties combined with the strong reduction of the intensity of the (111) superlattice neutron diffraction line in milled samples confirm that disorder induced by the shear deformation of grinding differs from the disorder induced by temperature. Therefore, it appears impossible to find an annealing temperature that can provide as-quenched $Ni_2MnSn$ samples with the same chemical disorder as for milled samples. These conclusions appear to be consistent with the preferential formation of $L2_1$ APBs and of B2 APBs in annealed alloys and in as-milled alloys respectively. Similar differences between thermal and mechanical disorder were found for $Co_2MnSn$ alloys [332]. Doubt is thus cast upon the universal validity of phase diagrams of ground ordered alloys which consider that mechanical energy and thermal energy have identical effects.

## 6.3. Reordering of Ground Disordered Alloys

The high density of defects of materials disordered by milling, especially vacancies and grain boundaries, enhance the kinetics of ordering, enabling studies at lower temperatures and more practical times than in coarse-grained quenched alloys. For example, a metastable B2 phase has been prepared in Fe–V alloys with equiatomic compositions by quenching from above ~1500 K and annealing the unstable bcc phase for a few hours at 870 K [335–337], or for a few days at temperatures between 700 and 800 K [337]. Annealing for only 8 h at 723 K is needed to reach the steady state of B2 order for as-milled bcc $Fe_{0.53}V_{0.47}$ [338].

The study of ordering in nanocrystalline alloys is itself a topic of widespread current interest. The formation of B2, $L1_2$, and $D0_3$ order in several nanocrystalline alloys has been reported, including Ti–Al, Fe–Al, Fe–Si, Fe–Co, Ni–Al, and Cu–Au, sometimes with ternary additions [339–358]. These studies have emphasized various aspects of defects and diffusion in nanostructured alloys, with comparison to coarse-grained materials. A number of features seem common to the reordering of chemically disordered nanocrystalline materials, in spite of differences in their methods of synthesis (e.g., ball-milling [339–340, 344, 346–349, 352–353, 355], plastic deformation [356], gas-phase condensation with compaction [350, 351], sputtering [345], ion irradiation

[357]), microstructures (isolated clusters [345] or more typically micrometer-sized particles composed of nanometer-sized grains), and ordered structures. Reordering can occur at low temperatures and involves only few jumps of nonequilibrium vacancies that were not promptly annihilated at sinks [346, 350–353, 356–358]. Grain boundaries probably prevent order from propagating from one grain to another [344, 348]. It is less clear if chemical disorder exists near grain boundaries or antiphase boundaries.

A curious feature of ordered nanocrystals is that the steady-state value of the long-range order (LRO) parameter is generally lower than that of bulk samples [345, 348–351]. For example, the relative long-range order parameter of $Fe_{0.53}Al_{0.47}$ synthesized by gas-phase condensation and high-pressure compaction, annealed at 800 K and below, stabilizes at 0.8 instead of increasing to 1.0 [350, 351]. Recent studies lead to the conclusion that this suppressed order parameter is not intrinsic to the nanocrystalline structure but that it is a kinetic effect associated with low temperatures of annealing. The example of the ordering of ground nearly equiatomic Fe–V alloys is described.

## 6.4. Ordering of Nearly Equiatomic Nanostructured Fe–V Alloys

The equilibrium Fe–V phase diagram shows complete mutual solubility of Fe and V in a bcc $\alpha$-phase at high temperatures and shows a $\sigma$-phase below ~1500 K in the central part of the diagram. Owing to the slow kinetics of the $\alpha \rightarrow \sigma$ transformation, as also found for nearly equiatomic Fe–Cr alloys, the $\sigma$-phase formation can be bypassed kinetically, and a disordered bcc phase can be obtained at low temperatures by rapid cooling [335]. A chemical ordering transformation into an ordered B2 phase can then occur on the bcc lattice during annealing at low temperatures [336, 337]. For example, a metastable B2 phase has been prepared in Fe–V alloys with equiatomic compositions by quenching from above ~1500 K, and annealing the unstable $\alpha$-phase for a few hours at 870 K, or for a few days at temperatures between 700 and 800 K [335]. Although the B2 phase does not appear on the equilibrium phase diagram, a metastable Fe–V phase diagram for the A2 and B2 phases, without $\sigma$-phase, has been theoretically calculated [336].

Nanocrystalline nearly equiatomic bcc Fe–V alloys can be synthesized by mechanical alloying for instance [337] and then ordered by annealing at low temperatures [338]. The values of the LRO parameter $S$ are most reliable for the lower annealing temperatures, where enhanced kinetics in nanocrystalline materials allow steady state to be reached in reasonable times. The high density of grain boundaries in nanocrystals promotes the formation of $\sigma$-phase at higher temperatures. Although the formation of $\sigma$-phase is relatively sluggish, it is indeed much faster in these nanocrystalline Fe–V alloys than in coarse-grained Fe–V. In a conventional coarse-grained $Fe_{0.50}V_{0.50}$ alloy annealed for 120 h at 873 K, $\sigma$-phase forms only near free surfaces, and negligibly in the bulk [338]. A $Fe_{0.53}V_{0.47}$ alloy annealed for 100 h at 873 K is fully transformed into $\sigma$-phase while only 30 min suffice at 973 K. In contrast, the metastable steady state of $Fe_{0.53}V_{0.47}$ is in the B2 single-phase region between 700 and 873 K [338]. The LRO parameter, $S$,

of a B2 $Fe_{1-x}V_x$ alloy is $S = 2([Fe]_{Fe-1+x})$, where $[X]_Y$ $(X, Y = Fe, V)$ is the concentration of atomic species X on sublattice Y, where the designation Y for the sublattice refers to its majority species. The LRO parameter reaches its minimum value, $S = 0$, when the alloy is fully disordered while its maximum value is $S_m = 1 - 2|\Delta x|$, where $\Delta x = x - 0.5$, for a negligible concentration of vacancies.

Figure 10 presents the LRO parameter measured by neutron diffractometry as a function of annealing time at 723 K and other temperatures. At 723 K, $S$ increases rapidly at first and reaches a plateau between 8 and 24 h. The very small size of the ordered domains in the as-milled $Fe_{0.53}V_{0.47}$ is comparable to the 2.5 nm domain size reported for ball-milled B2 FeAl [352]. At 723 K, the ordered domain size increases with annealing time and matches the crystallite size after some hundreds of hours. Figure 11 compares the steady-state experimental values of the LRO parameter, $S$, as a function of $T/T_c$, along with LRO calculated by the cluster variation method, and from the classical Bragg–Williams model [338]. The experimental LRO parameters, $\sim0.80$, are smaller than the values expected for equilibrium. The measured steady-state LRO parameters for different V contents were found to be consistent with the aforementioned metastable Fe–V phase diagram [338]. The previous LRO parameters are close to those reported for nanocrystalline materials reordered at low temperature [350, 351]. The thermal stability of disordered mechanosynthesized $Ni_{40}Al_{40}T_{20}$ (T = Cr, Fe) was recently investigated [359]. The highest value of the long-range order parameter in mechanosynthesized NiAl was measured to be about 0.75 during reordering at 873 K. Grain growth was found to slow down once the order parameter reaches a steady value at any annealing temperature for the investigated alloys. Preliminary investigations indicate that reordering of disordered $Ni_2MnSn$ occurs already by annealing at 523 K for times as short as 5 hours [360].

The kinetics and mechanisms of chemical ordering could be altered by the nanocrystalline nature of the material. Any material with a $\sim7$ nm grain size has indeed a high density of grain boundaries. An even higher density of antiphase boundaries exists in these materials, since the

**Figure 11.** Reduced long-range order parameter of $Fe_{1-x}V_x$ as a function of $T/T_c$ calculated with the CVM model and the Bragg–Williams model. Full circles are experimental values of the steady state values for $x = 0.47$ and full triangle are for $x = 0.39$. Reprinted with permission from [338], T. Ziller et al., *Phys. Rev. B* 65, 024204 (2002). © 2002, American Physical Society.

domain sizes are only 2–3 nm in the early stages of ordering. Monte Carlo simulations of ordering with a vacancy mechanism at low temperatures have revealed a high density of antisite defects once ordered domain formation is complete [361–363]. The high antisite population is quite different from the clean ordered domains during ordering by interchanges of atom pairs, for example, even when the domain structures are comparable [361]. Antiphase domain boundaries serve as traps for vacancies [361], reducing their effectiveness in annealing out the antisite atoms, and the motion of the APBs is not always conservative. This transient population of antisite atoms is responsible for a slow coarsening regime at low temperature [363]. Once the APBs are eliminated, the last antisite atoms are removed slowly [361–363]. Mössbauer spectroscopy proved useful to quantify the fraction of antisite Fe atoms in partially ordered FeV alloys and to evidence the role of antisite defects [338]. The fraction of antisite atoms was shown to decrease when $S$ increases at early annealing times. A further reduction of the latter fraction was measured when nanocrystals are single domains without APBs. The steady-state LRO parameter is smaller than the equilibrium value because of residual antisite defects that do not anneal out on the time scale of the experiments. The LRO parameters in these Fe–V alloys were not sensitive to grain growth. Little change in $S$ (about 0.7) was for instance observed at 723 K when most grain growth occurred [338]. The elimination of antisite defects requires some longer range diffusion, which is very slow in ordered domains at low temperatures. The kinetics at the later stages of annealing may also be suppressed by a low vacancy concentration. At the higher temperature of 873 K, however, once the domain size grows to the crystal size, $S$ then increases from 0.64 to 0.75, which is close to the value expected in thermodynamic metastable equilibrium (Fig. 11) [338].

**Figure 10.** Long-range order parameter at room temperature of as-milled $Fe_{0.53}V_{0.47}$ as a function of annealing time at different temperatures. Reprinted with permission from [338], T. Ziller et al., *Phys. Rev. B* 65, 024204 (2002). © 2002, American Physical Society.

In summary, reordering results first from the elimination of antiphase boundaries and second from the removal of the last antisite defects which is very slow in ordered domains at low temperatures. Thermal reordering takes place prior to recrystallization, and in a temperature range similar to the milling temperature [364]. The reduction of the steady-state value of the long-range order parameter is due to a kinetic effect associated with the low temperatures of annealing.

Besides their historical and practical importance [303–307], order–disorder transformations play an important role in the understanding of the physics of mechanical alloying. Some of the most convincing proof of the very existence of dynamical equilibrium under milling is for example provided by ground FeAl alloys [314, 358, 364] which further show that initially disordered alloys may reorder under milling if the pertinent parameters, a dynamical parameter and the milling temperature, are adequately chosen. As briefly described for Heusler alloys and as emphasized by Martin et al. [314, 358, 364], the destruction of long-range order is a result of the plastic shear of grains (e.g., one dislocation gliding along its slip plane leaves a planar stacking fault behind). Alternatively, one pair of jogged dislocations on a single slip plane leaves behind a tube of stacking faults, etc. Moreover, shear induced vacancies enhance the atomic mobility and hence speed up the reordering process in the time interval between two collisions. These mechanically induced "ballistic jumps" occur in a collective manner along the shear planes. As suggested by computer simulations, these space and time correlations of ballistic jumps might result in original microstructures [364].

# 7. ALLOYING BY HIGH-ENERGY BALL-MILLING (SUPERSATURATED SOLID SOLUTIONS)

## 7.1. Introduction

The fundamental problems of the mechanisms of mixing of elements by milling and of the resulting formation of phases such as extended solid solutions, in particular in binary metallic systems of elements which have limited solid solubilities or are immiscible in equilibrium, intermetallic compounds, amorphous phases, or the two-phase coexistence in alloys for certain concentration ranges are still thoroughly investigated. Some examples are Cr–Sn, Fe–Cr, Fe–Cu, Fe–Sn, Fe–Ta, Co–Cu, Ni–Cu, Ni–Ag, Cu–Ta, Ag–Cu [365–392]. The interest in the characterization and modeling of supersaturated solid solutions formed in a large number of systems with positive heats of mixing is obviously not restricted to mechanosynthesized materials but extends to materials produced by all kinds of methods [393–398].

To reach sound conclusions about their actual structures on a nanometer scale (are they compositionally homogeneous or decomposed?), techniques which yield both global information and local information on ground powders must be combined. In that way, it is possible to follow not only the average properties of powder particles but also their fluctuations in the whole sample both during milling and in as-milled materials. Single-phase structures have been, for instance, obtained by mechanical alloying in a broad concentration range in the archetypal Fe–Cu system, for example,

fcc Cu(Fe) solid solution for iron contents lower than 45 at% and bcc Fe(Cu) solid solution for iron contents higher than 55 at% [15–17, 23–27].

In between, the two phases coexist [379, 381]. However, some results of Mössbauer spectrometry and atom probe investigations indicate that these solid solutions are chemically heterogeneous on a nanometer scale [379, 381, 389–391]. In a recent work on nanocrystalline $Fe_yCu_{1-y}$ ($0.141 \leq y \leq 0.450$) alloys produced by ball-milling [390], Fernandez et al. used a small-angle X-ray scattering technique to conclude that the synthesized alloys are heterogeneous on a nanometer scale since composition fluctuations were detected inside nanocrystalline grains. Wanderka et al. [389] investigated the microstructure and composition on the nanometer scale of mechanically alloyed $Cu_{50}Fe_{50}$ with a tomographic atom probe. They concluded that samples contain nanometer-sized regions with strongly varying composition. Further, supersaturated solid solutions formed deep inside a miscibility gap through rapid quenching or solid state routes may have decomposition features on the scale of a few nanometers as shown recently for sputtered fcc Ag–Cu solid solutions [397] or for mechanically alloyed $Fe_{30}Cr_{70}$ alloys [392] and for milled as-cast $Fe_{30}Cr_{70}$ alloys as will be further discussed.

In the following, we denote as $p-A_xB_y$ the initial mixture of powders of element A and of powders of element B in the atomic ratio $x:y$.

## 7.2. Composition Fluctuations during Mechanical Alloying: Two Notable Times

Given milling conditions, $t_m$ is defined as the current milling time and the synthesis time $t_f$ as the *minimum* time needed to enter a stationary state in which all kinds of powder characteristics remain unchanged when milling for $t_m \geq t_f$ (hardness, magnetic properties, average grain sizes, crystallographic structures, etc.).

Besides the synthesis time, $t_f$, a second characteristic milling time $t_{cm}$ was considered and termed "chemical mixing time" [399], $t_{cm} \leq t_f$. To define it, let us consider for instance a binary mixture of elemental powders with a mean composition $A_{1-x}B_x$ (Fig. 12). Powder particles are initially either pure A or pure B. The time $t_{cm}$ is then the *minimum* milling time at which *all powder particles* have essentially the final chemical composition $A_{1-x}B_x$. The particle scale is relevant because $t_{cm}$ can be measured, for instance using a microprobe [399], and because it is the shortest possible synthesis time, $t_f \geq t_{cm}$. Even if they have the expected composition, powder particles may be made up of various phases whose structures and compositions may still evolve for $t_{cm} \leq t_m \leq t_f$ (Fig. 12). For $t_m \leq t_{cm}$, mixing occurs simultaneously at different scales with a broad distribution of characteristics from particle to particle. Both $t_f$ and $t_{cm}$ were obtained, as will be described, for $Fe_{1-x}T_x$ elemental powder mixtures ground in a planetary ball mill, with $x = 0.50, 0.70, 0.72$ for T = V, Cr, and Mn respectively [399]. The synthesis time depends strongly on the considered Fe–T alloy while chemical mixing times were estimated to be similar whatever the element $T$, $t_{cm} \approx 3$–4 h, in the milling conditions described in [399] (planetary ball mill Fritsch Pulverisette 7 with a powder-to-ball weight ratio of 1/20).
**Figure 12.** Two characteristic times, the chemical mixing time $t_{cm}$ and the synthesis time $t_f$, illustrated for milling of Fe–T elemental powder mixtures.

### 7.2.1. Simple Method to Estimate the Chemical Mixing Time

To estimate the chemical mixing time $t_{cm}$ of A and B, a powder mixture p-$A_{1-x}B_x$ is ground for a time $t_m$ and the A content $x(i, t_m)$ of every powder particle ($i = 1, \ldots, N$) is imagined to be measured with standard methods. The fluctuation of the A content from particle to particle at time $t_m$ is then conveniently characterized by a standard deviation $\sigma(t_m)$ of the distribution of composition found in that way:

$$\sigma^2(t_m) = \frac{1}{N} \sum_{i=1}^{N} (x(i, t_m) - x)^2)$$

The chemical mixing time $t_{cm}$ is thus the shortest milling time for which $\sigma(t_{cm}) \approx 0$ in the considered experimental conditions. For instance, microprobe analyses performed on about 20–30 powder particles for samples of p-$Fe_{1-x}T_x$ (T = V, Cr, Mn) ground for $t_m$ yield a good estimate of $\sigma(t_m)$ (Fig. 13) [399]. The milling time dependence of the fluctuation $\sigma(t_m)$ appears to be well approximated by an exponential decrease in the case of some Fe–T binary systems,

$$\sigma(t_m) = \sigma(0) \exp\left(-\frac{t_m}{\tau_{cm}}\right) \qquad (1)$$

with a time constant $\tau_{cm}$. Time constants $\tau_{cm} = 39$ ($\pm3$) min, $\tau_{cm} = 55$ ($\pm5$) min, and $\tau_{cm} = 66$ ($\pm3$) min were obtained for T = V, Cr, Mn respectively. The times for which $\sigma \approx 0$ are then found to be similar, $t_{cm} \approx 4\tau_m \approx 3$–4 h, and for all alloys in the given milling conditions. The times, $\approx4$ h, needed to observe a stationary hardness and stationary shapes of hyperfine magnetic field distributions for T = V, Cr were found to both be of the order of $t_{cm}$. Figure 13 further shows the milling time dependence of the relative fraction

**Figure 13.** Milling time dependences of $\sigma(t_m)/\sigma(0)$ [and of $R_{Fe}(t_m)$ obtained from Mössbauer spectra] for p-$Fe_{0.28}Mn_{0.72}$ (left) and p-$Fe_{0.50}V_{0.50}$ (right).

$R_{Fe}(t_m)$ of Fe atoms which give rise to the "$\alpha$-Fe" contribution in Mössbauer spectra of p-$Fe_{0.50}V_{0.50}$. $R_{Fe}(t_m)$ clearly shows that the chemical mixing time $t_{cm}$ is much less than the synthesis time $t_f$ for this alloy. The typical chemical mixing times estimated in these experiments are not short as compared to the synthesis times (more than about 50%) and must be borne in mind when characterizing ground powders which have not yet reached a stationary dynamical state.

The importance of the chemical mixing time was evidenced too in a recent investigation of the mechanical alloying of Fe–Ge alloys [400]. For p-$Fe_{0.75}Ge_{0.25}$, mechanical alloying was indeed found to occur in two steps: for $t_m < t_{cm} \approx 4$ h, the mixture of Fe and Ge refines down to a nanometer scale with the formation of solute supersaturated regions near interfaces, possibly by a dislocation pumping solute mechanism. The latter process consists of repeated sequences of solute diffusion in dislocation cores, pinning and depinning due to stresses applied during shocks. An homogenization process occurs for longer milling times [400].

The time $t_f$ needed to reach a final stationary state is obtained to be of the order of $\approx8$–10 h for V and Cr, a time much larger than $t_{cm}$, while it is of the order of $t_{cm}$, being $\approx5$–6 h, for Mn. The long synthesis times reflect the fundamental role of competing mechanisms in the establishment of dynamical stationary states with a trend to unmixing in nearly equiatomic Fe–Cr and a trend to ordering in nearly equiatomic Fe–V alloys. By contrast Fe and Mn tend to mix, as shown by the large equilibrium solubility of Fe in Mn.

### 7.3. Composition Fluctuations in Mechanosynthesized Materials: The Example of p-$Fe_{0.30}Cr_{0.70}$

A considerable amount of theoretical and experimental work has been devoted to coarse-grained Fe–Cr alloys, a binary system which exhibits among others a wide miscibility gap, stable or metastable, below about 1000 K [400]. Mechanical alloying of p-$Fe_{1-x}Cr_x$ alloys has been thoroughly investigated for the whole range of $x$ [392, 399, 401, 410]. Homogeneous solid solutions and an amorphous phase, for $x \sim 0.70$ [403–405], were reported to be the dynamical equilibrium phases according to the composition and the milling conditions. However, recent investigations [409] demonstrate the favorable role of oxygen on the amorphous phase formation, particularly for contents larger than $\sim1.5$ wt%. Conclusions about the formation of homogeneous Fe–Cr solid solutions with nanosized grains were most often obtained from room-temperature (RT) Mössbauer spectra because heterogeneities can hardly be detected from broadened X-ray diffraction patterns of ground powders. Magnetization and magnetoresistance measurements [408] led, however, the reconsideration of the conclusions drawn from RT Mössbauer spectra about the formation of a solid solution in p-$Fe_{0.30}Cr_{0.70}$ alloys milled in classical experimental conditions (Fritsch Pulverisette 7 planetary ball mill with steel vial and seven balls with a powder-to-ball weight ratio $R = 1/22$ and a disc rotation speed $\Omega = 640$ rpm [392]) by evidencing the existence of composition fluctuations, whose amplitude $\Delta x$ is $\sim0.1$, on a scale of a few nanometers inside grains [392, 399, 408]. As described, the average chemical

compositions of all particles of ground powders are essentially the same for $t_m > \approx 3$–4 h in these milling conditions.

## 7.4. Steady State Structure of Milled $Fe_{0.30}Cr_{0.70}$

Detailed magnetic characterizations of $Fe_{0.34}Cr_{0.66}$ synthesized by high-energy ball-milling from p-$Fe_{0.30}Cr_{0.70}$ initial mixtures of chromium and iron powders are reported in [392]. They evidence the existence of a dominant superparamagnetic contribution from Fe-rich clusters at 400 K above the Curie temperature of the classical homogeneous alloy with the same composition, $T_c < \approx 380$ K [411]. X-ray diffraction patterns, transmission electron microscopy, and Mössbauer spectra at 7 K show no evidence of the formation of an amorphous phase which is known to be nonmagnetic at least down to 5 K. This indicates that oxygen contained in the starting powders does not play a significant role in the steady state achieved in these experimental conditions, as further confirmed by the results of chemical anlayses and of annealing experiments. The final ground $Fe_{0.34}Cr_{0.66}$ alloys were concluded to have complex structures with intragranular composition fluctuations of $\approx 0.1$ in amplitude at a scale of a few nm (of the order of 2–4 nm) which reflect the strong trend of Fe and Cr toward segregation. To show that the latter microstructure is a true dynamical equilibrium state, an as-cast $Fe_{0.30}Cr_{0.70}$ alloy was ball-milled in the same milling conditions as those used previously for mechanically alloyed powders of elemental Fe and Cr. Advantage was taken from a brittle–ductile transition located between room-temperature and liquid–nitrogen temperature to obtain coarse powder particles from a bulk as-cast alloy. The incorporation of steel from milling tools into ground powders was found to be negligible in such experimental conditions. The magnetic moment at 5 K is for instance 1.8 $\mu_B$/Fe atom for the as-cast alloy [412], in perfect agreement with the moment measured by Fischer et al. [411]. The reduced contamination explains why the Fe content is smaller in milled as-cast alloys than in alloys which were mechanosynthesized from elemental $Fe_{0.30}Cr_{0.70}$ mixtures. Magnetic susceptibilities (Fig. 14) were measured with a commercial susceptometer between 5 and 350 K with an ac field of 2 Oe at four frequencies ranging from 10 Hz to 10 kHz. The experimental results were similar for all investigated frequencies. When $T$ decreases, the ac susceptibility $\chi(T)$ of the as-cast alloy (Fig. 14) exhibits a broad transition around $\approx 290$ K, reaches a maximum at $\approx 200$ K and then decreases when $T$ decreases down to 5 K. These characteristics reflect the influence of short-range order, namely a strong tendency to clustering [411], on magnetic properties as clearly shown by the effect of annealing on Fe–Cr alloys with compositions similar to those investigated by Delcroix et al. [412]. The ac susceptibility of the mechanosynthesized alloy exhibits a clear ferromagnetic transition at $\approx 170$ K, the Curie temperature of an alloy with a Cr content $x \approx 0.75$. Then it reaches a maximum at $\approx 150$ K and decreases when $T$ decreases down to 50 K. It decreases more markedly below 50 K, as expected from the reentrant transition from a ferromagnetic phase to a cluster-glass-like state for $x \approx 0.75$ [392]. The susceptibility of the as-cast alloy milled for 4 h 30 (Fig. 14) is very close to that of the MA alloy with

**Figure 14.** Ac susceptibility of $Fe_{0.30}Cr_{0.70}$ (1) mechanically alloyed (crosses, MA, $t_m = 12$ h), (2) as-cast (empty circles), (3) and as-cast and milled for various times (empty diamonds: $t_m = 4$ h 30, solid diamonds: $t_m = 10$ h).

a small temperature shift likely due to the composition difference. Finally, the susceptibility of the alloy ground for 10 h shows a transition at the same temperature as the alloy ground for 4 h 30, but it is more abrupt for the former alloy. This suggests that the distribution of Fe contents in Fe-rich clusters become narrower with milling time. As discussed in [392], the overall behavior of $\chi(T)$ of as-milled samples is dominated by the contribution of Cr-rich zones. It complements the information drawn from high-temperature magnetization which is dominated by superparamagnetic Fe-rich clusters.

In summary, both mechanically ground and mechanically alloyed $Fe_{0.30}Cr_{0.70}$ alloys exhibit similar stationary microstructures with intragranular composition fluctuations of $\approx 0.1$ in amplitude at a scale of a few nm. They differ from those found for a macroscopic phase separation. These results reinforce the conclusion of a recent study of $Ag_{0.50}Cu_{0.50}$ alloys [397] about the likely phase separation on ultrafine scales that escaped detection in many alloys obtained inside miscibility gaps which are often believed to be homogeneous. He et al. further question the reliability of diffraction methods to determine the true level of supersaturation or the homogeneity of a solid solution (see also [413]).

To conclude, the characterization of composition fluctuations is essential for a thorough description of the mechanical alloying process and of mechanosynthesized materials.

## 8. CONCLUSION

Investigations performed for a period of about 20 years provide realistic ideas about the actual potentialities of synthesis methods which involve mechanical energy and about the problems they raise. Mechanosynthesis is a promising synthesis method for all kinds of nanomaterials, often with original features, and a step in the preparation of consolidated materials with improved properties. Milling must no more be kept in mind as the sole millenial method of

powder processing but it must considered nowadays as being also a modern technique, mechanosynthesis, of preparation and transformation of materials which turns progressively simple mills into true "mechanoreactors" [414]. For both applied and fundamental aspects, it is necessary to characterize and master the "microstructures" of the demanding class of nanostructured materials for which there are expectations of improved properties and of promising applications. Besides the chemical engineering and materials synthesis aspects mentioned, the physical understanding of mechanosynthesis still requires detailed investigations particularly in systems for which thermal and mechanical energy compete (order–disorder, unmixing–mixing) to drive milled materials to dynamical stationary states far from equilibrium with original microstructural features. Mechanosynthesized nanostructured materials belong to a larger family whose properties still remain to be characterized and understood. For instance, how do such materials plastically deform when there is no apparent activity of dislocations? Which are the characteristics of phase separation in nanostructured materials?

As already mentioned, important aspects of mechanosynthesis of nanostructured materials have not been covered in this chapter. This is the case for instance for computer simulations of mechanical alloying which provide already some information about original morphologies that may be formed thanks to competing interactions between elements to be mixed [35] but, as emphasized by Martin, a safe modeling of the shearing event itself is still lacking [314]. This is further the case for the synthesis of all kinds of compounds (intermetallic compounds, "Xides" where X stands for bor, carb, nitr, alumin, phosph, silic, etc., and metallic glasses) but many of them are prepared in a straightforward way simply by grinding elemental powder mixtures. Further, applications of nanostructured materials often require them to be processed in a temperature range in which they may undergo grain growth and thus risk losing their specific properties. Lund and Schuh [415–416] explored recently driven alloy systems (irradiation, mechanical alloying, severe plastic deformation) to test the assumption according to which only completely random configurations are dynamically stable in the limit where ballistic effects are dominant. Their molecular simulations of driven binary alloys suggest that complex ordered or segregated structures may evolve even in the absence of thermally activated diffusion [415]. They have indeed found that binary alloys can mix, demix, and even order under an external driving force at $T = 0$ K. Lund and Schuh emphasize that atoms would have a microscopic degree of freedom to select their preferred nearest neighbors, whenever there is a force enabling their motion, in systems with local stresses due to either an atomic size mismatch or a high density of crystalline defects. In the latter systems, the formation of preferred bonds would result from subatomic translations since there is no fixed lattice site for a given atom.

"Micromégas," the hero of the Voltaire's *Conte philosophique* which echoes Swift's *Gulliver's Travels*, imagines an animal "not quite one 600,000th of an inch in height" [417] ("qui aurait à peu près la six-cent millième partie d'un pouce en hauteur"), that is, an animal whose height is about 40 nm. Micromégas seems thus to be the right giant we

need to close this chapter on mechanical alloying and nanostructured materials, a class of materials in which widely different scales are linked too [417]:

> "Quel plaisir sentit Micromégas en voyant remuer ces petites machines, en examinant tous leurs tours, en les suivant dans toutes leurs opérations!"
>
> "What pleasure Micromégas felt in watching the movements of those little machines, in examining all their feats, in following all their operations!"

# GLOSSARY

**Ball milling (BM)**  A process consisting of mechanical mixing of powders based on prealloyed components (as example intermetallic phases, ceramic compounds).

**Combustion**  A reaction which is found to liberate quasi-instantaneously its exothermic energy.

**Field activated pressure assisted sintering (FAPAS)**  Compared to a classical sintering process under pressure, a current is applied in order to assist the sintering. A current exhibiting a high intensity (up to 8,000 A) under low voltage (10 V) is applied.

**Grinding**  Mechanical processing leading to a decrease in the crystallite grain size. The initial material is pure element or alone compound.

**Mechanical activated annealing processing (M2AP)**  Before an annealing treatment, a former mechanical step is introduced leading to a mechanical activation of the powders.

**Mechanical activated self-heat-sustaining (MASHS)**  For SHS (see SHS terms), before igniting SHS reaction, a first step is performed consisting of short duration mechanical alloying of elementary component. The duration is enough to generate a 3D nanoscale distribution of the elementary component inside each micrometer powder grain.

**Mechanical activation processing (MA processing)**  Before powder metallurgy processing (i.e., sintering, densification, reactive sintering), a step consisting of a short duration mechanical alloying is performed.

**Mechanical alloying (MA)**  A process consisting of a mechanical mixing at the nanoscale of elementary components. A long duration of such a mechanical process is expected to lead to the formation a stationary end product constituted by definite compounds.

**Mechanochemistry**  Processing involving mechanical treatment in order to achieve chemical reactions.

**Milling**  A mechanical processing for treatment of powders. Introduction of a component helping the milling is defined as wet milling. Without such an additive, it is the so-called dry milling.

**Nanocomposites**  Dense materials composed of various materials. One of the latter has a nanoscale dimension.

**Nanoparticles**  Isolated particles whose diameters are well below 100 nm, classically less than 10 nm.

**Self-heat-sustaining (reaction) (SHS)**  An exothermic reaction between two elementary components exhibiting enough energy to be self-sustaining (i.e., without the need for an external energy source).

**Solid state reaction**    Reaction occurring below the melting point of any elementary component or compounds.

**Spark plasma sintering**    A process leading to bulk materials by a sintering step using pulse electric discharge. Due to the high intensity of the current, plasma may occur between the various powder grains.

**Thermomechanical treatment**    A treatment of materials combining thermal effect and mechanical solications, both being successive or simultaneously performed.

**Ultrafine (particles)**    Particles which are isolated each from each other and exhibiting a nanometer scale (less than 100 nm).

## CONTENTS

## 1. INTRODUCTION

In recent years a wide range of nanostructured materials has been introduced. These novel materials are produced in various forms such as nanopowders, nanostructured particulates, fibers, tubes, thin films, as well as bulk by using a number of processing routes. Nanostructured materials have many interesting properties. These include a number of useful mechanical properties related to strength, hardness, elastic properties, toughness, plasticity, etc. In this chapter these properties are described and discussed in detail with a reference to existing or potential practical applications.

Distinction of different forms of nanostructured materials may be made by their dimensionality [1, 2]. Nanostructural materials may exist in (i) zero-dimensional atomic clusters (all three dimensions in nanoscale), (ii) one- or two-dimensional multilayers or filamentary structures (one or two dimensions in nanoscale, one or two in macroscale), and (iii) bulk (all dimensions in macroscale) with three-dimensional nanocrystalline grains (see Fig. 1).

There is a variety of processes suitable for producing nanocrystalline materials. Bulky nanocrystalline materials may be produced, for example, by electrodeposition, severe plastic deformation (SPD) of preforms, or by using various powder metallurgical routes to consolidate nanopowders or powders with nanocrystalline structure produced by, for example, mechanical alloying (MA). The bulk form of these materials includes electrodeposited sheets, equal channel angular pressed (ECAP) rods, ball-milled and consolidated pellets, composite films produced by a variety of deposition techniques, etc. It should be noted that their properties are related not only to their nanostructure, but also to the processing method by which they are produced, because the detailed microstructural features may differ after various processing routes even at the same nominal composition and grain size. These microstructural features include type of grain boundaries, grain shape, crystal defects, pores
**Figure 1.** Schematic illustration of various nanomaterials having a different number of dimensions [1, 2]; zero-dimensional powder, one-dimensional thin deposited layer, surface coating with nanostructure in two-dimensions, and three-dimensional bulk nanomaterial.

and their distribution, other flaws, impurities, and surface condition.

Mechanical testing of nanocrystalline materials is generally different from that used for their coarse-grained counterparts because the amount of nanocrystalline material is in many cases so small that conventional test methods with large bulk samples cannot be used. Therefore, methods using small amounts of material have often been used instead of conventional testing. Results have been obtained either by modified traditional testing methods or by specially designed tests that probe materials with small dimension, such as instrumented nanoindentation. Most of the data that exist are from the nanostructured thin films or bulk materials processed by powder metallurgy (PM) techniques or by severe plastic deformation (SPD). These data are not always as reliable as those obtained from conventional bulk samples. Further elaboration of results is also subject to uncertainty because the determination of the grain size in nanoscale is more tedious and subject to larger experimental errors than in materials with conventional grain sizes.

Nevertheless, it has been shown that nanocrystalline materials have special mechanical properties. Typically the strength of crystalline materials is increased with decreasing grain size and materials with small grain size often exhibit also superplastic behavior. Nanocrystallinity may also have a positive influence on fatigue properties of metals and toughness of ceramic materials. Ductility, however, may also be decreased due to increased tendency to flow localization, but hardness and wear properties of materials and coatings can be improved.

There are several recent reviews on mechanical properties of nanocrystalline materials (e.g., [3–5], to mention a few) and the reader is referred also to them for a more thorough review of different particular subjects. In this chapter, we wish to give a collective view on various current developments related to mechanical properties of nanocrystalline materials.

# 2. THEORETICAL BACKGROUND OF MECHANICAL PROPERTIES

The main feature distinguishing nanomaterials from conventional materials is the large fraction of atoms located in the grain/interphase boundaries. Grains are typically equiaxed with a narrow and lognormal size distribution and dislocations are seldom seen inside the grains. Those that are seen are typically in sessile configurations [6]. Level of various defects arising from processing may be present in significant amounts and they all influence the mechanical properties. Even in nominally fully dense nanocrystalline materials there are 1- to 2-nm-sized pores and smaller nanovoids [7]. Two divergent views exist on the nature of grain boundaries in nanomaterials. According to the classic interpretation, the nature of grain boundaries in nanomaterials is no different from the nature of grain boundaries in coarse-grained materials [8]. However, based on a more recent study by computer simulation, it has been suggested that in nanomaterials a long-range periodicity does not exist, the grain boundary energy and width distributions are narrower and the grain boundaries wider than in bicrystals, and that the grain boundaries are an isotropic, cement-like phase different from glasses or bicrystals [9]. The grain boundary structure results in enhanced solute solubilities and enhanced diffusion as well as a different thermodynamic behavior [10]. Therefore, retention of nanocrystallinity at elevated temperatures either during processing or in service is quite difficult.

## 2.1. Scale Dependence of Strength and Elastic Properties

### 2.1.1. Dependence of Strength (and Hardness) on the Grain Size

It has been known for a long time that refining the grain size of materials increases their strength, that is, the yield and flow stress as well as stress to rupture. The theoretical background for increasing strength with decreasing crystalline size lies in the theory for dislocation slip in crystalline materials. This tendency has been explained by using three different models, that is, the pile-up model, the work-hardening model, and the composite model; see, for example, the review of Lasalmonie and Strudel [11]. In nanocrystalline materials the conventional dislocation mechanisms cease to be operational. As the size of a Frank–Read dislocation source cannot exceed the size of a grain, such sources become inoperable with decreasing grain size under typical loads. Recent simulations on nanocrystalline Al have also demonstrated that the nucleation of complete dislocations at the grain boundary becomes impossible as the grain size becomes smaller than the so-called splitting distance of the dislocation [12].

The grain size ($d$) dependence of the yield strength ($\sigma_y$) with materials of conventional grain size in the micrometer range typically follows an expression of the type

$$\sigma_y = \sigma_0 + k/d^{1/2} \qquad (1)$$

where $\sigma_0$ is the friction stress and $k$ is a material-dependent constant. This relation is known as the Hall–Petch relation

originally proposed by Hall [13] and Petch [14]. However, this relation has been found to break in nanometer-scale materials. At fine grain sizes (in the submicron range), the slope becomes lower and at ultrafine grain sizes, $k$ may become negative [15–17]. The latter occurs when the grain size decreases to the range of few tens of nanometers although in some cases increase in flow stress has been reported down to the grain size of 10 nm [18, 19].

Several models have been proposed to explain the inverse Hall–Petch relation, that is, grain boundary deformation mode effect [20], triple junction volume effect [21], size-dependent line tension effect [22, 23] composite model [24, 25], and that of Takeuchi [26]. All the models incorporate a softening mechanism at fine grain sizes. Wang et al. [27] have been able to explain the different deviations from the Hall–Petch relation at different grain sizes by describing the material as a composite consisting of four different phases (crystal, grain boundary, triple line junctions, and quadruple node phases) with different strengths and relative volume fractions. Due to four fitting parameters, this model is capable of describing any kind of strength variations with grain size. However, it does not provide a physical explanation for the operational mechanisms.

One plausible physical explanation for the softening is grain boundary sliding and rotation, which can explain both the accelerated deformation rates and the softening at the finest grain sizes and the hardening at larger grain sizes. This explanation is decribed by Padmanathan and co-workers [28–31]. According to their model, the deviation from the Hall–Petch behavior, which eventually leads to the inverse Hall–Petch behavior, can be attributed to competition between the grain boundary sliding controlled process and dislocation dominated deformation. These mechanisms are independent and the one that in particular conditions of grain size, alloying, temperature, and strain rate requires lower stress to operate will be the favored mode of deformation. In general, when the deformation is dislocation controlled, the grain refinement increases the stress required, and when the grain boundary sliding is the dominant mechanism, the grain refinement will decrease the stress to deformation.

The latter explanation is finding support from the atomistic modeling of deformation in nanocrystalline materials. Recent molecular-dynamics simulations have revealed an inverse Hall–Petch behavior for very small grain sizes attributed to grain boundary (GB) sliding [32–35]. The simulation of nanoindentation in 5- and 12-nm nanocrystalline gold has shown that GBs act as a sink for partial dislocations emitted under the indenter and there is a collective motion of grains pointing towards the presence of GB sliding; that is, grain boundaries for a number of grains that are randomly oriented may straighten and slide collectively. Neighboring grains may rotate and form also larger grains [36, 37]. This mechanism supposedly works without diffusion accommodation and has been criticized by Yamakov et al. [12], who claim observation of GB sliding does not rule out the diffusion-assisted creep mechanisms even at room temperature.

One should also note that the experimental results are influenced by the detailed GB structure of the nanostructured materials, which in turn is dependent on the particular method with which the materials have been produced. For instance, despite the similar grain size, the deformation behavior of Cu produced by ECAP is significantly different in the as-pressed state than after a short anneal at 473 K, which results in recovery of the defect structure at grain boundaries and a sharp decrease of internal stresses [5]. This means that in addition to the mean grain size, the defect density at grain boundaries influences the strength properties of nanostructured materials. See Figure 2.

### 2.1.2. Elastic and Anelastic Properties of Nanocrystalline Materials

There are very few theoretical considerations related to the elasticity of nanocrystalline materials. Some early experimental results have prompted ideas on elastic properties being dependent on the volume fraction of lower-density grain boundary phase in relation to the bulk phase [39]. Later, however, the experimental results [40, 41] have, according to Morris [2], quite convincingly showed that the grain size refinement does not play any obvious role in modifying Young's modulus, shear modulus, or bulk modulus, but the observed reduction is inherited from the quality (porosity content) of the processed material.

On the other hand, detailed studies of nanostructured copper samples processed by equal channel angular (ECA) pressing have been carried out by using ultrasound method [42]. According to this study, the values of elastic moduli in nanocrystalline copper were lower by 10–15% as compared to coarse-grained copper. The explanation was based on the differences of elastic properties of near grain boundary regions and grain interiors. The change in elastic values of nanostructured copper could be explained if it was assumed that the elastic modulus of the near grain boundary regions is 15–17% of the value of the elastic modulus of the coarse-grained copper. Reduction of elastic modulus in ECA pressed copper and copper composites has also been obtained in other studies [43–45]. Some new modeling results support the decreasing of elastic modulus values at very small grain sizes. However, this is realized in a substantial level only at grain sizes below 10 nm [46].

Internal friction studies are used to study the deviation of the material from Hooke's law and its anelastic behavior. Internal friction studies show that the damping for nanocrystalline materials is significantly higher than in coarse-grained

**Figure 2.** Schematic illustration in two dimensions of grain arrangements in a nanocrystalline (a) and conventional polycrystalline (b) material. Forming of a mesoscopic planar interface can occur if atoms in the darker regions rearrange [38]. Rearrangement is favored in the nanocrystalline material because of the three orders of magnitude smaller thickness of the critical region.

materials. For example, studies on ECA pressed copper have revealed that damping in nanocrystalline material is higher by a factor of 4–5 than in coarse-grained material processed by annealing at high temperatures and even higher by a factor of 2–3 as compared to the level of damping in gray cast iron ($50 \times 10^{-4}$), typically used as a reference for damping [40, 47]. Previous studies have also shown that the onset of the intense growth of internal friction is significantly lower (by 120 K) in nanocrystalline materials than in coarse-grained materials. Similar results have been obtained for the nanocrystalline copper obtained by consolidating mechanically milled powders by hot isostatic pressing [48]. Furthermore, it has been noticed that the dislocation-associated peak typically present in coarse-grained materials at low temperatures is absent, indicating that there are only few mobile dislocations in nanocrystalline materials.

The internal friction curve of nanocrystalline ECA copper has a strong maximum of the so-called grain boundary peak at 475 K associated with the intensification of grain boundary sliding in the material. According to Valiev et al. [4], these anomalies are associated not only with small grain sizes but also with specific structure connected with nonequilibrium grain boundaries formed in ECA processed material and their transformation from nonequilibrium grain boundaries to equilibrium grain boundaries.

Internal friction studies have been performed also in other nanocrystalline materials, such as Pd [49], Al [50–52], Au [53], and Fe [54]. In general, a damping peak superimposed on a background increasing with temperature is observed. Furthermore, some additional peaks may be observed related to, for example, grain boundary impurities and films [49].

### 2.1.3. Fatigue of Nanocrystalline Materials

In fatigue (cyclic loading), material undergoes reversed deformation which results in accumulation of damage and finally fracture. Cyclic deformation produces typically at some advanced stage microstructural features, that is, dislocation cells that are typical of the plastic strain amplitude in question. The relaxed dislocation cell structure that develops during fatigue testing is typically in the half-micron level. In nanostructured materials, it may therefore be expected that the continuous deformation will lead to cyclic softening and an extensive growth of crystal structure. Data obtained on low cycle fatigue of nanocrystalline ECA processed copper seems to support this idea [55–58].

On the other hand, it has been shown that the fatigue behavior of nanocrystalline Ni produced by electrodeposition is exactly similar to that of conventional Ni [59] and in another study that the formation of nanostructures by severe plastic deformation results in a significant increase in fatigue strength and life [3]. These contradictory results may at least partly be explained by the differences in the details of the nanostructures. Hashimoto et al. [60] have studied the fatigue response of different types of nanostructures produced by ECA. At a constant plastic amplitude fatigue, the material having a rather homogeneous nanocrystalline structure showed cyclic hardening while the material having a banded structure with elongated grains and fragments of low angle boundaries showed cyclic softening. Similarly, significant changes in the anelastic response of materials having

nominally the same grain size have been observed [53]. The extent of Bauschinger effect in nanocrystalline ECA pressed copper was found to increase substantially in a short low-temperature annealing, which did not alter the grain size but recovered the grain boundary structure. These results demonstrate the significant influence of the type of nanostructure on the cyclic response.

After the early studies, the cyclic response of nanocrystalline materials has been a subject of growing interest and several investigations on different materials have been carried out [61–67]. As a conclusion from these studies, ECA-produced copper and 5056 Al-Mg alloy exhibit notable improvement of fatigue properties in load-controlled cycling while under constant strain amplitude they last considerably shorter than their coarse-grained counterparts. On the other hand, ECA pressed titanium shows no cyclic softening or degradation in strain-controlled cyclic loading [58]. Based on these studies, Vinogradov et al. have proposed a one-parameter dislocation-based model to describe the experimental results. According to this model the cyclic saturation stress at high strains takes the form

$$\tau_s = \tau_o + \alpha\mu b/(Ly)^{1/2} \qquad (2)$$

where $\tau_o$ is the minimum stress for the dislocations to move, $\alpha$ is a geometrical factor of the order of 0.5, $\mu$ is the shear modulus, $L$ is the slip path of the dislocations with a Burgers vector $b$, and $y$ is the so-called annihilation length. This simple relation seems to be applicable both for an aluminum alloy [64] and for titanium [61]. Most of the characteristic features of the fatigue behavior of ultrafine grain size materials can be understood based on the ordinary dislocation kinetic, dislocation hardening, and Hall–Petch hardening. On the other hand, the susceptibility of the ECA pressed materials to strain localization limits their tensile and fatigue ductility and in practice to a large extent determines the fatigue performance. However, there still exists very little information on the fatigue behavior of nanocrystalline materials in the range of few nanometers up to few tens of nanometers.

### 2.1.4. Creep of Nanocrystalline Materials

In creep, the material gradually undergoes straining under the load which may be well below the loads causing macroscopic deformation, for example, in tension. It is well known that creep may be ascribed to a number of different deformation processes, which typically operate more or less in parallel under given conditions. Under particular conditions of stress and temperature, it may be possible to identify a single process responsible for the measured creep rate. At very low stresses and small grain sizes, vacancies rather than dislocations are generally held responsible for the observed creep rate. Two models, Nabarro–Herring creep and Coble creep, can be used to account for plastic flow under those circumstances [5]. Nabarro–Herring creep involves the vacancy diffusion through the grain volume and Coble creep involves vacancy diffusion along grain boundaries. Nabarro–Herring creep has an inverse square dependence and Coble creep has an inverse cubic dependence of grain size with creep rate. Coble creep predominates over Nabarro–Herring creep at low homologous temperatures

and very small normalized grain sizes. A number of studies have been designed to study the low-temperature creep in nanocrystalline materials since, for example, in nanocrystalline copper the diffusivity at room temperature has been reported to be orders of magnitude higher than the grain boundary diffusivity of regular polycrystalline copper [68]. Such high diffusivities have been proposed to be responsible for the additional modes of deformation which may contribute to softening at fine grain sizes [15].

The studies on creep behavior of nanostructural materials have established that they typically exhibit very high creep rates. The behavior has typically been explained in terms of grain boundary diffusional creep in combination with triple point diffusion [69–71], but as Mohammed and Li [5] have pointed out, some of the characteristics reported, such as instantaneous strain and primary creep with decreasing creep rate [72, 73], are not typical of diffusional creep. Although a number of studies on creep of nanocrystalline materials have already been conducted, the full picture of creep deformation is still somewhat unclear. However, it may be concluded that the creep properties of nanocrystalline materials are very sensitive to their microstructure. Therefore two nanocrystalline materials with the same nominal composition and structure may exhibit different deformation behavior. A current review on the subject is given by Mohammed and Li [5].

## 2.2. Plasticity of Nanocrystalline Materials

Plasticity of nanocrystalline materials is of interest from both theoretical and practical points of view. The practical aspects are related both to the ease of producing complicated forms by plastic deformation as well as to the service performance of these materials. As discussed in the previous section, the susceptibility of, for example, fine-grained ECA pressed materials to strain localization limits their tensile and fatigue ductility and in practice to a large extent determines their fatigue performance. On the other hand, the increasing relative amount of atoms at grain boundaries and grain junctions with decreasing grain size results in enhanced diffusion rates in nanocrystalline materials as compared to standard polycrystalline materials.

### 2.2.1. Ductility of Nanocrystalline Materials

The ductility of nanocrystalline materials can be examined by tensile testing. In a tensile test ductility is related to the elongation at fracture or the reduction of area (at necking) at fracture. A classical approach to theoretical consideration of the ductility of nanomaterials is that of Morris [2], who uses the so-called Considére construction to describe the respective importance of stress level and work-hardening rate in controlling the geometric instability responsible for the onset of necking. Generally, a high work-hardening rate will result in large strain at the instability while a low work-hardening rate, typical of nanomaterials, will result in a small strain to failure or in extreme case no strain at all.

However, the stability of flow and consequently the degree of ductility of a (ductile) material in tensile test depends, in addition to its strain hardening, also on strain rate hardening characteristics (see, e.g., Hart [74]). As both of these characteristics may differ from those of the coarse

(or conventional) grain size materials, it is expected that the ductility of nanostructural materials differ from that of their coarse-grained counterparts.

A more complete treatment of the conditions for necking would include the strain rate sensitivity of the flow stress of nanostructural materials, which as already mentioned, typically also is different from that of coarse-grained materials. Hart [74] has shown that the instability in tensile test is determined by the equation

$$\gamma + m \geq 1 \tag{3}$$

where $\gamma$ is the strain-hardening rate and $m$ is the strain rate sensitivity of the flow stress. Since for metals $m$ is generally less than unity (in fact, generally much less than unity), the strain-hardening exponent $\gamma$ must be clearly greater than zero for the flow to be stable. As nanocrystalline metals show only little strain hardening in tension, their tensile strain at the flow at necking often remains small.

### 2.2.2. Superplasticity

Many materials are known to exhibit superplasticity in proper conditions. In the superplastic state, elongations of several hundred or even more than one thousand percent are obtained. Typical attributes to superplastic deformation are a proper temperature–strain rate regime (typically temperature around $0.5$–$0.6T_m$, where $T_m$ is the melting point of the material, and strain rates around $10^{-3}$–$10^{-4}$ s$^{-1}$), a small grain size (typically less than 10 $\mu$m), and a relatively stable microstructure of the material during deformation [75, 76]. It is possible to describe superplasticity by a constitutive equation of the form

$$\dot{\varepsilon} = A(DGb/KT)(b/d)^p(\sigma/E)^n \tag{4}$$

where $\dot{\varepsilon}$ is the strain rate, $A$ is a constant, $D$ is the coefficient of grain boundary diffusion, $G$ is the shear modulus, $b$ is the Burgers vector, $K$ is the Boltzmann constant, $T$ is the temperature, $d$ is the grain size, $p$ is the grain size exponent (usually equal to 2), $\sigma$ is the flow stress, $E$ is Young's modulus, and $n$ is the stress exponent. This law would predict the decrease of the temperature or increase in strain rate regime with decreasing grain size where superplasticity occurs. A closer examination of this relation shows that the slow strain rates associated with superplasticity in the conventional materials having a grain size around 1 $\mu$m could be accelerated by several orders of magnitude or correspondingly the temperature may be decreased even by several hundreds of degrees. The superplasticity in nanocrystalline materials is therefore of special interest as it would extend the phenomenon to lower temperatures or higher strain rates, thus opening new technological opportunities.

One of the requirements in order to technologically utilize the low-temperature or high strain rate superplasticity of nanomaterials is to control the grain growth during processing. During superplastic deformation both static and dynamic grain growth may occur. The static grain growth can be described by [3]

$$D_s^N - D_0^N = kt \tag{5}$$

where $D_s$ is the grain size after temperature exposure, $D_0$ is the grain size at the beginning of temperature exposure, $N$ is the grain size exponent (2 in pure materials near the melting point and 3–4 in many practical cases), $k$ is a rate constant with an Arrhenius dependence ($k = k_0 \exp(Q/RT)$), and $t$ is time. Because of the processing time needed for superplastic forming, static grain growth is always a concern. However, dynamic grain growth is in practice much more severe than static grain growth. Dynamic grain growth occurs because of the applied strain and may cause the grain size to grow severalfold during forming even at low temperatures. The increment of grain growth solely of dynamic origin ($\Delta D_d$) is independent of time and temperature and may be described by [3]

$$\Delta D_d = D_f - D_s = c\varepsilon \qquad (6)$$

where $D_f$ is the grain size after forming, $D_s$ is the grain size before forming, $c$ is a material constant, and $\varepsilon$ is the strain in forming. Because of the grain growth (both static and dynamic), deformation becomes increasingly difficult with increasing strain.

So far superplasticity has been demonstrated at elevated temperatures for several nanocrystalline metal and ceramic systems. The major systems investigated so far include several Al-Ni-Mm alloys [77, 78], Ti, Al, or Mg-based SPD alloys [79–82], boron doped $Ni_3Al$-alloy [83, 84], Y-TZP [85–88], $TiO_2$ [89–91], and $MgO \cdot Al_2O_3$ spinels [92]. Evidence of superplasticity in ceramic nanomaterials has mainly been obtained by other than tensile testing, that is, compressive testing, hardness testing, or bulge testing, because of difficulties in producing fully dense nanocrystalline specimens of adequate size for tensile testing.

Large ductility in compression is not necessarily an evidence of superplasticity since neck instability and cavitation failure are absent in compressive deformation [93]. An example of excellent compressive properties but poor tensile behavior is that of Fe-28Al-2Cr alloy [94]. It was possible to deform this to a strain of >1.4 in compression, whereas no tensile ductility was observed. The flow stress in compression (2.1 GPa) was considerably higher than the tensile fracture stress (0.65 GPa). Tensile superplasticity of nanocrystalline materials has been studied more extensively over the last years since the first evidence of tensile superplasticity was reported [95] in 1993.

According to studies so far, superplasticity of nanomaterials occurs most likely as a result of grain boundary sliding and some diffusional accommodation without visible dislocation activity in the grains. In order to limit the grain growth, both solute and second-phase additions have been used to pin the grain boundaries with a mixed success [96, 97].

## 2.3. Fracture Toughness of Nanocrystalline Materials

Fracture toughness of the material is related to the ability of the material to sustain the creation and propagation to failure of local flaws and cracks. During loading the pre-existing subcritical flaws or cracks will grow as some localized straining will take place ahead of the flaw. When the critical size is reached, a catastrophic failure will take place. Fracture

toughness of nanocrystalline materials may be quite different from that of bulk materials. [Chan [98] assumed that the fracture toughness and the yield stress remain constant, but that the starting flaw size is decreased as the grain size is decreased the critical stress to be imposed for a flaw to grow will increase.] As a result, the strain to failure will be increased as the grain size is reduced. A dramatic increase in fracture strain will occur as the grain size reaches a characteristic value for the material (combination of fracture toughness and yield stress). Of course, then the flaw size has to decrease with grain size (which may not always be the case). Other assumptions must also be valid for the theory to work; that is, the critical stress intensity factor at the point of catastrophic failure should be constant and independent of grain size, and the plastic properties including yielding must be independent of grain size. Morris [2] has criticized especially the last assumption and refined the analysis of Chan by adapting the classical Hall–Petch relationship (Eq. (1)) to describe the dependence of yield strength on grain size. He arrived at the following critical crack length ($c$) at the failure point for a material of toughness $K_c$ when a stress equal to the yield stress is applied:

$$c = 1/\pi[K_c/(\sigma_0 + kd^{-n})]^2 \qquad (7)$$

where $\sigma_0$ is the friction stress, $k$ is a material-dependent constant, and $d$ is the grain size. This equation gives a possibility to examine whether the material tends to become more or less brittle as the grain size changes for a material at a given fracture toughness level. Using this equation Morris and Morris [99, 100] have shown that the critical flaw size is only slightly and subtly different from the change of grain size, and in the absence of any change in the intrinsic property of fracture toughness, the critical flaw size and the grain size change in a closely correlated manner. Based on the analysis, Morris and Morris conclude that it is impossible to tell whether the nanocrystalline state will offer any improved ductility/failure characteristics. A complete analysis on the subject can be found in [98] with the further refinements in [2].

# 3. MODELING OF MECHANICAL PROPERTIES OF NANOSTRUCTURED MATERIALS

Mechanical behavior of nanostructured materials is frequently investigated using various simulation techniques, due to difficulties associated with *in-situ* observation of deformed nanostructured material components. Hence, the modeling by finite element method, molecular dynamics, or atomistic calculations enables us to conclude on the phenomena that govern the mechanical response of these particular solids, and in consequence, to conclude on their mechanical properties. Since the cross-sectional dimensions of nanostructured components or entire material approach the scale of interatomic distances (it is already possible to fabricate the 1- to 5-unit-cells-thick ceramic plates [101] or $SiO_2/SiC$ nanorods with 100 atoms across [102, 103]), their size challenges the classical approach used in continuum mechanics, and as a result, the scale effects cannot be ruled

out in the modeling. This makes it difficult to perform the simulation of deformation of nanostructures, which is based in the classical continuum approach.

Furthermore, it should be noted that all the above listed methods of modeling are used to simulate also nanoindentation testing, the probing technique which is frequently used to test nanostructured materials. The FEM-based analysis of the contact problems is already well developed, while molecular dynamics and atomistic simulations have recently gained common interest (refer to the next section).

## 3.1. Finite Element Method

Despite the drawbacks of the traditional mechanical approach, finite element simulation of the deformation and fracture of nanostructures is widely used. It appears, however, in this area of research as a hybrid method supplemented by either empirical atomistic models such as this used by Robertson et al. [104] to study uniaxial tensile and compressive response of carbon nanotubes, or multiscale robust simulation of surface deformation (see, e.g., [105]) that allowed the authors to conclude on the microscopic aspects of phase transformation in silicon while investigating different interatomic potentials and various finite element meshes. In the latter approach the constitutive response of the material is obtained from atomistic calculations, which contrasts standard FEM methodology that employs empirical-phenomenological rule.

Moreover, the recent comparison of finite element modeling and artificial neural network (ANN) appears quite beneficial for nanostructured materials and contacts in nanoscale. This type of approach allowed Muliana et al. [106] to resolve the long-persisting dilemma concerning the nanoindentation deformation of hard films/multilayer structure deposited on soft substrate—something already investigated by Myers et al. [107] and Nowak et al. [108, 109]. The ANN models have demonstrated excellent predictive capability for indentation of nonlinear materials.

FEM modeling on the mechanical behavior of nanostructures proved to be efficient when one tackles the problems associated directly with application of a new structure. The proper example is here mechanical analysis of micromechanical clips for optical fibers, offered recently by Lu et al. [110], that targets the performance and reliability of new silicon nitride fiber-clips [111, 112] which might make the production and assembly process of full integrated optoelectronic systems cheap and reliable. Consequently, Lu et al. [110] used FEM to determine stress fields near the corner of the clip/substrate system and developed theoretical models to predict its failure.

Furthermore, the finite element simulation has become widely used in studying deformation phenomena in microscale and in new mechanical processing oriented towards nanotechnology. The FEM-assisted analysis of anomalous surface deformation of sapphire [113], stress and cracks in nanostrip casting process [114], tribology in nanomanufacturing and nanopowders for solid lubrication [115], nanomechanical properties of cutting tools for nanomanufacturing [116], material removal during submicroscale polishing [117], estimation of nanoscale zone in corroded surface ceramic layers [118], and cohesive strength of thin films [119], serve as selected examples of the present trend in research. These studies are again followed by FEM-aided nanoindentation exploration of mechanical response of microsprings and microcantilevers—the subject being in the center of interest for microfabrication [120].

## 3.2. Molecular Dynamics and Atomistic Simulation

Given the recently used direct machining of material surface to fabricate nanostructured components, it became necessary to achieve better understanding of such processes as adhesion, cutting, or surface deformation at atomistic level, where continuum mechanics cannot be applied. Hence, the molecular dynamic (MD) simulation method that allows one to study the behavior of atoms during short time interactions appears as a proper tool to model indentation, friction, adhesion, fracture, and ultraprecise cutting on the atomic scale [121]. In particular, nanoindentation is the area of research in which MD simulation was already exercised for several years, since the nanoscale contact problem falls clearly beyond the frames of continuum mechanics.

The studies of this kind made use of realistic many-body interatomic potentials to obtain information concerning the way in which the defects are created under the tip as well as the fate of individual atoms. This provides a new insight into such phenomena as pressure-induced phase transformations, elastic to plastic transition, or amorphization of the tested material, as demonstrated in the case of nanoindentation of silicon structure [121–124], as well as FCC and BCC crystalline lattices in contact with a rigid [125] or atomistic modeled [126] tip.

The above-mentioned conventional MD studies were followed by *ab initio* quantum mechanical approach [127] and local strain diagnostics [128] that provided a complete picture of atomic distribution near elastic contact and clarified origins of plastic deformation and amorphization in nanoindented silicon, respectively. Furthermore, the similar classical two-dimensional MD analysis applied to nanocutting process by Zhang and Tanaka [129] and Shimizu et al. [130] was improved in terms of a three-dimensional approach offered by Fang and Weng [131], who used canonical MD ensemble corresponding to their copper crystal processed with the diamond pin tool.

It should be emphasized at this stage that the MD approach to nanoindentation or nanocutting reviewed in this section are in fact nothing other than hybrid FEM-MD methods which we discussed in the previous section [104, 105]. In contrast to this combined approach, the atomistic simulation represented here by the work of Astala et al. [127] has different character and provides better insight into atomistic processes, despite the fact that the size of the simulated cluster is considerably smaller than the experimental contact area (the common problem for the atomistic numerical models of this kind).

The excellent example of the atomistic simulation of elastic properties of nanostructured materials was given by Miller and Shenoy [132] who used direct simulation of nanoscale structures using embedded atom method for FCC lattice and Stillinger–Weber potentials for diamond structures. Their size-dependent modeling of effective stiffness

properties $D$ of nanosized elements such as plates and beams led to the general formulation of the deviation of elastic property from that defined by conventional mechanics $D_c$ [132]:

$$\frac{D - D_C}{D_C} = \alpha \frac{S}{E} \frac{1}{h} \qquad (8)$$

where $\alpha$ defines nondimensional constant that is function of geometry, $S$ stands for surface elastic constant, $E$ is elastic modulus of bulk material, and $h$ denotes length—the size of the structure. The authors found that $S/E$ parameter sets the scale at which the effect of the free surface becomes significant [132]. They verified their simulated results by both uniaxial loading and pure bending of small-size plates and bars.

For the sake of completeness of the present review, one should mention interesting modeling of dendrimers for nanoapplication [133] as well as recent numerical approach to phase transitions in nanoscopic layered systems [134]. Moreover, the detailed review of the status and perspectives of nanoscale device modeling was presented by Macucci et al. [135] who targeted development of nanoelectronic devices and quantitative predictive capabilities.

### 3.3. Simulation of Nanotribology

Tribology describes phenomena on the contacting surfaces of materials in motion related to each other. The interactions at the contacting surfaces are closely related to atomic and molecular size effects, that is, nanosize effects. The MD simulation methods have successfully been used to describe a number of such phenomena [136]. However, most realistic tribological systems are of such complexity, including surface topography variations, impurities, and lubricants, that the present computers are capable to simulate tribology only partially [137]. When using empirical interatomic potentials, it is possible to simulate relatively large systems containing millions of atoms. MD methods have been used, for example, to simulate the elastohydrodynamic contact of real rough surfaces in the presence of hydrocarbon lubricants [138].

FEM modeling of sliding contact surfaces has been carried out by taking into account realistic asperity textures of the surfaces. Dimensions down to 100 nm have been assessed in the simulations of the contact area and coefficient of friction [139, 140]. Molecular dynamic simulation of contacting surfaces has been done mostly to simulate an indentation to a solid surface. Recently simulations of indentation of an ideal rigid tip to Al have taken into account the melting of material [136]. Common phenomena in the indentation simulation, such as local melting and dislocation nucleation, were observed. The effect of Al orientation and temperature were investigated. The results provided information on nanoscale phenomena present in such processes as wear in engine piston rings and metal forming.

Modeling of stress distributions related to crack initiation and delamination of thin films has been investigated [141]. Simulations have also been used to design coated surfaces with multilayer and gradient structure with high adhesion and crack growth inhibition [142]. Recently, FEM modeling

has been used successfully to simulate the contact scratch testing experiment in order to experimentally determine the fracture toughness of the coated surface [143].

## 4. EXPERIMENTAL METHODS DESIGNED FOR PROBING OF MECHANICAL PROPERTIES OF NANOSTRUCTURED MATERIALS

Many of the traditional methods used for testing of mechanical properties of materials may be used also for nanomaterials provided that adequate amount of material is available. However, in a number of occasions that is not possible. Then other methods must be used. Among them instrumented nanoindentation is the most important and will be described in detail here. Other methods are also briefly discussed.

### 4.1. Instrumented Nanoindentation

#### 4.1.1. Principle and Equipment

Conventional hardness measurement is insufficient to estimate the properties of, for example, thin nanostructured films, because of its low accuracy in the low-load indentation region that is due to limitations of the resolution of the optical systems attached to the hardness testers of conventional type. The development of the testing equipment has enabled the users to continuously monitor the load experienced by the indenter and the depth of penetration. This made it possible to overcome the limitations of the optical system and allowed us to derive new information on the complex mechanical behavior of materials deformed in a very small area. Thus, the nanoindentation appears as a unique method for studying the mechanical properties of solids with a tiny volume.

The idea of depth-sensing indentation measurements was already realized for the first time more than two decades ago [144], while the first nanoindentation testers were designed ten years later [145–148]. Further, the pioneering results of ultra low-load indentation reported by Pethica et al. [146] resulted in a rapid development of this new area of research that recently has found its important application in a case of nanostructured materials.

The nanoindentation experiments achieved a "new level," owing to the new phenomena available for study as a consequence of recent developments in this particular research equipment. This has stimulated an urgent need for a general theory of indentation-induced deformation, which would yield a sound basis for interpreting experimental results. Considerable effort has already been undertaken to analyze the data of depth-sensing tests and to relate them to the observed phenomena [146, 148–152].

The significant progress has been achieved in this area through numerical modeling based on the finite element method [113, 153, 154]. However, the critical issue of this approach lies in the formulation of the pertinent constitutive equations as well as in the difficulty in estimating the elastic/plastic stress-state in the vicinity of the contact. The only case solved analytically is the pure elastic contact of spherical (Hertzian indentation [155, 156]) and axisymmetric

sharp indenters (cone indentation—Boussinesq stress field [157]).

Nanoindentation devices which allow us to use loads as low as fraction of millinewtons have recently been developed in response to an increasing number of requirements for the mechanical testing of crystalline thin films designed for electronics. Some commercial instruments operate automatically after initial setup and measure independently force and displacement experienced by the indenter tip. The successful examination of nanomaterials is in a part due to the selected tester. Indeed, the precision of measurements is of primary importance when one deals with new, advanced materials, which have never been characterized so far.

Indentation techniques may be broadly classified according to the shape of the indenter used in experiments. It was found that sharp indenters, for example, the Berkovich pyramid, are useful in the investigation of mechanical properties in the smallest possible region, while the spherical tip is recommended for crystalline material with remarkable anisotropy.

### 4.1.2. Determination of Elastic Modulus

Hertzian theory [156] of contact between two nonrigid bodies yields the relationship between their Young's moduli:

$$\frac{1}{E_{\text{eff}}} = \frac{1 - \nu_1^2}{E_1} + \frac{1 - \nu_2^2}{E_2} \tag{9}$$

where $E_{\text{eff}}$ is the effective elastic modulus, which can be obtained from load-depth indentation results. Hence, one is able to determine the elastic modulus of the tested solid ($E_1$) based on the indentation data.

However, the contact of a sharp indenter into a solid surface inevitably involves plastic deformation, which makes it difficult to model the process and analyze the experimental data. Since an analytical solution of the elastic/plastic contact problem is not available [157], and the elastic contact between axisymmetric punches and isotropic and anisotropic half-spaces has been the subject of thorough investigations (see, e.g., [158–160]), most researchers assume elastic punch contact as suitable for modeling elastic/plastic surface deformation. Consequently, Bulychev et al. [161] proved that the relationship between stiffness $S$, effective elastic modulus $E_{\text{eff}}$, and the projected area of the contact $A$:

$$S = \frac{2\sqrt{A}}{\sqrt{\pi}} E_{\text{eff}} \tag{10}$$

holds for cylindrical, conical, and spherical indenters. The above universal formula seems to be valid for all indenter shapes being a body of revolution of a smooth function, as proved by King [162].

Oliver and Pharr [163] proposed the method of analyzing indentation data obtained with sharp indenter, while taking advantage of the punch contact problem. The authors assumed that, during the unloading cycle, the deformation of the tested solid is entirely elastic, and they applied the relationships derived for elastic contact of an axisymmetric punch, along with the approach by Doerner and Nix [149]. The latter is based on the assumption that a considerable

part of the unloading $P - h$ curve possesses a linear character, which makes the equations derived for punch problem [refer to Eqs. (9) and (10)] to hold when one considers the indentation unloading. The assumptions by Doerner and Nix, followed by Pharr and Oliver, require contact area to remain unchangeable during the indentation cycle. Doerner and Nix [149] argued that the residual indentation depth $h_r$ (see Fig. 3a) is affected by elastic recovery within the contact and it cannot be used to determine the contact area. In order to estimate the size of the plastic contact region and residual plastic depth $h_p$, the authors suggested subtraction of the elastic contribution from the maximum indentation depth $h_{\text{max}}$. Consequently, the elastically recovered depth $h_e$ can be obtained in the form

$$h_e = h_{\text{max}} - h_p = \frac{P_{\text{max}}}{S} \tag{11}$$
while the elastic modulus of the examined solid $E_1$ [Eq. (9)] may be calculated using the relationship

$$\frac{1 - \nu_1^2}{E_1} = \frac{1}{E_{\text{eff}}} - \frac{1 - \nu_2^2}{E_2} = \frac{2}{S\sqrt{\pi}}\sqrt{A} - \frac{1 - \nu_2^2}{E_2} \tag{12}$$

where $S$ defines the slope of the unloading curve ($S = dP/dh$), $P_{\text{max}}$ is the maximum load, and $A$ is the contact area.

**Figure 3.** (a) Schematic of the indentation load–displacement curve with the parameters used in the Doerner and Nix analysis. (b) Schematic of the indentation load–displacement curve with the parameters used in the Oliver and Pharr analysis.

The Oliver–Pharr analysis of depth-sensing indentation [150, 163] approximates the unloading curve by a power-law relationship:

$$P = B \cdot (h - h_f)^m \qquad (13)$$

where $h_f$ is the residual displacement after unloading determined by the curve fitting with $B$ and $m$ values as fitting parameters. Oliver and Pharr stated that the depth at the contact $h_c$ (see Fig. 3b) appears to be dependent on the initial unloading slope $S$ as well as the maximum penetration depth $h_{max}$. The discussed dependence yields the simple relationship for the $h_c$ parameter:

$$h_c = h_{max} - \varepsilon \cdot \frac{P_{max}}{S} \qquad (14)$$

where $\varepsilon$-value equals 1, 0.75, and 0.73 for a flat punch, the Berkovich tip, and cone-shaped indenter, respectively.

The essential point of the Oliver and Pharr analysis [163] is the evaluation of the shape function $A = f(d_c)$, which expresses the relation between the projected contact area $A$ and its distance $d_c$ from the indenter tip. The method employs the $P - h$ data obtained for a model-specimen for which the authors developed a simple empirical calibration procedure which avoids the imaging of indents. As a result, Oliver and Pharr found the value of effective elastic modulus $E_{eff}$ using the following equation [163]:

$$E_{eff} = \frac{\sqrt{\pi}}{2\beta} \frac{S}{\sqrt{A}} \qquad (15)$$

where $\beta$ depends on the geometry of the indenter and equals 1.034 for the Berkovich tip.

It should be emphasized that the method by Oliver and Pharr [163] is perhaps the most widely used nowadays to routinely analyze the data obtained by means of various nanoindentation systems.

The measurement of Young's modulus proposed by Field and Swain for the spherical indenter employs stepwise indentation with multiple partial unloading [164–166]. The stress field is well-defined in the solid deformed by an axisymmetric tip, whose radius may be selected to control the depth of penetration [164–167]. Furthermore, the indentation with multiple partial unloading produced data which allowed Field and Swain to separate the elastic and plastic components of indentation (Fig. 4) and, in a consequence, to estimate the elastic modulus at each step of the penetration. The above-mentioned fact is of great importance for the application of the method, since such a separation is essential for extracting information relating to material properties [166].

Taking advantage of the basic relationship between force $P$ and the depth of the elastic penetration for a spherical indenter which was derived originally by Hertz [155, 156], and reviewed by Johnson [157], Field and Swain were able to derive a simple formula for calculating the elastic modulus $E_{eff}$ [165]:

$$E_{eff} = \frac{0.75 \cdot P}{a \cdot (h_t - h_r)} \qquad (16)$$

where $h_t - h_r$ denotes the elastic depth recovery.

**Figure 4.** Typical load–partial-unload force-displacement data obtained for an elastic/plastic material.

The stepwise indentation allowed the authors a near-continuous assessment of the effective Young's modulus with the depth of penetration.

Hainsworth et al. [168] noticed that the unloading cycle hardly fits the existing models by Oliver and Pharr [163, 169] or Field and Swain [165, 170], and proposed the original method of Young's modulus evaluation by using the loading part of an indentation cycle. Hainsworth et al. [168] concluded that the information on elastic and plastic properties of a tested solid may be obtained by analysis of the loading curve that follows the quadratic relationship. They found the simple relationship between the contact radius $a$, indentation load $P$, and hardness $H$:

$$a = \sqrt{\frac{P}{H}} \qquad (17)$$

Further, following the approach by Loubet et al. [171], Hainsworth et al. [168] derived the power-law dependence between indentation load and depth:

$$P = K_m h^2 \qquad (18)$$

where

$$K_m = E \cdot \left( \phi \cdot \sqrt{\frac{E}{H}} + \psi \cdot \sqrt{\frac{H}{E}} \right)^{-2} \qquad (19)$$

The empirically determined $\phi$ and $\psi$ values depend on the indenter geometry, while $E$ stands for Young's modulus of the material. They verified Eq. (18) for a number of materials with widely varying $E/H$ ratio (steel, bronze, copper, iron, silicon crystals, as well as TiN and $CN_x$ thin films) and concluded that the $P - h^2$ relationship holds for $\phi = 0.194$ and $\psi = 0930$ [168].

In sum, Hainsworth et al. [168] predicted the shape of the loading indentation curves which allows us to determine the commensurate value of Young's modulus $E$ of the indented material in the case when hardness $H$ is known.

Taljat et al. [172] investigated the unloading cycle of a ball-indentation process by the FEM analysis with the stress-strain curve of the indented material used as independent variable (input) in FEM calculations. They defined Young's modulus of the indented solid as a functional dependence on

a normalized unloading slope $S_u$ and the estimate of deformation $d/D$ (ratio of the diameter of the impression and indenter) [172]:

$$E = f\left(S_u, \frac{d}{D}\right) = \left[C_1\left(\frac{d}{D}\right)^{C'}\right] \cdot S_u \qquad (20)$$

where $C_1$ and $C'$ constants were determined using FEM analysis. The authors estimated the indenter deformation employing an analytical solution for the displacement of the center of the contact circle and subtracted it from the total indenter compliance—the correction essential in the calculation of elastic modulus [172].

The complete study of elastic loading and elastic/plastic unloading of a spherical indenter was accomplished by Gerberich et al. [173]. Their method of Young's modulus evaluation suits the requirements of ultra low-load experiments and was scrutinized for numerous materials [173]. The original analysis of the elastic displacement above ($h_1$) and below ($h_2$) the contact line (refer to Fig. 5) by Gerberich et al. [173] contrasts the elastic analysis by Field and Swain [166] who assumed the simplified relationship $h_1 = h_2$.

The solution of elastic and rigid plastic contact problems with the boundary conditions allowed the authors to determine elastic displacements ($h_E$, $h_t$), contact radius ($a$), the total indentation load ($P$), that led to the expression which describes the unloading curve, and consequently, the effective modulus $E_{\text{eff}}$ [173]:

$$E_{\text{eff}} = \frac{3 \cdot R \cdot P}{4 \cdot \left[\left(2 - \frac{h_E^{\max}}{h_t^{\max}}\right) \cdot Rh_E - \left(1 - \frac{h_E^{\max}}{2h_t^{\max}}\right) \cdot h_E^2\right]^{1/2}} \qquad (21)$$

where $R$ is a radius of the spherical indenter. Hence, Gerberich et al. [173] were the first to provide a complete method of estimating the elastic modulus of an indented material. It has been demonstrated that accurate simulation of elasticity may be in special cases elaborated to yield even compositional differences in the nanolayer composites [174].

### 4.1.3. Determination of Hardness

The physical importance of hardness $H$—denoted according to Meyer's concept—lies in the relationship between the $H$-value and the fundamental physical parameters such as yield strength $\sigma_Y$ or Young's modulus $E$. Despite being

**Figure 5.** The geometry of elastic penetration of spherical indenter into a solid surface. Model by Gerberich et al. [173].

widely used by engineers, hardness appears to be an ill-defined parameter which does not describe a single material property, as criticized by Söderlund and Rowcliffe [175]. The measured hardness is affected by indentation-induced cracking, densification, strain hardening, and creep, and it depends on Young's modulus $E$, yield strength $\sigma_Y$, toughness $K_{\text{IC}}$, work-hardening exponent $n$, stress-dependent creep rate $\varepsilon^c$, as well as the applied maximum indentation load $P_{\max}$. With the advent of nanostructured materials and nanoindentation instruments, confusion arose as to how to determine the hardness parameter from the monitored displacement of the indenter. Starting with the pioneering work by Oliver et al. [176], efforts were being made to settle the characteristic contact area $A'$ at each step of the penetration, and consequently to determine Meyer's hardness as

$$H = P/A' \qquad (22)$$

As a result, the estimation of the depth–hardness profile became the standard procedure in the commercially available nanodepth-sensing indentation instruments.

Furthermore, the original definition of hardness $\boldsymbol{H}$, which appears a load-independent parameter, was introduced by Sakai and Nowak [177]. In contrast to the other approaches, $\boldsymbol{H}$ is a physical parameter defined on the basis of the energy consumed for the irreversible deformation of an indented material.

Doerner and Nix [149] considered the hardness as the average pressure under the acting indenter. They proposed the subtraction of the elastic contribution $h_e$ from indentation depth $h$ measured during a depth-sensing test, in order to evaluate the level of hardness. Further, they have shown that plastic indentation depth $h_p$ may be determined by extrapolating to zero load the line which is fit tangent to the unloading $P - h$ curve (see Fig. 3). Doerner and Nix were well aware of the drawbacks of their assumption of a perfect shape of a pyramidal indenter [149]. They also admitted that the estimation of the influence of the strain rate on the obtained results was beyond the resolution of the proposed method.

Since the main difficulty associated with evaluation of the level of hardness lies in the estimation of the projected area $A'$ of permanent indentation [refer to Eq. (22)], Pharr, Oliver, and co-workers determined the empirically assessed shape of indenter at the contact depth $h_c$ $A = f(d_c)$ [150, 163]. The $f(d_c)$ function can be assessed from the depth-sensing indentation data which allow us to evaluate the relationship between the area $A$ and the contact depth $h_c$. The shape-function derived for a perfect Berkovich geometry,

$$f(d_c) = 24.56d_c^2 \qquad (23)$$

was used by Oliver and Pharr as a first estimate of the contact area [150], while to determine a realistic shape of the indenter, they used a standard specimen [150, 163, 169]. They carried out numerous indentations under various maximum loads $P_{\max}$ in fused quartz or fused silica materials with well-defined isotropic properties, and the fitting procedure was applied several times in an iteration method to achieve suitable accuracy [163]. Once the $f(d_c)$ function was determined, it was possible to evaluate the hardness from the

indentation results according to Eq. (22). Recently, Pharr and associates have provided us with a new insight into hardness analysis by investigating the influence of pileup on the hardness of the indented solid [169].

Since the direct measurement of the contact area is usually impossible, the FEM simulation is effectively used to determine hardness. Numerical simulation allows us nowadays to conclude on a variety of mechanical parameters, such as contact stiffness, the effective elastic modulus, and yield strength, and may be used to predict the actual surface profile or the shape of the plastic zone created directly under an acting indenter. All these advantages, combined with the high computational capabilities that are readily available today, have caused interest in FEM-aided analysis of indentation data particularly in the case of unknown materials or nanostructures.

Hill, Storåkers, and co-workers derived general expressions for the influence of the Brinell head-shape on the load and surface deformation by solving a class of boundary-value problems in elasticity [178, 179]. They also applied a novel FEM procedure to the deformation theory of plasticity [178, 180, 181]. Numerical simulations were performed for the elastoplastic homogeneous half-space, indented to a fixed depth by a smooth rigid ball. The solid was deformed according to the power-law hardening rigid-plastic model.

Hill et al. determined the distribution of contact pressure, the profile of the deformed surface, and the contours of representative strain. Further, Storåkers and Larsson derived the universal relationship for hardness at creep applicable in the case of the Boussinesq and Brinell indentation [180]:

$$\frac{P}{\pi \alpha^2} = \alpha \cdot \sigma_c \left\{ \left( \frac{\beta}{(2n+1)D} \right)^2 \left( \frac{P}{\pi \alpha \sigma_c} \right) t^{-2} \right\}^{1/(2n+1)} \quad (24)$$

where $a$ is the contact radius under the ball indenter of diameter $D$, $t$ denotes time, $\alpha$ and $\beta$ are constants and $\sigma_c$, $n$ are material parameters defined by the stress-strain ($\sigma - \varepsilon$) creep law given by Norton [182].

The studies by Storåkers, Hill, Larsson, and associates proved that the indentation-deformation occurs in the low-strain-hardening materials close to the indenter [178–181], which indicates the necessity to contract the mesh to a smaller size during subsequent stages of the simulation.

FEM analysis of sharp indentation was first performed by Bhattacharya and Nix [183] and subsequently, by Lursen and Simo [154]. The authors performed their calculations for an axisymmetric cone of equal volume with a pyramid shape indenter in order to reduce computer time necessary for calculations.

Bhattacharya and Nix provided the computer-simulation study of the frictionless penetration process of perfectly rigid tip as well as completely adhesive indentation contact using incremental elastoplasticity [153]. The authors applied constitutive equations of an elastic-plastic von Mises type with no strain hardening and with a linear, isotropic strain hardening. The mesh used in FEM procedure was fine right under the tip (four node elements, 0.02 $\mu$m thick) which made it possible to estimate the radius of the contact area, the parameter being essential to determining the hardness value. The authors extended their considerations to the various combinations of hard/soft thin films and substrates [183]

and their report introduces the evaluation of the thin-film hardness.

Hence, Bhattacharya and Nix were the first to demonstrate the successful simulation of the ultra-low-load indentation using the finite element method with simple constitutive data.

Following the pioneering research by Bhattacharya and Nix [153, 183], Lursen and Simo presented a detailed numerical simulation of surface deformation of elastic/power-law plastic materials [154]. The work addressed axisymmetric cone indentation into bulk aluminum and silicon as well as thin films of various degrees of thickness. They emphasized numerical evaluation of the contact area and the surface profile near impression.

Recently, Nowak et al. had applied the FEM simulation of the penetration by an axisymmetric indenter into the multilayer system to explain the surprising difference in the hardness of virgin and ion-treated, 50- to 300-nm thin HfN films [109]. The FEM calculations allowed them to conclude that bombardment with highly energetic ions (MeV energy range) results in formation of the amorphous silicon interlayer located under the top-film.

The axisymmetric approximation of the pyramidal tip is hardly acceptable in the case of anisotropic materials. Thus, the three-dimensional (3D) FEM analysis of a sharp indentation has become highly required.

The first attempt to perform a 3D finite element simulation of indentation by Wang and Bangert [184] was soon followed by a complete analysis of the Vickers indentation by Giannakopoulos et al. [185]. The latter formulated the problem as the penetration of a rigid indenter into a homogeneous, isotropic, rate-independent body. It was assumed that Hook's law and the Prandl–Reuss equations govern the elastic and elastoplastic behavior of the deformed material, respectively [185].

The small strain formulation, elastic analysis by Giannakopoulos et al. allowed them to conclude on the parabolic relationship between the indentation load $P$ and depth $h$ at the loading cycle, and to determine hardness as the average contact pressure $p_{av}$, while the deformation was found to be directly dependent on indentation depth [185]. Elastoplastic examination of the loading process led to the evaluation of the effect of the pileup and yield stress on the Vickers hardness $HV$ ($p_{av} = HV$). This resulted in the universal formula for the Vickers hardness:

$$p_{av} = C \cdot \sigma_u \left( 1 + \frac{\sigma_v}{\sigma_u} \right) \cdot \left( 1 + \ln \frac{E \cdot \tan 22°}{3\sigma_y} \right) \cdot \left( 1 - \frac{u_{2\,max}}{h} \right)$$
$$(25)$$

where $C$ is constant, $u_{2\,max}$ defines the maximum positive surface displacement caused by material pileup, while $\sigma_u$ and $\sigma_Y$ stand for the ultimate stress and yield stress, respectively.

Calculations of steady-state hydrostatic stress and Mises effective stress profiles for materials with and without strain hardening, indicate that strain hardening suppresses pileup at the contact boundary [185]. The maximum tensile principal stress at loading, predicted in the vicinity of indenter tip, helped the authors to localize the region in which the fracture is likely to be initiated.

Pursuing their successful FEM-added study of the Vickers indentation [185, 186], the authors provided a common analysis of the deformation induced around a triangular indenter of Berkovich type which is mostly used in nanoindentation testers [187]. Larsson et al. [187] found that the $P - h$ relationship for a triangular tip is again parabolic, when the indentation is simulated using either an elastic or an elastoplastic approach.

Corresponding formulae denoting the average contact pressure under a Berkovich indenter (the estimation of the Berkovich hardness) were also derived for elastic [Eq. (26)] and elastoplastic [Eq. (27)] cases [187]:

$$p_{av} = 0.2201 \cdot (1 - 0.21\nu - 0.01\nu^2 - 0.41\nu^3) \cdot \frac{E}{1 - \nu^2} \quad (26)$$

$$p_{av} = 0.245 \cdot \sigma_y \left(1 + \frac{\sigma_u}{\sigma_y}\right) \cdot \left(1 + \ln \frac{E \cdot \tan 24.7°}{3\sigma_y}\right) \quad (27)$$

This accounts for the pileup effect and provides the universal formula for Berkovich hardness.

The complete 3D FEM analysis of sharp indentation into pressure-sensitive materials was offered by Giannakopoulos and Larsson in 1997 [188], who introduced pressure sensitivity of the studied material according to the classic model of pressure-sensitive flow, proposed by Drucker and Prager for ideal soils [189].

The results obtained using such an incremental elastoplastic law comprised the solution of complete load-unload cycles, the determination of the contact area, evaluation of the average contact pressure, local mechanical fields (the Mises effective stress), and their singularities near the tip and edges of the indenter. A large plastic strain and small elastic strain approach, as well as high and low, linearly isotropic strain-hardening effects were considered. It was found that the relationship between the indentation load $P$ and depth $h$ is parabolic, similar to earlier FEM-aided studies by Giannakopoulos and Larsson [185, 187]:

$$P = -\int \sigma_{2j} N_j d\Gamma_c = Ch^2 \quad (28)$$

where $\Gamma_c$ denotes the actual contact area, $N_j$ stands for an inward vector normal to the surface within the contact area, and $C$ is constant. The calculations proved that the total energy $U_r$ spent for indentation depends on the maximum indentation load to power 3/2:

$$U_r = \int_0^{h_{max}} Pdh = \frac{P_{max}^{3/2}}{3C^{1/2}} \quad (29)$$

The general formula for the average contact pressure $p_{av}$ (equivalent to the Meyer hardness) derived for pressure-sensitive materials reads

$$p_{av} = 0.77 \cdot \frac{3(1 + q)(\sigma_y + qp_0)}{3 + q}$$
$$\cdot \left(\frac{(3 + q)E}{3(1 + \nu)(\sigma_y + qp_0)}\right)^{2q/(3(1+q))} - (\sigma_y + qp_0) \quad (30)$$

where $q = 3a_0/(3 - a_0)$, while $a_0$ is the material constant that measures pressure sensitivity and $p_0$ is a far-field hydrostatic compression.

The recent FEM simulations resulted in the general theory of indentation of piezoelectric solids [190] and clarified the evolution of the surface residual stress and deformation field in compositionally graded materials [191, 192]. Furthermore, the research is coming closer to the requirements imposed by the structure of nanomaterials targeting small-scale structures. In the latter case the FEM analysis which works yet for thin multilayered systems [107–109, 193] must be replaced by atomistic simulations (see, e.g., [124, 194]) or hybrid methods which combine advantages of FEM and elements of molecular dynamics calculations (refer to [105]). Another trend observed nowadays is improvement of FEM analysis by employing artificial neural network within the code [106].

All of this indicates that, despite unavoidable simplifications, the finite element calculations proved to be quite useful when studying the mechanics of indentation. Without the FEM approach, several complicated problems which concern surface deformation of solids would be still unsolved.

A new concept of hardness, based on the amount of energy irreversibly consumed to create a unit volume of indentation impression in a perfectly plastic material, was proposed by Sakai and Nowak in 1992 [177], while its complete version was published by Sakai in 1993 [195]. The propounded theory—the energy principle of indentation (EPI)—is quite revolutionary in the traditional engineering field of hardness testing, where all the definitions have only been made on an empirical basis. Although not as popular as the approach by Oliver and Pharr [163], the EPI method has been widely recognized.

Starting with the idea of hardness being a measure of the material resistance against plastic deformation induced by a rigid indenter, the EPI approach is based on the assumption that hardness should be directly related to the energy $U_r$ expended for irreversible deformation of the tested solid [177, 195]. The above-mentioned energy can be readily determined from depth-sensing indentation data $(P - h)$, since it is represented by the area bound by loading and unloading curves (see Fig. 6). In the case of the perfectly elastic contact, the energy $U_r$ equals zero (see Fig. 6a), while it attains the maximum value for the indentation in perfectly plastic material (Fig. 6b). Usually one deals with a combined response typical for elastoplastic contact (Fig. 6c).

Taking advantage of the determined shape of the $P - h$ function, it was possible for Sakai and Nowak to calculate the

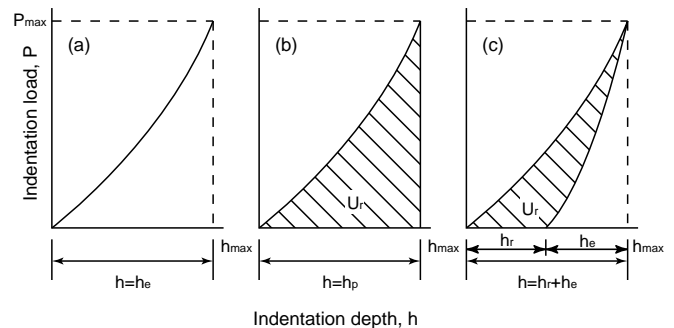

**Figure 6.** Typical loading–unloading indentation curves for the perfectly elastic (a), plastic (b), and elastic-plastic material which exhibits an appreciable elastic recovery (c).

energy expended for an irreversible indentation deformation of the tested solid [177, 195]. In the case of an elastic-plastic material illustrated in Figure 6c, the $U_r$ energy was obtained through integrating $P(h)$ function with respect to $h$:

$$U_r = \int_0^{h_{\max}} P_L(h)\, dh - \int_{h_r}^{h_{\max}} P_{UL}(h)\, dh \qquad (31)$$

where $P_L(h)$ and $P_{UL}(h)$ stand for loading and unloading $P - h$ functions. Furthermore, Sakai and Nowak derived the relationship between $U_r$ and the applied maximum load $P_{\max}$, which in turn allows us to determine $H$ from the plotted $U_r - P_{\max}^{3/2}$ experimental data in a relatively easy way [177]:

$$U_r = (3 \cdot \sqrt{\alpha_0} \cdot \tan\psi)^{-1} \cdot H^{-1/2} \cdot P_{\max}^{3/2} = C \cdot P_{\max}^{3/2} \qquad (32)$$

Indeed, when one determines the slope $C$ of the linear function $U_r - P_{\max}^{3/2}$ measured for several maximum loads $P_{\max}^{3/2}$, it is possible to estimate the value of the true hardness $H$, given the determined shape of a sharp indenter (geometry described by the angle $\alpha_0$ and $\psi$). It is worth emphasizing that the hardness $H$ is a physically well-based parameter which appears to be load-independent, in contrast to the conventionally measured hardness $H$.

### 4.1.4. Determination of Creep, Stress Relaxation, and Other Attributes to Local Plasticity

Indentation experiments can also be used to study the deformation mechanisms of nanocrystalline materials. They offer convenient means to determine, for example, the strain rate sensitivity of the material. Strain rate sensitivity $m$ is the slope of a plot of log applied stress versus log strain rate, that is, the inverse of the stress exponent $n$ in Eq. (4). The effective strain rate $\dot{\varepsilon}_{\text{eff}}$ is obtained from

$$\dot{\varepsilon}_{\text{eff}} = \dot{x}_p / \sqrt{A} \qquad (33)$$

where $A = A(x_p)$ is projected contact area and $x_p$ is the plastic depth beneath the indenter.

In order to determine the rate sensitivity of hardness (stress) by indentation tests, various approaches can be used, for example, indentation creep, rate change, or load relaxation experiments [148, 196]. In an indentation load relaxation experiment, the indenter is pushed into the specimen surface until a predetermined load is reached; then the depth is held fixed, allowing the load to relax as elastic displacement due to the specimen and load-train is gradually traded for plastic penetration. In the indentation creep experiment, the indenter is pushed into the specimen surface at a fixed rate of displacement until a predetermined load is reached; then the load is held constant, allowing the penetration depth to increase with time while the penetration is monitored. In an indentation creep test, the load slightly decreases as the projected area increases during the test, in contrast to a tensile creep test with a constant load, where the stress gradually increases with decreasing cross-sectional area of the test specimen. In the indentation rate change experiments, the indenter is pushed into the sample surface at a fixed rate of displacement until a predetermined load, upon which the indenter is partially unloaded, then reloaded at a second rate of displacement.

## 4.2. Atomic Force Microscopy and Measurement of Mechanical Properties

In the previous section we elaborated about the nanoindentation technique being frequently the most suitable tool to examine mechanical properties of multilayered and nanostructured materials. The method proved effective independent of crystallinity of the probed material; that is, it works equally well for crystalline structures [197–199] and amorphized [200, 201] surfaces.

Another powerful tool to study nanostructured materials is the atomic force microscope (AFM), which can be used both to image the details of the structure and to determine the mechanical properties of the investigated surface.

The crucial part of the AFM is a cantilever with the microfabricated tip which remains in contact with the investigated surface. The deflection of the tip, which is made of silicon or silicon nitride, may be very precisely measured by using optical lever, interferometric, or electronic tunneling method [202]. Consequently, one may acquire force-distance curves that are analogous to the discussed $P - h$ indentation curves with accuracy as high as 2.5 nm and 0.01 nm for lateral and vertical dimensions, respectively. The contact force can be estimated with a resolution of 1 pN [202].

It is worth emphasizing here, after an excellent review of the subject by Cappella and Dieter [202], that AFM force-displacement curve is not recording of tip-sample interaction, contrary to nanoindentation plots. However, this curve results from tip-surface interaction and the elastic force of cantilever. The measurement allows us to determine the elastoplastic properties. One should keep in mind, however, that the AFM experiment is in a much finer scale than the nanoindentation method.

The AFM evaluation of elastoplastic response of the surface is continuously improving. A proper example could be here a new scanning Moiré method, which allowed to determine in-plane deformation by AFM [203], while the detailed thermal fluctuation measurement allowed Catlege et al. [204] to conclude on the spring constant of cantilevers used in AFM.

Furthermore, Kracke and Damaschke [205] recently used a scanning force microscope to measure nanohardness and nanoelasticity of thin gold films. Due to advantages offered by this particular method, the authors were able to estimate properties of single gold island formed during film formation.

In sum, the AFM measurement of mechanical properties of nanostructured materials must be considered as one of the most powerful methods available nowadays for investigating the nanomaterials.

## 4.3. Methods for Exploring Nanotribological Properties

Most tribological contacts occur at the asperities of the surface. The nanoscale tribological events have been investigated successfully with the help of the recent development

of proximity probes and tip-based microscopes and surface force apparatus with the help of computational techniques simulating the tip contact. The concept of nanotribology has been introduced in association with experimental and theoretical investigations of interfacial processes on atomic and molecular scales, which occur during adhesion, friction, scratching, wear, nanoindentation, and thin-film lubrication at sliding surfaces [206]. The main tools at present are surface force apparatus (SFA), scanning tunneling microscope (STM), atomic force microscope (AFM), and friction force microscope (FFM). The comparison of the operating parameters of these methods is shown in Table 1.

### 4.3.1. Wear Tests for Nanostructured Materials

The magnetic media are constantly in development of higher data storage capacity which demands the reduction of the coating thickness on the media [207]. Of importance in terms of the tribological properties are the 5- to 10-nm-thick protective layer of diamond-like carbon (DLC) and the 0.5- to 2-nm thick perfluoropolyether lubricant layer. As an example, AFM has been used to investigate the wear evolution of a magnetic disc coated with DLC. On nanoscale it was observed that the wear is not uniform and initiates at nanoscratches [208]. AFM wear tests have been used to evaluate the wear resistance of the ultrathin DLC coatings prepared by varying the deposition parameters [207]. The surface defects present at the nanoscratches act as initiation sites for wear. FFM has been used to indicate any imperfections and variation of the coating thickness on the magnetic disk. AFM has also been used to compare the tribological properties of DLC coatings by varying the deposition method and coating thickness (from 2.5 to 20 nm). The 20-nm-thick coatings had the highest wear resistance [209].

### 4.3.2. Determination of Friction in Nanostructured Materials

FFM provides the means to map the surface of material on nanoscale. FFM method has been used to investigate the properties of nanostructured carbon coatings (ns-C) [210]. It was found that the friction varied depending on the individual carbon nanocluster and the overall friction behavior was dependent on the parameters of the cluster beam.

## 5. MECHANICAL PROPERTIES OF NANOSTRUCTURED MATERIALS

### 5.1. Nanoparticles, Nanotubes, and Nanofibers

#### 5.1.1. Nanoparticles with Various Aspect Ratios

Nanoscale particles (spheres, rods, wires) can be fabricated with a variety of different methods and the methods have been applied to a multitude of materials. Generally, mechanical properties of individual nanoparticles, irrespective of their morphology, become near to ideal properties of flawless single crystals. This is due to the size effects associated to characteristic lengths of mechanical properties of materials as discussed previously. However, the large proportional number of surface atoms has an additional effect.

Proportion of surface atoms to bulk atoms has been suggested to produce size dependency in elastic properties of nanosized particles. The size dependency has been modeled using continuum mechanics [132]. An important length scale in the phenomena was identified to be the ratio of the surface elastic modulus to the elastic modulus of the bulk of the material. Typically, the size dependency starts to be significant in particle sizes of a few nanometers depending on material.

The strength of small wires (whiskers) has been observed to approach the theoretical cohesive strength of solid matter already in submicrometer size range [211]. The theoretical cohesive strength lies in the range of 0.03 to 0.17 times the modulus of elasticity. In case of metallic nanowires, the exceptionally high strength has been confirmed experimentally in studies of nanometer-size gold contacts using scanning tunneling microscope [212, 213]. For comparison, gold is the softest of all metals in larger dimensions.

Mechanical properties of nanoparticles have been contrasted here with bulk properties of materials. However, structural forms of nanoparticles that are characteristic of the nanometer scale only, such as fullerenes and nanotubes, are also observed.

#### 5.1.2. Nanotubes

Nanotubes are large macromolecules similar to a sheet of graphite rolled into a cylinder and capped with half fullerene at both ends. Essentially, they are one-dimensional

**Table 1.** Comparison of typical operating parameters in SFA, STM, and AFM/FFM used for micro/nanotribological studies [206].

| Operating parameter | SFA | STM[a] | AFM/FFM |
|---|---|---|---|
| Radius of mating surface/tip | ~10 mm | 5–100 nm | 5–100 nm |
| Radius of contact area | 10–40 $\mu$m | N/A | 0.05–0.5 nm |
| Normal load | 10–100 mN | N/A | <0.1–500 nN |
| Sliding velocity | 0.001–100 $\mu$m/s | 0.02–2 $\mu$m/s (scan size ~ 1 nm × 1 nm to 125 $\mu$m × 125 $\mu$m; scan rate < 1–122 Hz) | 0.02–2 $\mu$m/s (scan size ~ 1 nm × 1 nm to 125 $\mu$m × 125 $\mu$m; scan rate < 1–122 Hz) |
| Sample limitations | Typically atomically smooth, optically transparent mica; opaque ceramic, smooth surfaces can also be used | Electrically conducting samples | None |

[a] Can only be used for atomic-scale imaging.

nanostructures having nanometer scale diameter, and length ranging from nanometers to millimeters. Since the discovery of carbon nanotubes in 1991 [214], two kind of tubes have been found: single-walled carbon nanotubes (SWNTs) with only one cylinder of an atomic layer, and multiwalled carbon nanotubes (MWNTs), with cylinders inside each other. The atomic structure of nanotubes is described in terms of the tube chirality, which is defined by pair of integers $(n, m)$ expressing the chiral vector. The chiral vector can be understood as a description of how the hexagonal sheets have been "rolled." According to the atomic structure, nanotubes can be grouped into three categories: armchair $(n = m)$, zigzag $(n = 0$ or $m = 0)$, and chiral (any other $n$ and $m$) [215]. An additional feature of carbon nanotubes is that the carbon SWNTs tend to self-assemble into "ropes," which consist of hundreds of SWNTs in a two-dimensional triangular lattice [216]. Besides the carbon, materials such as BN, $BC_3$, $BC_2N$, $WS_2$, and $MoS_2$ have been discovered to form nanotubes. It has been suggested that all compounds having layered structures in the bulk are likely to form nanotubes [217–219].

There is a growing body of evidence indicating that nanotubes have exceptional mechanical properties. Theoretical calculations based on in-plane C—C bond in graphite, which is one of the strongest chemical bonds known in nature, indicate that nanotubes are very strong materials having axial elastic modulus in TPa range [220–223]. The first Young's modulus measurement of carbon MWNTs was performed utilizing amplitude of their intrinsic thermal vibration. This transmission electron microscopy study gave an axial Young's modulus of 1.8 TPa as an average of 11 samples [224]. Carbon SWNTs have been studied with the same technique yielding an average axial Young's modulus of 1.25 TPa [225]. Another technique to measure Young's modulus of nanotubes is based on bending anchored samples with AFM. With this technique, the results of 1.28 TPa [226] and 0.81 TPa [227] have been reported for carbon MWNTs. As expected, all the values are close to the value of in-plane modulus of graphite sheet, which indicates that chirality and tube diameter of nanotubes have only minor influence on axial elastic properties. The studies of carbon SWNT ropes show that also they are high axial modulus fibers (∼1 TPa) [228, 229]. In case of other materials than carbon, the vibration amplitude technique has been used for determining the properties of BN MWNTs giving the axial Young's modulus of 1.22 TPa [230]. Recently, tight-binding calculations of axial Young's modulus for C, BN, $BC_3$, $BC_2N$, and $C_3N_4$ nanotubes with various chirality have been published. For the exact values, the original reference should be consulted [231].

Theoretical analysis predicts that nanotubes can sustain extreme strains in tension without breaking [232, 233]. Tensile strengths of individual carbon MWNTs have been measured with "nanostressing stage" located within a scanning electron microscope. The measured tensile strengths of the outermost layer of MWNTs ranged from 11 to 63 GPa [234]. The values are high compared to conventional fibers but not as high as expected. Carbon SWNT ropes have been studied with the same technique, resulting in tensile strength on the perimeter of the rope ranging from 13 to 52 GPa [235].

The hollow structure and closed topology of nanotubes produce extraordinary mechanical response in bending. It has been shown that carbon MWNTs can be bent repeatedly through large angles without failure [236]. In fact, deformations such as buckling can be fully reversible. Combination of experimental and theoretical work has shown that the bending angle up to 110° does not produce any damage in atomic arrangement, despite the formation of complex kink shapes [237]. The first direct bending strength measurement of large-diameter carbon MWNTs was performed with AFM. The average value of bending strength in the point of elastic buckling was 14.2 GPa [226]. The ability of carbon nanotubes to sustain load elastically at large bending angles enables them to store or absorb considerable energy.

As far as property variations are concerned, the synthesis method of carbon nanotubes has been reported to affect their mechanical properties. The carbon MWNTs synthesized by arc-discharge method have much higher bending strength than those produced by catalytic decomposition of hydrocarbons. The difference in the results is explained by presence of defects in the latter nanotubes [227].

In literature reports on mechanical properties of individual nanotubes, most authors use estimated tube wall thickness for defining Young's modulus and tensile strength. Obviously, if the total occupied cross-sectional area is used, the values would be much lower. Propably the most impressive mechanical property of nanotubes is their specific strength, because of the low weight. Consequently, nanotubes are expected to be useful structural reinforcement in high-performance light-weight composites.

## 5.2. Layered Materials

### 5.2.1. Multilayered Materials

The multilayer coatings are a means to produce tailored surfaces. The multilayer coatings optimization with optimum mechanical properties has been reviewed by several authors [238, 239]. Holleck and Schier [239] have reviewed the mechanical properties and design principles of multilayer coatings. The multilayer coating may be classified into coatings with (1) a limited number of single layers in order to combine the different properties of the individual materials used; (2) a high number of non-isostructural coatings, where the amount of interface volume as sites for energy dissipation is important; (3) superlattice coatings, where isostructural single-layer materials with similar chemical bonding, atomic radii, and lattice distance and with layer thickness similar to the lattice dimensions are used. Superlattice coatings have been reported to have higher hardness as expected to result from the individual layers following the rule of mixture, for example, in TiN/(V, Nb)N coatings [240].

One trend in development of coatings is to increase the surface hardness. Coatings are usually divided into two groups: (1) hard coatings having a hardness up to 40 GPa, and (2) superhard coatings having a hardness over 40 GPa. Compared to a large number of hard materials, there are only a few superhard materials, that is, cubic boron nitride (c-BN), amorphous diamond-like carbon (DLC), amorphous carbon nitride (a-CN x), and polycrystalline diamond. Superlattice coatings are one means to obtain also superhardness.

Superlattice coatings are nanometer-scale multilayers composed of two different alternating layers with a superlattice period, that is, the bilayer thickness of two materials, ranging from 5 to 10 nm. The bilayers of these superlattices can be metal layers, nitrides, carbides, or oxides of different materials or a combination of one layer made of nitride, carbide, or oxide of one metal and the second layer made of another metal. According to the composition of the bilayer, superlattice coatings can be divided into five groups: (1) metal superlattices, (2) nitride superlattices, (3) carbide superlattices, (4) oxide superlattices, and (5) nitride, carbide, or oxide/metal superlattices [241]. Single crystal superlattice coatings have been reported to have hardness values in the range of 45 to 56 GPa (e.g., TiN/VN 56 GPa, TiN/CN$_x$ 20–50 GPa). The nitride/metal multilayers are less hard but more ductile (e.g., TiN/Ti). The toughness of the coating increases the adhesion of the coating to its substrate, giving a fundamental advantage to the coating.

A typical hard multilayer is the sputter deposited nitride film, for example, CrN/TiN, AlN/TiN. The hardness is a result of dislocation blocking and the metastable phases in the nanolayered structure. For example, AlN normally forms in a hexagonal structure, but when the deposited layer thickness is less than 2 nm, a cubic rock-salt structure of AlN is resulted corresponding to about a 50% increase of the film hardness. Hard metastable CrCu nanocomposite coatings have also been reported [242].

When using the layer thickness as a parameter similar to grain size, Hall–Petch relation (see Eq. (1)) was observed in the hardness and abrasive wear experiments. Ti/TiN multilayer coatings have wear resistance similar to TiN coating (1 N, alumina ball 25% RH, 5 m/s) [243]. The Hall–Petch relation in tensile strength has been observed also for polycrystalline silicon coatings [244].

Multilayered films have higher elasticity and hardness and better tribological properties as compared to the constituent layer materials alone [245], for example, in case PECVD is used to coat nanostructured Si:H and SiC:H multilayers. These multilayers have been proposed for various applications as protective coatings because of their properties (hard, tough, corrosion resistant, and high-temperature tolerant) [246, 247].

Properties of amorphous hydrogenated carbon (a-C:H) films are strongly dependent on the deposition parameters. By cyclically alternating the deposition parameters, a nanolayered coating may be produced. Thus nanoscaled multilayer films with modulated layer properties may be grown by using computer-controlled PACVD methods [248]. The wear resistance, for example, is optimal with both high and low elastic modulus layers when the single layer thickness is 12–14 nm. When Ti is incorporated, a hard coating suitable for bone implants, providing enhanced bone ingrowth and reducing bone resorption, can be produced.

The toughness of the TiC-metal multilayered film was observed to be better than that of the monolytic films, whereas the value of hardness depends on the choice of metal [249]. The optimum hardness and toughness values were obtained with TiC-Fe multilayer with modulation thickness of about 6–8 nm.

The abrasive wear resistance of multilayer coating of Cr-CrN has been modeled by Berger et al. [250]. The theory is based on a physical model for how the microscale abrasion mechanisms result in the macroscopic abrasive wear resistance of multilayer coatings. The model results in a linear rule of mixtures for the wear resistances of the two interlayers plus that of a wear-resistant supported zone, that is, the transition zone from Cr to CrN. Despite its simple rule of mixtures, the model agrees very well with the experimental results.

### 5.2.2. Design Rules for Multilayered Materials

The important parameters in designing multilayered materials are the lamellae thickness and bond type of the materials. Holleck suggested the use of multilayers of different ceramic materials, such as TiC and TiB$_2$, selected on the basis of their dominant bonding mechanism, that is, metallic, covalent, or ionic [251]. Multilayer coatings are a practical method to produce coatings of covalent bonded materials such as AlN, BN, SiC, or B$_4$C, since those materials, as single-layer coatings to metallic substrates, have a low adhesion [239]. On the other hand, covalent bonded materials adhere well to metallic hard materials such as TiC and TiN. Thus it is possible to introduce the hard covalent layer as interlayers into the multilayer coating. Holleck has also demonstrated improvements in hardness, indentation toughness, adhesion, and wear performance under optimized layer thickness conditions. For example, high values of hardness at elevated temperature (800 °C) have been reported for multilayer coatings with B$_4$C, BN and AlN interlayers embedded into TiN/TiC multilayer coatings. Also TiC-C nanocomposite coatings have shown promising tribological properties [252].

The properties of the interface play an important role in determining the mechanical properties of multilayer coatings. The properties of the interface are determined by the various deposition parameters used, but they depend also on the layer materials. The interface is typically a diffuse layer with a thickness varying from 1 to 3 nm. The total volume of the interface region depends on the thickness of individual interface region and the layers. Thus the interface volume may vary widely from only a few percent to almost 100%. The different toughening mechanisms are a result of the fine-grained microstructure, crack deflection, reduced stress concentration, nanoplasticity of the interfaces, and periodical stress and strain fields [239, 253, 254].

Leyland and Matthews [255] have reviewed the significance of H/E ratio of the coatings to the tribological behavior of the surface. Based on the contact mechanical models, it is determined that a high H/E value is beneficial in obtaining a wear-resistant surface with optimal properties of elastic strain to failure, critical yield pressure for plastic deformation, and fracture toughness. In practical applications it is advantageous to have a closely matched strain behavior between coating and substrate. Multilayer and nanocomposite coatings particularly with functional gradient properties have been investigated to optimize this effect. The coatings studied include Ti-B-N/Ti-B-C [256–263] and Ti-Al-B-N [264–268] nanocomposite coatings. For the CrN ceramic nitride and also for the metallic Cr+10 at. % nitrogen, the H/E value is about 0.05. By adding copper (<5 at. %) in

the Cr-Cu-N system at low nitrogen content (<10 at. %), it is possible to obtain high hardness values (H 20–25 GPa) while keeping the H value low (H 280 GPa). Thus the H/E value is increased up to 0.09 [269]. In conclusion, optimal H/E values may be obtained by using metallic nanocomposite coatings based on binary mixtures of a transition metal with another, low-miscibility, metal. It is required that the transition-metal component can be strengthened by solution hardening with interstitial elements (such as B, C, N), without creating a high-modulus ceramic phase [255].

The multilayer coatings provide three means to combine material properties: combination of several materials (multilayers), metastable materials, and graded structures. The tailored multilayer coating of Ti-TiC-DLC and $CN_x$ with excellent tribological properties has been demonstrated by Voevodin [142]. Graded nanoscale layer or interlayer designs have been used to reduce stresses of the films [270, 271].

### 5.2.3. Nanocrystalline Coatings

Nanocrystalline alloy films may be grown from, for example, NiCr (80/20 wt. %) and TiSi (90/10 at. %) [272]. Crystal size less than 100 nm results if the plasma parameters (ion energy, ion/neutral arrival rate, temperature) are such that sufficient crystal nucleation takes place and also grain growth is not too rapid. In addition, alloy species must have more than 15% difference in atomic radius and a large negative enthalpy of formation.

Veprek et al. have proposed a simple concept for the design of superhard coating material [273, 274]: (1) one has to use ternary or quaternary systems, which show strong segregation into two binary compounds, (2) low-temperature deposition should be applied in order to avoid interdiffusion in heterostructures, (3) one should use one amorphous phase in order to avoid lattice misfit, and (4) use nanometer range size crystalline material, the grains of which do not contain dislocations. Experimentally these design rules have been verified in a superhard nc-TiN/a-Si$_3$N4/na-TiSi$_2$ coating produced by PACVD [275]. Up to 100 GPa hardness values were obtained when about 10-nm TiN crystals are separated by roughly a nanolayer of Si$_3$N$_4$, with TiSi$_2$ precipitates at the interfaces. Respectively, nanocrystalline TiN/a-BN coating prepared by plasma CVD was reported to have a hardness of 45–50 GPa [276]. The very high hardness values obtained by indentation measurements are also explained by the small size of the critical flaw on the surface. This is due to self-organizing of the stable nanostructure during the coating process [277].

### 5.3. Monolithic Bulk Materials

### 5.3.1. Strength and Ductility of Nanocrystalline Metals

The grain size refinement of metallic materials has been a subject of intensive research over the recent years, since in principle grain size refinement is a strengthening method that does not increase the material cost. Many of the studies on the mechanical behavior of the nanocrystalline metals have provided data that are largely a reflection of the influence of sample imperfections. This is implied by the

large scatter of individual experiments, but also as regards data trends observed between different studies. Therefore, it has been very difficult to make decisive conclusions on the strength increase or softening at smallest grain sizes of nanocrystalline metals. However, tensile testing using a microtensile tester [278] has shown that substantial increase in strength for nanocrystalline Cu can be achieved. Samples with 26-nm nominal grain size have over 850 MPa in tensile fracture stress, and for nanocrystalline nickel with the grain size of 21 nm, strength values over 2.1 GPa in compression were reported, this being within an order of magnitude of theoretical strength for nickel [279].

Because the fabrication techniques have greatly limited the availability of reliable tensile test data on nanostructural materials, the most convincing results so far have been obtained by hardness tests. Siegel [280] has collected data on various materials which show convincingly the hardening independently of the method of synthesis. The pure nanocrystalline materials can be 2–7 times harder than their coarse-grained counterparts [280, 286]. In Figure 7, dependence of hardness on grain size/layer thickness for different classes of nanocrystalline materials is given.

The behavior at the smallest grain sizes (<20 nm) varies from hardening to softening. A negative Hall–Petch relationship (softening) is found, for example, in copper and palladium [15].

Nanostructured materials with a grain size of 20–40 nm fabricated by gas condensation or ball-milling and subsequent consolidation have been found to exhibit low

**Figure 7.** Dependence of hardness on grain size/layer thickness for different classes of nanocrystalline materials. Examples are given for metallic (Cu [17, 220, 282, 287] and Pb [220, 282]) and layered nanocomposites (TiN/NbN [288], VNbN/VN [289], Fe/Pt [290–292], Cu/Cr [293], Cu/Nb [293], Cu/Ni [293, 294], Ag/Cr [295], Fe/Cr [291, 292], Mo/NbN [296], and W/NbN [296]).

tensile ductility [2, 279]. This is manifested by a strong tendency of these materials to strain localization in a tensile test. In some cases annealing after consolidation and/or polishing has been found to increase the strength and ductility of nanomaterials in tension [6]. In the latter study Young's modulus of fully dense nanomaterials was comparable to that of the coarse-grained counterpart, but decreased two- to sixfold when pores and flaws were present.

It is not yet well understood whether the brittle behavior is an intrinsic feature of nanocrystalline materials, or whether it is caused by processing difficulties such as imperfect consolidation of nanocrystalline powders. Most of the experimental results so far indicate little ductility in tension for grain sizes below 25 nm [297, 298] for materials which are ductile when coarse-grained. A summary of the reported results on tensile ductility is given in Figure 8.

While in many cases the low ductility may be attributed to the flaws and inhomogeneities of the microstructure dependent on the method of preparation, it seems that the deformation mechanisms related to the lack of strain hardening are also important factors contributing to mechanical instability and localized deformation already at low strains. In this respect the deformation and fracture behavior of nanocrystalline materials resemble that of amorphous metals.

In compression the behavior may be different. Lu et al. [307] have reported that nanocrystalline copper having a mean grain size of 20 nm may be cold-rolled up to 5100% strain without cracking, and further cold-rolling was still possible. Such extreme extensibility has not been observed in conventional copper, which typically cracks already after extensions of about 800%.

Metallic nanostructured materials with the highest thermal stability are so far based on aluminum [308, 309]. Considerable improvements in strength have been obtained,
for example, with a nanostructured version of spray-atomized 5083 Al alloy as compared to the commercial grade [310]. The alloy having a grain size of about 30 nm was found to have a 30% increase in yield strength and ultimate strength over the strongest commercially available form of 5083 Al with no decrease in tensile ductility.

Also wear properties of nanocrystalline metals are expected to be better than those of their coarse-grained counterparts because of the generally higher hardness of nanocrystalline metals. The few studies on wear of metallic nanocrystalline materials seem to confirm this. Takagi and co-workers [311, 312] have studied the wear properties of nanocrystalline aluminum alloys and their composites and noticed improvement of sliding wear properties both at room temperature and elevated temperature (473 K). Thermally sprayed nanostructured Co-Cr coatings have also been developed in order to diminish wear in prosthesis [313].

### 5.3.2. Creep and Superplasticity of Nanocrystalline Metals

Pure metals usually do not exhibit superplastic behavior due to the low stability of their microstructure to thermally induced changes at the elevated temperatures needed for the superplasticity to occur. This applies also to nanocrystalline metals, which are often unstable even at room temperature. Therefore, superplastic behavior is usually encountered in alloys, which are stable enough at the relevant temperatures [75, 76, 314, 315].

A summary of the studies on creep and superplasticity of nanocrystalline metallic and intermetallic materials is presented in Table 2. Neither of the two models, that is, Nabarro–Herring creep and Coble creep, described earlier can be used to fully account for plastic flow under the reported circumstances. In general, it seems that the strain rate sensitivity is increased as the grain size is decreased independent of the particular deformation mechanisms (range of *n*). It is clear that at low temperatures the Coble creep does not account for the creep behavior. Also, it is typical that the activation energy for deformation is higher than than of the grain boundary diffusivity. It may also be concluded that the creep properties of nanocrystalline materials are very sensitive to their microstructure. Therefore two nanocrystalline materials with same nominal composition and structure may exhibit different deformation behavior.

Based on the experimental findings, it is clear that tensile superplasticity occurs at higher strain rates and lower temperatures in nanocrystalline materials than in their coarse-grained counterparts. However, it is not possible to obtain low-temperature superplasticity in pure metals in which grain sizes are less than 100 nm; the superplastic flow at low temperatures is neutralized by the onset of significant grain growth at the same temperature range [5].

### 5.3.3. Single-Phase Ceramics

Ceramics are inherently brittle materials. In most structural ceramics, deformation rarely involves dislocation movement at low temperatures with exception of severe multiaxial compressive stress-state situations. In Figure 9 the grain

**Figure 8.** Tensile elongation to failure vs. grain size for several metals and alloys [220, 299–306].

size dependence of dislocation processes and grain boundary sliding has been schematically compared in cases of ceramics and other materials reflecting differences in interatomic bonding. From the point of view of mechanical

**Figure 9.** Grain size dependence of dislocation processes and grain boundary sliding compared in cases of ceramics and other materials. The interatomic bonding determines the location of a particular material in the framework. Temperature is a factor determining the activity of the processes and influences also the relative importance of the two processes. This is not shown in the figure.

properties, the scientific interest in nanophase ceramics is predominantly motivated by the prospects for superplastic deformation. Furthermore, structural reliability in single-phase ceramics is associated with microstructural uniformity, which is usually better in the case of finer grain sizes. The promise of room-temperature ductility in nominally brittle single-phase ceramics with nanometer-range grain size has not been realized. Recent tests, where macroscopic, dense nanocrystalline specimens have been used, have not shown enhanced ductility at room temperature [3].

Superplasticity is phenomenologically defined as the ability of a material to exhibit exceptionally large tensile elongation during loading. The resulting deformation is often in hundreds of percent also for ceramics. This is highly significant, since ceramics are usually formed into shapes before firing and in case of tight dimensional requirements they have to be machined after the firing. There are two basic types of superplasticity, which are termed transformation and structural superplasticity. Only structural superplasticity is associated to nanostructure of materials and is discussed here. General requirements for structural superplasticity are small, stable grain size and relatively high homologous processing temperature. An additional requirement, relevant for superplastic behavior in ceramic materials, is lack of intergranular brittleness. The superplastic flow derives from diffusion-controlled processes at grain boundaries, which has been discussed earlier.

The first clear demonstration of superplastic behavior in single-phase ceramic materials with sub-micrometer grain size occurred in 1986 when Wakai et al. reported tensile elongations of over 100% in an yttria-stabilized tetragonal zirconia [328]. There are earlier reports on enhanced plastic deformation capability of ceramics in compressive loading. However, this is not a best test for superplastic flow, since it ignores to a large extent the effect of possible intergranular brittleness. As a grain boundary effect, also the presence of second phase at grain boundaries has to be considered not only in case of ceramic composites, but in the case of other ceramics as well. Introduction of glassy phases at grain boundaries has been shown to produce superplastic behavior. It is common to refer to ceramics as single-phase materials even though, due to very low solubility limits, they may contain thin glassy layers at their grain boundaries.

A majority of investigations on structural superplasticity in ceramics have concentrated on ytria-stabilized tetragonal zirconia. Other single-phase ceramics which have been found to be superplastic include alumina and hydroxyapatite. Polyphase ceramics have not been discussed here. The grain size of ceramics with superplasticity is less than 1 $\mu$m, which is smaller than in case of metals. Typical processing temperatures are at or above 0.5 $T_m$, where $T_m$ means absolute melting temperature. Applicable strain rates for superplastic deformation in ceramics are close to $10^{-4}$ sec$^{-1}$, which is an order of magnitude slower than for metals. Unlike in metals, tensile ductilities do not correlate well with strain-rate sensitivity in superplastic ceramics, because in practice, grain boundary decohesion always limits tensile ductility. A major concern in superplastic processing of ceramics is suppression of dynamic grain growth, which has led to utilization of additives that segregate on grain boundaries. Several reviews that summarize data on superplasticity of ceramics in case of sub-micrometer grain sizes have been published [329–334].

An examination of phenomenological relationship between factors affecting superplasticity indicates that the slow strain rates in ceramic superplasticity could be accelerated by orders of magnitude if the grain size were reduced sufficiently to true nanostructure range ($< 100$ nm). Equivalently, finer grain sizes lead to the same strain rates at lower temperatures. Both effects have been tentatively demonstrated in nanocrystalline ceramics [3]. However, this has been achieved nearly without exception by using compressive loading and small specimen sizes due to sample fabrication difficulties. To author's knowledge, only tensile test results have been reported for nanocrystalline 5 mol % ytria-stabilized zirconia with 75 nm grain size [335]. It was demonstrated that 70% engineering strain could be obtained at 1403 K processing temperature (0.46 $T_m$).

## 5.4. Nanocrystalline Composites

Nanocomposite materials can be defined as composites of more than one Gibbsian solid phase where at least one of the phases has dimensions in the nanometer range [336]. The solid phases may be in amorphous, semicrystalline, or crystalline state. The nanocomposite materials may be divided into four categories: intragranular, intergranular, hybrid, and nano/nano composites [337], where

the nanophase material locates at the interface, within the matrix (large) crystals, or in both of them, respectively. The nano/nano composite consists of two phases with grain sizes not more than 100 nm (Fig. 10).

### 5.4.1. Metal Matrix Nanocomposites

Nanocomposites incorporating mainly nanostructured ceramic particles or fibers in a metallic nanocrystalline matrix have been studied quite intensively over the last years. Among them are the nanostructured WC-Co composites that are being developed for tool applications. Chemical methods have been developed for producing premixed powders at the nanoscale level [338, 339]. To inhibit the grain growth of WC, sintering is carried out in a liquid state and small amount of grain growth inhibitors, such as VC, are added. According to Jia et al. [340], the hardness of nanocrystalline WC-Co is considerably higher than that of conventional WC-Co composite. This is not only a result of nanocrystalline structure but also due to the simultaneous alloy strengthening of the binder phase itself. Corresponding developments have been carried out in coating technologies by thermal spray both in plasma and HVOF spraying [335, 341].

Other metal-ceramic nanocomposite systems have also been studied including duplex Ni-TaC [342], Cu-Al$_2$O$_3$ [343], and NiCr-Cr$_3$C$_2$, [344, 345]. The Ni-TaC system is interesting because hardness values (12 GPa) comparable to WC-Co cermets are obtained with a much lower carbide content than in the latter material. The strength of Cu-0.5% Al$_2$O$_3$ material is not much different from that of pure nanocrystalline copper, but the apparent activation energy for creep is significantly higher than in the pure nanocrystalline copper. NiCr-Cr$_3$C$_2$ system has been developed primarily for coating applications where an increase of about 20% has been obtained as compared to commercial coatings. A recent review on the latest developments is in [345].

It has been proposed that incorporation of nanotubes instead of carbon fibers as reinforcing elements into plastic, ceramic, and metallic matrixes can potentially provide structural materials with dramatically improved modulus and strength [345]. Preliminary investigations on the synthesis of carbon-nanotube-metal-matrix composites with different

**Figure 10.** The classification of nanocomposites: (a) inter-type, (b) intra-type, (c) hybrid-type, (d) nano/nano-type [337].

techniques and different systems have been carried out by Laurent et al. [346], Kuzumaki et al. [347], Wu et al. [348], and Chen et al. [349]. However, only limited data are available at the moment on the mechanical properties of these novel composites, those showing so far only marginal improvements in the mechanical properties of the composites [345].

### 5.4.2. Ceramic Matrix Nanocomposites

According to Sternitzke, the different classes of ceramic nanocomposites are structural ceramics (e.g., $Al_2O_3$/SiC, $Si_3N_4$/SiC, MgO/SiC, Mullite/SiC) [350–352], low-temperature sol–gel derived, [353–357], glass ceramics, glass/metal (photosensitive glasses) [358–360], nanocomposite films (e.g., lead zinconate titanate (PZT)/nickel) [361], entrapment-type (e.g., zeolite/metallic or zeolite/organic complexes) [362], layered ceramics (e.g., pillared clays) [363], metal/ceramics (e.g., Fe-Cr/$Al_2O_3$, Ni/$Al_2O_3$) [364–366], and organoceramic (e.g., polymeric matrix/$PbTiO_3$) [367, 368].

In order to enhance the mechanical strength of the brittle ceramic materials, there are two approaches: increase fracture toughness by reduction of the critical flaw size or design ceramics with high flaw-tolerance [369]. The former approach includes development of the processing technologies to reduce the processing flaws [370]. In the latter case fracture toughness can be reached by introducing energy-dissipating components such as whiskers and platelets of particles into the ceramic microstructure [371–373]. These reinforcements deflect the crack or serve as bridging elements which hinder the further opening of the crack. One may include metallic particles which absorb energy by plastic deformation [253, 374]. A second phase which undergoes a phase transformation with a volume expansion initiated by the stress field of a propagating crack, has also been investigated [375]. The effect of these mechanisms responsible of the toughening of the nanocomposite ceramics has been reviewed by Sternitzke [336], Reimanis [376], and Bhaduri and Bhaduri [377]. Common observations are that the mechanical properties are very sensitive to the processing method of the nanocomposite and it is not always clear how the microstructure dictates the properties. However, there is a very large scatter of the reported strength values by numerous research groups [376]. At low temperature the $Al_2O_3$/SiC intragranular nanocomposites have been reported to have strength values up to 1000 MPa [378]. The fracture behavior changed to a transcrystalline mode. This resulted in a reduced wear rate and improved resistance against surface damage, due to grain boundary strengthening caused by SiC nanoinclusions [379, 380]. The effect on the toughness is marginal. On the other hand, $Al_2O_3$/$ZrO_2$ nano/nano composite has a low hardness but a high toughness (8–10 $K_{IC}$(MPa m$^{1/2}$) [381].

At high temperatures the benefits of the nanocomposites are more pronounced. The $Si_3N_4$/SiC nanocomposites show improved strength compared to $Si_3N_4$ in high temperatures [349, 382, 383]. $Si_3N_4$/30 vol. % SiC maintains the strength of about 1080 MPa up to 1400 °C temperature whereas the strength of $Si_3N_4$ is greatly reduced. Niihara and co-workers [384, 385] reported improved tensile creep at 1400 °C and

200 MPa stress in tension; monolithic $Si_3N_4$ failed after 0.4 h at 0.3% strain while the composite did not fail for 1000 h and at 1.5% strain. The nanophase SiC improved also the creep resistance of these materials with up to a threefold reduction in the steady-state creep rate [386, 387]. This is attributed to the SiC nanoparticles bridging the interface and reducing grain boundary sliding. In summary, the nanocomposite ceramics show improved fracture toughness and strength as compared to their single-phase counterparts, and the strength of the nanocomposites is equivalent to or better than the composites reinforced with a coarse second phase [375, 388].

Carbon nanotube composites offer a future potential to combine ceramic materials with the exceptional properties of CNT such as mechanical strength and electronic properties. CNT-metal-ceramic (CNT-Co-MgO and CNT-FeCo-$MgAl_2O_4$) composites have been developed by Peigney et al. [392].

Composites with about 2–6 wt. % of CNT had electrical conductivity in the range of 0.2 to 4.0 S cm$^{-1}$. Pull-out of the CNT was observed near the fracture surface but no macroscopic mechanical reinforcement was demonstrated. A 10% improvement in strength and fracture toughness of nano-SiC composite with 10 wt. % of CNT has been reported [390, 391]. The CNT composites have been reviewed by Thostenson et al. [392].

A summary of the mechanical properties of nanocrystalline materials is presented in Table 3.

## 6. APPLICATION OF NANOMATERIALS RELEVANT TO MECHANICAL PROPERTIES

Most of the applications of nanocrystalline materials so far have been introduced due to other than mechanical properties. In many applications, however, mechanical properties are of great importance even though the nanomaterial may not be directly applied for structural or mechanical purposes. Such applications may be found, for example, within electronics and sensor technology, where the nanomaterials are used because of their electrical, optical, or other functional properties. These materials have to withstand also stresses built up during processing or in use.

However, applications which are primarily induced because of the novel mechanical properties of nanocrystalline materials exist, and many more are under intensive study. Main hindrances for the development of structural applications of nanostructural materials lay in the difficulties in processing of the materials; either the processing technologies are not developed well enough yet or they are too expensive to justify the use of nanostructural materials. In the following, some examples of the existing and potential applications are reviewed.

### 6.1. Coating Applications

### 6.1.1. Applications Requiring Wear Resistance and Controlled Friction Properties

The development of materials to be used in more demanding conditions is typically solved by development of coatings. On the other hand, layered nanomaterial structures are

the means to enhance and tailor the coating properties to be used in, for example, such applications as gas turbines (thermal barrier coatings), bearings [411], tooling [412–416], optical [417], and magnetic recording media [207].

Thin-film growing methods often provide the means to grow layered coatings. This allows to design the properties of the coating in order to tailor the material surface. The idea is to introduce gradient structures, avoid sharp interfaces of different materials, and prevent the local stresses needed for crack initiation and growth. In macroscopic applications, tool coatings subjected to high stresses are an example of coatings. On the other hand, only very thin layers may be used as protective coatings for magnetic recording discs. In the following, some examples of multilayer films related to applications are described.

Multilayer Ti-TiN protective tool coating forms a superlattice, where the individual Ti and TiN layers are textured [002] and [111], respectively. The wear resistance of the multilayer film was best when the period thickness was 2.5 nm and when the Ti/TiN interface was pure [243]. Multilayered films have higher elasticity, hardness, and tribological

properties as compared to the constituent layer materials alone [245].

Complicated nanolayered films with gradient structure and nanocomposites including self-lubricating bearing or tooling materials such as $WS_2$ and diamond–like carbon (DLC) have been prepared with a hybrid technology combining laser ablation and magnetron sputtering [418, 419]. A self-adapting functional tribological layer formation was obtained: when sliding in humid air DLC forms a graphite-like layer and in vacuum a hexagonal $WS_2$ tribolayer is formed, both providing a COF below 0.1. Multilayered coatings have been developed also towards gradient structures in order to tailor the surface properties [420–424]. This enhances the adhesion of the protective coating used for wear protection in general.

Gell [425] has reviewed the potential use of nanocrystalline materials in gas turbine industry. In order to increase the operating temperature for better efficiency of gas turbines, the development of thermal barrier coatings is the single most important factor. Nanocrystalline coatings offer better thermal shock resistance, lower thermal conductivity, and better wear resistance than their conventional counterparts and therefore are especially interesting for use in this application. Consequently, strong effort has been made to develop nanocrystalline powders and their plasma spraying [426–436]. The developed alumina-titania coatings show superior wear resistance, adhesion, toughness, and spallation resistance and have been qualified by the U.S. Navy for use in a number of shipboard and submarine applications.

## 6.2. Structural Applications

### 6.2.1. Applications of Nanocrystalline Superplasticity

The increased rate of forming or the lower temperatures related to the superplastic deformation of nanocrystalline materials would make superplasticity more industrially accessible, extending its possible limits of use. With nanocrystalline metals, superplastic deformation may be possible to extend to such rapid and large-scale forming processes as forging. It has been demonstrated, for example, that it is possible to forge an 8- cm-long connecting rod from an extruded blank of an Al-alloy having a grain size of 80 nm in less than one second [77]. Forming experiments have also been carried out with nanocrystalline ceramics. It has been demonstrated that it is possible exactly to replicate die surfaces [90] and form cylinders of, for example, $TiO_2$ [89] and 3Y-TZP [85, 86].

In conclusion, experiences with forming of superplastic materials suggest that they may potentially be used especially in near-net shape processes. However, it has been claimed that the application of nanocrystalline materials would be limited to niche applications because other concurrent developments in control of superplasticity will increase the competitiveness of traditional superplastic materials [3]. It is speculated that nanocrystalline superplasticity will have an advantage over traditional superplastic materials when material chemistry may not be changed because of the nature of the application [e.g., in electronic applications] or when high strength after forming is demanded.

Another area of applications to superplastic materials is that of diffusion bonding. It has been shown that the use of a superplastic intermediate layer in diffusion bonding of non-superplastic stainless steel dramatically improves the properties of the joint especially if the mating surfaces are rough [437]. Nanocrystalline intermediate layers may thus offer possibility to reduce the processing time or temperature.

It has also been shown that nanocrystalline ceramics can be used for direct bonding of ceramic materials to each other. Superplasticity allows the mating surfaces to adapt better to surface asperities. The superplastic ceramic may also be in the form of an interlayer as in the case of metals. This interlayer may also be used to accommodate stresses in thermally mismatched structures as in metal-ceram joints and metal-ceram coating systems. When the compound is heated, a superplastic interlayer or coating could accommodate larger thermal mismatch strains than conventional interlayers or coatings without cracking by the processes of superplastic flow and stress relaxation [438].

Superplasticity may also be utilized in the processing of nanocrystalline ceramics themselves. Nanocrystalline ceramics are difficult to produce by pressureless sintering routes typically used for conventional ceramics, but they may be produced by sinter-forging, which uses the superplasticity of the material itself by closing pores with the aid of plastic flow [439]. It has also been demonstrated that nanocrystalline-based fiber-reinforced composites are denser, and because of significantly lower consolidation temperature, there is no damage to the fiber and no reaction occurs between the fiber and the matrix [440] as compared to conventional high-temperature processing. Also combustion synthesis can be realized at a lower temperature as shown by Uenishi et al. [441] for processing of $Al_3Ti$ from mechanically alloyed powders.

### 6.2.2. Application of Nanostructural Bulk Materials for Improved Strength and Ductility

Higher strength of nanocrystalline materials may be utilized in several potential applications, when processing of the materials is adequately developed. Gell [425] has reviewed the potential use of nanocrystalline materials in gas turbine industry. The highest pay-off applications are related to the improved engine performance which, in addition to higher operating temperature mentioned above, can be realized by higher motor speed. This requires the development of main shaft bearing materials and has led to the development of nanocrystalline M50 steel [442–444].

Also the need for tools with improved hardness/toughness properties has prompted interest in the development of nanostructured tool steels and improved properties have been demonstrated [445]. Similarly, development of WC-Co nanocomposites has been driven by the aim of obtaining cutting tools and hard metal coatings with superior properties as compared to their traditional counterparts. These materials are already starting to have commercial impact and are used in the manufacture of machine tools, drill bits, and wear parts [446]. Tools made of cemented carbide nanocomposites have enhanced hardness, fracture toughness, and wear resistance compared to their conventional counterparts.

Currently, nanocrystalline titanium is considered to be a potential material for medical implants. In order to obtain adequate strength, titanium alloys (mainly Ti-6Al-4V) are used, for example, for hip prostheses. Development of nanocrystalline pure titanium for such an application would allow the alloying content to be decreased for increased biocompatibility [447].

High-strength titanium alloys are also a subject of increasing interest for other applications where high strength is needed. For example, Zhernakov et al. [448] have demonstrated that both the static and the fatigue strength of commercially pure titanium fasteners and threaded articles can be substantially increased by ECA processing, producing a nanocrystalline grain structure.

An interesting technology for near-net shape forming of ceramic nanocrystalline materials is that of plasma spraying on a mandrel [449], which is afterwards removed. Both the mandrel and the plasma gun are computer controlled, allowing fabrication of complex shapes from nanocrystalline aluminum oxide. The fabrication of tapered alumina rings for space-based lightweight X-ray mirror shells with a smooth inside finish was demonstrated.

Nanocrystalline ceramics have also been considered for orthopaedic and dental implants of the future. Nanomaterials with improved mechanical properties could then replace some of the conventional biomaterials and could be tailored to meet clinical requirements associated with anatomical differences or patient age [450].

Incorporation of nanotubes instead of carbon fibers as reinforcing elements into plastic, ceramic, and metallic matrixes can potentially provide structural materials with dramatically improved modulus and strength. At the same time other functions such as electromagnetic shielding may be realized [451]. The focus of much of the research in nanotube-based composites has been on polymer-matrix materials, but the unique properties of carbon nanotubes can also be exploited in ceramic- or metal-matrix composites. So far the realized improvements in ceramic- and metal-matrix composites have been marginal and real applications are still awaiting. On the other hand, many improvements have taken place in use of nanoparticles as filler materials in polymers. These include fillers in dental polymers to improve their performance, for example, wear resistance or stiffness as in polymer-layered silicate nanocomposites. The detailed developments in this area are beyond the scope of the present review. Those interested can find more information on dental fillers, for example, in [452] and on polymer-layered silicate nanocomposites in [453].

Applications of nanocrystalline metallic materials have been limited because of low ductility in tension [454–456]. However, results of Lu et al. [307] on cold-rolling of nanocrystalline copper have opened up interesting views for developing novel processing for some metallic materials utilizing the nanocrystalline structure. It seems that the traditional deformation-annealing technique routinely used may be much simplified by using nanocrystalline metals as starting materials. With proper post-heat treatments, the microstructure may be easily controlled so that desired properties in the final product can be achieved.

## 6.3. Special Applications

The conductivity of CNT-ceramic composites has been applied for electric components and components in fuel injection applications to avoid risks related to static electricity [343, 387].

Low-Z nanocomposite ceramic materials (SiC, C-SiC, Si-SiC) have been shown to have high erosion resistance in high radiation and heat load conditions. This implies the application potential as a plasma facing material in fusion reactors [457, 458].

Carbon nanotube scanning probe tips for atomic probe microscopes are commercially available. Resolution of these microscopes depends on the sharpness of their probe tips, which deteriorate with operating time. The mechanical robustness of nanotubes dramatically increases probe life in comparison to conventional probe tips [459].

## 7. SUMMARY

In recent years a wide range of nanostructured materials has been introduced. These novel materials are produced in various forms such as nanopowders, nanostructured particulates, fibers, tubes, thin films as well as bulk by using a number of processing routes. Already the early theoretical predictions have shown that nanomaterials may have interesting mechanical properties in addition to their interesting functional properties. The bulk form of these materials includes electrodeposited sheets, equal channel angular pressed rods, ball-milled and consolidated pellets, composite films produced by a variety of deposition techniques, etc. Among the most interesting mechanical properties are, for example, their strength, hardness, elastic properties, toughness, and superplasticity.

In summary, it can be concluded that the elasticity of nanocrystalline materials is roughly the same as that of conventional materials unless the grain size is very small (<5 nm). In those cases the modeling results indicate that the elasticity is increased. The hardness and yield stress are steadily increased as the grain size is decreased until the grain size is below 20 nm. At smaller grain sizes the behavior varies dependent on the material system. For example, in pure Cu and Pd, softening is noticed. Some evidence exists that this is caused by the formation of collective grain boundary glide planes. High ductility predicted for the nanocrystalline ceramics and intermetallics at low temperatures has not been confirmed and the tensile ductility of metals has been found to decrease with decreasing grain size. Superplasticity has been observed at lower temperatures and higher strain rates in some nanocrystalline materials as compared to their coarse-grained counterparts. Some mechanical property related applications already exist while others are being developed. Due to the difficulties in producing bulk nanocrystalline materials, it is expected that nanocrystalline coatings will be first more widely applied.

## GLOSSARY

**Finite element method (FEM)** Method in which the domain to be analyzed is divided into elements, and then the displacement field within each element is interpolated

in terms of displacements at given points (nodes) around the element boundary.

**Molecular dynamics simulation (MD simulation)** Computer simulation of the molecular structure and motions of a system in response to external conditions.

**Nanoindentation** The method of testing the mechanical properties in near-surface region. The registration of load exerted on the diamond tip penetrating the surface and indentation depth make it possible to conclude on elastic and plastic properties of surface region or thin film.

**Nanotubes** Large macromolecules similar to a sheet of graphite rolled into a cylinder and capped with half fullerene at both ends.

**Neural networks** Mathematical models inspired by the neural circuit network of the human brain.

**Physical vapor deposition (PVD)** Thin-film vacuum coating method where the properties of the growing film are partly governed by the kinetic energy of the vapor species.

**Plasma assisted vapor deposition (PACVD)** Thin-film growing method, where the glow discharge plasma is used to enhance the growth of the film.

**Superlattice** Layered structure, which is composed of ultrathin layers of different materials providing new electronic and mechanical properties.

**Superplasticity** Ability of a material to exhibit exceptionally large tensile elongation during loading.

**Tribology** The science of rubbing surfaces, study of friction, lubrication, and wear.

# MEMS-Based Nanotechnology

## H. V. Jansen, N. R. Tas, J. W. Berenschot

*University of Twente, Enschede, The Netherlands*

## CONTENTS

## 1. MEMS-BASED NANOTECHNOLOGY

"Imagine working machines so small that it is imperceptible to the human eye and with gears no bigger than a dust particle. Visualize fluidic channels having a diameter of less than a thousand of atoms where most living cells cannot enter. Think about these systems being batch fabricated tens of thousands at a time, at a cost of only a few cents each. Fancy a realm where the world of design is turned upside down, and the seemingly impossible suddenly becomes easy; a place where gravity and inertia are no longer important, but the effects of atomic forces and surface science dominate. You are now in the microdomain, a world occupied by an explosive new technology known as microtechnology [6]."

### 1.1. Integrated Circuit Technology

The field of microtechnology is a logical follow-up to microelectronics. The advent of solid-state microelectronics dates from the invention of the bipolar transistor effect by Bardeen, Brattain, and Shockley in Bell Laboratories in 1947 (Fig. 1). The technology progressed during the early 1950s, using germanium as the semiconductor material. However, germanium proved unsuitable in certain applications and silicon became a practical substitute. Nowadays, silicon has almost fully supplanted germanium as a material for solid-state device fabrication.

In time, the size of the silicon transistor decreased and integrated circuits (ICs) came onto the market with resolution in the nanometer range. The silicon IC is surely one of the wonders of our age and has changed virtually every aspect of our lives. The hallmark of the IC technology (ICT) has been the ability to fabricate tens of millions of individual components on a silicon chip with an area of a few square cm using lithographic techniques (Fig. 2). As time has progressed, chip complexity increased at an exponential rate, primarily because of the constant shrinking of device geometries, improved manufacturing practice, basic discoveries, and clever inventions enabling specific functions to be implemented in new ways. This rapid advance in the number of transistors per chip and growth in the functionality of microelectronic circuits is truly phenomenal and has lead to ICs with continuously increasing capability and performance and has enabled information age.

In ICT, pattern transfer from partially transparent masks onto a substrate is accomplished almost exclusively via photolithography. It involves three sequential steps as illustrated in Figure 3:

- application of photoresist, which is a photosensitive emulsion layer, on top of a substrate;
- optical ultraviolet exposure to print the image from the mask onto the resist;
- immersion in an aqueous developer solution to dissolve the exposed resist and render visible the latent image.

### 1.2. Microsystem Technology

Due to the good mechanical characteristics of silicon, ICT appeared to be useful for the fabrication of a variety of structures. This new field became known as micromechanics and some typical examples of this field are found in Figure 4a–c. Almost at the same time other disciplines emerged like micro-optics (Fig. 4d) and microchemics (Fig. 4e, f). The integration of all these groups of microspecializations is nowadays known as micro system technology (MST). MST has become a fundamental tool for the fabrication of microtechnological devices and, in general, miniature sensors and actuators. Micromachining techniques include first the basic processing steps of ICT, namely, film
**Figure 1.** First transistor invented in the Bell laboratories.

formation, lithography, and film etching. In addition, they incorporate special micromachining processes which allow for the sculpturing of three-dimensional (3D) microstructures. Silicon micromachining can be subdivided into two main categories: bulk and surface micromachining. Bulk micromaching refers to the realization of structures out of the single-crystal silicon wafer. Devices fabricated with surface micromachining techniques are located on the wafer surface and consist most often of a stack of thin films between 100 nm and 10 $\mu$m thick. A typical surface micromachining process sequence for the cessation of a simple freestanding aluminum bridge is illustrated in Figure 5.

Within the field of MST, a group of systems has been paid special attention in the past decades: microelectromechanical systems (MEMS). This is due to its integratability with respect to ICT. The name "MEMS" should have been used for electromechanical transducers only, but especially in the United States the name MEMS became used in a much broader sense. Nowadays, it includes non-electromechanical devices also, such as optical switches or lab-on-chips. Nevertheless, in Europe most people still give these products the more logical name of microsystems, and the technology to create such devices is then called microsystem technology. So, in fact, a MEMS is just a specific MST product. In Japan, commonly, MST is called micromachining (MM). This might be caused by their opinion that the MEMS/MST products are created by fine mechanical techniques, if only a little smaller. This philosophy has resulted in a tendency to downscale fine mechanical equipment such as microdrills, spark erosion, and lasers in Japan, as opposed to the fine-tuning of IC equipment in the United States and Europe. But whatever people call these microtechniques, MM, MEMS, or MST, the results are—not rarely—astonishing and will influence the future of mankind one way or another.

**Figure 2.** Integrated circuits on a wafer.

1. Spin-coat a layer of photoresist.

2. Illuminate the resist through a mask.

3. Develop the resist.
**Figure 3.** Basic lithographic process.

Generally, the resulting structures from the MST process are relatively flat, and the urge for spatial structures for a stiffer construction stimulated the activities with respect to microstructuring by means of different methods. In addition, the brittleness of silicon and the need for materials with specific properties (e.g., optical properties) stimulated the microstructuring of different materials as well. The development of the so-called LIGA technology has given a stimulus with respect to high aspect ratio structuring of different materials. The materials range from metals such as

**Figure 4.** Typical products of microsystem technology. (a) Microsieve. (b) Microgripper. (c) Three-dimensional accelerometer. (d) Optical tip. (e) Micropipette. (f) Fluid dosing system.
**Figure 5.** Basic micromachining process.

nickel and gold and alloys such as nickel iron up to polymers such as poly-oxy-methylene, poly-methyl-methacrylate, polysterene, polycarbonate, and others. However, the use of synchrotron radiation and the resulting complicated fabrication of the mask make LIGA technology economically less attractive and more time consuming. Therefore, a variety of alternatives has been developed, such as ultraviolet (UV) "SU-8" lithography, laser ablation, microdrilling, ion milling, and spark erosion. Also, the innovations in dry etching enabled the fabrication of micromolds in silicon. This micromold can subsequently be electroplated resulting in a metal micromold.

So the field of MST explores the science of miniaturization. A question asking for a more specific definition is certain to generate a broad collection of replies, with few common characteristics other than "miniature." But such apparent divergence in the responses merely reflects the diversity of application this technology enables, rather than a lack of harmony. MST is simultaneously a toolbox, a physical product, and a methodology all in one:

- It is a portfolio of techniques and processes to design and create miniature systems.
- It is a physical product often specialized and unique to a final application. One can seldom buy a generic MST product at the neighborhood electronics store.
- MST is a way of making things. These "things" merge the functions of sensing and actuation with computation and communication to locally control physical parameters at the microscale, yet cause effects at much grander scales.

Although a universal definition is lacking, MST products possess a number of distinctive features. They are miniature *embedded* systems involving one or many *micromachined*

components or structures. Miniaturization methods and materials include micromachining in or on top of single crystal silicon and other materials based on planar lithographic techniques (known from the semiconductor industry) as well as more traditional materials and nonlithographic miniaturization options (known from fine mechanical engineering). All these techniques are specifically enhanced or modified for creating small three-dimensional structures with dimensions ranging from subcentimeters to submicrometers, involving electronics, sensors, actuators, or other microcomponents, and microsystems. In this way, MST products *enable* higher level functions, although in and of themselves their utility may be limited. A micromachined pressure sensor in one's hand is useless, but under the hood it controls the fuel–air mixture of the car engine. They often *integrate* smaller functions into one package for greater utility, for example, merging an acceleration sensor with electronic circuits for self-diagnostics. They can also bring *cost benefits*, directly through low unit pricing or indirectly by cutting service and maintenance costs.

MST is a relatively new technology which exploits the existing microelectronics infrastructure to create complex machines on a chip with micrometer feature sizes. These machines can have many functions, including on-chip sensing, communication, and actuation. So the next step in the silicon revolution will be different, and more important than simply packing more transistors onto the silicon. It might be the incorporation of new types of functionality onto the chip; structures that will enable the chip to not only sense but to act and communicate as well. This enables the creation of "intelligent" microsystems which know where they are and what is going on around them. This revolution will be enabled by MST and everyday we are finding more applications. MST focuses on a variety of defense and commercial applications (Table 1), applications ranging from inertial sensors for large scale commercial applications to locking mechanisms for weapon systems. Recent studies have estimated the market for intelligent micromachine-based systems to be around 100 Billion Euro/year.

Although the vast majority of today's MST products are best categorized as components or subsystems, the emphasis in MST technology is on the "systems" aspect. True microsystems may still be a few years away, but their development and evolution rely on the success of today's components, especially as these components are integrated to perform functions ever increasing in complexity. Building microsystems is an evolutionary process. We spent the last 30 years learning how to build micromachined components. Only recently have we begun to learn about their seamless integration into subsystems, and ultimately into complete microsystems.

One notable example is the evolution of crash sensors for airbag safety systems. Early sensors were merely mechanical switches. They later evolved into micromechanical sensors that directly measured acceleration. The current generation of devices integrates electronic circuitry with a mechanical sensor to provide self-diagnostics and a digital output. It is anticipated that the next generation of devices will also incorporate the entire airbag deployment circuitry that decides whether to inflate the airbag. As the technology matures, the airbag crash sensor may be integrated one

**Table 1.** R&D fields and topics in microtechnology.

| Commercial applications | Military applications |
| --- | --- |
| Mass data storage systems | low-power, high-density mass data storage devices |
| Miniature biochemical analytical instruments | miniature fluidic systems for early detection of biochemical warfare |
| Cardiac management systems (e.g., pacemakers, catheters) | integrated fluidic systems for miniature propellant and combustion control |
| Drug delivery systems (e.g., insulin, analgesics) | inertial systems for munitions guidance and personal navigation |
| Neurological disorders (e.g., neurostimulation) | weapons safting, arming, and fuzzing |
| Engine and propulsion control | head- and night-display systems |
| Automotive safety, braking and suspension systems | active, conformable surfaces for distributed aerodynamic control aircraft |
| Telecommunication optical fiber components and switches | distributed unattended sensors for asset tracking, environmental and security surveillance |
| Invasive and noninvasive biomedical sensors | embedded sensors and actuators for condition-based maintenance |
| Distributed sensors for condition-based maintenance and monitoring structural health | integrated micro-opto-mechanical components for identify-friend-or-foe systems |
| Distributed control of aerodynamic and hydrodynamic systems | electromechanical signal processing for small and low-power wireless communication |
| Electromechanical signal processing | |

day with micromachined yaw-rate and other inertial sensors to form a complete microsystem responsible for passenger safety and vehicle stability. But examples of future microsystems are not limited to automotive applications. Efforts to develop micromachined components for the control of fluids are just beginning to bear fruit. These could lead one day to the integration of micropumps with microvalves and reservoirs to build new miniature drug delivery systems.

## 1.3. Nanosystem Technology

The area of nanotechnology is one step beyond microtechnology and can be defined as: *The area of science and technology where dimensions in the range of 100 nm play a critical role*. The term "nano" stands for "one billionth" and is inspired by the ancient Greek word "nanos," meaning dwarf. But nanotechnology is everything but a dwarf technology. It encompasses precision engineering as well as the lithographic technology known from the microtechnology, but also chemical and biochemical synthesis and biomedical multiplication techniques in areas as diverse as semiconductor electronics, scanning probe microscopy analysis, microsystems or MEMS, telecommunication, information technology, protein duplication, gene therapy, and drug delivery.

Nanotechnology has created of new world of terminology, a kind of "nanodictionary." For example, two fundamental different approaches in nanotechnology are graphically termed "top-down" and "bottom-up." Top-down refers to making miniature (or "nanoture") structures by lithographic printing and nonlithographic machining techniques, the basic techniques for manufacturing microelectronics and microsystems. Bottom-up, or molecular engineering (such as self-assembled films), applies to building organic or inorganic structures atom-by-atom, or molecule-by-molecule, and having its origin in the chemical and biochemical industry. A recent dramatic breakthrough that may herald the beginning of the bottom-up nanotechnology has been the discovery of spinning molecular structures. These may open the door to realizing the holy grail of power generation and

controllable motion at the molecular level, with huge applications for medicine and information technology. Clearly, a prime feature of nanotechnology is that it is the one area of research and development which is truly multidisciplinary. Research at the nanoscale is unified by the need to share knowledge, tools, and techniques, as well as information on the physics affecting atomic and molecular interactions in this new realm. Materials scientists, mechanical and electronic engineers, and medical researchers are now forming teams with biologists, physicists, chemists, and even mathematicians. For sure, nanotechnology is the technical underpinning of the microelectronic and microsystem technologies and they will likely all advance together.

Recently, the necessity to establish a fundamental plan for nanotechnology was discovered. For example, in mid 2001, the National Science and Technology Advisory Board of Korea established a national master plan for nanotechnology to invest 1.4 billion Euros within 10 years. The plan contains three axes of national activities: research and development, Education and Training, and Facility and Infrastructure. The R&D program generally focuses on four fields (Table 2): nanoprocesses, nanostructures, nanofunctions, and nanosystems. The Nanoprocesses include processing methods in the nanometer regime, such as chemical synthesis, evaporation, lithography, and plasma etching. Nanostructures consist of one-, two-, or three-dimensional nanostructures, such as multinanolayers, nanotubes, quantum dots, and photonic crystals. Nanofunctions place focus on the creation of properties and functionalities of nanocomponents and nanocompounds, such as highstrength or highendurance, electron/light emission, information storage, molecule detection, particle separation, nonlinear optics, and thermal isolation. Nanosystems contain nanosensors, nanoactuators, nanodevices, and nanosystems, such as single-electron devices, photonic waveguides, molecular systems, biochips, biomotors, solar/fuel cells, and NEMS (nanoelectromechanical systems).

Despite the importance of bottom-up molecular engineering, this chapter emphasizes the top-down strategies leaning on the MST. This means that also a related and very relevant subject likely to become "hot nanonews" in the near future

**Table 2.** R&D fields and topics in nanotechnology.

| Field | Area | Topic |
|---|---|---|
| Nanoprocesses | bottom-up | self-assembly, self-duplication, photosynthesis, chemical synthesis, bioanalogic process |
| | top-down | physical vapor deposition, chemical vapor deposition, forming, evaporation–condensation, thermal growing, arc, plasma, alloying, crushing, sol–gel, chemical deposition, printing, patterning, lithography, molding, deformation, etching, chemical mechanical polishing, electrochemical etching |
| Nanostructures | one dimension | quantum well, nanolayer, nanosurface, multinanolayers |
| | two dimensions | quantum line, nanotube, nanowire |
| | three dimensions | quantum dot, nanopowder, self-assembled, polymeric, bulk (porous), photonic crystal |
| | others | ER/MR fluids, compound chemicals |
| Nanofunctions | property | strength, hardness, toughness, friction/loss, elasticity, isolation, endurance |
| | functionality | single electron, electron/light emission, spectroscopy, nonlinear optics, spin storage, information storage, molecule recognition/detection, detection, membrane, transport, particle separation, electro-osmotic flow, process enhancement, combustion |
| Nanosystems | sensors | single-electron devices, molecule detector, bolometer |
| | actuators | spintronic, molecular engine, biomotor, NEMS |
| | transducers | NEMS, solar/fuel cells, LED, Laser |
| | devices | photonic waveguide, super capacitor, nano-CMOS, DNA chip, biochip, bioanalogical |

is missing in this chapter, that is, the combination of top-down with bottom-up strategies or a "nanolink." Moreover, the most prominent printing technology in the semiconductor manufacturing facilities—projection lithography—is treated only briefly. This is because progress in this area is self-sustained, as microelectronics will evolve in a natural way into nanoelectronics. For example, it is expected that sub-50 nm projection lithography using extreme UV (EUV) will produce the next generation nanoelectronics within 5 years and 15 nm EUV projection printing has already been demonstrated.

Nevertheless, enough issues remain to be found in this chapter and the drive to establish off-the-road printing techniques is found in the need for rapid prototyping techniques orders in magnitudes cheaper than the equipment needed for EUV projection printing (typically 10 million Euros investments per tool). Moreover, some very useful methods have been proposed recently to improve the resolution of state-of-the-art printing techniques, not depending on the specific underlying printing method. For example, a new add-on technology for existing lithography—the so-called sidewall patterning technology—is able to enhance the resolution of the existing lithography by a factor of two or more without the need for new expensive equipment. Using this technique, sub-50 nm printing on top of 2 $\mu$m projection lithography has been demonstrated.

In "MEMS-based nanotechnology," the tools available from the MST will be treated and classified. The goal is to familiarize the reader with most of the established MST tools, directions, materials, and jargon in order to facilitate a confident choice of fabrication method for a particular problem. By combining the tools in a subsequent order, systems can be realized with the sub-100 nm critical dimensions,

that is, the regime of nanosystem technology (NST). Basically, this chapter is a comprehensive incomplete overview of MST with respect to methods and materials. In particular, the lithography-based ICT is treated as it covers almost the entire MST. In subsequent sections, the following technology issues are discussed; wafer fabrication, film formation, lithography, film etching, and micromachining. Film formation means the deposition or growth of a (thin) film without the direct intent to create a pattern. Film etching is the process of the removal of film or substrate material again without the specific intent to directly form a pattern. Lithography on the other hand is meant to shape a film with a pattern formed by a printing mask or writing stylus. Micromachining is the set of design and fabrication tools that precisely machine and form miniature structures and elements at a scale well below the limits of our human perceptive faculties, the microscale.

Important to notice in a micromachining process flow is the repetitive emergence of these steps; this is schematically shown in Figure 6. Therefore, the arrangement of this section is determined by this schematic. Every section will end with "Conclusion and Nanoperspective" in which some closing remarks will be given with respect to the applicability of the given techniques in nanotechnology. For more details concerning the microfabrication technology, the reader is encouraged to read excellent "standard" works such as [1–7].

Sze, *Fundamentals of Microfabrication* by Marc Madou, *The MEMS Handbook* by Mohammed Gad-el-Hak, *Silicon Micromachining* by Miko Elwenspoek and Henri Jansen, *Nanotechnology* by A. ten Wolde, and *Handbook of Microlithography, Micromachining, and Microfabrication* by P. Rai-Choudhury.
**Figure 6.** (a) Arrangement of sections in this Chapter. (b) An abstract representation of a typical process flow found in micromachining.

## 2. WAFER FABRICATION

Before a device fabrication process is actually started we have to select an appropriate wafer. The wafer can be silicon when device integration with electronics is requested, gallium-arsenide for laser applications, quartz for radio-frequency (rf) devices, or borosilicate glass for electro-osmotic flow devices. Due to the small feature sizes, the lithographic process is quite sensitive to dust particles. Therefore, this section appropriately introduces the chapter by informing where to process wafers, discussing different types of wafers, and how to clean the wafer sufficiently.

### 2.1. Cleanroom

A MEMS fabrication facility requires a clean processing room, especially in the area used for lithography (Figs. 7 and 8). The need for such a cleanroom arises because dust particles in the air can settle on wafers and lithographic masks and can cause defects in the devices that result in

**Figure 7.** MESA+ outside the cleanroom.

failure. For example, a dust particle incorporated into a growing oxide film can result in device failure due to an unintended low breakdown voltage. The situation is even more critical in the lithographic area. When dust particles adhere to the surface of a photomask, they behave as opaque patterns on the mask, and these patterns will be transferred to the underlying layers along with the circuit patterns on the mask. Therefore, in a cleanroom, the total number of dust particles per unit volume must be tightly controlled along with temperature and humidity. Classifications of cleanrooms are established by the number of particles that are one micrometer or larger in a cubic foot of space per minute; Class $= [\wp] * (\wp)^2$, where $\wp$ represents the size of the particle in micrometers and $[\wp]$ is the number of those particles per cubic foot per minute. So a class 100 cleanroom is one which has a 1 $\mu$m diameter dust count of 100 particles/min ft$^3$. And in a class 1 cleanroom only one such a particle can be found per minute in the same volume, which is about a million times less than that of ordinary room air. Clearly, due to the ever-shrinking sizes of electronic and mechanical components, the cleanroom condition is getting more stringent too. For example, going from 500 toward 50 nm lithography, needs a 100 times cleaner environment to achieve the same defect density; a class 0.01

**Figure 8.** MESA+ inside the cleanroom.

is needed instead of class 1. But cleaner environments are much more difficult to construct and more expensive to maintain. Therefore, minienvironments such as cluster tools are becoming more and more mandatory to perpetrate state-of-the-art nanotechnology.

## 2.2. Wafer Selection

Almost every MEMS is processed on top of a wafer; therefore, a wafer must be chosen to start. In general this means specifying wafer material (e.g., silicon, germanium, quartz, Pyrex glass, or silicon carbide), conductivity type ($n$ or $p$), resistivity (doping level), crystal orientation ($\langle 100 \rangle$, $\langle 111 \rangle$, ...), wafer size, and a number of other parameters having to do with flatness, trace impurity levels, and so on. The major choices in the IC technology are the type, resistivity, and orientation of a silicon wafer. In MEMS this is mainly wafer material, flatness, and orientation. (The importance of orientation is found when discussing wet anisotropic etching more in detail in Section 5.3.3, and that of flatness when discussing wafer bonding in Section 3.7.10). The choice of the substrate material (wafer) is given by considering the application for which the device will be used. Important criteria are mechanical strength, chemical inertness, optical transparency, radio-frequency losses, and so on. Three classes of materials are found in MEMS technology: single-crystal, polycrystal, and amorphous wafer materials.

Being a semiconductor, the chemical binding between single-crystal silicon (SCS) atoms is covalent. Covalent-binding potentials are strongly anisotropic and they have a deep minimum. This is in great contrast to metal-binding potentials, and consequently, crystal dislocations are much more movable in metals than in semiconductor or insulator materials. Therefore, metals are ductile and semiconductors or glasses are brittle. SCS can be made almost perfect—virtually without any defects or impurities in the crystal lattice and no dislocation lines in the silicon lattice that are able to move at room temperature (Fig. 9).
Therefore, SCS can only be deformed elastically (i.e. without any plastic deferability and no mechanical hysteresis). This pure elastic behavior makes SCS a material of strength comparable to amorphous stainless steel and mechanically superior to any metal in many applications. However, the introduction of a dislocation line immediately causes a crack in the brittle SCS and it will break while the ductile metals can stand a much larger strain than SCS. Mechanical engineers often try to avoid the use of brittle materials for very obvious reasons. But ductile materials are easily plastically deformed, meaning that these materials are subject to mechanical hysteresis.

Important and well-known materials for high-speed rotating micromachines, such as Si and SiC, are superior to the materials commonly used in macromachines like steel, titanium, and nickel-based superalloys. Micromechanical structures have been shown to be able to reach yield strengths above 10 GPa, with average strengths around 7 GPa. However, since the materials are brittle, the probability of fracture has to be taken into account, using Weibull statistics. This is also the reason brittle materials are not used in large machines, although often superior in miniaturized machines (i.e., for too large machines the probability of fracture becomes unacceptable). An additional material consideration is that thermal shock increases with length scale. Thus, materials that have high temperature capabilities but are not considered high temperature structural ceramics due to their susceptibility to thermal shock are viable at the millimeter and below length scales. These materials, like aluminum and sapphire, have not been much concerned for micromachining.

Although single-crystal silicon is still the number one in use for many MEMS applications, new materials emerge having special properties. Single-crystal gallium-arsenide (GaAs) has electro-optical properties and is therefore found in laser applications. Single-crystal quartz has piezoelectric properties, which is of use in resonating devices. The arrangement of silicon atoms in quartz is similar to that of SCS, but in quartz there is an oxygen atom between each pair of Si atoms (Fig. 10). In this figure, the heart of a tetrahedral contains a Si atom surrounded by four O atoms. The O atoms connect the tetrahedrals at the corners. Moreover, its chemical inertness makes it suitable for biological and/or chemical applications. For the same reason, amorphous stainless steel is becoming increasingly

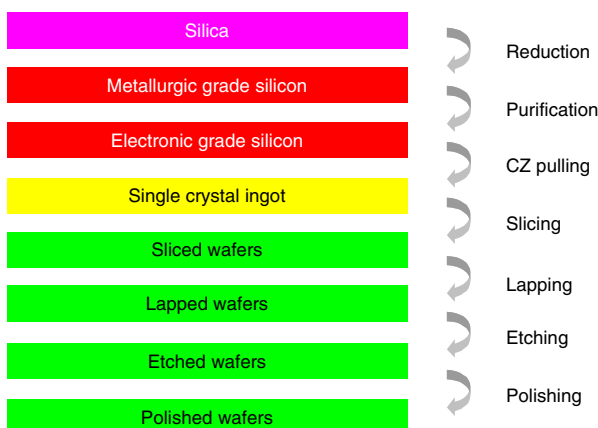
**Figure 9.** Single-crystal silicon. Reprinted with permission from www. webelements.com.

**Figure 10.** A piece of beta quartz. Reprinted with permission from www.webelements.com.

popular. The amorphous alkali glasses (e.g., Pyrex) have high ionic mobility at relatively low process temperatures. This makes Pyrex wafers suitable for wafer-bonding purposes. For on-chip radio-frequency applications, high-resistivity substrates are of prime importance. Although chromium-doped GaAs or quartz does satisfy this basic requirement, there are much cheaper solutions such as alkali-free glass (e.g., AF45™ from Schott). Other, less frequently found wafer materials are synthetic polymers (e.g., polycarbonate), alumina ($Al_2O_3$), graphite (C), and silicon carbide (SiC). When low-budget devices are requested, plastic wafers for single-use devices are increasingly found. The future could show the use of biodegradable organic wafers for medical applications.

In recent years the growth and development of semiconductor devices in the electronics industry has been nothing less than remarkable. In an electrical goods store nowadays, there are very few items that do not comprise semiconductors. Some people, however, are unaware that the most important prerequisite material for semiconductor technology is high purity silicon, a very sensitive and chemically reactive substance, easily fragmented through mishandling. Due to the dominant position of SCS, the next section will describe the production of SCS more in detail. This procedure is roughly the same for all the other wafer materials, although normally less high-tech (e.g., amorphous materials).

## 2.3. Single-Crystal Semiconductor Wafer Production

The starting material to produce SCS is silicon dioxide (or silica), which is chemically processed to form high-purity polycrystalline silicon (abbreviated: polysilicon) from which single crystals (or monocrystals) are grown (Fig. 11). The single-crystal ingots are grinded to define the diameter of the material and sawed (sliced) into wafers. Finally, these afers are lapped, etched, and polished to provide smooth, specular surfaces on which or from which microdevices will be made. In the subsequent sections, the just mentioned processing steps will be described in more detail.


### 2.3.1. Polycrystalline Silicon (Polysilicon) Rod Production

The starting material for silicon is a relatively pure form of sand ($SiO_2$) called quartzite. This is placed in a furnace with various forms of carbon (coal, coke, and wood chips). While a number of reactions take place in the furnace, the overall reaction is

$$SiC + SiO_2 \rightarrow Si + SiO^\uparrow + CO^\uparrow$$
This process produces metallurgic-grade silicon (MGS) with a purity of about 98%. Next, the silicon is pulverized (Fig. 12) and treated with hydrogen chloride (HCl) to form trichlorosilane ($SiHCl_3$). The $SiHCl_3$ is a liquid at room temperature. Fractional distillation of the liquid removes the unwanted impurities. The purified $SiHCl_3$ is then used in a hydrogen reduction reaction to prepare the electronic-grade silicon (EGS). The resulting purified polysilicon is grown on the surface of an electrically heated silicon rod, which serves as the nucleation point for the deposition of silicon (Fig. 13):

$$Si_{bulk} + SiHCl_3 + H_2 = Si_{bulk} - Si + x * HCl$$
$$+ (3 - x)/2 * (H_2 + Cl_2)$$
The resulting substance is then cleaned and etched with fluoronitric acid ($HNO_3 + HF$) to obtain a more than adequate surface for the next step. Pure EGS generally has impurity concentrations in the parts-per-billion range. Polycrystalline EGS is the raw material used to prepare SCS.

### 2.3.2. Single-Crystal Silicon Ingot Production

In general, semiconductor-grade devices cannot be fabricated directly from polysilicon without it first being converted into a single-crystal ingot form. Silicon single-crystal ingots are usually produced by either the Czochralski (CZ) method or the Float Zone (FZ) method.

***CZ Single Crystal*** Virtually all the silicon crystals and wafers for the IC and MEMS industry are prepared by the CZ technique. The CZ technique for silicon crystal growth uses an apparatus called a puller. In the crystal-growing process, polysilicon is placed in a quartz crucible (Fig. 14) and the furnace is heated with a graphite resistor element above

**Figure 11.** SCS manufacturing process.

**Figure 12.** Pulverized MGS. Reprinted with permission from http://www.memc.com/.
**Figure 13.** Polycrystalline silicon rod.

the melting temperature of silicon (i.e., 1420 °C) in an inert gas atmosphere. A suitable oriented seed crystal (e.g., ⟨111⟩) is suspended over the crucible in a seed holder and the seed is inserted into the melt. Part of it melts, but the tip of the remaining seed crystal still touches the liquid surface. It is then slowly withdrawn (pulled) while rotating with a typical pull rate of a few millimeters per minute (Figs. 15 and 17). The surface tension between the seed and the molten silicon causes a small amount of the liquid to rise with the seed and cool into a single-crystalline ingot (Fig. 16) with the same orientation as the seed and with a specified diameter. In crystal growth, a known amount of dopant is added to the melt to obtain a desired doping concentration. For silicon, boron (p-type Si) and phosphorus (n-type Si) are the most common dopants.

***FZ Single Crystal*** The float zone process can be used to grow silicon that has a lower contamination level than that obtained by the CZ technique. In the FZ process, a high-purity polysilicon rod with a seed crystal at the bottom is placed in an inert atmosphere and held in a vertical position which is rotated. During the operation, a small zone of the crystal is kept molten by a radio-frequency heater, which is moved from the seed upward so that this floating zone traverses the length of the rod (Figs. 18 and 19). The molten silicon is retained by surface tension between the melting and growing solid-silicon faces. As the zone moves upward, a single crystal freezes at the zone's retreating end and grows

**Figure 15.** Schematic view of CZ furnace. Reprinted with permission from http://www.memc.com/.

as an extension of the seed crystal until the entire polysilicon rod has been converted to a single crystal.

The FZ technique can be used to purify a single-crystal rod (i.e., to remove impurities), because the impurities have difficulties in passing the molten zone. There is a substantial reduction of impurity concentration in the rod after each pass. Multiple passes can be performed on a rod much more easily than a crystal can be grown, cropped off the end region, and regrown from the melt. Therefore, the FZ process is ideally suited for crystal purification. Because of this purification, materials with higher resistivities can be obtained from the FZ process than from the CZ process. Furthermore, since no crucible is used in the

**Figure 14.** Polysilicon in crucible.

**Figure 16.** SCS ingot.
**Figure 17.** Process of single-crystal pulling and growing. Reprinted with permission from http://www.memc.com/.

**Figure 19.** Schematic view of FZ furnace. Reprinted with permission from http://www.memc.com/.

FZ process, there is no oxygen contamination from the crucible (as with CZ growth). At the present time, FZ crystals are used mainly for high-power, high-voltage devices and rf devices, where high-resistivity wafer materials are required.

As the wafer diameter size increased, there was a corresponding higher incidence of crystals with lineage defects. Thus, the FZ method compared to the CZ method was more difficult with larger diameters and proved to be extremely unstable and unpredictable. Even the slightest vibration often meant that the whole process would fail. Compared to the CZ method, the FZ method brought a reduced yield and lower electric power efficiency. Finally, with the introduction of the 100 mm diameter single-crystalline technology, the FZ method almost vanished.

### 2.3.3. Ingot Grinding

After a crystal is grown, the first shaping operation is to remove the seed (to be reused) and the other end of the ingot. The next operation is to grind the surface so that the diameter of the material is defined. After that, one or more flat regions are ground along the length of the ingot. These regions, or flats, mark the specific crystal orientation of the ingot and the conductivity type of the material. The most common wafer orientations in SCS manufacturing are shown in Figure 20: $\langle 100 \rangle$, $\langle 011 \rangle$, and $\langle 111 \rangle$ wafers (this subject will be treated in more detail in Section 5.3.3). The largest flat, the primary flat, allows a mechanical locator in automatic processing equipment to position the wafer and to orient the devices relative to the crystal in a specific manner. Other smaller flats, the secondary flats, are ground to identify orientation and conductivity type of the crystal. Once these

**Figure 18.** FZ crystal growth.

**Figure 20.** Most common Si wafers in microtechnology. * = primary flat, ** = secondary flat.

operations have been done, the ingot is ready to be sliced by a diamond saw into wafers.

### 2.3.4. Wafer Slicing

Slicing determines four wafer parameters: surface orientation (e.g., $\langle 111 \rangle$), thickness (depending on wafer diameter, e.g., 700 micrometers), taper (i.e., wafer-thickness variation from one end to another), and wafer bow (i.e., surface curvature of the wafer, measured from the center of the wafer to its edge). Wafer slicing can be done either with an outer saw (Fig. 21), an inner saw, or a wire saw. However, in most cases the traditional outer saw is not used anymore due to kerfs of the blade and irregularities in shape. Also, with increasing ingot diameter, gradually "bowing" became a serious problem for the inner saw technique that was affecting production rate. Therefore, in 1994 wire saws were introduced.

In a few cases, customers demand nonstandard crystal orientation (i.e., not $\langle 100 \rangle$, $\langle 110 \rangle$, or $\langle 111 \rangle$). In such cases, the SCS ingot is sawed under a specified angle creating elliptical-shaped wafers instead of the usual circular-shaped wafers. Due to the off-the-road procedure, normally the wafers are much more expensive (Fig. 22).

### 2.3.5. Wafer-Edge Profiling

After the sawing process, the individual slices have sharp, fragile edges. These edges must be rounded or "profiled" in order to provide strength to the wafer (Fig. 23). Profiling will ultimately prevent chipping or breakage in subsequent internal processing and during device fabrication. Without edge profiling, the wafer is susceptible to edge fractures.

### 2.3.6. Wafer Lapping

In order to increase symmetry and remove surface roughness from saw cuts and process damage, the sliced wafer is now mechanically lapped. That is, both sides of the wafer are lapped using a mixture of abrasive alumna ($Al_2O_3$) powder and glycerine, which is fed through a chute onto two conversely rotating base plates (Fig. 24). Wafers are simultaneously revolving separately and within an orbiting carrier, which creates four-way rotation and produces a very smooth finished product (i.e., a typical flatness uniformity within 2 micrometers). This lapping style has remained more or less unchanged from 1962 until the present.

**Figure 22.** Sliced wafers.

### 2.3.7. Wafer Etching

The surface of the lapped wafers should be cleaned (etched) to remove any remaining microcracks or surface damage introduced by the alumna abrasive in the previous lap stage. Etching is done chemically using a corrosive mixture of nitric acid and glacial acetic acid solution (Fig. 25). This acidic surface dissolving technique is preferred in Japan over the more caustic U.S. etching method, which uses a sodium hydroxide (NaOH) base solution.

### 2.3.8. Wafer Polishing

The final step of wafer fabrication is chemical–mechanical polishing (CMP). This method is currently employed and involves both mechanical and chemical polishing mechanisms. Its purpose is to provide a smooth, specular surface where device features can be defined by lithographic processes (see Section 4) or to improve bondability (refer to Section 3.7.10). Wafers are fixed to a hard ceramic base plate using a wax bonding method. These are then lowered against a synthetic-leather-made polishing pad, attached to a metal plate and buffed to a state of minimum roughness with a solution of silica powder, which is dissolved in deionized water and controlled at a pH 10–11 with sodium hydroxide alkaline solvent (Fig. 26). This method improves parallelism, creates the surface mirror, and removes any remaining surface roughness (Fig. 27). The combined effect of the mechanical and chemical approach also ensures that there is no additional damage during the process.

### 2.3.9. Wafer Cleaning

Using the latest cleaning and inspection technologies, the final stages of SCS manufacturing can all be carried out with no handling or contamination. This means that each wafer arrives in perfect condition ready for immediate use by the end user. In each of these areas, there is considerable ongoing research that we will briefly describe in this section. Typically, the cleaning procedure of SCS consists of three steps: (1) First, the wafer is oxidized and (organic) particles are removed. (2) Next, the oxide is removed and (inorganic) particles are liberated and removed from the surface. (3) Finally, the surface is replaced by super clean new natural oxides, which grow on the surface.

***RCA Cleaning***    The RCA cleaning method was developed by the American Corporation RCA in 1970 and instantly adopted by silicon wafer producers worldwide. The process had three steps, beginning with the SC-1 solution, which is comprised of ammonia, hydrogen peroxide, and water, to remove organic impurities and particles from the wafer surface. Next, natural oxides and metal impurities are removed with hydrofluoric acid solution. Then, finally, the SC-2 solution, a mixture of hydrochloric acid and hydrogen peroxide, is put onto the now bare surface and the surface is oxidized. Even now the RCA method is used although concentrations, temperatures, and time adjustments differ among companies, as do the chemical recycling processes and the option to use ultrasonic waves. In general, the number of particles on the surface of the final product does not exceed 10 with diameters larger than 0.16 $\mu$m particles, with the density of surface metal ions at less than $10^{10}$ atoms/cm$^2$. Yet nanotechnology inspires one to investigate improved methods to decrease particle contamination. For example, hydrogen peroxide ($H_2O_2$) is unstable at the temperatures used in the SC-1 and SC-2 solutions and decomposes into $H_2O$

**Figure 26.** Schematic view of polishing machine. Reprinted with permission from http://www.memc.com/.

and $O_2$. In the SC-1 solution, if the concentration of $H_2O_2$ drops too much, the $NH_4OH$ will attack silicon.

***Ozonized Cleaning***    A number of replacement cleaning procedures have been proposed. A particularly interesting procedure is to use ozonized ultrapure water. The process is all at room temperature, uses far fewer chemicals than the standard RCA clean, and is claimed to be as effective in cleaning wafers. A strong oxidant (ozon, $O_3$) is used to oxidize organics and metals. Megasonic agitation is used to loosen particles that may have adhered to the wafers. The final steps involve an HF etch of the surface. This strips away the chemical oxide that naturally grows as part of the cleaning procedure. The silicon surface atoms are left with dangling (incomplete) bonds which are highly reactive and which form hydrogen bonds with H atoms from the HF solution [2, 3]. The hydrogen-passivated surface that results is ready for immediate further processing, such as film deposition. There are some concerns with using a final HF step for wafers whose next processing step is oxidation. The hydrogen-passivated silicon {100} surface is roughened by the H passivation process and may lead to poorer quality thin oxides grown on these surfaces. In addition, the hydrogen-passivated surface is very sensitive to ambient effects between the time the cleaning ends and the next process step begins, so special care may have to be taken in transporting and handling such wafers. Of course, as in the case of RCA cleaning, one could opt for an additional ozon-oxidation step to form a clean and stable surface oxide.

***Dry Cleaning***    There has also been considerable recent work on "dry" cleaning procedures including vapors, plasmas, sputtering, and photochemically enhanced cleaning

**Figure 25.** Wafer cleaning.

**Figure 27.** Polished SCS wafers.

in which UV energy is used to help break surface bonds and release contaminants on the wafer surface. This work has been motivated both by the environmental issues associated with wet chemistries and the increasing use of cluster tools in IC manufacturing. In these tools, multiple-process steps, often on single wafers, are performed in a single machine by moving wafers from one chamber to another. There is great interest in accomplishing the cleaning process in one of these chambers because wafers would then move directly to the process step under well-controlled ambient conditions, minimizing contamination between cleaning and the next step.

### 2.3.10. Wafer Inspection

A real crystal (such as a silicon wafer) differs from the ideal crystal in important ways. It is finite; thus, surface atoms are incompletely bonded. Furthermore, it has defects, which strongly influence the electrical, mechanical, chemical, and optical properties of the semiconductor. There are four categories of defects: point defects (i.e., incorporated foreign atoms into the semiconductor lattice or missing silicon atoms), line defects (i.e., an extra plane of atoms in the lattice, also known as edge dislocation), area defects (represents a large area discontinuity in the lattice such as twins and grainboundaries), and volume defects (i.e., precipitates of impurities or dopant atoms). Point defects are particularly important subjects in the kinetics of diffusion and oxidation processes. All these topics can be found in specific literature [1]. The oxygen and carbon concentrations are substantially higher in CZ crystals than in FZ crystals due to the dissolution of the silica crucible (for oxygen) and transport to the melt from the graphite susceptor during crystal growth. Typical carbon and oxygen concentrations range from $10^{16}$ to about $10^{17}$ atoms/cm$^3$ and low $10^{17}$ to $10^{18}$ atoms/cm$^3$, respectively (the atomic density of silicon is $5 \times 10^{22}$ atoms/cm$^3$). Carbon in silicon occupies substitutional lattice sites and its presence aids the formation of defects. Oxygen, however, has both deleterious and beneficial effects. It can act as a donor, distorting the resistivity of the crystal. On the other hand, oxygen in an interstitial lattice site can increase the yield strength of silicon. In addition, the precipitates of oxygen due to the solubility effect can be used for gettering (see next section). It is possible to obtain silicon crystals that are virtually free of dislocations (500 dislocation/cm$^2$ or less). In spite of this, high-resistivity silicon is very difficult to achieve and is limited to ca. $10^4$ $\Omega$ cm. To obtain high-resistivity crystals, gallium arsenide can be doped with chromium to give a starting resistivity of $10^9 \Omega$ cm. Another option to increase the resistivity is to start with an insulating material like quartz crystal, which is, of course, not a semiconductor.

### 2.3.11. Postwafer Production

Previously, wafer manufacturers only produced up to the polished-wafer stage while device manufacturers (the "customer") would continue from these stages. However, as market prices came down and demand for ICs increased, the competition for high performance wafers for semiconductors became more and more intense. In reaction to this pressure and as a result of the increase in technical

know-how, product lines were expanded to include epitaxial (EPI) wafers, diffused wafers, and silicon-on-insulator (SOI) wafers. Moreover, oxygen donors (silicon and oxygen compounds) cause incorrect resistivity values during the intentional doping process and must be annihilated using a continuous wafer heat treatment called wafer gettering. Gettering is a general term meaning a process that removes harmful defects or impurities such as iron and copper from the wafer surface by diffusing a contaminant into the substance. When the wafer is subjected to high-temperature treatment (e.g., 1050 °C in $N_2$), oxygen evaporates from the surface. This lowers the oxygen content near the surface, so that precipitation of oxygen does not occur there. The treatment creates a defect-free zone. Additional thermal cycles can be used to promote the formation of oxygen precipitates in the interior of the wafer for gettering of impurities. They are then cooled again at a similar high speed to prevent regeneration of the doner. As the silicon matrix is very stable, excess oxygen will precipitate to form irregular fields and thereby create free space in which the impurities can be trapped. In 1988, polysilicon chemical vapor deposition (CVD) was introduced as an effective gettering source. Polycrystal could be placed at the backside of the silicon wafer to attract impurities into the irregular space.

***EPI Wafer*** In 1963, EPI wafers entered the world market. It is a technology closely related to crystal pulling from a melt and it involves the deposition of a single-crystal semiconductor layer upon a single-crystal semiconductor substrate, so that the lattice of the newly formed film duplicates that of the substrate (Fig. 28). This is called epitaxy, from the Greek words epi (meaning "on") and taxis (meaning "arrangement"). Epitaxial processes are differentiated from the melt pulling process in that the epitaxial layer can be deposited at a temperature substantially below the melting point. If the film is of the same material as the substrate, the process is called homoepitaxy, epitaxy, or simply epi. If the deposit is made on a chemically different substrate, usually of closely matched lattice spacing and thermal expansion, the process is termed heteroepitaxy. The key reason for EPI growth is to create an extremely pure layer with different, usually lower, concentration of electrically active dopant to the substrate. The dopant in the film can be n- or p-type and is independent of the substrate doping. The three types of epitaxial film formation processes currently employed are vapor-phase (VPE), liquid-phase (LPE), and molecular beam epitaxy (MBE) as can be found in Section 3.7. Depending on the device to be made, the EPI

**Figure 28.** Vertical EPI reactor.

layer must meet a set of specifications for thickness, electrically active dopant concentration, defect density, and contamination. The gas used in this process is highly toxic and inflammable. One heteroepitaxy application is the deposition of silicon on sapphire ($Al_2O_3$) or "SOS." Mono-, di-, trichlorosilane, or silicon tetrachloride, and hydrogen are the source gases, which are combined with either diborane or phosphine gas to act as dopant atoms. In the period 1972–73, vertical and horizontal style reactor models were developed, along with cylindrical style, single wafer style reactors, and reduced pressure reactors, in response to customer demand.

***SOI Wafer*** Silicon devices have problems with inherent parasitic capacitances due to the relatively low maximum resistivity. One way to circumvent the problem is to fabricate silicon devices on an insulating substrate. The initial approach was to grow silicon epitaxially on a substrate of sapphire (called SOS). A more recent approach is the silicon-on-insulator process. SOI wafers have an oxide film under the active wafer top layer (Fig. 29). This allows for high speed operation of ICs with a minimum latch-up or punch-through and makes them especially good for memory devices such as next generation DRAMs and SRAMs. Moreover, it is believed that more and more microstructures will exploit SOI wafers. For example, crystalline layers of a predetermined thickness on a thin $SiO_2$ layer afford well-controlled suspended membranes. There are a few approaches to create a SOI wafer: SOI, BESOI, SIMOX, and Smart Cut®.

In the first method, a silicon wafer is oxidized and processed to give a flat surface with a pattern of exposed silicon area within the surrounding oxide. The surface is then coated with silicon to a thickness of 0.5 to 1 $\mu$m. However, only amorphous or polycrystalline silicon is formed on the almost entire amorphous $SiO_2$ substrate; therefore, a strip heat source can be used to recrystallize the deposited silicon into SCS. The heat source melts the polysilicon through to the substrate and the substrate acts as a seed to the molten silicon. As the heat source is moved laterally, SCS is grown laterally over the oxide-covered regions. Capping the molten zone with silicon dioxide and silicon nitride layers will improve the zone's thermal stability.

Recently the bonded BESOI (backside etched SOI) wafer has become widely used with the negligible thickness variation in the active layer of these wafers. After oxidizing a silicon wafer, the wafer is bonded with a second silicon wafer.
The stack is immersed in a silicon etch solution in which one of the silicon wafers is almost entirely removed. Only a thin SCS layer (between a few micrometers up to wafer thickness) is left to form the active layer.

The third method is SIMOX, which is an abbreviation for separation by implanted oxygen. It is a method of oxide film implantation beneath the surface of a SCS wafer, which results in a similar finished product to SOI wafers but with a completely different manufacturing process.

A fourth method, "Smart Cut®," is based on the technical principles of thermal oxidation, ion implantation, wafer bonding, and atomic level splitting (Fig. 30). Its key feature, hydrogen implantation, irreversibly weakens the silicon crystal at the desired depth. This acts as an atomic scalpel to lift off a thin layer of silicon, bonded on a base wafer of your choice. For example, a very thin perfect monocrystalline silicon layer is transferred onto a silicon support wafer, which has been covered first with an insulating layer of silicon dioxide. The resulting SOI wafer is now ready for the microchip manufacturing process. A key advantage of Smart Cut® compared to other SOI approaches is that it relies on existing standard microelectronic manufacturing equipment. As a result, this innovative technology is the only industrial process in use today that enables high-volume production of SOI wafers. This technology offers unique flexibility, in terms of wafer diameter, SOI and buried oxide layer thickness, and uniformities.

***Diffused Wafer*** In 1970, diffused wafers were developed. The structure of a diffused wafer is similar to an EPI wafer although it has a thicker active layer and both sides of the

**Figure 29.** Sample structure of SOI product.

**Figure 30.** Smart Cut® SOI wafer production.

lapped or etched wafers have been diffused with either phosphorus or boron (Fig. 31). They are mainly used in power transistor devices.

In some applications a very homogeneous distribution of dopants is required. To obtain this, we use a float zone silicon slice that has an average doping concentration well below the required amount. The slice is then irradiated with thermal neutrons. This process gives rise to fractional transmutation of silicon into phosphorous and dopes the silicon $n$-type. Because the penetration depth of neutrons in silicon is about 100 cm, doping is very uniform throughout the slice.

## 2.4. Single-Crystal Quartz Wafer Production

Quartz in some respects presents us with an even more ideal substrate material than silicon because of its nearly temperature-independent thermal expansion coefficient. A variety of quartz micromachined piezoelectric devices are on the market such as electronic filters, resonators, and wristwatch tuning forks.

Natural quartz has been replaced by alpha quartz grown in large single crystals using a hydrothermal process. It is not at all like the growing of single-crystal silicon. It occurs at 350 °C in a sealed vessel usually called an autoclave. Two growth methods are used. One uses sodium carbonate as a mineralizer; the pressure in the autoclave is about 60 atmospheres. The other uses sodium hydroxide where the pressure is about 125 atmospheres. Most likely, crystal would be needed to be made to the requested specifications of size, thickness, angle tolerance, surface finish, etc. All planes can be made up to the physical size of available stones. For the $\langle 100 \rangle = Y$–cut wafer, the $Y$ axis is normal to major face, for the $\langle 110 \rangle = X$–cut, the $X$ axis is normal to major face. The $\langle 111 \rangle$-oriented quartz wafer is not a standard wafer.

## 2.5. Amorphous Float Glass Wafer Production

Float glass offers the quality of plate glass combined with the lower production cost traditionally associated with sheet glass manufacturing. Float glass is virtually distortion and defect free, making it ideal for various premium-glazing applications in buildings and homes or for automotive glass along with hundreds of other glass fabrications. Float glass manufacturing is not unlike the manufacturing of commodities like steel or plastic. Each of the processes requires raw materials to be weighed, mixed, melted at high temperatures, formed into continuous ribbons, cooled, and cut into a size that fits its use. Float glass manufacturing is described in the following.

### 2.5.1. Charging the Raw Materials

Float glass is made from a combination of several ingredients such as sand, soda ash, dolomite, limestone, salt cake, and cullet (Fig. 32). The raw materials are kept in different silos. After being weighed separately they are mixed and then poured into the charging hopper along with the cullet (crushed scrap glass).

### 2.5.2. Melting in the Furnace

The raw materials are melted in the furnace at a temperature of 1550 °C produced by powerful fuel-oil and/or gas burners. As it melts, the mixture vitrifies and flows slowly down inside the furnace, undergoing a process known as "fining." During this process, the molten glass is kept at a high temperature for several hours, enabling bubbles of air trapped within it to escape.

### 2.5.3. Floating on a Tin Bath

From the working end of the melting furnace, the glass flows through the canal area and then into the float furnace (tin bath or float bath) onto molten tin. The molten glass forms a continuous ribbon that floats on the molten tin with a thickness that can range from 2 to 12 mm. The float furnace atmosphere is controlled using a mixture of nitrogen and hydrogen gas to prevent the tin from oxidizing. From one end of the bath to the other, the temperature of the glass and of the tin gradually drops from 1100 to 600 °C allowing the glass to become flat and parallel. Top rollers on either side draw out the glass mechanically to give it the required thickness and width.

### 2.5.4. Annealing

The glass emerges from the tin bath in the form of a continuous strip. This is led by way of a roller conveyor to an annealing tunnel, known as a "lehr." Here, the glass is gradually cooled in a controlled way, in order to ensure perfect flatness and eliminate any internal mechanical stresses, which could cause breakage. The glass comes out of the lehr at ambient temperature, ready for cutting.

**Figure 31.** Schematic view of a diffusion furnace.

**Figure 32.** Raw materials.

### *2.5.5. Cutting*

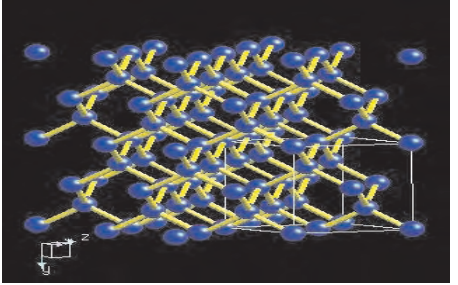
The cooled glass ribbon exits the lehr and is conveyed to the cutting area by a system of rollers and drives linked to the lehr drive system. The glass is scored with carbide cutting wheels, parallel and perpendicular to the ribbon travel, into sizes that meet the plant's customer requirements. The scored glass ribbon is then separated into lites for packaging for transfer to the wareroom for storage or shipment to the customer.

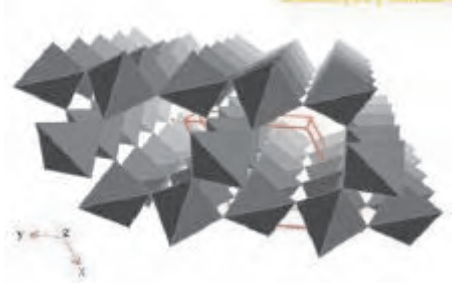
## 2.6. Wafer Cleaning

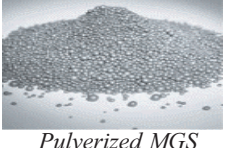
After selecting a wafer and in between different wafer processing steps, the device manufacturer should clean the wafers to remove traces of dust. This cleaning procedure may be identical to the silicon wafer production facility cleaning procedures (Section 2.3.9.) but normally is less severe in MST facilities. However, in NST it might be necessary to perform a full three-step cleaning process. Standard cleaning often consists of fuming (70%) nitric acid to remove organic dust and boiling nitric acid to remove metallic particles. Because standard cleaning is an oxidizing agent, silicon wafers will be coated with a thin native oxide. This oxide is sometimes beneficial to improve adhesion of resist, which is applied during the lithography. When this oxide is unintended, the cleaning can be ended with a short dip of the wafer in HF to remove the oxide.

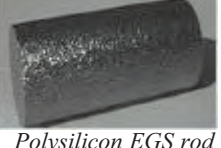
## 2.7. Conclusion and Nanoperspective

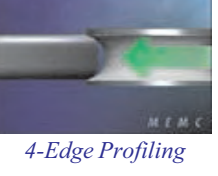
In this chapter, a typical fabrication process of SCS substrates has been treated. Polished wafers, as raw materials for ICs and other devices, are made from single-crystal ingots that have been precisely cut and chemically polished. First, silicon ingots are sliced into wafers using a diamond saw or wire saw. The resulting sliced wafers are then lapped mechanically to remove any surface roughness. The surface of the lapped wafers is then etched in an acidic solution to remove any remaining process damage. Finally the etched wafers become polished wafers after surface polishing. The next beautiful virtual reality movies show how the silicon wafer production process is accomplished (Table 3). When the semiconductor behavior is not requested or even is a disadvantage (as in the case of rf components or chemical applications), float glass offers the same ultraflat wafer surface as currently available for single crystalline material, but for a much lower price. This can become crucial to enable the widespread introduction of microcomponents in the near future. The most prominent part of the float glass production process is the tin bath, which removes almost any surface irregularity.

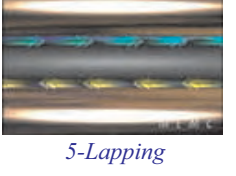
The goals for the nanofuture are fairly clear—cleaner environments in which to process wafers, better cleaning procedures that remove particles and trace contaminants more reliably, and better gettering procedures for eliminating contaminants from device regions of wafers. Traditionally, semiconductor manufacturing facilities have used the approach of providing cleanrooms in which to manufacture the chips. While this has been very successful, it is in some sense a wasteful approach because the volume of the cleanroom is far larger than the wafers that are being processed.


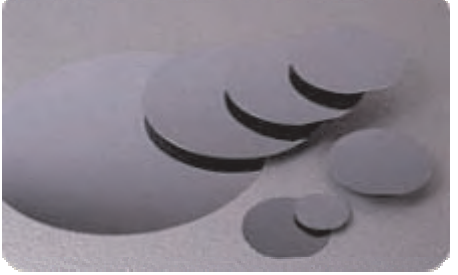


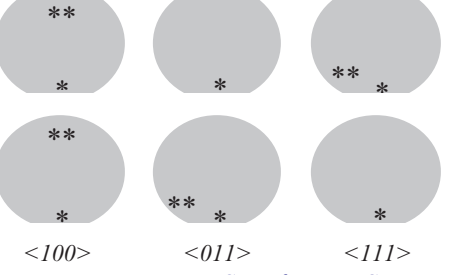


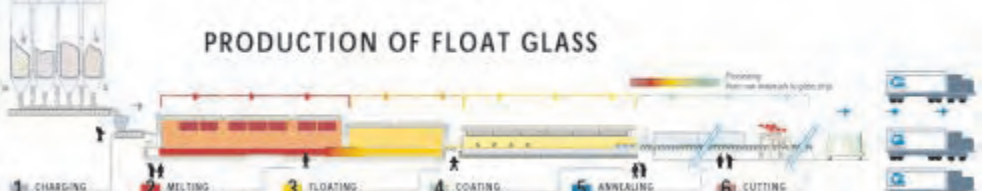












There are approaches to minimizing the actual volume of "cleanroom" which must be maintained. These approaches keep the wafers in sealed minienvironments in which they are transported from one machine or process to another. An alternative approach is to combine equipment to a single cluster tool. The wafer in such a system is transported from one module to the other with the help of a central robotic-arm system. Economics may play a significant role in determining how extensively such minienvironments are used in the "nanofuture," since the costs associated with constructing and operating large ultra-clean-rooms are very large. Gettering methods have remained relatively unchanged for the past decade. It is likely that intrinsic gettering will dominate the "nanofuture" because with smaller devices, thermal budgets for processing will have to decrease. Moreover, with decreasing size, the effect of local inhomogeneous doping becomes critical with respect to device performance. Therefore, tighter controls on oxygen concentration in CZ wafers will be required and may reintroduce FZ wafers.

Although the history of silicon production for semiconductor devices dates back only 30 years, it has become the most pervasive technology of the 20th century. As we move into the 21st century there will be no reprieve for manufacturers as revolutionary applications for ICs in areas such as supercomputers are continually researched and developed to support the so-called information age. All around the world large investment is being made into the more efficient, lower cost mass memory components for future generations. And in terms of machinery, the catch up race between new manufacturing technology and the development of corresponding evaluating equipment has clearly become a neverending game of cat and mouse as each in turn surpasses the other.

## 3. FILM FORMATION

After a substrate or wafer has been selected, the next step generally is to form a thin solid film (or layer) on top of the substrate. The material of this film is chosen such that it reflects the specific task of the microdevice to be constructed. Film formation generally means the *deposition* of a new layer on top of a substrate. *Growth* of a film, as in oxidation of a silicon wafer, differs from straight deposition due to the consumption of the substrate (sub)surface material while forming the film. The film can be formed on the substrate—physically or chemically—from a gas state, liquid state, or solid state. Gas-phase film formation methods are of key importance in microtechnology and are found schematically in Figure 33. The mechanism for physical film deposition (Fig. 33a) is quite straightforward: the reactants are transported to the surface and adsorb. Physical film growth (Fig. 33b) is possible due to the subsurface implantation of high-velocity particles—most often ionic species. The chemical film deposition (Fig. 33c) involves three essential steps, which are identical to chemical film etching—only the direction of transport is reversed: the reactants are transported to the surface (e.g., ionic) and adsorb. Then surface reactions occur (e.g., thermally activated). Finally the products from the surface are desorbed and transported away from the surface (e.g., by dissolving). Finally, in chemical film growth (Fig. 33d) the reactants adsorb first, and then they diffuse into the substrate and react. Basic requirements

**Table 3.** Schematic overview of wafer production methods.

for a good formation process are that the reactants must be able to be transported to the wafer surface, and the products—if any—must be transported away easily. The latter means that soluble, gaseous, or volatile products are needed in film formation.

The choice of film material and film formation method is very important because it influences the material proper-ties, such as film conductivity, structure, stress, and adhesion, which determine the device characteristics in the end. Depending on the film formation method, layer thickness will be influenced by the topography of the underlying substrate, that is, the step coverage is influenced by the film formation method. Moreover, the deposited film might mix (alloy) with the underlying layer due to
**Figure 33.** Schematics of a film formation processes from the gas phase. (a) Physical vapor deposition. (b) Physical vapor growth. (c) Chemical vapor deposition. (d) Chemical vapor growth.

temperature-controlled diffusive mass transport, which might degrade device performance in time (device drifting). The film formation process should be uniform, should be safe to use, and should cause minimal damage to structures on the chip. The process should be clean, with low particulate production and little film contamination, and should be cost effective. Finally, when a film is formed, device features generally are defined by lithographic and etch processes; therefore, each film must both perform its intended function and be compatible with overall processing sequence. That is, the film must withstand the required chemical treatment and thermal cycle while its structure remains stable. Unarguably, many parameters, such as temperature and reactant composition, will influence the formation rate depending on the mechanism involved and surface impurities sometimes play an important role and might produce unreliable results

(film delamination). This makes film formation a very difficult subject. The subdivision of film formation methods into gas, liquid, and solid states is so important that most sections have been organized in this way. The scope of this chapter is to give a short description of each of the subjects described and to emphasize those most important for microtechnology. Principles of the underlying physical and chemical phenomena are explained. In the final section, typical layers formed with these techniques will be treated, such as silicon oxide and aluminum.

## 3.1. Film Materials and Their Use

Film formation processes span a wide range of materials from inorganic to organic. Besides the typical metallic elements (e.g., Al, Cu or Au) and alloys (e.g., Ni–Fe or Pb–Sn), a plethora of exotic compounds are used to construct micromachines ranging from enzyme layers to shape memory alloys (e.g., Ni–Ti), piezoelectrics (e.g., ZnO), and superconductive materials (e.g., $YBa_2Cu_3O_{7-x}$). In Table 4, the elements are listed in the well-known periodic table. Information about a specific element and its compounds can be found by clicking on the element.

Films can be classified into three groups: conductors (e.g., metal films), semiconductors (e.g., silicon films), and insulators (e.g., dielectric films). These films can be either amorphous (e.g., glass), polycrystalline (e.g., polysilicon), or monocrystalline (e.g., epitaxial silicon). Conducting films are used for electrical interconnection, Ohmic contact to $n^+$- and $p^+$-layers, rectifying metal–semiconductor contact, catalytic and seed layers, or as electrode material in electrostatically driven devices. Semiconducting films are used

**Table 4.** Elements with their characteristics and compounds.

*Source:* Reprinted with permission from www.webelements.com.

as a conductive material for multilevel metallization, electronic material, or as a structural layer to create free moving MEMS structures. Insulating layers such as deposited silicon oxide and silicon nitride are used for isolation between conducting layers, for etching, diffusion, and ion implantation masks, for capping doped films to prevent loss of dopants, as a sacrificial layer in surface micromachining, and for passivation to protect devices from impurities, moisture, and scratches.

## 3.2. Film Stress and Strain

Stresses and strains that develop in interconnect layers and structures can greatly affect their physical integrity and long-term stability. For instance, excessive compressive or tensile stress results in failures such as cracking, blistering, and loss of adhesion (delamination or peeling), shape problems such as bending, shrinking, curling, or buckling of structures, as well as reliability problems such as void and hillock formation and long term shifts in material properties. Further, the resonance frequency of typical micromachined structures such as doubly supported (clamped–clamped) beams increases with increasing tensile stress. Also, the deflection of a diaphragm as a result of an applied pressure decreases with increasing tensile stress in the diaphragm material. If the diaphragm is used, for example, in a capacitive microphone, this leads to a reduced sensitivity. Therefore, a proper understanding of the residual stress state of the formed film is of prime importance to the MST design engineer.

Let us start with a typical example of film stress: the growth of a silica ($SiO_2$) film on top of a silicon substrate. It occurs when an oxygen atom is inserted between two silicon atoms at elevated temperatures in an oxygen or steam ambient (furnace). The Si–Si separation then increases from 2.35 to 3.08 Å [170], which implies isotropic expansion of 31%. Therefore, the oxidation of silicon induces a drastic expansion of the silicon lattice. The expansion of the layer is free in the direction toward the surface of the silica film (the $z$-direction in Fig. 34), but strained parallel to it. As a result, this anisotropic expansion induces a compressive stress $\sigma$ parallel to the surface:

$$\sigma = \sigma_{xx} = \sigma_{yy} \qquad \sigma_{zz} = \sigma_{zx} = \sigma_{zy} = \sigma_{xy} = 0 \qquad (1)$$

A direct consequence of this built-in compressive stress, $\sigma_f$, in the silica thin film (the subscript $f$ standing for film) is that the substrate itself will build up a compensating tensile
stress, $\sigma_s$, to balance forces ($\Sigma F = 0$, no translation occurs). So if a film with thickness $t_f$ is formed on both sides of a substrate with thickness $t_s$ (Fig. 34), then $\Sigma F = \sigma_f t_f + \sigma_s t_s + \sigma_f t_f = 0$ or

$$\sigma_s = -2m \, \sigma_f \qquad (2)$$

$$m = t_f / t_s \qquad (3)$$

For example, 250 nm of silica film with an assumed compressive stress of $\sigma_f = 300$ MPa, thermally grown on both sides of a 500 $\mu$m thick silicon substrate wafer, will result in a tensile stress of $\sigma_s = 300$ kPa in the silicon substrate. With the help of Hooke's law and the expression for the fractional change in length, the stretching is calculated (this relative change in length $\Delta l$ with respect to the original length $l$ is called the strain $\varepsilon$) [43]:

$$\acute{Y} = Y/(1 - \nu_s) \qquad (4)$$

$$\varepsilon = \sigma / \acute{Y} \qquad (5)$$

$$\Delta l = \varepsilon l \qquad (6)$$

Here, Poisson's ratio (see Table 5 [171]) $\nu_s$ is the lateral contraction per unit width divided by the longitudinal extension per unit length and the Young's modulus (or the modulus of elasticity) $Y$ refers to longitudinal strain with respect to the axial (or normal) stress when the load is applied in the $x$-direction and the $y$- and $z$-directions are not constraint (i.e., a beam under stress). $\acute{Y} = Y/(1 - \nu_s)$ refers to a *surface* under stress to account for the boundary condition that only the $z$-direction is free to move. Other frequently found moduli having different boundary conditions are the bulk, rigidity, and shear modulus. The bulk modulus refers to the ratio of pressure to the decrease in volume—this is the inverse of compressibility. The rigidity modulus refers to the change of shape produced by a tangential stress and the shear modulus to the deformation caused by shear or parallel stresses.

Using Eqs. (1)–(6), it is shown that a silicon substrate will be stretched for almost 200 nm along its diameter of 100 mm when a layer of 250 nm silica is grown. This means that if one transfers two times the same mask pattern to a silicon substrate—the first time just before oxidation and the second time directly after—that the pattern will not correspond anymore. Likewise, a 250 nm thick stoichiometric LPCVD silicon nitride film having a tensile stress of ca. 1000 MPa will compress the silicon wafer by almost 700 nm.

Evidently, tuning the residual stress (or strain) in a thin film formation process in the first place necessitates methods to measure the residual film stress. However, before this subject about stress diagnostics will be given, the two most common kinds of residual stresses in thin films will be

**Figure 34.** Tensile substrate stress to balance for the compressive film stress.

considered: thermal and intrinsic stresses. Due to the difference in thermal–mechanical properties between the film and substrate, thermal stress is usually unavoidable. Intrinsic stress is generated during film formation and is strongly dependent on process conditions. These stresses are causing, for example, structural buckling or even film fracture and the stress gradient in a single layer causing, for example, structural bending or curling.

### 3.2.1. Thermal Stress

A common source of stress in thin films is caused by differences in thermal expansion between two layers, which are tightly connected. Thermal expansion, $\alpha$, is the change in dimension of a material as its temperature is altered and depends on the material, crystal orientation, and temperature [173]. It is usually expressed as a fractional change in length per unit temperature change:

$$\varepsilon = \Delta l / l = \alpha \Delta T \tag{7}$$

Table 6 shows the thermal expansion of some materials common in microtechnology. The identical thermal expansion of Kovar steel with Pyrex glass is not a coincidence. By altering the steel composition, this expansion has been adjusted with respect to that of Pyrex to prevent high interfacial stresses—and therefore delamination or blistering—between these materials during thermal cycles in the fabrication process. It should be noted that the thermal expansion normally increases with temperature [173]. For example, for silicon this dependency is best fitted with the formula [67]

$$\alpha_{Si}(T) = 3{,}725 * [1 - \exp\{-0{,}00588 * (T - 124)\}]$$
$$+ 0{,}0005548 * T \quad [\mu m/mK] \tag{8}$$

With this expression, the total strain is calculated with

$$\varepsilon = \Delta l / l = \int_{To}^{T1} \alpha(T) \, dT \tag{9}$$

As found in Figure 35, the thermal expansion of silicon varies from about zero at 130 K to 4.5 $\mu$m/mK at 1400 K. It has an average value of about 3.9 $\mu$m/mK between room temperature and 1300 K. Likewise, silica and silicon-nitride have an average value of 0.8 and 3.2 $\mu$m/mK respectively between room temperature and 1300 K. Next, the influence of a change in temperature on a stack of layers, which are often found in microfabrication, will be treated mathematically. In the first case the growth of a thin film on both sides of a substrate, typically for CVD processes, is studied. The second case shows the result of a deposited thin film at only one side of the substrate as usually found in PVD processes or after stripping only one side after a CVD process.

**Table 6.** Thermal expansion $\alpha[\mu m/mK]$ at 300 K.

**Figure 35.** The thermal expansion of silicon compounds as a function of the temperature.

**Double-Side Film Formation** In many processes in microtechnology a layer is formed on both sides of a substrate material at elevated temperature. After cooling down toward room temperature, stress will occur. In this section the magnitude of this stress is calculated. As a typical example, the thermal oxidation of a silicon wafer at 1100 °C is taken (Fig. 36). At this temperature, the amorphous silica film with thickness $t_f$ is viscoelastic and there are no stresses in both the materials [173, 180]. However, when the temperature is lowered to 1000 °C, the silica film hardens out and stresses start to develop between the silica film and silicon substrate due to the difference in thermal expansion. Let the length of the film and substrate at $T_h$=1000 °C be $l_h$. Then, after cooling down to room temperature $T_c$, the film and substrate material would like to shrink to $l_{fc}$ and $l_{sc}$, respectively (in this case, the silicon wants to shrink more than the silica):

$$l_{fc} = l_h(1 + \alpha_f \Delta T) \tag{10}$$

$$l_{sc} = l_h(1 + \alpha_s \Delta T) \tag{11}$$

However, as the film and substrate are tightly connected, the length of the stack will be $l_c$, which is somewhere in between $l_{fc}$ and $l_{sc}$. Therefore, the film will have a strain $\varepsilon_{fc} = (l_c - l_{fc})/l_{fc}$ and, identically, the substrate will have a

**Figure 36.** Thermal stress caused by a double-side silica film covering a silicon substrate.

strain $\varepsilon_{sc} = (l_c - l_{sc})/l_{sc}$. Due to these strains, stresses will develop:

$$\sigma_{fc} = \acute{Y}_f \, \varepsilon_{fc} = \acute{Y}_f(l_c - l_{fc})/l_{fc} \qquad (12)$$

$$\sigma_{sc} = \acute{Y}_s \, \varepsilon_{sc} = \acute{Y}_s(l_c - l_{sc})/l_{sc} \qquad (13)$$

From Eqs. (12) and (13), $l_c$ is eliminated and Eqs. (10) and (11) are used to arrive at

$$\alpha_{sf}\Delta T \acute{Y}_s \acute{Y}_f = (1 + \alpha_f \Delta T)\acute{Y}_s \sigma_{fc} - (1 + \alpha_s \Delta T)\acute{Y}_f \sigma_{sc} \qquad (14)$$

with $\alpha_{sf} = (\alpha_s - \alpha_f)$. In general, $\alpha \Delta T \ll 1$, and therefore

$$\alpha_{sf} \, \Delta T \, \acute{Y}_s \, \acute{Y}_f = \acute{Y}_s \, \sigma_{fc} - \acute{Y}_f \, \sigma_{sc} \qquad (15)$$

There is no translation of the stack ($\Sigma F = 0$). Thus $\sigma_{sc} = -2\sigma_{fc} \, t_f/t_s$,

$$\sigma_{fc} = \alpha_{sf} \, \Delta T \, \acute{Y}_f / (1 + 2mn) \qquad (16)$$

$$\sigma_{sc} = -2m \, \sigma_{fc} \qquad (17)$$

With $m = t_f/t_s$ and $n = \acute{Y}_f/\acute{Y}_s$. In most situations, $2mn \ll 1$ and therefore

$$\sigma_{fc} = \alpha_{sf} \, \Delta T \, \acute{Y}_f \qquad (18)$$

$$\sigma_{sc} = -2m \, \sigma_{fc} \qquad (19)$$

When Eq. (18) is used for the thermal oxidation of a silicon wafer at a temperature above 1000 °C, the calculated compressive stress in the silica thin film is about 280 MPa, which is indeed close to the measured value of 300 MPa [168]. Of course, both the thermal expansion and Young's modulus depend on temperature and we should have used instead

$$\sigma_{fc} = \int_{Th}^{Tc} \alpha_{sf}(T) \, \acute{Y}_f(T) \, dT \qquad (20)$$

***Single-Side Film Formation*** On many occasions a thin film exists at only one side of a substrate wafer. As an instructive example, the stress distribution inside the thermally grown silica film of the former section is taken after the bottom film is removed (Fig. 37). When the silica-silicon stack is at an elevated temperature $T_h = 1000$ °C, no stresses between the materials will occur and the structure appears straight (Fig. 37a). After cooling down to $T_c$ = room temperature, the silica film will develop a compressive film stress with approximately the same value as in case of the double-side silica film. However, due to the nonsymmetric stress, the structure will bend and the substrate will develop stress proportional to its position along the $z$-direction (Fig. 37b). To be able to predict the stresses inside the stack and the wafer curvature, the structure is best understood by considering it as a bimorph. In the bimaterial laminated plate theory, the bending is calculated by considering the so-called neutral zones $l_{fc}$ and $l_{sc}$. These are zones—one zone for each of the materials—in which no stresses exist and the zones lay not necessarily inside the layer (Fig. 37c),

$$l_{fc} = l_h(1 + \alpha_f \Delta T) = (\rho + t_n)\varphi \qquad (21)$$

$$l_{sc} = l_h(1 + \alpha_s \Delta T) = \rho \varphi \qquad (22)$$

**Figure 37.** Thermal stress caused by a single-side silica film covering a silicon substrate (a), Leads to stresses and bending of the silica-silicon stack (b). Parameters to determine film stress (c).

in which $t_n$ is used to represent the distance between the two neutral zones and $\rho$ is the radius of curvature. From these equations, the angle $\varphi$ is eliminated and the radius of curvature is found:

$$\rho = t_n(1 + \alpha_s \Delta T)/\alpha_{fs} \, \Delta T \sim t_n/\alpha_{fs} \, \Delta T \qquad (23)$$

The distance between the neutral zones is found after a tedious but straightforward calculation with the help of two conditions: there is no translation and the bending of the stack is stable. $\Sigma F = \Sigma M = 0$,

$$t_n/t = 2/3 + (m^2 n - 1)^2/6mn(m + 1)^2 \qquad (24)$$

with $t = t_f + t_s$, $m = t_f/t_s$, and $n = \acute{Y}_f/\acute{Y}_s$. When $m \ll 1$ and $mn \ll 1$, as usually is the case, then

$$t_n/t \sim 1/6mn \qquad (25)$$

$$\rho \sim t/6mn \, \alpha_{fs} \, \Delta T \qquad (26)$$

Again using Hooke's law and the expression for the fractional change in length we find the stress at the surface of both materials and at their interface,

$$Surface: \quad \sigma_{fc} = \acute{Y}_f \alpha_{sf} \Delta T[-am + b]/c \sim +\acute{Y}_f \alpha_{sf} \Delta T \quad (27)$$

$$Interface: \quad \sigma_{fc} = \acute{Y}_f \alpha_{sf} \Delta T[+am + b]/c \qquad (28)$$

$$Interface: \quad \sigma_{sc} = \acute{Y}_f \alpha_{sf} \Delta T[-a - bmn]/c \sim -4m \, \sigma_{fc} \quad (29)$$

$$Surface: \quad \sigma_{sc} = \acute{Y}_f \alpha_{sf} \Delta T[+a - bmn]/c \sim +2m \, \sigma_{fc} \quad (30)$$

with $a = 3mn(m + 1)$, $b = m^3 n + 1$, $c = 9mn(m + 1)^2 + (m^2 n - 1)^2$. Notice the difference between Eq. (19) and Eq. (29).

### 3.2.2. Intrinsic Stress

Another type of stress in films is called "intrinsic" stress. This is the stress present after deposition, at the deposition temperature. There are several mechanisms that might be responsible for the generation of intrinsic stress. Typical examples include incorporation of atoms (e.g., residual gases, precipitation inclusion, or energetic ion bombardment), chemical reaction as in thermal oxidation [171, 172, 181], recrystallization, dislocation rearrangements, lattice mismatch between film and substrate, excess vacancy annihilation, grain boundary relaxation, and phase transformations. As many of these effects are strongly temperature dependent, the residual intrinsic stress is sturdily influenced by postannealing steps. Therefore, if the deposition has been performed at an elevated temperature, the residual stress measured at room temperature afterward would include contributions from both the intrinsic stress and the thermal stress and the influence of thermal annealing should be considered.

As a typical example, a single-side PECVD silica film is taken [168]. Since these films are deposited at low temperature (e.g., 300–400 °C), lack of surface diffusivities of molecules may lead to considerable porosity. As a consequence, the films contain a significant concentration of hydrogen in the range of 3–5%, which makes an important contribution on the intrinsic compressive stress, bowing the wafer with the film on the convex surface. This compressive intrinsic stress can be lowered by out gassing the incorporated hydrogen at temperatures typically around 500 °C for 1 hour in nitrogen ambient—the process of densification (Fig. 38a). Thermal stress develops in thin films when high temperatures are involved and can be reached on purpose (annealing steps) or "unintentionally" (extra LPCVD film formation steps). Therefore, in order to understand the behavior of intrinsic stress, the thermal stress component must be subtracted from the measured residual stress. For simplicity, thermal stress can be estimated based on the assumption of constant material properties: $\sigma_{fc} = \alpha_{sf}\Delta T \acute{Y}_f$ [Eq. (18)]. Figure 38b shows a typical example of the decomposition of residual stress in a single-side PECVD silica film deposited at 300 °C, where the thermal stress is assumed to be zero. Apparently, the variation of stress with temperature is due to two superimposed effects: a constant linear thermal stress component, and a time and temperature dependent nonlinear irreversible intrinsic stress component. It should
be noted that the room temperature residual stress might be identical for a longer anneal step at a lower temperature to that for a shorter anneal step at a higher temperature. In the end it is in the first place, the hydrogen content influencing the intrinsic stress.

As temperature increases, residual gases are driven out due to the increase in chemical potential. In addition, the surface diffusivities of solid structure are also enhanced. Shrinkage then occurs in order to reduce the surface energy, and room temperature tensile intrinsic stress is generated. The tendency toward shrinkage is retained as temperature increases and the hydrogen content drops to below 0.2% at temperatures higher than 750 °C. However, as the temperature further increases silica films become viscoelastic and residual stress is gradually relieved by material flow [180]. As a result, the room temperature residual stress in silica films becomes again strongly compressive when cooled from very high densification temperature exceeding 750 °C (Fig. 39). Finally, silica films become stress-free at temperatures higher than about 900 °C and the residual stress becomes solely thermal stress.

### 3.2.3. Stress Gradient

Bending of even a single-layer structure can be caused by the existence of a stress gradient and is typically observed when releasing the structural layer in surface micromachining (Fig. 40). For example, during the deposition of a layer of aluminum, it is possible that the substrate heats up due to the impact and slowly increases in temperature during deposition. This means that the initial atomic layers have been deposited at a lower temperature than the final atomic layers. Therefore, after the film has been deposited a built-in thermal stress gradient will form causing bending of the structure. Another example is found in doping silicon. Inhomogeneous doping will result in an inhomogeneous internal stress gradient. Also, the formation and growth of grains in polycrystalline films as found in most metallic films will

**Figure 39.** Room temperature residual stress as function of the anneal temperature.

**Figure 38.** Residual film stress during a 500 °C anneal (a). Decomposition of residual stress into thermal and intrinsic stress (b).

**Figure 40.** Stress gradient in a single layer.

cause a stress gradient. For the formation of nanofilms it is important to realize that the initial layers ($<10$ nm) vary considerably in stress due to the mismatch with the underlying lattice of the substrate [183]. If the temperature during formation of a film with thickness $t_f$ increases with $\Delta T_{\text{form}}$, then the radius of curvature will be

$$\rho = t_f/(\alpha_f \Delta T_{\text{form}}) \tag{31}$$

### 3.2.4. Film Fracture

The ability to deposit films is limited by residual stress, which can result in substrate distortion or cracking of the film or even of the substrate. These stress problems tend to increase with thickness and annealing temperature and are a prime limitation to the deposition of very thick thin films. The excessive wafer-bow after densification causes difficulties for subsequent lithographic processing. Moreover, since wafer curvature (in case of single-side film formation processes) and film cracking both seriously impact process integrity and device reliability, it is important to elucidate the factors contributing to residual stresses in thin films and optimize the film formation process so as to reduce wafer curvature and to avoid film cracking. The critical annealing temperature at which cracking occurs can be predicted using mixed mode fracture mechanics as will be briefly treated in this section. Finally, some engineering solutions will be discussed to overcome fracture.

It is well known that film cracking only occurs when the film experiences a tensile stress. For example, since the thermal expansion of a silica film is less than that of silicon, cooling from the deposition temperature leads to compressive stresses in the silica film and will not result in failure. However, since the critical stress for shear flow in Si at 1000 °C is about 3.4 MPa, it is entirely plausible to see plastic deformation of silicon beneath discontinuities in growing $SiO_2$ layers (near the edges of windows, etc.) [181, 185]. The fracture mechanics of thin films has been analyzed by Hutchinson and Suo [167] and Zhang et al. [168]. The strain energy release rate $G_f$ [J/m$^2$] for a crack propagating in a thin film is given by

$$G_f = Z t_f \sigma_f^2 / \acute{Y}_f \tag{32}$$

$Z$ is a dimensionless parameter which depends on the particular cracking pattern. For example, short microcracks at the surface are often initiated from the edge and arrested by the interface. Sometimes the film exhibits long channelling cracks and a connected channel network surrounding islands of the intact film. For the microcracks $Z \sim 4$ and for the long cracks $Z \sim 2$. Fracture occurs when $G_f$ exceeds the intrinsic fracture energy $G_{\text{frac}}$ of the film material: $G_f > G_{\text{frac}}$. Using Eqs. (18) and (31) and $\sigma = \sigma_T + \sigma_I$ ($\sigma_I$ is the intrinsic stress at a certain temperature), the critical temperature

for fracture $T_{\text{frac}}$ can thus be expressed as a function of film thickness $t_f$:

$$T_{\text{frac}} > T_0 - (\sigma_I/\acute{Y}_f \alpha_{sf}) + \sqrt{(G_{\text{frac}}/Z\acute{Y}_f t_f \alpha_{sf}^2)} \tag{33}$$

Apparently, $T_{\text{frac}}$ decreases with increasing intrinsic tensile film stress, increasing difference in thermal expansion between the substrate and film $\alpha_{sf}$, and the square root of the film thickness.

### 3.2.5. Stress and Strain Diagnostics

Several methods have been developed to measure residual film stress, for instance wafer curvature, load-deflection technique (bulge method), dynamic methods relying on the shift of the resonant frequency in atomic force microscope (AFM) cantilevers, and *in-situ* micromachined stress and strain diagnostics.

*Wafer Curvature* A common way to measure stress in a film is by measuring how much a substrate bends after the film is deposited or processed (i.e., wafer curvature). In the absence of any movement restraints, the structure in Figure 41 will bend in order to balance the force moments caused by the stresses. For the top film in compressive stress (it wants to expand more than the bottom layer), as is the case in this example, the entire structure will bend with the edges downward relative to the middle. The amount of bending is dependent on the internal mechanical properties of the film and substrate (specifically Young's modulus and Poisson's ratio), the thickness, and the stresses in the film and substrate. By measuring the amount of bending, and knowing the film thickness and mechanical constraints, one can extract the stress in the film. If we assume that the film thickness is much smaller than the thickness of the substrate and that the film is in an isotropic biaxial stress state (i.e., $\sigma_z = 0$ and $\sigma_x = \sigma_y$), then the biaxial stress in the film $\sigma_f(=\sigma_x = \sigma_y)$ as derived from Eqs. (26) and (27) equals [178, 179]

$$\sigma_f = \frac{\acute{Y}_s}{6} \frac{t_s^2}{\rho t_f} = \frac{4}{3} \frac{Y_s}{(1 - \nu_s)} \frac{t_s^2 \delta}{D^2 t_f} \tag{34}$$

Here $Y_s$ is Young's modulus of the substrate, $\nu_s$ is Poisson's ratio for the substrate (typically $\nu_s = 1/4$), $t_s$ is the substrate thickness, $\rho$ is the radius of curvature (i.e., a measure of

**Figure 41.** Wafer curvature.

the bending), and $t_f$ is the film thickness. Alternatively, the deflection $\delta (\sim D^2/8\rho$ using simple goniometric considerations) at the center of a surface scan over a distance $D$ is a measure for the residual stress. In practice, the deflection or curvature is measured before and after the film is deposited (or before and after the film is processed in some way), since the wafer might not be flat to start with. Thus $1/\rho$ would be given by $(1/\rho_{\text{final}} - 1/\rho_{\text{initial}})$. The difference in curvature is then related to the stress induced by depositing or processing the film.

***Micromachined Diagnostics*** Specific freely suspended (freestanding) micromachined structures are often realized which, because of their sensitivity to residual stress, are useful for making *in-situ* measurements of residual stress. For instance, average compressive strain can be measured by determining the critical buckling length of clamped–clamped beams (Fig. 42a). For this, an array of clamped–clamped beams with stepwise increasing length is realized. The transition length between buckling and nonbuckling provides information on the residual compressive stress in the film. However, when the thin film exhibits a stress gradient in the normal direction, the buckling load is often decreased enormously. Tensile stress can be measured by a series of ring and beam structures, which are constrained to the substrate at two points (Fig. 42b). Tensile stress in the film results in a compressive load on the beam as shown. Curvature of a cantilever (single-supported) beam is a measure for the stress gradient in the direction of the film thickness (Fig. 42c). Other stress-diagnostic structures are so-called $T$ and $H$, diamond, and push–pull structures, and rotating pointers with or without Vernier gauges (Fig. 42d).

## 3.3. Film Adhesion

Film adhesion is an important property to be considered in film formation. Due to insufficient adhesion, freshly applied films can locally detach or even delaminate from the substrate. Evidently, this delamination is undesirable and proper surface modification is needed to promote correct film attachment to the substrate. Sometimes the adhesion can be improved simply by cleaning the substrate surface, but these solvents usually remove only oils and greases, leaving more tenacious materials such as surface oxides, which may prevent interdiffusion and thus adhesion. For films
formed from the gas phase, the adhesion is generally promoted by including plasma presputtering, which removes the surface oxide, before forming the new layer (Fig. 43). In case of liquid-phase film formation, (chemical) surface modifiers are coated prior to the new film being formed. In case of solid-phase-formed films, surface properties such as roughness are important and, therefore, the substrate is commonly polished before the next layer is formed.

## 3.4. Film Step Coverage, Planarization, and Capping

In general, before forming a new thin film, the surface of a substrate will have a complex topography (Fig. 44). Trenches and patterned layers from earlier process steps will cover the surface. Conventional methods experience difficulty in depositing metals or oxides conformal on such stepped surfaces. In many cases, more film tends to build on top surfaces than into trenches or at their sidewalls, showing a pronounced tendency for narrow spaces to be covered before completely filled, creating voids. Step coverage relates the surface topography of a deposited or grown film to the previous wafer irregularities. Films formed from the gas phase differ from films from the liquid phase in what kind of forces control the layer thickness along these surface steps. The same accounts for films deposited from the solid phase. For gas-phase-formed films, the layer thickness largely depends on the phenomena from the individual atoms such as gas-phase collisions and surface migration. In the case of liquid-phase-formed films, bulk properties of the deposited film are more important such as gravitational forces, surface tension, and wettability. To improve step coverage an option is to etch back a formed layer using polymer or spin-on-glass (SOG) with subsequent plasma etching or CMP.
### 3.4.1. Gas-Phase Film Formation

In this overview, the term step coverage is used when the film is formed out of the gas phase. The layer thickness along the step largely depends on the trajectory of the individual particle in the gas phase and on the substrate surface before coming at rest. In the gas phase we have to consider the mean free path between collisions of the particle before reaching the substrate surface. Then, when a particle

**Figure 43.** Surface treatment to improve adhesion.

**Figure 44.** Processed wafer surface during MEMS processing.

has reached the surface, the required reaction analysis is the same, regardless of the formation method. In the ideal, or conformal, step coverage film, the thickness is uniform along all surfaces of the step (Fig. 45). This conformal coverage is due to the rapid migration of reactants after adsorption on the step surface and before a bond is established with the underlying substrate.

The molecular phenomena at the surface to be considered include thermally activated processes such as sticking coefficient, surface adsorption, surface diffusion, surface reaction, desorption, and film or crystal growth. A process controlling step coverage and trench filling issues is that of desorption of reacting species before any reaction can occur. This is related to the sticking probability and becomes important in low-pressure systems, since the desorbed species redeposit elsewhere such as the sidewall of a trench or contact hole. In CVD processes the emission and redeposition process may occur quite readily, corresponding to a low sticking coefficient, and can lead to better coverage. Surface migration or diffusion can also occur on a more long-range scale on nonflat topographies due to surface curvature and surface energy reduction considerations. This can affect coverage and filling in a similar manner to sticking probability. Surface migration is increasing with the kinetic energy of the adsorbed species and, therefore, a higher temperature will normally improve step coverage. High-temperature CVD deposited polysilicon and silicon nitride, and thermally grown silicon oxide, often show conformal step coverage. In physical vapor deposition (PVD), the sticking probability of the depositing species is usually very close to one, meaning that they stick where they hit and there is little or no redeposition of material to other regions. Surface diffusion is also very slow at low temperatures. In addition, there is also no resputtering of material in evaporation systems, as in the case of PECVD or sputter PVD, due to ion bombardment.
All these issues lead to very poor step coverage. Clearly, heating the substrate during deposition may improve step coverage.

At lower temperatures, the surface migration is minimal and gas-phase collisions determine step coverage. Two major categories can be distinguished: low-pressure direct line-of-sight impingement methods and high-pressure diffusive–convective mass transfer techniques.

At the lower pressures employed in a PVD reactor, the vaporized material encounters few intermolecular collisions while travelling to the substrate. Modeling of deposition rates is a relatively straightforward geometrical line-of-sight exercise in this case. Figure 46 shows an example of a nonconformal step coverage, which results when reactants travel almost without intermolecular gas-phase collisions and adsorb and react without significant surface migration. In this instance the deposition rate is proportional to the arrival angle of the gas molecules. Reactants arriving along the top horizontal surface come from many different angles and $\phi_1$, the arrival angle, varies in two dimensions from 0 to 180° while reactants arriving at the top of a vertical wall have an arrival angle $\phi_2$ that varies from 0 to 90°. Thus the film thickness on the top surface is double that of a corner wall. Further down the wall, $\phi_3$ is related to the width of the opening, and the film thickness is proportional to $\phi_3 \approx$ arctan $(W/H)$ where $H$ is the distance from the top surface and $W$ is the width of the opening. This type of step coverage is thin along the vertical walls, with a possible crack at the bottom of the step caused by self-shadowing. Most evaporated or sputtered metal films have step coverage similar to this. As will be found in the section concerning resist lithography this type of step coverage can be used for lift-off pattern transfer.

In the case of a CVD reactor, the diffusive–convective transport to the substrate due to the higher pressures used involves many intermolecular collisions (except for deep trenches smaller in dimension than the mean free path between collisions). Accordingly, mass and heat transfer modeling of deposition rates becomes more complex. In Figure 47, the mean free path is too short to reach the bottom and there is little surface migration. In such cases, the film thickness is directly proportional to the range of feasible angles of arrival, $\phi$, of the depositing species. The arrival angle at a planar surface is $\phi_1 = 180°$. At the top of a vertical step, the arrival rate is nonzero over a range of $\phi_2 = 270°$; the resultant film thickness is 270/180, or 1.5 times greater than for the planar case. At the bottom corner of a

**Figure 45.** Ideal (conformal) step coverage. Rapid surface migration.

**Figure 46.** Non-conformal step coverage. Little surface migration and large mean free path.
**Figure 47.** Nonconformal step coverage. Little surface migration and small mean free path.

trench the arrival angle is only 90°, and the film thickness is 90/180, or one-half that of the planar case. The CVD profile of Figure 47, where the mean free path is short compared to the trench dimensions and there is no surface migration, reflects the 90, 180, 270 arrival angles. The thick cusp at the top of the step and the thin crevice at the bottom combine to give a reentrant shape that is particularly difficult to cover with PVD material in a subsequent process step. Gas depletion effects also are observed along the trench walls. Low-temperature plasma-deposited silicon oxide and silicon nitride are typical examples of this kind of step coverage.

### 3.4.2. Liquid-Phase Film Formation

For films formed from a liquid solution, bulk properties of the film and substrate determine the step coverage of the formed layer. Important phenomena to consider are surface free energy, wettability, and viscosity and include inertia effects caused by fast rotation in a spindle as in spin coating. In general, the term planarization is used in such cases. In the ideal case, the deposited film will perfectly fill any surface irregularity and forms a flat surface as shown in Figure 48. This result is then called full or ideal planarization.

When planarization is not ideal, the term degree-of-planarization (DOP) is used, defined as DOP = $(1 - [T_{plan}/T_{step}])$ as shown in Figure 49. A smoothing liquid should exhibit two properties, that is, filling in gaps and flattening of a film's top surface. Currently, polyimides and BCB polymers are able to planarize large pitch geometry to a 95% level with a single coat. Reluctance to expand the use of polyimide as an insulating material at this point is linked to its poor barrier properties toward moisture and ions. It is important to notice that the DOP depends on the dimension of a trench; a small but deep trench ($T_{plan1}$ in Fig. 49) is much easier to planarize than a wide trench ($T_{plan2}$). Clearly,

**Figure 49.** Degree of planarization (DOP).

the thickness of the coating at the bottom of the trenches far away from the edges of structures will be identical to the thickness of the coating on top of the structures, again far away from edges. Another phenomenon (typically observed during spin-coating) is the forming of so-called edge bead at the edges of structures (including the edge of the wafer). It is caused by the influence of centrifugal forces on the surface tension forces.

### 3.4.3. Solid-Phase Film Formation

When a film is formed from the solid phase, such as the placement of a foil—by way of lamination or bonding—on top of a structured surface, bulk properties of the solid film, such as the modulus of elasticity and stress relaxation, determine the step coverage. In such cases, film capping can be used as a measure to describe the step coverage. In the ideal case, the film will nicely stretch along the valleys forming a straight bridge or membrane cap as found in Figure 50. This result is then called ideal capping. In general, a thicker film is much more difficult to deform than a thin film. Therefore, thick films such as bonded wafers on top of patterned substrates look like the perfect capping.

In general, the newly formed film will cap trenches and holes and, therefore, gas inclusion (including vacuum inclusion) cannot be prevented. The difference in pressure between the capped volume and the environment will cause bending of the film as shown in Figure 51. Film stress caused by differences in (thermal) extension between the substrate and the film will have the same effect. For example, when the film is under compressive stress, the film might buckle and deform as indicated in Figure 51. When the film creates a tensile stress with respect to the underlying substrate, the film will nicely stretch across the valley and will have an almost perfect capping.

### 3.5. Film Mixing/Alloying

Bimetallic systems exhibit eutectic characteristics; that is, the addition of either component lowers the system's melting point below that of either metal. For example, in the

**Figure 48.** Ideal planarization.

**Figure 50.** Ideal capping.

**Figure 51.** Film deformation.

Al–Si system the minimum melting temperature, called the eutectic temperature, is 577 °C, corresponding to an 11.3% Si–88.7% Al composition. The melting points of pure aluminum and pure silicon are 660 and 1412 °C respectively. Because of the eutectic characteristics, during aluminum deposition the temperature on the silicon substrate must be limited to less than 577 °C. Hence, wherever aluminum contacts silicon, the silicon will dissolve into the aluminum during annealing. For example, the solubility $S$ of silicon in aluminum is 0.25 wt% at 400 °C and $S = 0.8$ wt% at 500 °C. The opposite, that is, the dissolving of aluminum into silicon, will also occur but is only pronounced at temperatures close to the melting point of silicon. The amount of silicon dissolved will depend not only on the solubility at the annealing temperature but also on the volume of aluminum to be saturated with silicon. Consider a long aluminum metal line with a thickness $H$ and a width of $W$ in contact with an area of $WZ$ of silicon. After an annealing time $t$, the silicon will diffuse a distance of approximately $\sqrt{(Dt)}$ along the aluminum line from the edge of the contact, where $D$ is the diffusion coefficient given by $0.04 \exp(-0.92/kT)$ for silicon diffusion in deposited aluminum films. Assuming that this length of aluminum is completely saturated with silicon, the depth to which silicon will be consumed is

$$b \sim 2(H/Z)S\sqrt{(Dt)} \qquad (35)$$

The diffusion coefficient of silicon in aluminum at 500 °C is about $D = 2 \times 10^{-8}$ cm$^2$/s and $S = 0.8$ wt%. Therefore, after a time $t = 30$ min, $\sqrt{(Dt)}$ is 60 $\mu$m. When $Z = 1$ $\mu$m and $H = 1$ $\mu$m, aluminum will fill a depth of ca. 1 $\mu$m from which silicon is consumed. In a practical situation, the dissolution of silicon does not take place uniformly but rather at only a few points. Therefore, the effective area is less than the actual contact area. Hence $b$ is much larger. In such situations spikes are formed at only a few points where aluminum is penetrating the silicon. One way to minimize the aluminum spiking is to add silicon to the aluminum by co-evaporation until the amount of silicon contained by the alloy satisfies the solubility requirement. Another option is to form a layer in between the two mixing layers (i.e., a barrier layer such as tantalum or titanium).

## 3.6. Film Structure

Thin films are formed to establish specific electrical, mechanical, or chemical properties. It is well known that these properties may be quite different from those of the bulk, particularly if the film thickness is very small. These "anomalous" properties are due to the peculiar (nano)structure of the film. This structure—in turn—is dictated by processes which occur during film formation. So the film formation method, the film thickness, and the resulting film structure greatly affect the film properties. The film structure is characterized by crystallographic orientation, texture, defects, crystal size, and morphology. Evidently, many parameters will affect the film structure such as the energy and direction of the incoming particles, its binding energy to the substrate and to each other, the temperature of the substrate, surface mobility, substrate surface morphology (crystalline, amorphous, rough, etc.), deposition rate, and the presence of "alien" particles. The surface morphology of surfaces can be subdivided into three types: monocrystalline, polycrystalline, and amorphous as shown in Figure 52. In crystalline solids (Fig. 52a), the atoms are neatly stacked and this order extends to macroscopic dimensions. Polycrystalline films are different and can be either microstructured or nanostructured (Fig. 52b). Microstructured films show structural variation (morphology) on a micrometer scale. In nanostructured films (also called nanophase films), this variation has decreased to nanoscale dimensions. Finally, amorphous films (Fig. 52c) exhibit short-range order only—the average distance between neighboring atoms or molecules corresponds to the film density. Because the nanoscale lies in between the microscopic and the atomic scale, it is also referred to as the mesoscopic domain (meso = Greek for middle).

The first (initial) formed monolayers of a film often determine the resulting film structure and therefore, in general, two stages are distinguished in film formation: the initial stage (nucleation, island, and coalescence) and actual stage

**Figure 52.** Film structure. (a) Monocrystalline. (b) Polycrystalline. (c) Amorphous.

as shown in Figure 53. During the initial stage, chemical and physical properties of the substrate, and interaction between substrate and particles (atoms or molecules) arriving, play an important role. The process of nucleation (Fig. 53a) can be briefly described as follows: incoming particles collide with the substrate surface, adsorb, migrate (up to 50 nm or more), collide with each other, cluster, and show a stable condensate when a specific critical dimension is reached. Energetically, the surface of a (crystalline) substrate surface is like an egg carton, with each of the depressions constituting a temporary resting point or adsorption site for the depositing and migrating atoms. At each "hop," the atom will either jump over the barrier into an adjacent site or might reevaporate (a measure for this is the sticking probability). After a time, the atom will either evaporate from the surface or will join another migrating atom to form a doublet, which is less mobile and more stable than a single atom. The change of forming a doublet will depend on the single atom density and hence on the arrival rate and sticking probability. In time, the doublets will be joined with other atoms to form triplets, quadruplets, and so on. This leads to the formation of quasi-stable islands, each containing tens or hundreds of atoms at a density of $10^{10}/cm^2$ (i.e., one island every 100 nm). Growth of the islands is three-dimensional, but the growth parallel to the substrate is greater than that normal to it. This is probably because deposition occurs largely by the surface diffusion of monomers on the substrate, rather than by direct impingement from the vapor phase. During the next phase of the initial stage (Fig. 53b), the islands grow in size rather than in number. Each island is usually single crystal or contains just a few crystals. Eventually, the islands grow large enough to touch—this is the agglomeration or coalescence stage (Fig. 53c). Coalescence proceeds until the film reaches continuity (Fig. 53d), but this may occur in some cases until the film is several tens of nm in average thickness. During the initial formation, the film typically consists of hills and valleys. The initial phase is known well and experimentally observed with for example, transmission electron microscopy and it appears that the islands often display liquidlike behaviour during coalescence. There are often crystallographic reorientations as a result of competition between the structures of the coalescing islands.

**Figure 53.** Film deposition stages. (a) Nucleation stage. (b) Island stage. (c) Coalescence stage. (d) Actual stage.

On a monocrystalline substrate, the islands orientations may be determined by the substrate structure so that nucleation and coalescence lead to a single crystal film. This is the phenomenon of epitaxy. If surface atoms are mobile, they have a greater opportunity of finding low energy positions, consistent with the crystal lattice. Mobility is enhanced by increased substrate temperature, but since it also takes time to find an energetically favorable lattice position, crystal formation is also encouraged by low deposition rates. Hence, on single crystal substrates, for each deposition rate there will be a temperature, the epitaxial temperature $T_{epi}$, above which single crystal films can be formed. Obviously, on a polycrystalline substrate the orientation of the resulting film is polycrystalline too, but on an amorphous substrate the surface lattice will be random and the initial deposition will favor the ⟨111⟩-orientation due to the higher packing density. The same mechanisms hold as in single crystal formation so that high substrate temperature and low deposition rate lead to large grains and low density of crystal defects.

After an initial layer—covering the substrate—has formed, actual formation begins, during which only interaction occurs between particles of the film material. Important parameters are the energy of the particles arriving at the film surface, energy absorption at the time of collision, chemical and physical interaction between adatoms and film surface, pressure, and temperature. These parameters determine, to a great extent, the morphology (overall shape of the film and the geometry of crystallites or amorphous structures inside the film) and texture (orientation of crystallites). The structure of the film is found to be extremely sensitive to deposition conditions. For example, high-energetic electron or ion bombardment either prior to or during deposition is found to encourage film continuity and reduce epitaxial temperatures. Several mechanisms can cause the formation of oriented layers. If the lattice constants of substrate and film material approximately match each other, epitaxial deposition can occur and even if they do not match, oriented deposition is often observed. Increase of orientation during actual deposition is based on different deposition rates of the crystal planes. Starting from random crystal orientation in the initial layer, crystals with the fastest depositing crystal plane parallel to the substrate, such as the (111)-plane, "survive" at the cost of the others. This phenomenon is also known as "survival of the fastest" and implies a related increase of crystal orientation and grain size with film thickness (taperwise film formation). Even when the film is initially well oriented, taperwise film formation might occur due to thermodynamically driven coalescence of crystallites (grain-boundary movement).

In general, the morphology of the film is greatly affected by the temperature of the substrate $T_s$ and the melting temperature $T_m$ of the film material. There is a trend with increasing temperature for the morphology to change from amorphous to fine-grained polycrystalline to polycrystalline to monocrystalline. When $T_s < 0.3T_m$, called zone I, amorphous or porous layers with rough surfaces are formed due to low adatom mobility (slow surface diffusion) and shadowing. When $0.3T_m < T_s < 0.45T_m$ (i.e., zone II), adatom mobility is high enough to overcome the shadow effect and deposition is controlled by surface diffusion, resulting in more dense layers with small columnar grains. When

$0.45 T_m < T_s < T_{epi}$, zone III, due to bulk diffusion, smaller grains coalesce to form larger, not necessarily columnar, grains. Finally when $T_s > T_{epi}$, epitaxial layers might form at single-crystalline substrate surfaces because grains and boundaries vanish. Homogeneous gas-phase reactions might incorporate nanosized particles into a film during deposition, altering the film morphology. The impact of fast moving particles from the gas phase alters film morphology even further. For example, due to collisions with argon ions (in plasma enhanced deposition), the energy of the particles arriving at the surface decreases with argon pressure, leaving less energy for surface diffusion. Besides, at high pressures, adsorbed argon limits adatom mobility. Therefore, the transition temperatures between zone I and II increase with pressure. The transition temperature between zone II and III is independent of pressure, since this transition is determined by bulk diffusion.

## 3.7. Film-Formation Methods

Considerations in selecting a film formation process are, for example, the substrate temperature and morphology, film deposition rate, uniformity, structure, stress and adhesion, electrical and mechanical properties, and chemical composition and inertness of the films. In general, for the deposition of thin films used in microelectronics, low-pressure gas-phase processes are preferred over the older conventional chemical liquid-phase methods such as electroplating, because deposition from an aqueous solution often produces poorer quality films. On the other hand, electrochemical deposition is gaining renewed interest with microstructures because of their emerging importance to replication of photoresist molds. As listed in Table 7, thin films can be formed by various methods and are conveniently divided into deposition or growth from the gas phase, liquid phase, and solid phase. The methods include chemical vapor deposition, physical vapor deposition, chemical vapor growth (CVG), and physical vapor growth (PVG). The most common CVD processes are low-pressure CVD, atmospheric-pressure CVD, VPE, plasma-enhanced CVD, metal-organic CVD, and pyrolysis. Well-known PVD processes are evaporation, laser ablation, plasma sputter deposition, MBE, cluster beam, and ion plating. The vapor growth group has only a few members; thermal oxidation and diffusion (both CVG) and ion implantation (PVG). Liquid-phase film formation methods, involving thin and thick organic materials, are of extreme importance to the construction of chemical and biological sensors. Except for liquid-phase epitaxy and self-assembling monolayers (SAMs), most chemical liquid deposition (CLD) processes are electrochemically driven, such as electroplating, immersion plating, and electroless plating. Physical liquid deposition (PLD) processes are all kinds of coating techniques such as spinning, dipping, spraying, painting, casting, and melting. There is only one practical electrochemical liquid growth (ECLG) method: anodization. The solid-phase film formation is important in packaging and the development of encapsulated mechanical structures. We can distinguish between physical solid deposition (PSD) methods (including direct, anodic, adhesive, eutectic, and compression bonding) and chemical solid growth (CSG) methods (solid-source diffusion such as doping).

### 3.7.1. Chemical Vapor Deposition

During chemical vapor deposition, the constituents of a vapor phase, often diluted with an inert carrier gas, are introduced into a reaction chamber and adsorbed on a heated surface. The adatoms undergo migration and film-forming reactions to form the desired film. In CVD, the diffusive–convective transport to the substrate involves many intermolecular collisions. Therefore, the reactions forming a solid material do not always occur on or close to the heated substrate (heterogeneous reactions) but can also occur in the gas phase (homogeneous reactions). As homogeneous

**Table 7.** Film formation methods.

| State | Technique | Example | State | Technique | Example |
|-------|-----------|---------|-------|-----------|---------|

reactions lead to gas-phase cluster deposition and result in poor adhesion, low density, and high defect films (pinholes), heterogeneous reactions are preferred. The most favorable end-product of a CVD reaction is a stoichiometric-correct film. Several activation barriers need to be surmounted to arrive at this stoichiometric film. Some energy source, such as thermal, photons, electron or ion bombardment, is required to achieve this. The CVD method is very versatile and can create amorphous, polycrystalline, uniaxially oriented polycrystalline, and epitaxial layers with a high degree of purity and control. Figure 54 illustrates the various transport and reaction processes underlying CVD with the numbers representing the following:

1. mass transport of reactant gases and diluents in the bulk gas flow region to the deposition zone
2. homogeneous gas-phase reactions leading to film precursors and by-products
3. mass transport of film precursors and reactants to the substrate surface
4. adsorption of film precursors and reactants on the substrate surface
5. heterogeneous surface reactions of adatoms occurring selectively on the heated surface
6. surface migration of film formers to the deposit sites
7. incorporation of film constituents into the depositing film, that is, nucleation (island formation)
8. desorption of by-products of the surface reactions
9. mass transport of by-products in the bulk gas flow region away from the deposition zone

A full treatment of the kinetics of CVD processes would involve all the steps in Figure 54. However, it is often sufficient to consider the fluxes for the mass transport (i.e., diffusion) and surface reactions processes only and equate them under steady state conditions.

**Diffusion-Controlled Processes** The mass transport in the gas phase takes place through diffusion proportional to the diffusivity of the gas $D$ and the concentration gradient $\Delta c$ across the boundary layer that separates the bulk flow (source) and substrate surface (sink). The flux of deposited material is found with the help of Fick's first law: $\phi = D\, dc/dx = D(3\Delta c/2L)\sqrt{R_e}$, where $L$ stands for the length

of the plate being deposited on and $R_e$ is Reynolds number which is proportional to the gas flow velocity $U$ and inversely proportional to the source gas molecular weight $M$. According to this equation, the film deposition rate $DR$ should depend on the square root of $U$ and be inversely proportional to the square root of $M$. Therefore, $DR(U)/DR_{Uo} = \sqrt{[U/U_o]}$, where the constant $DR_{Uo}$ represents the deposition rate at velocity $U_o$. Taking the logarithm of both sides we arrive at

$$\log[DR(U)/DR_{Uo}] = \log\left[\sqrt{(U/U_o)}\,\right]$$
$$= 1/2\ \log[U/U_o] \qquad (36)$$

**Thermally Activated Processes** The surface-reaction processes can be modeled by a thermally activated phenomenon—as shown in Figure 55, left—proceeding at a rate $DR(T) = DR_\infty \exp(-E_a/kT)$, where $DR_\infty$ is the maximum deposition rate (also called the frequency factor) at $T \Rightarrow \infty$, $E_a$ is the activation energy (J), $T$ is the temperature (K), and the Boltzmann's constant $k = 1.38 \times 10^{-23}$ J/K. Many times it is more convenient to express the activation energy in electronvolts (1 eV $= 1.60 \times 10^{-19}$ J). In such cases, we take $k = 86 \times 10^{-6}$ eV/K. Identically, when the activation energy is expressed in J/mol, we write $DR(T) = DR_\infty \times \exp(-E_a/RT)$, with the molar gas constant $R = 8.3$ J/molK. Replacing $E_a/k$ ($E_a$ in J) or $E_a/R$ ($E_a$ in J/mol) with $T_a$ we find: $DR(T)/DR_\infty = \exp(-T_a/T)$. $T_a$ is the activation temperature, the temperature $T$ at which the rate $DR$ is $\exp(-1) \sim 0.37$ times the maximum value $DR_\infty$. For

**Figure 55.** Temperature-controlled processes. Left: Relative rate $DR/DR_\infty$ versus temperature $T$ for various activation energies. Right: Arrhenius plot of the same function [i.e., $\log(DR/DR_\infty)$ versus reciprocal temperature $1/T$].

**Figure 54.** Schematic of a CVD process.

example, an activation energy of 1 eV resembles an activation temperature of 11,604 K. Taking the logarithm of both sides we arrive at the Arrhenius equation:

$$\ln[DR(T)/DR_\infty] = 2.30 * \log[DR(T)/DR_\infty] = -T_a/T \quad (37)$$

So if $\ln[DR(T)/DR_\infty]$ is plotted against the reciprocal temperature $1/T$, a straight line is found with slope $-T_a$ and from this slope the activation energy of the rate determining surface process can be deduced (Fig. 55, right). When the temperature changes from $T_1$ to $T_2$,

$$\log[DR(T_1)/DR(T_2)] = (T_a/2.3) * (1/T_2 - 1/T_1) \quad (38)$$

For example, when the activation temperature is 11,604 K ($E_a = 1$ eV) and the temperature changes from $T_1 = 100$ K to $T_2 =$ infinite (i.e., the reciprocal temperature $1/T$ changes from 0.01 toward zero), then we compute $\log[DR(T_1)/DR(T_2)] = (11604/2.3) * (-0.01) = -50$ (Fig. 55, right). For small changes in temperature ($T_1 \sim T_2$) we arrive at $1/T_2 - 1/T_1 = (T_1 - T_2)/T_1*T_2 \sim (T_1 - T_2)/T^2$ [i.e., $d(1/T) = -d(T)/T^2$]. So

$$T_a = T^2 * 2.3 * \log[DR(T_1)/DR(T_2)]/(T_2 - T_1) \quad (39)$$

Assume a process near room temperature (300 K) where the deposition rate doubles with an increase in temperature of 9 K. Then $T_a = (300)^2 * 2.3 * \log[2]/9 = 10,000 * 2.3 * 0.3 = 6900$ K is calculated and thus the activation energy is $6900/11,604 \sim 0.6$ eV. At room temperature, the thermal energy $kT = 0.026$ eV and, therefore, processes having an activation energy $E_a < 0.02$ eV will nearly depend on temperature above room temperature because the thermionic deposition rate is almost saturated. Saying it differently, processes which are almost independent of temperature are indicative for processes having small activation energy.

***Diffusion and Thermionic Processes***   In general, the deposition rate will depend on both the mass-transport and the surface-reaction processes. At high flow rates, the growth rate reaches a maximum and then becomes independent of flow. In this regime, the surface-reaction rate controls the deposition, no matter how high the flow rate is increased. This regime is referred to as surface-reaction limited deposition. On the other hand, at high temperatures, the reaction rate cannot proceed any faster than the rate at which the reactant gases are supplied to the substrate by mass transport, no matter how high the temperature is raised. This situation is referred to as mass-transport (or diffusion) limited deposition. These two limiting cases are analogous to the CVG oxidation cases (see Section 3.7.3), but the deposition rate in both regimes is now linear with time; neither is parabolic. In the intermediate region where both the mass-transport and the reaction rate are important it is possible to arrive at the deposition rate by combining the flow-rate and reaction rate dependent equations so that the smaller of the two dominates (two processes acting in series):

$$DR(T, U) = DR(T) * DR(U)/[DR(T) + DR(U)] \quad (40)$$

$$DR(T, U)/DR_\infty = \exp(-T_a/T) * \sqrt{(U/U_o)}$$
$$/[(DR_\infty/DR_{Uo}) \exp(-T_a/T)$$
$$+ \sqrt{(U/U_o)}] \quad (41)$$

$$2.3 * \log[DR(T, U)/DR_\infty] = (-T_a/T) + 1/2 \ln(U/U_o)$$
$$- \ln[(DR_\infty/DR_{Uo}) \exp(-T_a/T)$$
$$+ \sqrt{(U/U_o)}] \quad (42)$$

The resulting deposition rate behaves as shown in Figure 56. The transition region is located where $DR(T) = DR(U)$, that is, at $T_{trans} = T_a/[\ln(DR_\infty/DR_{Uo}) + 1/2 \ln(U_o/U)]$.

Thin films deposited by CVD may be doped during the deposition process. This is common for oxides, polysilicon, and epitaxial silicon. The dopant is introduced at the same time as the silicon tetrachloride during epitaxial growth. Gaseous diborane ($B_2H_6$) is used as the *p*-type dopant, while phosphine ($PH_3$) and arsine ($AsH_3$) are used as *n*-type dopants. Gas mixtures are ordinarily used with hydrogen as the diluent to allow reasonable control of flow rates for the desired doping concentrations. CVD can be used to deposit compounds, such as $SiO_2$ and $Si_3N_4$, as well as elements. However alloys, such as Al(2%Cu), are much more difficult. The problem is usually that separate reactions are required for each constituent (Al and Cu in our example) and it is difficult to avoid unwanted reactions between the different reactant species, or precursors. In addition, it is hard to control the exact composition of the alloy, because unlike compounds where limited compositions result (very close to 2:1 oxygen-to-silicon in $SiO_2$), a wide range of alloy compositions are possible. PVD methods are usually better suited for alloy deposition. The most common CVD processes will be treated next: APCVD and LPCVD, VPE, PECVD and HDPECVD, and pyrolysis. Other, less common, approaches such as VLPCVD very low pressure CVD and MOCVD metal-organic chemical-vapor deposition, which uses metal-organic compounds to grow a film, will not be discussed in detail.

***APCVD vs LPCVD***   The thermal energy is the sole driving force in high temperature CVD reactors such as APCVD (atmospheric-pressure CVD) and LPCVD (low-pressure CVD). In a hot-wall LPCVD reactor, a quartz tube is heated by a three-zone furnace and gas is introduced at one end

**Figure 56.** Arrhenius plot for a CVD process.

and pumped out at the opposite end. The quartz tube wall is hot because it is adjacent to the furnace. Typical reaction chamber pressures vary from 30 to 250 Pa (0.25 to 2 Torr) and temperatures are normally 300 to 900 °C. Among the benefits of this reactor are that it deposits films with excellent uniformity and large throughput. However, the gases used may be toxic, corrosive, or flammable. The APCVD reactor is similar to resistance heated hot-wall oxidation furnace except that different gases are used at the gas inlet. In contrast, in a cold-wall APCVD reactor such as the epitaxial reactor, the wafers are heated by using a graphite susceptor, which is heated by rf induction.

A direct practical application of the possible rate-limiting processes is the way substrates are stacked in LPCVD vs APCVD reactors. In a LPCVD reactor, the diffusion of the gas species is increased by a factor 1000 over that in APCVD due to the difference in pressure, resulting in a one order of magnitude increase in the transport of reactants to the substrate. The rate-limiting step becomes the surface reaction. This is an important result because it is easier to achieve a uniform temperature distribution than a uniform arrival of gas species across a wafer surface. Therefore, deposition is more uniform at higher flow and lower temperature settings. LPCVD reactors enable wafers to be stacked vertically at very close spacing as the rate of arrivals of reactants is less important. Polysilicon is usually deposited at lower temperatures in LPCVD systems and in the surface-reaction regime. Here the gas-phase processes are not important (so that stacking of wafers is possible), but the deposition is very temperature sensitive. On the other hand, APCVD, operating in the mass-transport-limited regime, must be designed such that all locations on the wafer and all wafers are supplied with an equal flux of reactant species. In this case the wafers often are placed horizontally.

***VPE-APCVD*** Among various epitaxial processes, vapor phase epitaxy is by far the most important. Epitaxial Si deposition has traditionally been done at higher temperatures (typically in APCVD systems) to ensure that all the Si atoms being deposited are incorporated into lattice sites in order to obtain a single-crystal thin film. This means that epitaxial Si in these systems is deposited in the mass transport regime where gas-phase processes are important. The epitaxial process offers an important means of controlling the doping profiles so that device and circuit performance can be optimized. For example, a semiconductor layer with a relatively low doping concentration can be grown epitaxially upon a substrate, which contains the same type of dopant in a much higher concentration (e.g., *n*-type silicon on a $n^+$-silicon substrate or undoped layer on top of a silicon wafer). In this way the series resistance associated with the substrate can be substantially reduced. Many device structures, especially for microwave and photonic devices, can be made on top of such so-called epi-wafers. Four silicon sources have been used for VPE-APCVD growth: silicon tetrachloride ($SiCl_4$, reacting at 1200 °C), trichlorosilane ($SiHCl_3$, 1150 °C), dichlorosilane ($SiH_2Cl_2$, 1100 °C), and silane ($SiH_4$, 1000 °C). The overall reaction of $SiCl_4$, the most widely used source, that results in the deposition of silicon layers is

$$SiCl_4 + 2H_2 \Longleftrightarrow Si + 4HCl \qquad (43)$$

An additional competing reaction is taking place that results in etching:

$$SiCl_4 + Si \Longleftrightarrow 2SiCl_2 \qquad (44)$$
As a result, if the silicon tetrachloride concentration is too high or if the carrier gas entering the reactor contains HCl, etching with speeds up to 5 $\mu$m/min rather than deposition of silicon will take place. Actually, this etching operation is used for *in-situ* cleaning of the silicon wafer prior to epitaxial growth.

***Pyrolysis LPCVD*** Very-low-temperature CVD will become more important as microdevices incorporate materials (e.g., aluminum or polymers) not able to withstand high post-temperatures. For example, a low-pressure reactor operated between 600 and 650 °C is used to deposit polysilicon by pyrolyzing silane according to

$$SiH_4 \rightarrow Si + 2H_2 \qquad (45)$$

***MOCVD*** To improve step coverage, sometimes metals can be deposited by MOCVD using metal-organic compounds such as tri-isobutyl aluminum:

$$2[(CH_3)_2CHCH_2]_3Al \rightarrow 2Al + 3H_2 + \text{by-products} \qquad (46)$$
***PECVD and HDPECVD*** Sometimes there are restrictions on the temperature that the substrate can be exposed to when depositing a film. The most obvious example is when depositing a silicon dioxide when an aluminum layer is already in place. The melting point of Al is 660 °C, and any subsequent processing temperature must be less then about 450 °C. Another example is the use of the lift-off technique where the resin should withstand the deposition temperature. Finally, phase transitions may occur at temperatures substantially lower than the melting temperature of the layer deposited (such as between amorphous silicon and polysilicon or eutectic alloying).

For lower temperature deposition, an additional energy source is needed, as found in PECVD (plasma-enhanced CVD). PECVD is an energy-enhanced CVD method, because plasma energy is added to the thermal energy of a conventional CVD system. The parallel-plate PECVD consists of a cylindrical glass or aluminum chamber sealed with aluminum endplates (Fig. 57). Inside are two parallel aluminum electrodes. Wafers are placed on the lower electrode (anode), which is heated between 100 and 400 °C by

**Figure 57.** Thin film PECVD reactor.

resistance heaters. Process gas flows through the discharge from outlets located along the circumference of the lower electrode. An rf voltage is applied to the upper electrode, while the lower electrode is grounded. The rf voltage causes a plasma discharge between the electrodes. In the plasma, interactions with the high-energy electrons cause the reactant gases to dissociate and ionize into a variety of species. Most species are extremely reactive, such as $SiH_3$ in deposition and F in etching, and are absorbed onto the wafer surface, migrate, interact, rearrange, and chemically recombine to form the film. The net result is that the deposition can occur at much lower temperatures. However, its throughput is low, especially for large-diameter wafers, and the wafers may become contaminated if loosely adhering deposits fall on them (flaking).

The reactions and processes that occur in a PECVD system are complicated and difficult to predict. The complexity of the plasma reactions can lead to nonstoichiometric compositions of films (e.g., Si-rich $SiO_2$), as well as the incorporation of $H_2$ or $N_2$ by-products into the film. This can result in outgassing, peeling, or cracking of the film during subsequent processing. Film density and stress may also vary, depending on the conditions of the deposition. PECVD can result in fairly good coverage and filling of nonplanar topography (such as TEOS $SiO_2$ deposition: Section 3.8.2), better than what might be expected at these low temperatures, probably due to surface emission and redeposition events caused by ion bombardment.

HDPECVD utilizes a very high-density plasma and a separate rf bias applied on the substrate to obtain very good filling of narrow gaps. It is used primarily for silicon dioxide depositions. The high-density source can be generated by a variety of sources such as inductively coupled plasma (ICP) and results in a dense film at low temperatures and with a very low chamber pressure in the 1–10 mTorr range. Sputtering—the knocking off of atoms from a solid by incident ions when the solid is electrically biased—occurs preferentially on sloped surfaces rather than on vertical or horizontal surfaces. This simultaneous sputtering of the film during its deposition can result in planarized and void-free films.

***Other CVD Systems*** Most of the low-temperature methods use energy-enhanced CVD techniques (e.g., a focused electron beam) to deposit dielectric films between 25 and 300 °C. An other energy-enhanced CVD method uses UV radiation to form vapor phase reactants that enhance the deposition rates. Silicon dioxide films have been deposited at a rate of 15 nm/min at temperatures as low as 50 °C by means of UV radiation.

### 3.7.2. Physical Vapor Deposition

Rather than relying on chemical reactions to produce the reacting species to form the film as in CVD, PVD methods use mainly physical processes to deposit films. PVD is more versatile than CVD, allowing for the deposition of almost any material. PVD is done under vacuum using, either the evaporation of a solid or molten source or by using energetic gaseous ions in a plasma to knock off—or sputter/dislodge—the atoms from a source target. These atoms or molecules then travel through a vacuum or a very

low-pressure gas phase, impinge on the wafers, and condense on the surface to form the film. The key distinguishing attribute of a PVD reactor is that the deposition of the material onto the substrate is a line-of-sight impingement-type deposition.

In an evaporation system, the vacuum chamber is evacuated by a roughing pump from atmospheric pressure to a pressure of about 15 Pa, followed by high-vacuum pumping to reduce the pressure to $10^{-3}$ Pa ($\sim 10^{-5}$ Torr) or lower. System cleanliness is required to reduce the pump-down period. To remove a major source of trapped atmospheric gas, all interior film buildup must be removed. To ensure uniform thickness of the deposited film, appropriate mechanical motion of the substrate of evaporation similar to that of the planetary system can be employed to expose the substrate to the same average number of evaporated atoms.

During film sputter deposition, approximately 1 Pa argon pressure is needed. Sequential deposition of different films is possible if several sources are available in the chamber. Using multiple sources also facilitates co-evaporation or co-sputtering to produce compounds, alloy films, or multilayer depositions, where Ti and Al layers may be deposited one after the other in the chamber without breaking vacuum. Similar cleanliness precautions as in the case of evaporation should be observed for sputter deposition.

Compounds such as silica are much harder to evaporate in the right composition as alloys with single-source sputter systems. The composition of the vapor phase is usually not the same as the source compound, and chemical reactions and molecular changes often occur as the material is evaporated. Sputter deposition generally does a much better job in depositing compositionally uniform films of both alloys and compounds. This is because the sputter rates of elements are usually much closer to each other than their vapor pressures are. In addition, because sputtering occurs just from the top surface of the target and little mixing from the layers below takes place (as opposed to evaporation where the mixing in the melt wipes out any concentration gradients), a steady-state condition soon develops. Initially, the element with the higher sputter rate does preferentially sputter off more from the surface. This leaves the top surface enriched with the element of the lower sputter yield. But now more of the element with the lower sputter yield is knocked off since the surface region is enriched with that element; a steady-state is achieved.

PVD reactors may use a solid, liquid, or vapor raw material in a variety of source configurations. The magnetron in some sputtering systems operates at voltages an order of magnitude below the e-beam source voltage and thus generates less penetrating radiation. In sputtering, the source is not heated to high temperatures and the vapor pressure of the source is not a consideration as in vacuum–evaporation. Other PVD techniques, very useful in the deposition of complex compound materials for example, e.g. nanotechnology, are MBE and laser ablation deposition. Ion-plating and cluster deposition are based on a combination of evaporation and plasma ionization and offer some of the advantages inherent to both techniques.

***Evaporation PVD*** Thermal evaporation represents one of the oldest ($\sim 100$ years!) thin-film deposition techniques. Evaporation is based on the boiling off or sublimation of

a heated material onto a substrate in a vacuum. The substances used most frequently for thin-film formation by evaporation are elements or simple compounds whose vapor pressure exceeds 1 mTorr for temperatures below 2000 °C and typically deposit at a rate from 50 to 1000 nm/min. Three common techniques are used to evaporate materials: electron-beam (e-beam) evaporation, resistance-heated evaporation, and rf induction-heated evaporation.

In an electron-beam evaporation, the most popular evaporation system, a thermionic filament supplies the electron current to the beam and the electrons are accelerated by an electric field (3 to 20 kV) to strike the surface of a charge (e.g., aluminum) which melts locally (Fig. 58). To prevent impurities from the filament reaching the charge that is placed in a recess in a water-cooled copper hearth, a magnetic field bends the e-beam path thus screening the impurities. Moreover, the metal forms its own crucible and the contact with the hearth is too cool for physical or chemical reactions, resulting in minimal source-contamination problems. Very high deposition rates on the order of 1 $\mu$m/min are possible in this system depending upon source-to-substrate distance. E-beam heaters can achieve high temperatures so that a wide range of materials can be evaporated such as aluminum and its alloys, silicon, palladium, titanium, molybdenum, platinum, tungsten, etc. and several dielectrics such as silicon dioxide. A disadvantage of the e-beam process is the generation of X-rays by the e-beam. This ionizing radiation can penetrate the surface layers of the devices, causing damage such as the creation of oxide-trapped charges. Therefore, subsequent annealing is required to remove such damage. The X-ray damage may

be avoided by using a focused, high-power laser beam (see section on laser ablation).

In a resistance-heated source, a refractory metal (i.e., a metal such as tungsten with a high melting point) is coiled into a filament or formed into a containment structure and a small piece of material (e.g., aluminum) is placed. Resistance-heated evaporation is simple and inexpensive and produces no ionizing radiation. Its disadvantages are possible contamination from the heater filament and limited film thickness because of the small charge than in the case of electron-beam evaporation. Moreover, resistance heaters cannot achieve temperatures as high as e-beam heaters so that a smaller range of materials can be evaporated. For example, refractory metals such as platinum, molybdenum, tantalum, and tungsten do not easily heat to the temperatures required to reach a sufficient vapor pressure.

In some cases an evaporation source is heated by rf induction with frequencies of several hundred kilohertz. In rf induction heating, a water-cooled rf coupling coil surrounds a crucible with the material to be evaporated. Usually boron nitride is used to form the crucible. Again there is no radiation problem and contamination may occur.

Evaporation registers a low energy impact on the substrate ($\sim$0.1 eV); that is, no surface damage results except when using e-beam evaporation. As a result of the low-energy impact, adhesion is generally poor in evaporation and delamination might occur. The problem of delamination can be diminished when incorporating an *in-situ* plasma treatment or depositing an additional adhesion layer such as Cr, Ta, or Ti prior to the evaporation. The plasma is able to remove surface contaminants such as water and can activate the surface to improve adhesion.

There is a need for a good vacuum; even at a pressure of $10^{-5}$ Torr, five contaminating monolayers per second arrive at the substrate and might react. (Note: The number of atoms per unit area corresponding to a 3 Å thick monolayer for a metal is about $10^{15}$/cm$^2$.) Especially, water vapor and oxygen gas may cause the formation of oxygen impurities. On the other hand, when one wants to form the oxides of the deposited metals, evaporation is performed in a low-pressure oxygen atmosphere. When oxygen is added one refers to reactive evaporation. The oxygen supply comes from a jet directed at the substrate during deposition. To obtain the correct stoichiometry the deposition needs to take place on a heated substrate.

If a high vacuum is established, most atoms/molecules will deposit on the substrate without suffering intervening collisions with other gas molecules. This results in a line-of-sight deposition. The fraction of particles scattered by collisions with atoms of residual gas is proportional to $1 - \exp(-d/\lambda)$ where $d$ is the distance between source and substrate (see Fig. 59) and $\lambda$ is the mean free path between collisions of the particles. At 0.01 mTorr the mean free path in air hovers about 5 m. The source-to-wafer distance must be smaller than the mean free path of the residual gas. Typically, this distance is 25 to 70 cm. The arrival rate $A$ at distance $d$ from a small evaporation source follows the cosine law of deposition: $A \sim \cos \beta / d^2$ where $\beta$ is the angle between the normal to the substrate and the radial vector joining the source to the arrival point being considered. The straight-line deposition of evaporant leads to difficulties in obtaining

**Figure 58.** Thin film deposition by evaporation.

**Figure 59.** Shadowing in evaporation.

a continuous coating over topographical steps on a wafer, a problem known as shadowing. This is of particular concern in microdevices where high aspect ratio features are requested. Figure 59 illustrates the problem. Since the thickness of the deposited film $t$ is proportional to $\cos \beta$ (in case of no surface migration of the deposit), the ratio of the film thickness is given as $t_1/t_2 = \cos \beta_1 / \cos \beta_2$. In case of a steep wall, the ratio can be 10 or more. The thinner section $t_2$ is susceptible to cracking at the extreme ends of the interval. Rotating the wafers in a planetary motion does help to widen the range of arrival angles but shadowing still occurs. To overcome the nonconformal deposition, the substrate can be heated during deposition (300 to 400 °C) to increase the surface mobility of the arriving atoms or the wafers can be rotated individually so that the angle $\beta$ varies during deposition. Nevertheless, a nonconformal step coverage is beneficial when considering the so-called lift-off technique (see Section on lithography).

***Laser Ablation PVD*** Laser ablation deposition uses intense laser radiation to erode a target and deposit the eroded material onto a substrate. A high-energy focused laser beam avoids the X-ray damage to the substrate encountered with e-beam evaporation. A high-energy excimer laser pulse coming from, for example, a KrF laser at 248 nm with a pulse energy in the focus of 2 J/cm$^2$ is directed onto the material to be deposited. The energy of the very short wavelength radiation is absorbed in the upper surface of the target, resulting in an extreme temperature flash, evaporating a small amount of material. This material, partially ionized in the laser-induced plasma, is deposited onto a substrate almost without decomposition. This technique is particularly useful when dealing with complex compounds, as in the case of the deposition of high temperature superconductor films, for example, $YBa_2Cu_3O_{7-x}$. Pulsed laser deposition faithfully replicates the atomic ratios present in the hot isostatically pressed target disc onto the thin film coating. Achieving complex stoichiometries presents more difficulties than with any other deposition technology. Approximately 10,000 pulses (pulse length of 20 ns and a repetition rate of 15 pulses per second) are needed to achieve a film thickness of 100 nm (i.e., approximately 10 nm/min). Normally, the laser deposited films are amorphous. The energy necessary

to crystallize the film comes from heating the substrate (700 to 900 °C) and from the energy transferred from the intense laser beam to the substrate via atomic clusters. Because of the small source size, laser ablation is not useful for large-scale coatings but is very useful in forming ultrathin layers for nanoapplications.

***Sputter PVD*** Sputtering is preferred over evaporation in many applications due to a wider choice of materials to work with, better step coverage, and better adhesion to the substrate. Several sputter systems exist such as dc, reactive, rf, and magnetron sputtering as will be explained next.

Figure 60 illustrates schematically a dc sputter deposition system. In the sputter system an inert gas is fed into the reactor at low pressure. A voltage is applied across two electrodes and plasma is created. The top electrode, the cathode or "target" where a negative dc voltage is applied, is actually the source material to be deposited, a plate of aluminum for example. The bottom electrode—the anode where the wafers are located—is another metal plate and is grounded. The positive ions from the plasma source, usually $Ar^+$, are accelerated through the potential gradient where they bombard the target. Through momentum transfer, atoms near the surface of the target material become volatile and are transported as a vapor to the substrate. At the substrate the film forms through deposition (the vapor condenses). Since the target acts as an electrode in the dc mode of sputter deposition, the target of source material must be conductive. Therefore, Al, W, Ti, silicides and other metallic components can be sputtered this way. Sometimes sputtering of the wafer is desirable—for example to improve adhesion. In such cases, a negative bias is applied to the wafer electrode. Positive argon ions from the plasma will now be accelerated to the wafer and sputter off atoms, thus removing any contaminants or native oxides. In addition it will improve adhesion due to the creation of surface dangling bonds by the ion impact.

In reactive sputtering, a reactive gas is introduced in the reactor in addition to the argon plasma, and the compound is formed by the elements of that gas combining with the sputtered material. For example, TiN can be deposited by sputtering Ti in the presence of nitrogen. dc sputtering is not suitable for insulator deposition. Therefore, in radio frequency sputtering an rf voltage source is used to couple capacitively through the insulating target, so that conducting electrodes are not necessary. In magnetron sputtering, magnets are used to increase the ionization efficiency of the plasma. Electrons originating at the cathode are trapped in a

**Figure 60.** Thin film deposition by dc sputtering.

spiral motion and confined by the magnetic fields until they collide with an argon atom. This can speed up the deposition 10 to 100 times faster than without magnets.

Having a larger target and higher gas phase pressure than evaporation means that the arrival angles of the atoms at the wafer surface are more widely distributed which generally improves step coverage. Also, the number of resputtered atoms on the wafer surface is higher for sputtering due to the bombardment of energetic particles, which increases the arrival angle distribution even more. In some cases, though, we actually want to narrow the arrival distribution—for example when filling a deep via with metal. This can be achieved using collimated and ionized sputtering systems. In collimated sputtering, a plate with holes is placed between the target and the wafer. The collimator acts as a physical filter to low-angle sputtered atoms. In ionized sputtering an rf antenna is used instead to direct ionized atoms toward the substrate and increasing directionality. Another way is applying bias to the substrate, which allows a minimal sputter etching concurrently with the deposition. In this way, sharp edges of the deposit are reduced during the sputter deposition due to the angle-dependent sputter yield. Surfaces with pointed and sloped features are removed more easily than horizontal or vertical surfaces. Not only does this help planarize the film, but overhang that can develop when depositing into a trench or hole is preferentially sputtered away, allowing for a better filling of the hole. Another factor may be that the resputtered atoms allow for some redeposition on sidewalls. By increasing the ion energy, the resputtering and redeposition of the atoms can be increased, resulting in better sidewall coverage. Another option for improved hole filling is to do the deposition and etching sequentially, as opposed to simultaneously. This can be done in a cluster tool with separate chambers for each process or using a plasma system, which allows both sputter deposition and etching such as in downstream cascade arc plasma (Section 5.3).

Deposition rates depend on source-to-substrate distance and can be as high as 1 $\mu$m/min for aluminum and its alloys. A typical sputter yield (i.e., ejected atoms per incident ion) is between 0.1 and 10 atoms/ion and is a function of ion energy and their direction. Below the so-called threshold energy, the ions have not enough energy to break the metallic bonds and subsequently the sputter yield is very low. The yield increases rapidly from the threshold energy level, which is usually in the range of 10 to 100 eV for common metals (e.g., 13 eV for Al, 15 eV for Pd, and 34 eV for Pt). To minimize the energy required to eject an atom from the target, the process uses ion energy within the range for which the sputter yield is about one atom per ion. Ion energies in the range of 0.5 to 3 keV typically are used for dc sputter deposition as nuclear collisions are predominant in this range. At ion bombardment energies in the range of 10 keV to 1 MeV, the sputter yield reaches a maximum and then gradually declines in value as a result of deep ion implantation. Average ejection energies of ions from the target range between 10 and 100 eV. At those energies, the incident ion can penetrate a substrate one to two atomic layers into the surface on which it lands. As a result, the adhesion of sputtered films is superior to films deposited by other methods. An ion coming in at low, glancing angle will not be as successful at dislodging an atom, with the ion itself being

reflected off the surface (specular reflection). At the other extreme, ions arriving normal to the surface will push a surface atom further into the target but not necessary sputter it off. The sputter yield peaks at some angles less than 90°, just as is the case in ion beam etching (Section 5.3). The angles that the sputtered atoms leave the surface of the targets are usually found to be diffusely distributed, with an ideal cosine-emitted angle distribution.

### Molecular-Beam PVD (Epitaxial Crystal Deposition)
Molecular-beam epitaxy is a PVD epitaxial process involving the reaction under ultrahigh vacuum conditions ($<10^{-10}$ Torr). In MBE, the heated single-crystal (400 to 800 °C) is placed in the path of streams of atoms from heated cells that contain the material of interest. These atomic streams impinge, in a line-of-sight fashion, on the surface-creating layers with a structure controlled by crystal structure of the surface, the thermodynamics of the constituents, and the sample temperature. MBE can achieve precise control in both chemical compositions and doping profiles. Single-crystal multilayer structures with dimensions of the order of atomic layers can be made using MBE. The deposition rate of MBE is very low (i.e., about 20 nm/min), which accounts for the ultrahigh vacuum needed to obtain high-purity epilayers. Because MBE uses an evaporation method, the basic kinetic theory of gases in a vacuum system has to be considered. We will not go into detail, but as an example: at room temperature and at a pressure of 1 Torr it takes 2 $\mu$s to form a monolayer of oxygen. At $10^{-6}$ Torr this is 2 s and at $10^{-10}$ Torr it becomes 6 hr. Therefore, in order to avoid oxygen contamination it is of paramount importance to maintain ultrahigh vacuum conditions. Fast-acting shutters control the deposition. A few atomic layers of material lie between every shutter action. This becomes important when an ultrasharp profile is called for. The low deposition rate gives the operator better control over the film thickness. MBE has several potential advantages over CVD epitaxy (i.e., VPE); for example, the relatively low growth temperatures reduce diffusion and autodoping effects. Novel structures such as quantum devices and superlattices can be made. The limitations to consider lie in volume manufacturing and costs. The ultrahigh vacuum requirements make operation very expensive.

### Cluster-Beam PVD
When applying cluster-beam technology, ionized atom clusters (100 to 1000 atoms) are deposited on a substrate in a high vacuum ($10^{-5}$ to $10^{-7}$ Torr). Those atom clusters typically carry one elementary charge per cluster and therefore achieve the same energy in an electrical field as a single ion would. To make these atom clusters, a special evaporation cell must be used. The heating of the evaporant in an evaporation cell with a small opening causes adiabatic expansion, from more than 100 to $10^{-7}$ mbar, of the vapor upon exiting that cell. The expansion causes a sudden cooling, inducing the formation of atom clusters. These clusters are then partially ionized by an electron bombardment from a heated filament. Low energy neutral clusters (0.1 eV) and somewhat higher energy ionized clusters (a few eV) arrive at the surface where they flatten and form a film of excellent adhesion and purity, with a relatively low

number of defects. Cluster-beam epitaxy is possible at temperatures as low as 250 °C, and no charge buildup occurs when depositing on an insulator.

***Ion Plating PVD***   In ion plating, evaporation of a material is combined with ionization of the atom flux by an electron filament or plasma. The addition of a gas (e.g., nitrogen) to the reactor enables one to make new compounds (such as TiN) on the substrate surface with the gas reacting with the ionizing atoms from the evaporation source (Ti). Because of the high kinetic energy of the impacting ions, a very well adhering, dense TiN film with extraordinary low friction coefficient and high hardness coefficient (Vickers hardness of 50,000) forms. Because of the thermal nature of the process, very high deposition rates can be achieved.

### 3.7.3. Chemical Vapor Growth

Chemical and physical vapor growth are processes where the substrate material is transformed into a layer with different properties. Within this group, thermal oxidation is of prime importance in IC technology where thermally grown field and gate oxides can provide the highest quality oxides having the lowest interface trap densities. Diffusion and ion implantation are two key processes which are used to introduce controlled amounts of dopants into semiconductors. They are used to dope selectively the semiconductor substrate to produce either an *n*-type or *p*-type region. Both diffusion and ion implantation are used for fabricating microsystems because these processes generally complement each other. For example, diffusion is used to form deep subsurface doping profiles, whereas ion implantation is used to form shallow junctions.

***Thermal***   Semiconductors can be oxidized (or nitrided) by various methods. These include thermal oxidation, electrochemical anodization (see section on chemical liquid growth), and plasma reaction. Among these methods thermal oxidation is by far the most important for silicon devices. Silicon dioxide formed by thermal oxidation of silicon is used as a common insulating layer, as a mask, and as a sacrificial material. The oxidation temperature is generally in the range of 900 to 1200 °C and takes place in a furnace (Fig. 61). Because a silicon surface has a high affinity for oxygen, an oxide layer rapidly forms when silicon is exposed to an oxidizing ambient. The chemical reactions describing the thermal oxidation of silicon in oxygen or water vapor are given:

$$\text{Dry oxidation:} \quad \text{Si(s)} + \text{O}_2\text{(g)} \rightarrow \text{SiO}_2\text{(s)} \quad \text{(47a)}$$

**Figure 61.** Thermal oxidation furnace.

$$\text{Wet oxidation:} \quad \text{Si(s)} + 2\text{H}_2\text{O(g)} \rightarrow \text{SiO}_2\text{(s)} + \text{H}_2\text{(g)} \quad \text{(47b)}$$
The basic process involves shared valence electrons between silicon and oxygen; the silicon–oxygen bond structure is covalent. The basic structural unit of thermally grown silicon dioxide is a silicon ion surrounded tetrahedrally by four oxygen ions (Fig. 36). These tetrahedra are joined together at their corners by oxygen bridges in a variety of ways to form the various phases or structures of silicon dioxide (also called silica). Silica has several crystalline structures (e.g., quartz) and an amorphous structure. When silicon is thermally oxidized, the silicon dioxide structure is amorphous. Typically amorphous silica, with a formula weight $M = 60.1$, has a density of 2.21 g/cm$^3$, as compared to 2.65 g/cm$^3$ for quartz and 2.33 g/cm$^3$ for silicon ($M = 28.1$). The relatively open structure of the amorphous structure accounts for the lower density and allows a variety of impurities (such as sodium) to enter and diffuse readily through the silicon dioxide layer. Both types of thermal oxidation are carried out in a quartz tube. An oxide thickness of a few tenths of a micrometer is used most frequently, with a few micrometers being the practical upper limit for conventional thermal oxides, although layers thicker than 10 micrometers have been fabricated.

During the course of the oxidation process, the Si–SiO$_2$ interface moves into the silicon. Its volume expands and based on the densities and molecular weights of Si and SiO$_2$; we can calculate that for growth of an oxide of thickness $d$, a layer of silicon with a thickness of $(28.1/60.1) * (2.21/2.33) * d = 0.44d$ is consumed. This relationship holds importance for calculating step heights that form in silicon microstructures. The oxidation proceeds by gas-phase transport of oxidant to the surface, the diffusion of the oxidizing species through the oxide to the Si–SiO$_2$ interface, and the oxidation reaction itself. In the early stage of growth in dry oxidation, there is a large compressive stress in the oxide layer because the (volume) expansion is restricted laterally by the substrate underneath the growing film. Such stress reduces the oxygen diffusion coefficient in the oxide. Especially sharp silicon corners will develop large stresses and therefore these places will create a lag in oxidation. This effect is effectively used in the manufacturing of ultrasharp needles for scanning probe microscopy. As the oxide becomes thicker, the stress will be reduced due to the viscous flow of silica and the diffusion coefficient will approach its stress-free value. When the temperature is ramped down from, say 1000 °C, to room temperature after finishing the oxidation, the growing film will develop again a high compressive stress (∼300 MPa), but now it is caused by the difference in thermal expansion coefficient between silicon and silica as found in Section 2.2. Due to this oxide films with a certain critical thickness (in the order of a few micrometers) might start to delaminate from the substrate after cooling down if the ramping is too fast.

Using simple kinetics of thermal oxidation of silicon, it can be shown that the oxide thickness $x$ after an oxidizing time $t$ is given by the Deal–Grove equation [177],

$$x^2 + Ax = B(t + t_o) \quad \text{(48)}$$

where $t_o$ represents a shift to account for the initial oxide layer at $t = 0$. $A$ is a function of the surface reaction rate constant for oxidation $k$ and the diffusion constant of the oxidizing species in silica $D$ ($A = 2D/k$). $B$ is a measure of the diffusion process of the oxidizing species through the silica ($B = 2DC_0/C_1$). For small values of $x$ ($x \ll A$), this equation reduces to a linear law:

$$x = (B/A)(t + t_o) = k(C_0/C_1)(t + t_o) \qquad (49)$$

And for large values of $x$ ($x \gg A$), it reduces to a parabolic law:

$$x^2 = Bt = 2D(C_0/C_1)t \qquad (50)$$

Thus, during the early stage of oxide growth, when surface reaction is the rate-limiting factor, the oxide thickness varies linearly with time. For this reason, the term $B/A$ is referred to as the linear rate constant. As the oxide layer becomes thicker, the oxidant must diffuse through the oxide layer to react at the silicon–silica interface and the reaction becomes diffusion-limited. The oxide growth then becomes proportional to the square root of the oxidizing time, which results in a parabolic growth rate. Therefore, the term $B$ is referred to as the parabolic rate constant.

The temperature dependence of the linear rate constant $B/A$ varies as $\exp(-E_a/kT)$, where the activation energy $E_a$ found experimentally is about 2 eV for both dry and wet oxidations. This closely agrees with the energy required to break silicon–silicon bonds, that is, 1.83 eV. The temperature dependence of the parabolic rate constant $B$, which can also be described by $\exp(-E_a/kT)$, is different for dry and wet oxidation. The activation energy $E_a$ is 1.24 eV for dry oxidation, which is comparable to that for oxygen diffusion in fused silica (1.18 eV). The corresponding value for wet oxidation, 0.71 eV, compares favorably with the value of 0.79 eV for the activation energy of diffusion of water in fused silica [176]. Oxidation in high-pressure steam can produce substantial acceleration in the growth rate because the parabolic rate constant $B$ is proportional to the partial pressure of the oxidizing species in the gas phase. High-pressure oxidation offers the advantage of low-temperature processing at growth rates comparable to high-temperature, 1 atm conditions. Because wet oxidation occurs at a substantially greater rate than dry oxidation, any unintentional moisture accelerates the dry oxidation. Also, the common dopant elements, when present in silicon at high concentration levels, can enhance the oxidation behavior. The dopant impurities are redistributed at the growing Si–SiO$_2$ interface (i.e., the dopant segregates either into the silicon or into the oxide). The redistribution of the impurity at the interface influences the oxidation behavior. The quality of thermal silica depends heavily on its growth method. Dry oxidation in pure oxygen produces a better quality oxide than steam oxidation. Such a thermal oxide is stoichiometric, has a high density, and is basically pinhole free. Wet oxidation in steam water causes a loosening effect on the silica, making it more prone to impurity diffusion.

Experiments have indicated that the oxidation kinetics is a function of the crystallographic orientation of the silicon surface [169, 171]. The linear rate constant is related to the interface reaction kinetics and depends on the rate at which oxide atoms are incorporated into the silicon lattice with lattice constant $a = 0.543$ nm and $a^{-2} \sim 3.39 \times 10^{14}$ atoms/cm$^2$. This might depend on the silicon surface atom concentration, which is orientation dependent, $\{011\}:\{111\}:\{100\} = 2a^{-2}(\sqrt{2} : 2\sqrt{3}/3 : 1) \sim 1.41 : 1.15 : 1$, or the available bond density, which is also orientation dependent, $\{011\}:\{111\}:\{100\} = 2a^{-2}(\sqrt{2} : 2\sqrt{3}/3 : 2) \sim 1.41 : 1.15 : 2$. However, the experimental linear oxidation rate for silicon surfaces follows the sequence $\{011\} > \{111\} > \{311\} > \{511\} > \{100\}$, which resembles the surface atom concentration orientation dependency. For example, after 16 hours of oxidation at 800 °C of $\langle 011 \rangle$-, $\langle 111 \rangle$-, and $\langle 100 \rangle$-oriented wafers, 300 nm oxide grows on the $\langle 011 \rangle$-wafer, 280 nm Oxide on the $\langle 111 \rangle$-wafer, and 200 nm oxide on the $\langle 100 \rangle$-wafer, revealing a ratio of $\{011\}:\{111\}:\{100\} = 1.5 : 1.4 : 1$. So, because the density of silicon atoms on the $\{011\}$-plane is larger than that on the $\{111\}$ and $\{100\}$-plane, the linear rate constant for $\langle 011 \rangle$-silicon is also larger and oxidation proceeds faster in the initial growing process where the growing proceeds still linearly with time. The parabolic rate constant is independent of crystal orientation. This independence is expected, because it is a measure of the diffusion process of the oxidizing species through a random network layer of amorphous silica.

Addition of chlorine-containing chemicals during oxidation increases the dielectric breakdown strength and the rate of oxidation and improves the threshold voltage of many electronic devices However, too high concentrations of halogens at high temperatures can pit the silicon surface. In general, the quality of the silicon–silica interface fails to be of importance in the MEMS field unlike the IC industry. One notable exception being the ion sensitive field effect transistor (ISFET).

Understanding the stress associated with a film is important because high stress levels can contribute to wafer warpage, film cracking, and defect formation in the underlying silicon. Room temperature measurements following thermal oxidation of silicon show the film to be in a state of compression on the surface. Film stress values of 700 MPa are reported, with the stress attributed to the difference in thermal expansion for Si and SiO$_2$ (thermal stress) and stress resulting from the change in volume between silicon and its oxide (intrinsic oxidation stress). For more details on all the subjects described above, see [1]. Evidently, such stresses are of prime concern when dealing with extremely small structures as found in nanotechnology where natural oxides are major contributions to the total thickness of structures such as nanocantilevers.

***Diffusion*** Until the early 1970s, selective doping was done mainly by diffusion at elevated temperatures. In this method the dopant atoms are placed on or near the surface of the semiconductor wafer by deposition from gas phase of the dopant or by using doped-oxide sources. The dopant distribution is determined mainly by the temperature and diffusion time.

Diffusion of impurities is typically done by placing semiconductor wafers in a furnace and passing an inert gas that contains the desired dopant through it. The furnace and gas flow arrangements are similar to those used in thermal oxidation. The temperature usually ranges between 800 and

1200 °C for silicon. For diffusion in silicon, boron is the most popular dopant introducing a *p*-type impurity, while arsenic and phosphorous are used extensively as *n*-type dopants. These three elements are highly soluble in silicon as they have solubilities above $5 \times 10^{20}/\text{cm}^3$ (i.e., 1% of the silicon density!) in the diffusion temperature range. These dopants can be introduced in several ways, including solid sources (e.g., BN for boron, $As_2O_3$ for arsenic, and $P_2O_5$ for phosphorous), liquid sources ($BBr_3$, $AsCl_3$, and $POCl_3$), and gaseous sources ($B_2H_6$, $AsH_3$, and $PH_3$). Usually, the source material is transported to the semiconductor surface by an inert carrier gas (e.g., nitrogen) and is then reduced at the surface.

The diffusitivities of commonly used doping impurities (e.g., As, B, and P) are considerably smaller in silicon dioxide and silicon nitride than in silicon. Therefore silicon dioxide can be used as an effective mask against impurities. If we etch windows in the oxide and use the remaining oxide as a mask, we can incorporate dopant impurities into a silicon substrate in selective areas. For silicon dioxide, the diffusion process can be described as occurring in two steps. During the first step, the dopant impurities react with silicon dioxide to form a silicate glass. As the process continues, the thickness of the silicate glass increases until the entire silicon dioxide layer is converted into a silicate glass (e.g., phosphosilicate glass). After the glass forms, the second step begins. The dopant impurity diffuses through the glass; upon reaching the glass–silicon interface, it enters and diffuses into the silicon. During the first step, silicon dioxide is completely effective in masking the silicon against dopant impurities in the gas phase. Therefore, the thickness of silicon dioxide required for masking is determined by the rate of formation of the glass, which in turn is determined by the diffusion of the diffusant into the silicon dioxide. Because it has a higher diffusitivity in silicon dioxide, phosphorous requires thicker masking layers (between 20 and 80 times thicker) than boron. Silicon nitride is even more effective as a diffusion barrier than silicon dioxide. Therefore much thinner layers of silicon nitride are sufficient to effectively block dopants.

Dopant impurities near the silicon surface will be redistributed during thermal oxidation. The redistribution depends on several factors. When two solid phases are brought together, an impurity in one solid will redistribute between the two solids until it reaches equilibrium. The ratio of the equilibrium concentration of the impurity in the silicon to that in the silicon dioxide is called the segregation coefficient $k$. For $k < 1$, the oxide takes up the impurity and for $k > 1$ it rejects the impurity. An example is phosphorous, with $k$ approximately equal to 10.

### 3.7.4. Physical Vapor Growth

Ion implantation is the introduction of energetic, charged particles into a substrate such as silicon. The practical use of ion implantation in semiconductor technology has been mainly to change the electrical properties of the substrate or to form a buried oxide layer for SIMOX wafers (see Section 2.3.11).

***Ion Implantation*** Since the early 1970s, many doping operations have been performed by ion implantation. In this process the dopant ions (e.g., $B^+$ and $As^+$) are implanted into the semiconductor by means of a high-energy ion beam. Typical ion energies are between 30 and 300 keV, and typical ion doses vary from $10^{11}$ to $10^{16}$ ions/cm$^2$. The high-energy ion beam passes through vertical and horizontal scanners and is implanted into the semiconductor substrate. The energetic ions lose their energy through collisions with electrons and nuclei in the substrate and finally come to rest. Due to the kinetic energy of the impinging ions, the doping concentration has a peak inside the semiconductor and the profile of the dopant distribution is determined mainly by the ion mass and the implanted-ion energy. The advantages of the ion implantation process are precise control of the total amount of dopants, improved reproducibility of impurity levels, and lower temperature processing.

For heavy ions, the energy loss is primarily due to nuclear collisions; therefore substantial lattice disorder (damage) occurs. When the displaced atoms per unit volume approach the atomic density of the semiconductor, the material becomes amorphous. For 100-keV arsenic ions, the dose required to make amorphous silicon is $6 \times 10^{13}/\text{cm}^2$. Much of the energy loss for light ions (e.g., $B^+$ in silicon) is due to electronic collisions, which do not cause lattice damage. The ions lose their energies as they penetrate deeper into the substrate. Eventually, the ion energy is reduced sufficiently for nuclear stopping to become dominant. Therefore, most of the lattice disorder occurs near the final ion position at a depth up to a few hundreds of nm.

***Solid-Phase Epitaxy*** Because of the damaged region that results from ion implantation, semiconductor parameters such as mobility and lifetime are severely degraded. In addition, most of the ions implanted are not located in substitutional sites. To activate the implanted ions and to restore mobility and other material parameters, we must anneal the semiconductor at an appropriate combination of time and temperature in a furnace. For boron implantation, higher annealing temperatures are needed for higher doses. For phosphorus at lower doses, the annealing behavior is similar to that for boron. However, when the dose is greater than $10^{15}/\text{cm}^2$, the annealing temperature drops to about 600 °C. This phenomenon is related to the solid-phase epitaxy process. At such high doses, the silicon surface layer becomes amorphous. The single-crystal semiconductor underneath the amorphous layer serves as a seeding area for recrystallization of the amorphous layer. The epitaxial-growth rate along the $\langle 100 \rangle$-direction is 10 nm/min at 500 °C and 50 nm/min at 600 °C, with activation energy at 2.4 eV. Therefore, a 500 nm amorphous layer can be restored in a few minutes. During the solid-phase epitaxial process, the impurity dopant atoms are incorporated into the lattice sites along with the host atoms; thus, full activation can be obtained at relatively low temperatures. Note that a thin layer of damaged silicon on top of a silicon dioxide layer will not be repaired due to the missing subsurface single-crystal seeding area.

In order to achieve low temperature recrystallization for boron implantation, we can implant inert ions into silicon to form an amorphous layer. The silicon can then be annealed at low temperatures (600 °C) by the solid-phase epitaxy process to remove the implanted damage from the dopant ions. Another possibility to restore the crystal lattice without the

need of a furnace is to use electron-beam annealing or laser-beam annealing. With low-temperature e-beam annealing we can activate the dopant fully with minimal redistribution, while the high-temperature furnace annealing substantially broadens the profile.

### 3.7.5. Chemical Liquid Deposition

In the IC industry one tends to avoid wet chemistry when a dry deposition method presents itself, but MEMS needs are forcing reconsideration of electrochemical techniques as a viable solution. In micromachining, electrochemical liquid deposition (ECLD) is used to make structural microelements from a wide variety of metals, metal alloys, and even composite materials. Moreover, ECLD enables the metal replication of high-aspect-ratio resist molds while maintaining the highest fidelity. A chemical liquid deposition method that has been developed for copper is electrolytic plating. This can be done with the use of external electrodes and applied current. Applying an external voltage is generally referred to as electroplating. Deposition without an applied field is called electrodeless or electroless deposition and, when the substrate surface is replaced by a deposit, the process is called immersion plating. These processes are used commonly in printed circuit board manufacturing and on-chip interconnect fabrication. While the electroless method has received a lot of attention in recent years, mostly due to its selectivity deposition capabilities, the electroplating method has become the current method of choice for copper deposition in integrated circuits.

***Electroplating***   In electroplating, the wafers are mounted on a cathode and immersed into a plating solution that contains metallic ions ($M^{2+}$ such as $Ni^{2+}$ or $Cu^{2+}$) as shown in Figure 62. An inert anode, made of graphite (or platinum), for example, is also immersed into the solution. A voltage is applied between the two electrodes and the current drives the metal ions (or cations) toward the wafer at the cathode, forming, for example, nickel on the surface. The negative anions are attracted to the positive anode, which picks up electrons forming $Cl_2$, according to the electrochemical reaction

$$\text{Red:} \quad M^{2+} + 2e^- \rightarrow M \quad \text{(reduction at cathode)} \quad (51)$$

$$\text{Ox:} \quad 2Cl^- \rightarrow Cl_2 + 2e^- \quad \text{(oxidation at anode)} \quad (52)$$

**Figure 62.** Electroplating set-up.

A thin seed layer, Au (or Cu), is often deposited first over the wafer so that electrical contacts can be made to the surface of the wafer and so that nickel is electroplated over the entire wafer surface. This seed layer formation can be done by PVD or CVD techniques.
Excellent filling can be achieved with electroplating and is enhanced by using "leveling" agents or additives into the solution. These chemicals inhibit the deposition. They preferentially adsorb on the top surfaces of the topography rather than on the bottom of trenches or vias due to diffusion limitations. The top surfaces and corners then receive less deposition than the bottoms of trenches, resulting in excellent filling ability. Low resistivity and high deposition rate can be achieved with electroplating. Important process parameters are pH, current density, temperature, agitation, and solution composition.

***Immersion Plating***   Simple metal displacement reactions where the surface of a less noble metal such as zinc immersed in a copper sulphate solution gets replaced by a copper surface feature the simplest example of electrochemical deposition, known as immersion plating. No external potential is applied, and both anodic and cathodic partial reactions occur on the same electrode surface. Zinc gives off two electrons and goes into solution while copper ions receive two electrons and deposit as a metal:

$$\text{Red:} \quad Cu^{2+} + 2e^- \rightarrow Cu \quad (53)$$

$$\text{Ox:} \quad Zn \rightarrow Zn^{2+} + 2e^- \quad (54)$$
The surface of the zinc substrate becomes a mosaic of anodic (zinc) and cathodic (copper) sites, which could have nano-applications. The displacement process is continuous until the entire surface is covered with copper. At this point, oxidation (dissolution) of the zinc anode virtually stops and copper deposition ceases. The process only proceeds slowly by way of diffusion of copper and zinc ions through the copper deposit and is quite identical in time-dependent growth behavior with the thermal oxidation process. Deposits range up to 3 micrometers thick.

***Electroless Plating***   Electroless deposition involves the formation of thick metallic films from electrolytic solution without the use of external electrodes (as in electroplating) and without the dissolution of the substrate (as in immersion plating). In order to achieve this, it is essential that a sustainable oxidation reaction be employed. Simultaneous oxidation–reduction reactions between two half-reactions occur to deposit the film from solution. By this method, both blanket and selective films of good quality, low resistivity, and good filling properties can be obtained. In a typical process, the solution contains formaldehyde (HCOH) as a reducing agent and CuEDTA as the oxidizing agent and source of copper. The two half-reactions with their redox potentials in this pH = 12 solution are:

$$\text{Red:} \quad [CuEDTA]^{2-} + 2e^- \rightarrow Cu + EDTA^{4-} \quad (V = -0.26)$$
$$(55)$$

$$\text{Ox:} \quad 2HCOH + 4OH^- \rightarrow 2HCOO^- + 2H_2O + H_2 + 2e^-$$
$$(V = 0.32) \quad (56)$$
The hydroxide ion is commonly produced from sodium or potassium hydroxide. The net potential is positive so that the combined reaction to deposit copper is thermodynamically favorable. In parallel to the oxidation reaction, more or less severe hydrogen reduction goes on, which might upset the quality of the deposit. Stabilizers (i.e., catalytic poisons such as thiourea and $Pb^{2+}$) are needed as the solutions are thermodynamically unstable; deposition might start spontaneously onto the container walls. In addition, buffers, accelerators (exaltants), and complexing and surfactant agents are commonly added to the solution. In order for the copper to be deposited, a thin seeding layer is required to catalyze the electroless process. These are often Pd, Au, or Cu layers, CVD or PVD deposited. Alternatively, the wafer surface is activated by dipping it into $SnCl_2/HCl$ or $PdCl_2/HCl$. For selective electroless deposition, the seed layers should only be in the locations where the copper deposit is desired. This can be done by selectively etching the seed layer itself or using lift-off techniques. A problem with the electroless method has to do with contamination. The seed layer materials can all act as deep-level traps in underlying silicon. Of more concern are the alkali ions needed for the highly basic solution. Sodium and potassium ions can drift in silica and alter the electrical properties of the device; therefore tetra-methyl-ammonium-hydroxide $[N(C_2H_5)_4OH]$, or TMAH, is often used instead. Electroless plating is an inexpensive technique enabling plating of conductors (such as nickel, copper, cobalt, platinum, or gold). Metal alloys, such as nickel–boron or palladium–nickel, can be produced by co-deposition.

***Liquid Phase Epitaxy***   This is the growth of epitaxial layers on crystalline substrates by direct precipitation from the liquid phase. LPE is suited only to deposit thin epi layers because it has a slow deposition rate. It is also found to be useful to grow multilayered structures in which precise doping and composition controls are required.

***SAM***   Self-assembled monolayers are indispensable for many nanoprocesses. SAMs are close-packed monolayers of molecules—just like a soap molecule—with a head attached to the underlying substrate and a tail pointing upward. The composition of the head depends on the substrate it has to be connected with: typically a silane head (SiOH or SiCl) for silicon substrates and a thiol head (SH) for gold substrates. The tail can have a varying composition and functionality and is typically between 4 and 10 carbon atoms in length (i.e., a few nm). Deposition of SAMs is a simple method to modify surface wetting properties of a variety of substrate materials. Because SAMs are close-packed, they are virtually pinhole free. Moreover, they are self-assembled and thus the thickness is highly controllable. Finally, due to the "free-to-choose" tail composition, the properties of a surface can be varied almost without any constriction.

For example, hexamethyl disiloxane is a SAM used as an intermediate layer to promote adhesion of resist film to silicon-based substrates. Another example, by controlling the water content in the solvent, SAMs of trichlorosilanes can be formed on silica substrates in a short period of time. The photochemistry of the 2-nitrobenzyl group can be used for photocleavable SAMs. Ultraviolet irradiation through masks placed on top of SAM-modified surfaces leads to the production of hydrophilic carboxylate groups in the irradiated regions leaving the nonirradiated regions hydrophobic. Once photopatterned, aqueous solutions can be confined to the irradiated hydrophilic regions, which results in surface-directed flow devices. Another important group has applications in biochemistry. These are SAMs having a "proteinphilic," which can be very specific for certain enzymes. SAMs are also found in lithographs as seen in Section 4.2.3.

### 3.7.6. Physical Liquid Deposition

In physical liquid deposition, an amount of liquid is deposited (coated) first on a substrate and then it is hardened to form a solid film. Several methods exist such as dipping, spraying, painting, casting, or melting as will be treated in this section.

***Spinning***   Spin coating has been optimized for deposition of thin layers of polymer on round and nearly ideally flat surface silicon wafers. For example in photoresist spinning, the wafer is held on a vacuum spindle, and $\sim 1$ cm$^3$ of liquid resist is applied to the center of the wafer. The wafer is then rapidly accelerated up to a constant rotational speed (generally in the range 1000 to 10,000 rpm), which is maintained for about 30 s to give a uniform film. During spinning, the centrifugal forces push the excess solution over the edge of the wafer, and the residue on the wafer remains due to surface tension. The thickness of the resulting resist film is given by $t_{Res} \sim \rho\alpha/\sqrt{\omega}$ with $\rho$ the liquid viscosity, $\alpha$ the percent solid content in the resist, and $\omega$ the spin speed. In this way films down to 10 nm and up to several tens of micrometer can be formed.

***Dipping***   In dip coating, a substrate is dipped into a solution containing a polymer and a solvent. After evaporation of the solvent, a thin layer forms on the surface. To obtain pinhole-free layers, the dipping is repeated several times interspersed with drying periods. Unlike spin coating, dip coating allows us to coat 3D surfaces such as wires uniformly. Thermoplastic and thermosetting coatings are formed by dipping a heated part into a container of resin particles set in motion by a stream of low-pressure air (fluidized-solid bed). Dip coating of a substrate in a dissolved polymer typifies the simplest method to apply an organic layer to a substrate.

***Spraying***   Spray coating may involve liquids, gases, or solids. Spray coating of a liquid involves pressurization by compressed air or pushing liquid mechanically through tiny orifices. Vapors are carried in an inert dry vapor carrier. In the case of a solid, a powdered plastic resin is melted and blown through a flame-shrouded nozzle. In electrostatic spraying a negatively charged plastic powder is spray gunned onto grounded conductive parts.

***Painting***   In some applications, it can be practical to introduce a given amount of material using a brush. Clearly, this technique is not microsystem-compatible and therefore only seldom used. Nevertheless, this process is suited in packaging where sometimes only very specific spots should be covered by a film.

***Casting*** Casting is based on the application of a given amount of dissolved material on a surface and letting the solvent evaporate. A rim structure is fashioned around the substrate, providing a "flat beaker" for the solution. This method provides a more uniform and a more reproducible layer than dip coating.

***Melting*** Melting is a technique similar to casting. Identically, it uses a dummy container to confine a liquid. The liquid is formed by melting granules of material, often a metal or polymer, in a nitrogen-purged furnace. In the liquid phase, a layer forms having a very high degree of planarization. After cooling down, the container is removed leaving a metallic layer on top of the substrate. Clearly, when using metal melting, the container should withstand the temperature. Alloying of the metallic layer with the container material (contamination) is a factor of concern.

### 3.7.7. Chemical Liquid Growth

In order to avoid the necessity of heating substrates to high temperatures as in the case for chemical vapor growth, it is possible to enhance oxidation by immersing parent metals in a chemical oxidizing liquid medium. In most cases this is the oxidation of a metal film in an electrolytic cell. The medium may be aqueous, nonaqueous, or a fused salt.

***Anodization*** Anodization is a widely used technique for obtaining amorphous, highly insulating, pinhole-free, and low-stress (due to the low temperature film growth) films and there is a very large commercial usage of these in electronic capacitors. Anodization is an oxidation process performed in an electrolytic cell as schematically shown in Figure 63 with an applied voltage ranging from 20 to 600 V. The material to be anodized becomes the anode (+) while a noble metal or graphite is made the cathode (−). When electric current is passed, the surface of the anode material is converted to an oxide having protective, insulating, or other properties. (At the cathode, the only important reaction is $H_2$ evolution.) The oxygen required originates from the electrolyte used and the coating progresses from the solution side inward, toward the metal, so that the last-formed oxide is adjacent to the metal. Depending on the solubility of the anodic reaction products, an insoluble layer (e.g., an oxide film) results or in the case of a soluble reaction product, the electrode etches. For example, if the primary oxidizing agent is water, the resulting oxides generally are porous, whereas organic electrolytes may lead to very dense oxides providing excellent passivation.
So anodic oxide coatings may be of two main types. One is the so-called barrier layer, which forms when the anodizing electrolyte has little capacity for dissolving the oxide. These coatings are essentially nonporous and their thickness is limited to about 1–2 nm/V applied. This thickness represents the distance through which ions can penetrate the oxide under the influence of the applied potential. Once this limiting thickness is reached, it is an effective barrier to further ionic or electronic flow. The current drops from a typical few tens of mA/cm$^2$ to a low leakage value and oxide formation stops. Scanning electron microscope (SEM) studies reveal the presence of close-packed cells of amorphous oxide. Their size is a function of the anodizing voltage and is typically around 100 nm. The oxide film, which forms on, for example, tantalum during anodic oxidation, is a product of the following electrochemical reaction.

$$\text{Red:} \qquad 10H^+ + 10e^- \rightarrow 5H_2 \qquad (57)$$

$$\text{Ox:} \qquad 2Ta + 10OH^- \rightarrow Ta_2O_5 + 5H_2O + 10e^- \qquad (58)$$
The rate-controlling process is the ion migration within the oxide film. At high fields the current density during the anodization depends exponentially on the field strength, and the rate of oxide growth is proportional to the density of the current. Since the current efficiency is about 100%, Faraday's law can be used for determining the amount of oxide formed from the quantity of electricity passed through the electrolytic cell. Figure 64 shows the behavior of voltage and current with time during anodization. The oxide formation usually consists of a constant current phase until a preselected voltage is reached. During this phase the oxide increases at a constant rate, according to the increase in potential, necessary to maintain the current. After the requested voltage is reached, the anodization continues until the ion current has decreased to a sufficiently low level of about 1% of its original value. This is to increase film uniformity and to remove pinholes. For example, at a current density of 1 mA/cm$^2$, the growth rate of tantalum pentoxide is about 0.57 nm/s. At this current density the measured voltage rise is 0.33 V/s, resulting in a growth constant of 1.73 nm/V for the formation. If this process continues until the voltage has risen to, for example, 100 V, the oxide thickness will be 173 nm.

**Figure 63.** Anodization setup.

**Figure 64.** Anodization steps: constant current–constant voltage.

When the electrolyte has appreciable solvent action on the oxide, the barrier layer does not reach its limiting thickness; current continues to flow, resulting in a porous oxide structure. Porous coatings may be quite thick—up to several tens of micrometers—but a thin barrier oxide layer always remains at the metal–oxide interface.

As in the case of thermal growth, only a limited number of materials form coherent oxides in anodization. These include the valve metals (Al, Ta, Nb, Zr, and Hf), either alone or as alloys within the group, Group IV and Group III–V semiconductors, and materials such as Bi, W, TaN, SiC, Sb, Y, Ti, Mg, Zn, Cu, Ag, Cd, and steel. The rate of formation of the oxide is a function of the current density and the final oxide thickness is limited to the voltage applied to the electrolytic cell. Asymptotic growth curves are obtained, as was the case for thermal growth. For the case of aluminum an anodization constant of approximately 1.3 nm/V and for tantalum 1.7 nm/V is found. The disadvantage of using a constant voltage approach is that the initial growth stages of anodization require very high current densities, and one way around this difficulty is to anodize initially using a constant current rather than a constant voltage. The limiting condition of the thickness of the film is the breakdown under high voltages, and in the case of aluminum and tantalum this occurs at oxide thicknesses of 1.5 and 1.1 $\mu$m respectively. Other factors can, however, limit the thickness to values less than those quoted, and in particular the purity of the substrate and composition of the electrolyte are important.

Although anodizing processes are used for many metals, aluminum is by far the most important. The mechanism of anodic oxidation is not completely understood. Faraday's law predicts that for each Faraday of electricity passed, ca. 9 grams of aluminum would react, forming 17 grams of alumna, for a "coating ratio" $[Al_2O_3]/2[Al] = 1.89$. This ratio is never observed; it seldom exceeds about 1.60. Although many electrolytes have been suggested and used for anodization of aluminum, $H_2SO_4$ is the most widely employed. Concentrations are from 12 to 25 wt%. For special effects or attainment of special properties, chromic acid anodic coatings are opaque, limited to about 10 micrometers in thickness. They are used as a base for paints or adhesive bonding. Phosphoric acid anodizing has been used as a basis for plating on aluminum, though it has been superseded by zincate.

Tantalum pentoxide films have been extensively studied for use in electronic devices. The high dielectric constants of these films make them very attractive as storage capacitors. Studies of tantalum films doped with 2–7 at% nitrogen demonstrated that the reliability and leak current characteristics of tantalum pentoxide capacitors obtained by anodization can be improved.

The anodic oxidation of titanium is important in the use of platinum-plated titanium anodes, because even through pores in the platinum coating, the titanium oxidizes anodically and resists the action of the electrolyte involved.

Oxidation of silicon never led to a commercially acceptable process, mainly because the interface state density at the $SiO_2/Si$ interface is prohibitively high for semiconductor applications. Instead, anodization of silicon in a highly concentrated HF solution (excellent etchant for the anodic oxidation product $SiO_2$) may lead to porous silicon and very

high aspect ratio pores, with diameters ranging from 2 nm to several micrometers. The growth rate and degree of porosity of the silicon can be controlled by the current density. More on this subject is found in Section 5.3.3.

### 3.7.8. Physical Liquid Growth

There is no practical process known.

### 3.7.9. Chemical Solid Deposition

There is no practical process known.

### 3.7.10. Physical Solid Deposition

Wafer bonding has been a subject of interest for many years and a wide variety of bonding techniques have been reported, such as direct, plasma, anodic, adhesive (polymer, glass, or solder), eutectic, and compression bonding (thermocompression or ultrasonic). The basic principle of bonding is that two solid materials fuse and adhere to each other if they are brought in sufficiently close contact. The cohesion of atoms and molecules in a solid material as well as those between two different solid materials is ensured by a number of basic bond types, which are covalent, metallic, ionic, or van der Waals. All these are bond types and based on Coulombic forces resulting from the attraction of opposing electrical charges. Covalent and van der Waals bonds are the dominating bonding mechanisms and the atoms of two opposing surfaces must be less than 0.5 nm apart because these forces do not extend further than this distance. On the other hand, direct Coulombic forces can reach up to a distance of several micrometers and are dominant whenever charging occurs. This charging is due to macroscopically adsorbing or desorbing electrons. These direct Coulombic forces become negligible when water molecules are present at the interface, which partly neutralizes the charge on the surface. This overview is taken from the thesis of Frank Niklaus, "Adhesive Wafer Bonding for Microelectronic and Microelectromechanical Systems." In this section, we are mainly concerned with wafer bonding in which two full wafers should join. Two other applications, wire bonding and bump bonding, are mostly found in packaging applications and are not treated here. Bonding can be performed between two identical wafers or two dissimilar wafers. In the latter case, high bonding temperatures might cause pronounced shear stresses at the bonding interface preventing a correct bond. In such cases, the composition of one of the wafer materials is often adapted for thermal matching. For example, materials which are fit to become bondable with silicon are Pyrex glass and Kovar steel.

***Direct Bonding*** Direct bonding is also referred to as fusion bonding or thermal bonding. In direct bonding two wafers are contacted without the assistance of any significant pressure, electrical fields, or intermediate layers. It relies on the tendency for very smooth and flat surfaces to adhere to each other. It typically involves wafer surface preparation and cleaning, room temperature contacting of the wafers, and an annealing step to increase the bond strength. Direct bonding can be applied to identical wafers (e.g., silicon-to-silicon annealing between 600 and 1200 °C) and even dissimilar materials such as silicon-to-glass (annealing between 400

and 600 °C). Direct bonding usually leads to strong bonds and is widely used in SOI technology.

**Plasma Bonding**  In this technique, the surfaces to be bonded are exposed to (oxygen) plasma for, for example, 30 seconds, dipped in deionized water, and then placed together. After 24 hr at room temperature, the surface energy is deemed sufficiently high (>1 J/m$^2$) to establish a bond.

**Anodic Bonding**  The terms electrostatic bonding and field assisted bonding are also commonly used for this bonding technique. Anodic bonding is based on joining conducting material (e.g., silicon) and a material with ion conductivity (e.g., alkali-containing glass such as Pyrex). Two contacted wafers are heated to 180–500 °C to mobilize the ions while a voltage of 200–1500 V is applied. The voltage creates a large electric field that pulls the wafer surfaces into intimate contact and fuses them together. Due to the high force of attraction that is created by the electric field, anodic bonding is more tolerant to surface roughness than direct bonding. It is also possible to anodically bond two wafers with intermediate layers like glass, aluminum, silicon nitride or polysilicon. Anodic bonding usually leads to strong and hermetic bonds and is widely used for microsensor fabrication and for hermetic sealing of micromachined devices.

**Adhesive Bonding**  Adhesive bonding uses organic (polymer) or inorganic (ceramics or solders) intermediate layers to create a bond between two wafers. The adhesive material deforms and flows so it can make sufficiently close contact with the wafer surface to create a bond. The adhesive layer is deposited on one or both of the wafers, for example, by spin coating, spraying, screen-printing, extrusion, sedimentation, PVD, CVD, plating, or laminating. The wafers are brought into intimate contact and the intermediate adhesive layer is cured, typically by applying heat or UV radiation and pressure. The exact bonding procedure depends very much on the adhesive material used. The advantage of adhesive bonding, as compared to anodic and direct bonding, is the ability to join various wafer materials. It does not require assisting electric fields, the intermediate bonding material is not very susceptible to particles and structure at the wafer surfaces, and, moreover, it is carried out at moderate temperatures, which minimizes bond interface shear stresses. Adhesive wafer bonding requires no special wafer surface treatments such as planarization making it a low-cost bonding process. The process and materials employed determine the hermeticity and controllability of the cavity ambient.

A huge variety of organic adhesives (mainly polymers) with different chemistries and material properties are available. The bonding temperatures for polymer adhesives vary between room temperature and 450 °C making the process CMOS compatible. However, hermetical sealing is limited due to the intermediate polymer material used. A typical polymer bonding is using benzocyclobutene (BCB), a commercially available polymer from Dow Chemical. BCB is selected for its minimal outgassing, low moisture uptake, liquidlike behavior during bonding, high resistivity, chemical resistance, low processing temperatures (<250 °C), and ease of processing.

Ceramic adhesives are mostly based on oxides or silicates. For example, melting glass bonding is a variation on adhesive polymer bonding in which an inorganic glass layer (glass or glass frit) is used as the intermediate bonding material. The glass deforms or reflows during heating and makes sufficiently close contact with the wafer surfaces to create a bond between them. Two different types of glasses are available: devitrifying glasses and vitreous glasses. Devitrifying glasses are thermosetting materials which crystallize during the heating process. The melting point of these glasses is permanently increased after the curing process. Vitreous glasses are thermoplastic materials, which melt and flow at the same melting temperature each time they are thermally processed. Glasses with curing temperatures between 400 and 1100 °C are available. The advantage of glass adhesive bonding over organic adhesive bonding is that glass adhesive is able to achieve hermetic bonds (to be used in packaging of microsystems).

In solder (adhesive) bonding, layers of metal or metal-alloy based solders are used to bond wafers. The metal layers can be applied by, for example, PVD, CVD, or plating. The solder reflows during heating and wets both wafer surfaces, which causes intimate contact and bonding of the surfaces. A popular solder material is lead–tin (Pb–Sn) solder that melts at a temperature below 250 °C. Gold–tin and copper–tin solders are also suitable solder materials. Most solder-bonding processes use flux to remove oxides from the metal surfaces. If oxides are present at the metal surfaces, they can prevent wetting of the surfaces with the liquid solder, which causes poor bonding. Using *in-situ* vacuum metal deposition and bonding may prevent the development of such oxides. Like the ceramic intermediate layer, solder is able to create a hermetic sealing. Solder bonding is widely used to create electrical contacts in flip-chip bonding.

**Eutectic Bonding**  Eutectic bonding is a variation of solder bonding in which the low melting temperatures of certain alloys are used to bond two wafers. This effect is used to join two wafers with dissimilar surface materials. When the wafers are brought into intimate contact (eventually with an additional heating and high pressure applied), diffusion mechanisms between the surface materials cause the creation of an alloy at the bond interface. The alloy has a lower melting temperature than the individual materials. Thus, the melting occurs only in an extremely thin layer directly at the bond interface. The most commonly used material combination is silicon (melting point–mp—is 1414 °C) and gold (mp = 1064 °C) with a eutectic temperature of 363 °C. Also, other combinations such as lead (mp = 328 °C) and tin (mp = 232 °C) have been used. Eutectic bonding can result in strong and hermetic bonds at low temperatures and is often used for packaging microsystems. The disadvantage of eutectic bonding is the difficulty to obtain complete bonding over large areas due to native oxides at the material surfaces. This problem can be minimized by *in-situ* vacuum metal deposition and prebonding.

**Compression Bonding**  This bonding is also referred to as solid-state welding. In this bonding scheme two surfaces, of which at least one is usually a metal layer, are brought into close contact by applying a high pressure. The pressure (continues hydraulic or instantaneous explosive) causes

plastic deformation of the metal, which results in intimate contact and bonding between opposing surfaces. The application of heat improves the resulting bond quality (thermocompression bonding). Instead of directly heating the bond interface, the heat can also be supplied by ultrasonic energy—the process of ultrasonic bonding. The application of ultrasonic energy has the advantage that native oxides, particles, and surface nonuniformities at the bond interface are removed by scrubbing the surfaces at the bond interface. Common materials for compression bonding are Au to Au, Al to Au, Al to Al, and Al to glass. Typical bonding parameters for Au to Au bonding are pressures of about 300 MPa and temperatures of about 500 °C. The disadvantage is that huge net forces are required when bonding larger wafer areas. Thus, compression-bonding schemes are mainly used in wire bonding and in bump bonding schemes in which only very small areas are bonded.

### 3.7.11. Chemical Solid Growth

In some cases it is possible to apply first a solid film on a substrate. This film is subsequently used to diffuse atoms into the substrate layer beneath it, generally at elevated temperatures. A typical example is the formation of a boron or phosphor glass on top of a silicon wafer. During an annealing step, boron or phosphor atoms diffuse from the glass into the silicon due to the concentration gradient. After this "drive-in" step, the remaining (and depleted) oxide layer is removed in an etching process. Another example is the creation of a silicate film after the indiffusion of metal atoms into silicon or glass (Au or Al).

### 3.7.12. Physical Solid Growth

There is no practical process known.

### 3.8. Film Formation Examples

Different types of equipment used for the formation of thin films were discussed in the previous section. In this section the techniques used today to form specific thin films will be briefly described (see also pp. 556–571 in Plummer for epi-Si, poly-Si, $SiN_x$, $SiO_x$, Al, Ti, TiW, W, $TiSi_2$, $WSi_2$, TiN, and Cu). Table 8 provides a summary of some materials together with their formation techniques and a typical function of the film.

### 3.8.1. Silicon

Using CVD silicon as the gate electrode in MOS devices is considered a significant development in MOS circuit technology. One important reason is that silicon surpasses aluminum for electrode reliability. The silicon is clearly

**Table 8.** MEMS materials, formation method, and typical application.

| Material | Formation technique | Function |
|---|---|---|
| Al | evaporation, sputtering, PECVD | conductor, microstructure |
| Ti | evaporation, sputtering, PECVD | conductor, adhesion layer |
| Cr | evaporation, sputtering, electroplating | adhesion layer |
| Au | evaporation, sputtering, electroless, electroplating | protective layer |
| Cu | evaporation, sputtering, electroless, electroplating | conductor |
| Mo | sputtering | conductor |
| Pd | sputtering | adhesion layer, gas selective membrane |
| Pt | sputtering | interdiffusion barrier |
| Ni | evaporation, sputtering, electroplating | microstructure |
| W | LPCVD, sputtering | conductor |
| Al–Si–Cu | evaporation, sputtering | electrical conductor |
| Ni–Cr | evaporation, sputtering | resistor |
| Permalloy | sputtering | magnetoresistor, thermistor |
| Ti–Ni | sputtering | shape memory alloy |
| $Al_2O_3$ | CVD, sputtering, anodization | insulator |
| $InO_x$ | sputtering | semiconductor |
| $Ta_2O_5$ | CVD, sputtering, anodization | insulator, dielectric |
| Tin oxide | sputtering | semiconductor |
| ZnO | sputtering | insulator, piezoelectric |
| TaN | sputtering | resistor |
| TiN | MOCVD, sputtering | |
| Epitaxial Si | LPCVD, APCVD, PVD, CLD | high-resistivity semiconductor |
| Alpha-Si–H | CVD, PECVD, sputtering | semiconductor |
| Polysilicon | CVD, PECVD, sputtering | conductor, microstructure |
| Silicides | CVD, PECVD, sputtering, diffusion | conductor |
| $n/p$ Type Si | implantation, diffusion | semiconductor, etch stop |
| Porous Si | anodization | porous membrane, LED |
| $SiO_2$ | oxidation, sputtering, anodization, CVD | (thermal) isolation, masking, encapsulation |
| $SiN_x$ | LPCVD, PECVD, nitridation | (thermal) isolation, masking, encapsulation |
| Hydrogel | silk screen | electrolyte |
| Photoresist | coating | mask, planarization, pattern transfer |
| Polyimide | coating | insulator, planarization, microstructure |

superior, especially for thinner oxides, due to spiking of aluminum. Additional uses include manufacture of conductors, high-value resistors, and sacrificial layer material.

A low-pressure reactor operated between 600 and 650 °C is used to deposit polysilicon by pyrolyzing silane according to

$$SiH_4 \rightarrow Si + 2H_2 \tag{59}$$

Of the two most common low-pressure processes, one operates at a pressure of 0.2 to 1.0 Torr using 100% silane, while the other process involves a diluted mixture of 20 to 30% silane in nitrogen at the same total pressure. Both processes can deposit polysilicon with high throughput and with good uniformity (i.e., thickness within 5%). At low silane partial pressure, the deposition rate is proportional to the silane pressure almost not depending on the temperature. At higher concentrations, saturation of the deposition rate occurs and the process becomes temperature controlled. Deposition at reduced pressure is generally limited to temperatures between 600 and 650 °C. In the temperature range, the deposition rate varies as $\exp(-E_a/kT)$, where the activation energy $E_a$ is 1.7 eV, which is essentially independent of the total pressure in the reactor. At higher temperatures, gas phase reactions that result in a rough, loosely adhering deposit become significant and silane depletion will occur, causing poor uniformity. At temperatures much lower than 600 °C, the deposition rate is too slow to be practical. Process parameters that affect the polysilicon structure are deposition temperature, dopants, and the heat cycle applied following the deposition step. While the initial deposited film appears amorphous when deposition occurs below 600 °C, a columnar structure results when polysilicon is deposited at a temperature of 600 to 650 °C. This structure is comprised of polycrystalline grains ranging in size from 30 to 300 nm, at a preferred orientation of $\langle 110 \rangle$. When phosphorus is diffused at 950 °C, the structure changes to crystallite, and grain size increases to an average of between 0.5 and 1.0 $\mu$m. When temperature is increased to 1050 °C during annealing, the grains reach a final size of 1 to 3 $\mu$m. Polysilicon can be doped by diffusion, or the addition of dopant gases during deposition, which is referred to as *in-situ* doping. The implantation method is most commonly used because of its lower processing temperatures.

An atmospheric-pressure reactor is used to deposit episilicon. Four silicon sources have been used for VPE-APCVD growth: silicon tetrachloride ($SiCl_4$, reacting at 1200 °C), trichlorosilane ($SiHCl_3$, 1150 °C), dichlorosilane ($SiH_2Cl_2$, 1100 °C), and silane ($SiH_4$, 1000 °C). The overall reaction of $SiCl_4$, the most widely used source, that results in the deposition of silicon layers is

$$SiCl_4 + 2H_2 \Longleftrightarrow Si + 4HCl \tag{60}$$

An additional competing reaction is taking place that results in etching,

$$SiCl_4 + Si \Longleftrightarrow 2SiCl_2 \tag{61}$$

As a result, if the silicon tetrachloride concentration is too high or if the carrier gas entering the reactor contains HCl, etching with speeds up to 5 $\mu$m/min rather than deposition

of silicon will take place. Actually, this etching operation is used for *in-situ* cleaning of the silicon wafer prior to epitaxial growth.

### 3.8.2. Silicon Oxide

In Section 3.7.3, the formation of silicon dioxide by way of thermal oxidation has already been discussed sufficiently. Although it is possible to evaporate, sputter, anodize, and even spin-coat silicon oxide layers, this section focuses on some CVD techniques. CVD oxides are used to complement the thermal oxides: A layer of undoped silicon dioxide is used to insulate multilevel metallization, to mask ion implantation and diffusion, and to increase the thickness of thermally grown field oxides. Short of using an ellipsometer to determine the oxide thickness, the silicon oxide thickness color table comes in handy (Table 9). Phosphorus-doped silicon dioxide (P-glass) is used both as an insulator between metal layers and as a final passivation layer over devices. Oxides doped with phosphorus, arsenic, or boron are used occasionally as diffusion sources.

Most of the ultra-low-temperature methods use energy-enhanced CVD techniques (e.g., a focused electron beam) to deposit dielectric films between 25 and 300 °C. PECVD processes utilize a plasma to overcome the chemical inertness at low temperature. As a result, many radicals and intermediate species still exist after reaction. Another energy-enhanced CVD method uses UV radiation to form vapor phase reactants that enhance the deposition rates. Silicon dioxide films have been deposited at a rate of 15 nm/min at temperatures as low as 50 °C by means of UV radiation. Sometimes it is convenient to use PVD deposition. Compounds such as silica are much harder to evaporate in the right composition as alloys with single-source sputter systems. The composition of the vapor phase is usually not the same as the source compound, and chemical reactions and molecular changes often occur as the material is evaporated. Sputter deposition generally does a much better job in depositing compositionally uniform films of both alloys and compounds.

For low-temperature deposition (300 to 500 °C), the films are formed by reacting silane, dopant, and oxygen. The

**Table 9.** Oxide thickness (nm) color table.

| Color | | | | |
|---|---|---|---|---|
| Grey | 10 | | | |
| Tan | 30 | | | |
| Brown | 50 | | | |
| Blue | 80 | | | |
| Violet | 100 | 280 | 460 | 650 |
| Blue | 150 | 300 | 490 | 680 |
| Green | 180 | 330 | 520 | 720 |
| Yellow | 210 | 370 | 560 | 750 |
| Orange | 220 | 400 | 600 | |
| Red | 250 | 440 | 620 | |

chemical reactions for phosphorus-doped oxides at 450 °C are

$$SiH_4 + O_2 \rightarrow SiO_2 + 2H_2 \tag{62}$$

$$4PH_3 + 5O_2 \rightarrow 2P_2O_5 + 6H_2 \tag{63}$$
The deposition process can be performed in an APCVD or LPCVD reactor. The low deposition temperature of the silane–oxygen reaction makes it a suitable process when films must be deposited over a layer of aluminum.

For intermediate-temperature CVD (500 to 800 °C), silicon dioxide can be formed by decomposing tetra-ethyl-ortho-silicate, $Si(OC_2H_5)_4$, in an LPCVD reactor. The compound, abbreviated TEOS, is vaporized from a liquid source and decomposes at 700 °C as follows:

$$Si(OC_2H_5)_4 \rightarrow SiO_2 + \text{by-products} \tag{64}$$
While the intermediate temperature required for the reaction prevents its use over aluminum or polymers, it is suitable for polysilicon gates requiring a uniform insulating layer with good step coverage. Residual stresses can be tuned with for example, the deposition temperature or pressure and can be below 100 MPa tensile. The oxides can be doped by adding small amounts of the dopant hydrides (phosphines, arsine, or diborane) similar to the process in epitaxial growth.

For high-temperature deposition (700–900 °C), silicon dioxide is formed by reacting, for example, 30 sccm dichlorosilane, $SiCl_2H_2$, with 90 sccm nitrous oxide at reduced pressure (~500 mTorr):

$$SiCl_2H_2 + 2N_2O \rightarrow SiO_2 + 2N_2 + 2HCl \tag{65}$$
This deposition at a rate of ca. 1 nm/min (and a refractive index of $\eta = 1.45$) gives excellent film uniformity and is sometimes used to deposit layers over polysilicon.

In general, there is a direct correlation between deposition temperature and film quality. The lower densities occur in films deposited below 500 °C. Heating deposited silicon dioxide at temperatures between 600 and 1000 °C causes densification, during which the oxide thickness decreases while the density increases to 2.2 g/cm$^3$. At higher temperatures, deposited films are structurally similar to silicon dioxide that has been thermally grown and the compressive stress rises to ca. 300 MPa and the refractive index to the usual 1.46 (at a wavelength of 633 nm). Oxides with lower indices are porous, such as the oxide from the silane–oxygen deposition. The porous nature of the oxide also is responsible for the lower dielectric strength. Dichlorosilane- and TEOS-oxide give a nearly conformal coverage due to rapid surface migration. However, during silane–oxide deposition, no surface migration takes place and the step coverage is determined by the arrival angle. A smooth topography is usually required for the deposited silicon dioxide that is used as an insulator between metal layers. If the oxide used to cover the lower metal is concave, circuit failure may result from an opening that may occur in the upper metal layer during deposition. Because P-glass deposited at low temperatures becomes soft and flows upon heating, it provides a smooth surface and is often used to insulate adjacent

metal layers. This process is called P-glass-flow. P-glass-flow depends on annealing time, temperature, phosphorus concentration, and annealing ambient. The etch rates of oxides in a hydrofluoric acid solution depend on deposition temperature, annealing history, and doping concentration. Usually, higher quality oxides are etched at lower rates.

Although silicon nitride is a much better diffusion barrier, silicon dioxide performs well as a mask against diffusion of the common dopants in silicon; the diffusion coefficient $D$ of boron at 900 °C in silica is $2.2 \times 10^{-19}$ cm$^2$/sec compared to $4.4 \times 10^{-16}$ in silicon; for phosphorous, $D$ equals $9.3 \times 10^{-19}$ cm$^2$/sec in silica compared to $7.7 \times 10^{-15}$ in silicon. For many other elements, silica forms a poor diffusion barrier. The amorphous oxide has a more open structure than crystalline quartz; only 43% of the space is occupied. Consequently, a wide variety of impurities (especially alkali ions such as sodium and potassium) can readily diffuse through amorphous silica. Diffusion through the open silica structure happens especially fast when the oxide is hydrated. One of the reasons for the poor performance of silicon dioxide-based ISFETs in aqueous solutions can be traced back to the simple observation that silica in water behaves like a sponge for ions. This is why, in such devices, silica is often topped off with the excellent ionic barrier material $Si_3N_4$. The use of silica as a diffusion mask often stems from convenience; silica is easy to grow, whereas one cannot put silicon nitride that easily onto silicon.

### 3.8.3. Silicon Nitride

Thin films of silicon nitride are of special interest for microtechnology. These films can be used for passivating devices, because they serve as good moisture barriers, prevent sodium diffusion, and provide excellent scratch protection. The films also can be used as masks for selective oxidation of silicon ("LOCOS"), because silicon nitride oxidizes very slowly. Another application is the use as an etching mask for wet chemical KOH etching and the use as a construction material in microsensors or in X-ray masks. Silicon nitride films can be deposited in a low-temperature (300 °C) PECVD process or an intermediate-temperature (750 °C) low-pressure (below 1 Torr) LPCVD process. The films deposited by PECVD are not stoichiometric and have low density (2.4 to 2.8 g/cm$^3$). Because of the low deposition temperature, these films can be deposited over the completely fabricated devices and serve as their final passivation. The LPCVD films deposited at ca. 800 °C and 200 mT have stresses ranging from low tensile (<300 MPa) for nonstoichiometric (silicon-rich) films up to high tensile (~1000 MPa) for stoichiometric ($Si_3N_4$) films with high density (2.9 to 3.1 g/cm$^3$).

In the PECVD process, silicon nitride is formed at 300 °C inside a radial-flow parallel-plate reactor either by reacting silane and ammonia in argon plasma or by reacting silane in a nitrogen discharge.

$$SiH_4 + NH_3 \rightarrow SiNH + 3H_2 \tag{66}$$

$$2SiH_4 + N_2 \rightarrow 2SiNH + 3H_2 \tag{67}$$
The products depend strongly on deposition conditions but the deposition rate generally increases with increasing temperature, power input, and reactant gas pressure. Large concentrations of hydrogen are contained in PECVD films. The plasma nitride film (SiN) used in semiconductor processing generally contains 20 to 25 at% hydrogen. Films with low tensile stress ($\sim 2$ GPa) can be prepared. Film resistivities range from $10^5$ to $10^{21}$ $\Omega$ cm depending on silicon-to-nitrogen ratio, while dielectric strengths are between 0.1 and 0.6 V/nm.

In the LPCVD process, for example, 30 sccm dichlorosilane (DCS) and 90 sccm ammonia react at reduced pressure ($\sim 300$ mTorr) to deposit silicon nitride at temperatures between 700 and 900 °C with good film uniformity, conformal step coverage, low speed (ca. 7 nm/min, $\eta = 2.00$), high wafer throughput, and often combined with the high temperature silicon oxide LPCVD. The reaction is

$$3SiCl_2H_2 + 4NH_3 \rightarrow Si_3N_4 + 6HCl + 6H_2 \qquad (68)$$
The activation energy for deposition is about 1.8 eV. It is found that—in decreasing order of importance—the gas flow ratio of Si and N containing precursors, temperature, and pressure are the most relevant parameters determining the electrical, mechanical, and optical properties of the films and the deposition rate and uniformity in film properties across a wafer. Standard processes as used in the IC industry employ an excess of ammonia, resulting in a nearly stoichiometric $Si_3N_4$ film. The LPCVD nitride is an amorphous dielectric with a dielectric constant of 6, containing up to 8 at% hydrogen. The resistivity at room temperature is about $10^{16}$ $\Omega$ cm, its dielectric strength is 1 V/nm, and the etch rate in buffered HF is less than 1 nm/min. The film's very high tensile stress of approximately 1 GPa makes films thicker than 200 nm sensitive for cracking and, therefore, the films are less suitable as a construction material. Stress reduction—and even stress reversal from tension to compression—can be accomplished when an excess of DCS is used. In such cases, silicon-rich layers (ending in polysilicon) will form with large variations in the optical refractive index, mechanical stress, and electrical resistivity. The deposition rate increases with increasing total pressure or dichlorosilane partial pressure and decreases with an increasing ammonia-to-dichlorosilane ratio.

### 3.8.4. Multilayer Silicon Compounds

The LPCVD reactor operating with dichlorosilane vapor is well suited to deposit a stack of alternating layers of, for example, silicon, silicon oxide, and silicon nitride by introducing alternatively additional amounts of hydrogen, nitrous oxide, and ammonia respectively. It is even possible to smoothly vary from stoichiometric silicon nitride to silicon-rich silicon nitride and back by smoothly varying the mass flow of ammonia during deposition. It is possible to deposit silicon oxynitride by simultaneously introducing both ammonia and nitrous oxide. In order to deposit a stack of alternating nanolayers it is important to notice that the mass flow controllers (MFCs) should be well controlled. Especially, the initialization of the MFC is a point of concern. Figure 65 shows a time diagram of the MFC flows of DCS, ammonia,

**Figure 65.** Multilayer LPCVD deposition.

and nitrous oxide of a freely chosen silicon compound nanostack using LPCVD at 800 °C and 300 mTorr. The stack starts with the growth of a 10 nm thin layer of polysilicon at 10 sccm DCS flow. Then 30 sccm ammonia is introduced to deposit 10 nm stoichiometric silicon nitride. After closing the ammonia flow and introducing nitrous oxide slowly, subsequently silicon-rich nitride, silicon oxynitride, silicon-rich oxide, and 10 nm of silica form. Finally, after closing the DCS flow, the nitrous oxide continues flowing to passivate the stack with pure silica.

### 3.8.5. Silicides

Silicides such as $TiSi_2$ and $TaSi_2$ have reasonably low resistivity ($<50$ $\mu\Omega$ cm) and are generally compatible with MEMS processing. These silicides remain stable during contact with polysilicon. Silicides may be formed in several ways; depositing a refractory metal film on (poly)silicon and sintering the structure, co-deposition the metal and silicon in a PVD system, or forming the silicide by CVD. All silicides can withstand much higher processing temperatures than aluminum. Of course, the eutectic temperature will limit the maximum process temperature of the silicide in contact with silicon.

### 3.8.6. Aluminum

Aluminum and its alloys are used extensively for metallization in microsystems, because of its low resistivity (i.e., 2.7 $\mu\Omega$ cm for Al and up to 3.5 $\mu\Omega$ cm for its alloys). Aluminum also adheres well to silicon dioxide. However, the use of aluminum creates problems such as spiking and electromigration. To improve the characteristics of pure aluminum, other materials are added, such as silicon (to prevent spiking) or copper (to prevent electromigration or hillocking).

Most often, aluminum is deposited in PVD systems. Resistance-heated evaporation is difficult with Al because during heating the surface of the aluminum melt is readily oxidized due to impurities deriving from the reactor or from the crucible. Instead, e-beam evaporation is used to break the surface oxide layer. Residual film stresses differ a lot but typically range between a few MPa up to several tens of MPa strongly depending on the deposition temperature.

To improve step coverage, aluminum can be deposited by MOCVD using metal-organic compounds such as tri-isobutyl aluminum:

$$2[(CH_3)_2CHCH_2]_3Al \rightarrow 2Al + 3H_2 + \text{by-products} \qquad (69)$$

As devices become smaller, the corresponding current density becomes larger. High current densities can cause device failure due to electromigration. The term electromigration refers to the transport of mass in metals under the influence of current. It occurs by the transfer of momentum from the electrons to the positive metal ions. When a high current passes through thin metal conductors, metal ions in some regions will pile up and voids will form in other regions. The pileup can short-circuit adjacent conductors while the voids can result in an open circuit. The electromigration resistance of aluminum film conductors can be increased by alloying with copper (e.g., Al with 0.5% Cu) or encapsulating the conductor in a dielectric.

### 3.8.7. Other Metals

CVD is attractive for metallization because it offers coatings of conformal nature with good step coverage and large throughput. The basic setup is the same as that used for deposition of dielectrics and polysilicon. CVD is capable of producing conformal step coverage over a wide range of topographical profiles often with lower electrical resistivity than that from PVD, which also suffers from the effects of shadowing and poor step coverage. One of the major applications of CVD metal deposition has been in the area of refractory-metal deposition. For example, tungsten's low electrical resistivity (5.3 $\mu\Omega$ cm) and its refractory nature make it a desirable metal for use in microfabrication. The following two chemical equations show both the pyrolysis and the reduction of tungsten:

$$WF_6 \rightarrow W + 3F_2 \tag{70}$$

$$WF_6 + 3H_2 \rightarrow W + 6HF \tag{71}$$
Many other metals such as molybdenum, tantalum, and titanium are of interest for microdevice applications. These metals can be deposited by hydrogen reduction in a LPCVD reactor having the overall reaction

$$2MCl_5 + 5H_2 \rightarrow 2M + 10HCl \tag{72}$$
where M stands for the aforementioned metals.

### 3.9. Conclusion and Nanoperspective

Developing near-term commercially viable products is of vital importance for the development of the nanofield. Near-term opportunities of nanomaterials lie in functional nanomaterials such as tougher and harder cutting tools, the superplasticity of ceramics during processing, high performance parts for the aerospace and the building industry, energy and filter technologies (novel solar cells and water purification), the automobile industry, optical and catalytic applications, and sensors. On a longer term, and dependent on the developments in the electronic industry, (opto)electronic applications of nanomaterials such as photonics may find a big market. Interdisciplinary cooperation in research and development is important for the realization of scientific breakthroughs and for new products such as hybrid coatings or nanoelectronic devices. Currently, the preparation technology of nanomaterials plays an important role in state-of-the-art science and dedicated scientific journals and conferences have appeared already. Fundamental physics and chemistry, as well as materials science and engineering, are involved in advancing the level of understanding and handling atomic arrangement and hence properties of nanomaterials. The nanoscale offers many opportunities for materials and devices with new properties that vary greatly in origin, composition, production method, properties, and price. It is hard to predict which of them will play a role in products based on nanotechnology, but the main challenges along the path to new commercially viable (MEMS-based) nanomaterials can be summarized as:

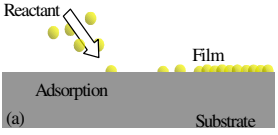
- *Fundamental physics:* Understanding nanomaterial formation and composition and the critical role of surfaces, interfaces, defects, and particulates is important.
- *Fabrication:* Reproducible and uniform production of nanomaterials is necessary.
- *Characterization:* Nanoscale resolution microscopes are essential tools for characterization.
- *Economics:* Cost-efficiency and scaleable production of nanomaterials is requested.

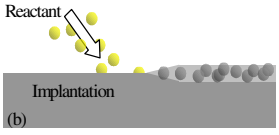
Nanomaterials can be divided into nanofilms, nanoparticles, and nanostructured films. In MEMS-based film formation, as described in this chapter, the formation of a film with a thickness between 1 and 100 nm is defined as a nanofilm or nanolayer. In nanofilms particles should be avoided. Particles might create pinholes and shorts, which influence the electrical, chemical, and mechanical strength of the layer. However, the formation of individual nanoparticles (i.e., a particle between 1 and 100 nm in diameter) can be beneficial in quantum devices and other applications. When such nanoparticles are "collected" or incorporated in an overall framework (thin film), it is called a nanostructured film. All these nanomaterials exhibit new or improved properties compared to the corresponding bulk material. This makes them attractive for applications such as quantum dot lasers, (electro)luminescent devices, novel solar cells, gas sensors, resistors and varistors, conductive and capacitive films, high-temperature superconductors, and thermoelectric, optical, and magnetic films. Both nanoparticles and nanostructured films were not treated in this chapter in detail but are likely to become very important in future nanotechnology. Therefore, some brief remarks will be given here.

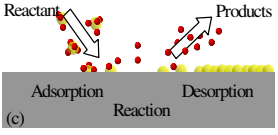
**Nanofilms** In order to form a nanofilm accurately it is important to have a process which is able to deposit or grow the film in such a way that the thickness, composition, and structure are guaranteed within certain specifications. In such cases film formation processes which are sensitive to particle creation (such as homogeneous gas phase reaction in CVD or dusty plasmas) and processes with high film-formation speed are avoided. Typical processes able to form nanolayers are LPCVD, MBE, laser ablation deposition, thermal and chemical oxidation, anodization, spin coating, and SAMs. The growth of ultrathin silica films follows different kinetics than "thick" films. For example, the thickness and growth rate of native oxides (<1 nm) strongly depend on surface preparation and the environmental conditions regarding exposure and seem to form layer-by-layer [184]. It is thus very difficult to prepare a native oxide of a

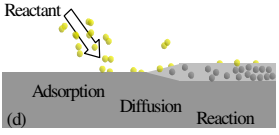
certain quality. Chemical oxides (1–3 nm) are more stable than native oxides and are produced in strongly oxidizing agents such as $HNO_3$, $H_2O_2$, or just water. This renders silicon more or less inert to further oxidation by air even up to about 600 °C. Growth of ultrathin thermal oxides (1–10 nm) at temperatures above 600 °C is influenced by the nature of oxidants for the surface reaction such as the presence of O or $O_2$, or by the stress present, or by the transport through micropores. In this regime the growth is linear with time although for the initial layers growth is repressed by high internal stresses [172, 183]. On the other hand for "ordinary" thermal oxides (>10 nm), the growth is parabolic with time because only the diffusion of the oxidant through the growing film is controlling the rate. At temperatures above about 1200 °C, silicon reacts with nitrogen, $N_2$, in the air as well as oxygen, to form the silicon nitrides SiN and $Si_3N_4$. The forming of large-scale single crystal nanofilms on top of amorphous layers might be difficult. Although preshaping the substrate (with a repetition smaller than the domain size) might induce single crystal formation, the accuracy of the lithography could prohibit this option. The surface condition will have a major influence on the properties of nanofilms. For example, condensed water, organic "dirt," or trapped ionic species will alter the initial film formation process and, therefore, the film adhesion, morphology, and structure. The growth of natural oxides is increasingly important due to stress considerations as the dimensions of freestanding structures are getting smaller and smaller. A short overview of these subjects, as found in this section, is depicted in Table 10.

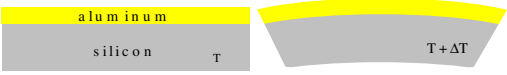
***Nanoparticles*** At present, many ways exist to synthesize nanoparticles, such as mechanical ball milling and gas-phase synthesis (such as dusty plasmas and CVDs). In the latter case, the particles are collected as a powder or deposited on a substrate. If the particles have dimensions comparable to the wavelength of the electrons, phonons, magnons, etc. inside the material, quantum mechanical effects predominate. A particle becomes a quantum dot and quantum confinement leads to a change in the density of states. The macroscopic properties (electronic, optical, electrical, magnetic, chemical, and mechanical) of materials can thus be affected substantially by small changes in the nanoparticle. It is important to realize that many aspects of nanoparticles in liquids have been (and are being) studied in colloid science. Due to their large surface-to-volume ratio, nanoparticles are very reactive. The particles tend to both agglomerate and oxidize, which causes substantial handling problem.

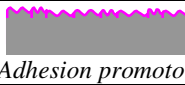
***Nanostructured Films*** Examples of nanostructured films are nanoporous, nanocrystalline, nanocomposite, and hybrid films. Nanoporous films have nanosized pores, nanocrystalline material consists of many crystalline domains, and nanocomposite film contains two or more phase-separated components with morphology of spheres, cylinders, or networks with nanodimensions. Nanohybrid films are constructed from a combination of polymeric organic components and inorganic or ceramic components that are chemically interconnected on a molecular level. Both the size of the nanostructure and the scale of order within


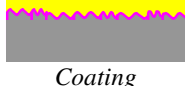


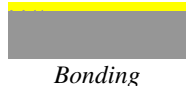


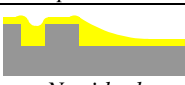


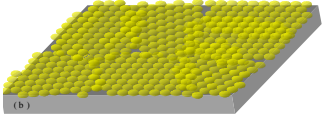


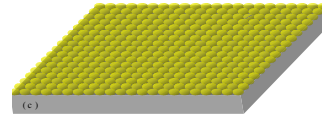












them affect the film properties and they often exhibit properties that are drastically different from those of conventional films. In many cases, this is a result of the large fraction of grain boundaries—the boundaries between the nanoparticles in the film—and hence by the percentage of surface atoms. This surface can border on the embedding matrix, on a nanoparticle, on air, or on vacuum in case of a pore or defect. Due to this, film properties become governed by surface properties. The size range of 1 to 100 nm implies a number of atoms per particle varying from several to ten million or more. For the smallest sizes, the surface-to-volume ratio becomes very large. For instance, for close-packed spheres the percentage of surface atoms is about 80% for a 50-atom particle and is still 20% for a 2000-atom particle. A very instructive example is glass. Although generally classified as an amorphous material, glass is in fact a nanostructured material. The nanoparticle is the silicon ion surrounded tetrahedrally by four oxygen ions. These tetrahedral are joined together at their corners by oxygen bridges in a variety of ways to form varies phases or structures of silica with very different properties. This nanostructure might explain the viscoelastic behavior of glass occurring even at relatively low temperature and is responsible for the spongelike behaviour of glass for water with ionic species such as sodium [170]. Mixing the silicon oxide with, for example, boron oxide creates a glass with thermoelectric properties and there are many more examples where the mixing of the silica nanoparticles with other ceramic nanoparticles or (alkali) ions influences the behavior of the glass drastically.
## 4. LITHOGRAPHY

A thin film deposited on the wafer surface is usually not interesting enough to form a microdevice. The thin film should be shaped to leave the desired pattern of the film on the wafer surface. For this purpose lithography has been introduced. Words such as printing, writing, and lithography have more or less the same meaning in daily life. However, in order to create a consistent terminology, in this section we will subdivide lithography into two independent techniques, printing and writing.

"Lithography" is Greek for "to write" [gráphein] with a "stone" [lithos]. A lithograph, for people interested in art, is a less expensive picture made by impressing in turn several flat, embossed slabs, each covered with greasy ink of a particular color, onto a piece of stout paper. In this way, many "originals" can be made from the same slab. The various colors must be accurately aligned with respect to one another within some registration tolerance to produce the effect intended by the artist who carved or etched the slabs. However, nowadays the term lithography has a somewhat broader meaning and includes not only mechanical impressing techniques. For example, the ability to print patterns using optical techniques with submicrometer features and to place those patterns on a substrate with better than 0.1 micrometer precision is what makes today's microcomponents (including microelectronics and microsystems) possible. The concept is simple as found in Fig. 66). (1) A radiation-sensitive resist is spun onto a substrate forming a thin layer on the surface. (2) The resist is then selectively exposed, by shining radiation (photons, electrons, or

**Figure 66.** Basic lithographic process. (1) Spin-coat a layer of photoresist. (2) Illuminate the resist through a mask. (3) Develop the resist.

ions) through a mask, which contains the pattern information for the particular layer being fabricated. That is, the mask is partly transparent and partly opaque to form this pattern. (3) The resist is then developed which completes the pattern transfer from the mask to the substrate. Therefore, the optical lithography used in the microcomponent industry is related to the imprinting lithography of the art world. The artist corresponds to the chip designer and the slabs are masks for the various thin film levels. The press corresponds to the exposure system, which also aligns it to a completed level. The ink may be compared with the radiation-sensitive resist and the paper can represent the substrate onto which the patterns will be transferred. Due to the fact that the method is identical with the planographic printing technique, in this section it will be defined as *print lithography*. So, although historically lithography was synonymous with stone writing, nowadays the word is best translated into printing instead of writing. As should be clear by now, to be able to perform print lithography, a mask is needed. For the fabrication of this mask we need calligraphy.

"Calligraphy" is Greek for "beautiful writing." It is a skilled penmanship practiced as a fine art. In the East calligraphy has been consistently practiced as a major aesthetic expression. In China, from the 5th century BC, when it was first used, calligraphy has always been considered equal, or even superior, to painting. Nowadays, calligraphy is a very basic step in cleanroom facilities. For example, the making of a mask, needed for print lithography, is done by transferring a pattern into a radiation sensitive resist layer while writing with a narrow beam. Due to the use of the narrow beam of electrons, ions, photons, or even a liquid to write a pattern on or in a substrate (including a resist film) we will define this technique as *write lithography*. Although the term write lithography seems to be a pleonasm, the author believes that it is a necessary amalgamation to discern it from print lithography. The pattern is normally transferred using a computer aided design (CAD) controlled *XY*-stage and, therefore, the writing process is relatively slow compared to print lithography. Therefore, the writing process is nowadays restricted to small-scale specialities and mask making for print lithography.

So writing (of a mask) and printing (with a mask) are two independent but indispensable techniques to perform lithography in present microcomponent development. Print lithography uses a broad beam exposure tool together with a mask to replicate a pattern in one flash and the pattern on this mask is usually fabricated with the help of narrow beam write lithography. Nevertheless, today's lithographic equipment consists of impressive machinery that is used to repeatedly image a pattern of a mask onto a silicon wafer, which is best specified as a combination of both printing and writing. This process is known as *stepper lithography*: the process of writing a replicating pattern with the help of a "stepper mask" in an *XY* fashion several times. Stepper lithography is not only used to produce a pattern directly on a wafer surface, but it can also be used to create a mask, which is then used in print lithography to replicate a pattern on a wafer.

The use of an intermediate resist layer to transfer a pattern is not strictly necessary (see section on resist lithography). It is possible to directly print or write with, for example, an ion beam into a layer without the help of resist. Although this normally lowers the selectivity between different layers (the physical nature of the ion beam is normally quite material insensitive), it increases the resolution enormously (radiation scattering in resist limits the resolution typically by a factor of two). This issue becomes increasingly important in sub-100 nm lithography (i.e., nanolithography) and will be treated in the section on direct lithography.

While the concept of lithography is simple, the actual implementation is very expensive and very complex, primarily because of the demands placed on this process. The performance of a lithographic process is determined by parameters such as resolution, depth of focus, exposure field, registration, throughput, defect density, and resist material. The *resolution* (Res) is the minimum feature dimension that can be transferred with high fidelity to a film on a wafer. It is basically determined by the wavelength of the radiation employed, according to Rayleigh's criterion: $\text{Res} = k_1 \lambda / NA$—the separation of two barely resolved point sources. Here $k_1$ is a system-dependent constant (typically around 0.5), $\lambda$ is the wavelength of the lithographic system, and NA ($= \sin \alpha$) is the numerical aperture, which indicates the radiation acceptance angle of the system. Meanwhile, the *depth of focus* (DOF) of this image changes with the wavelength and NA according to $\text{DOF} = k_2 \lambda / NA^2$, with $k_2 (\sim 0.5)$ an imaging constant depending for instance on the coherence of the source and on the resist. This shows that the resolution can be improved by either reducing the wavelength or increasing NA. However, the DOF degrades much more rapidly by increasing NA than by decreasing $\lambda$ and a reasonable DOF is needed to expose wafers with certain topography with height variations patterned in previous manufacturing steps. This explains the trend toward shorter wavelengths in lithography. *Exposure field* requirements result from ever-increasing chip sizes and the need to expose at least one full chip with each exposure. *Registration* (i.e., alignment or placement accuracy) is a measure of how accurately patterns on successive masks can be aligned with respect to previously defined patterns on the wafer. It remains at about one-third of the minimum feature size for each generation of technology. *Throughput* is

the number of wafers that can be exposed per hour for a given mask level and is directly determined by the kind of exposure tool used. Wafer exposure tools today cost about 10 million Euro and must be capable of printing on the order of 1 wafer per minute in order to meet cost objectives. *Defect density* or yield translates directly into yield loss and therefore higher costs for the finished chips. Defects introduced during the lithographic process are a significant contributor to final chip yield. Another important subject is the *resist material* itself (in case of resist lithography), which is a radiation-sensitive compound. Here the primary issues are sensitivity, contrast, tone, etch resistance, etch selectivity with respect to underlying layers, profile (3D), step coverage, resolution, and ruggedness. Sensitivity is a key characteristic and it determines the resist's efficiency in responding to a given amount of radiation.

In order to facilitate a confident choice to perform nano-lithography, sections on write lithography, print lithography, stepper lithography, and alternative and related lithography will be treated in succession.

## 4.1. Write Lithography

The overall write lithography (or writing) process is conceptually illustrated in Figure 67. The patterns that comprise the various layers in a microsystem are designed using CAD systems. Today these systems contain many advanced capabilities that greatly improve the efficiency of designing microcomponents having practically any shape. As already is the case for IC design, we envision libraries of previous designs that are known to work and are available, from which basic functions can be cut and pasted into new (more complex) designs. Software tools are used to help route the connections between functional blocks. Additional tools check the design to make sure that there are no violations of design rules. And finally, system-level simulation tools are available to predict the performance of the new design. Once the design is complete and ready to transfer to the fabrication facility, the information for each mask level is transferred to a machine that is either an electron, ion, or laser

**Figure 67.** Schematic of write lithography.

beam pattern generator (Fig. 67). These machines raster this narrow (focused) beam in an *XY* pattern across the substrate (wafer or mask blank) with the beam blanked on and off as necessary to generate the appropriate pattern. Generally the beam size is on the order of 0.1–0.5 micrometer. It is perhaps obvious that the e-beam (or ion beam) system could be used directly to write images on a wafer simply putting the electron sensitive resist on the wafer rather than on the mask. The reason this is not done in high-volume manufacturing is simply because the wafer throughput would be too slow. Typical e-beam pattern generators would require tens of minutes to expose a full wafer. This is much slower than optical steppers that typically have throughputs on the order of 1 wafer per minute.

In case the pattern generator is used to create a mask (to be used in print lithography), the mask itself is usually a fused silica plate covered with a thin layer (ca. 80 nm) of chromium and a layer of resist. A thin antireflection coating (10–15 nm) is also often used between the chrome and the resist to prevent reflections from the chrome layer, which can degrade pattern resolution. The beam exposes the resist which is then developed and used as an etch mask to transfer the mask pattern into the chrome. The chrome layer is usually wet etched. Once the chrome is etched, the resist is removed. The fused silica substrate has a highly polished surface so that light is not scattered as it passes through the mask and has a small thermal expansion coefficient so that mask dimensions are stable over small temperature changes. It is also obviously important that the silica has high transparency at the wavelength of radiation used in the wafer exposure system. In optical lithography, this is becoming more difficult to achieve in practice as the exposing wavelength moves deeper into the ultraviolet region to achieve higher resolution. Even though the mask material (basically $SiO_2$) has a large bandgap, trace impurities in the glass can degrade optical transparency because they can absorb light at these short wavelengths.

### 4.1.1. Electron Beam Writing

Electron beam writing (EBW) uses an electron gun for patterning. The gun is a device that can generate a beam of electrons with a suitable current density; a tungsten thermionic-emission cathode or single-crystal lanthanum boride ($LaB_6$) can be used for the electron gun. Condenser lenses are used to focus the electron beam to a spot size of 1–100 nm in diameter. Beam-blanking plates (to turn the electron beam on and off) and beam deflection coils are computer-controlled and operated at high rates (MHz) to direct the focused electron beam to any location in the scan field on the substrate. Because the scan field (typically 1 cm) is much smaller than the substrate diameter, a precision mechanical stage is used to position the substrate to be patterned. EBW offers higher resolution than optical lithography because of the small wavelength of the 10–50 keV electrons. The ultimate resolution of EBW is not limited by diffraction (the wavelength is of the order of $10^{-13}$ m, which is much smaller than atomic sizes), but by electron scattering in the resist (in case of resist lithography) and by the various aberrations of the electron optics. Due to its flexibility in creating patterns, EBW is widely used in research or small
volume production specialities, and it is the primary technique for mask fabrication. Electron resists are polymers. The behavior of an electron resist is similar to that of a photoresist; that is, a chemical or physical change is induced in the resist by radiation. This change allows the resist to be patterned. Common positive electron resists are poly(methyl methacrylate), called PMMA, and poly(butene-1 sulfone). Positive electron resists have resolutions of 0.1 micrometer or better. Poly(glycidyl methacrylate-co-ethyl acrylate), called COP, is a common negative electron resist. COP, like a negative photoresist, also swells during development so the resolutions are limited to about 1 micrometer.

To minimize the resolution limitation caused by the resist, it is possible to use an electron beam to directly deposit a layer from a precursor gas or to write directly into a layer (e.g., Teflon). Evaluation of practical parameters suggests that typical best resolution that may be expected is around 5 nm.

### 4.1.2. Ion Beam Writing

Ion beam writing (IBW) is important when the minimum feature dimension is reduced to about 0.2 micrometer and below. IBW can be operated in a shallow writing mode using PMMA as an ion beam resist. It can achieve higher resolution than optical, X-ray, or electron beam lithographic techniques because ions have a higher mass and therefore scatter less than electrons. In addition, resists are more sensitive to ions than to electrons.

Focused ion beam etching (FIBE) does not employ resist for pattern definition. It directly sputters material or directly deposits material from a focused ion beam. FIBE is mainly used for mask repair and offers patterned-doping and oxidation capability and very high resolution (10 nm). Ion implantation can also be used to do resistless pattern generation. One example is the etch rate enhancement in silicon dioxide when it is implanted with various ions. The etch rate is doubled when $10^{14}/cm^2$ argon ions are implanted. Thus, oxide layers can be patterned without any resist. Another example is the modification of the oxidation rate of implanted silicon. After silicon ions are implanted into the silicon substrate, followed by thermal oxidation, the thickness of silicon dioxide increases in the implanted area. On the other hand, nitrogen implantation into silicon retards the oxidation rate of the implanted area (a kind of LOCOS). These interesting effects of ion implantation are potentially very useful in the fabrication of submicrometer devices.

### 4.1.3. Mechanical Beam Writing

Recently, it has become clear that a scanning probe microscope, where a sharp probe moves within a distance of the order of 1 nm from a surface, not only allows to image this surface down to the atomic level but also allows one to modify it in a controlled way down to the nanometer level. Many techniques for scanning probe lithography (SPL) have been presented in literature.

On conducting surfaces, the scanning tunneling microscope (STM) tip can serve as a very-low-voltage electron source for the exposure of thin electron-sensitive resist layers, avoiding most of the resolution-limiting aspects of conventional electron beam lithography. Alternatively, by giving short voltage pulses, one can deposit small amounts of the tip material on the substrate via field evaporation or, after passivation with hydrogen atoms (using, e.g., hydrofluoric acid), one can locally depassivate and oxidize a surface such as silicon. At ultrahigh vacuum and low temperature (4 K), it is even possible to manipulate individual atoms or molecules on a conducting surface—by sliding atoms to exactly controlled positions, a structure can be built atom by atom, and one could even construct artificial molecules (i.e., "mechanosynthesis"). Nice examples can be found on the IBM website. In contrast to STM, the AFM can be used to pattern both conducting and nonconducting surfaces, but usually not with atomic resolution. The very controlled mechanical contact between the sharp tip and the surface allows one to etch small grooves in a soft layer or even to induce atomic scale modification.

The lithographic techniques discussed in the rest of this section do not provide the ultimate resolution that SPL can offer but are competitive down to 5 nm, and SPL is probably essential when resolution at the molecular scale is required. Currently, SPL suffers from a poor reproducibility at the nanometer level in most cases, and from a very low processing speed (throughput), which hampers a fast introduction in commercial production processes. A possible route toward mass production of nanoscale devices may rely on the fabrication of many probes in parallel or ultrafast scanning speeds. These contain large areas with arrays of nanotips and these multitips would then write a limited part of the nanocircuit in parallel. Recently, has become possible to write and read data using a polycarbonate sample and tips in parallel with integrated resistors that locally heat the tip.

### 4.1.4. Photon Beam Writing

With a laser source, it is possible to write a pattern on a surface directly by scanning the micrometer-sized laser beam over the surface most often in the presence of the suitable reactive gases. By adjusting the focal point of the laser continuously, it is even possible to grow three-dimensional microstructures such as fibers and springs in a wide variety of materials such as boron, carbon, tungsten, silicon, SiC, $SiN_x$, etc. Alternatively, a scanning near-field optical microscope might be useful to optically write very locally with a scanning probe a pattern: the process of scanning near-field optical writing.

### 4.2. Print Lithography

Figure 68 illustrates the steps of transfer of patterns with the help of print lithography (or printing). As an example, we will take optical lithography because it is the main lithographic technique. In our example, a pattern from a mask is transferred onto a silicon wafer that has a radiation-sensitive resist, for example, on top of an insulating $SiO_2$ layer formed on its surface. Resist is applied by dropping the solution on the wafer and rotating the wafer on a spinning wheel. After the spinning step, the wafer is given a pre-exposure baking (typically 80 to 100 °C) to remove the solvent from the resist film and to improve resist adhesion to the wafer. The wafer is aligned with respect to the mask in an optical lithographic system and the resist is exposed to ultraviolet

**Figure 68.** Schematic overview of print lithography.

light. The exposed (positive) resist is dissolved in the developer, which is usually done by spraying the wafer with the developer solution. The wafer is then rinsed and dried. After development, a postexposure baking (at 100 to 180 °C) may be required to increase the adhesion of the resist to the substrate. The wafer is then put in an ambient that etches the exposed insulating layer but does not attack the resist (e.g., buffered hydrofluoric acid is a typical $SiO_2$ etchant). Finally, the resist is stripped (e.g., using solvent, or plasma oxidation), leaving behind an insulator image that is the same as the opaque image on the mask. The insulator image can be used as a mask for subsequent processing. For example, emerging the patterned silicon wafer into a potassium hydroxide solution will etch the exposed silicon, but not the area covered by the insulator. This subject is more extensively described in Section 5 on film etching. The complete microchip is fabricated by applying the next layer and aligning the next mask in the sequence to the previous pattern and repeating the lithographic transfer process.

### 4.2.1. Electron Beam Printing

To increase the wafer throughput of EBW, different schemes have been developed. For example, the SCALPEL technique (scattering with angular limitation projection electron beam lithography) is a way to circumvent the sequential writing. In SCALPEL, a 100 nm thin silicon nitride membrane with a 50 nm tungsten pattern is uniformly illuminated by a parallel beam of electrons. Electrons passing through transparent areas (silicon nitride only) move virtually straight on, are focused by a magnetic lens, and pass through a back-focal-plane aperture to illuminate the wafer. Electrons passing through a tungsten scattering area form divergent beams that are largely blocked by the aperture and hence image contrast is obtained. In this way a 4:1 demagnified image of the mask is produced at the wafer plane. SCALPEL uses a scattering mask rather than absorbing mask, which is susceptible to heating at a limited acceleration voltage. An additional advantage over optical lithography is that the entire electron beam can be deflected by magnetic fields and each image is effectively assembled from many small pieces using a stepper approach. Patterns of 80 nm wide holes are possible and the ultimate resolution is about 35 nm.

### 4.2.2. Ion Beam Printing

Ion beam printing (IBP) is typically performed with hydrogen or helium ions. The image construction requires several complementary stencil masks. The machine exposes one image field (die) at a time and steps from die to die (i.e., stepper lithography). The electrostatic lens system operates at a 4:1 demagnification. Presently, the resolution of IBP is around 180 nm, a resolution which can also be obtained with advanced optical lithography in a much cheaper way. However, IBP has proven to print structures well below 100 nm. In the end, IBP is expected to be the cheapest solution for 50 nm resolution. The main risk factors are the stencil mask fabrication, the design of the ion imaging system, the demonstration of a good blur versus throughput, and the stitching of complementary masks.

### 4.2.3. Mechanical Printing

The technique of mechanical printing is quite versatile. For example, microcontact printing, or stamping, is a method of producing submicrometer details in nanometer thick monolayers, which are SAMs and self-ordening layers only one molecule thick. A related but essentially different method is imprinting in which a mold is pressed into a polymer film on a substrate. Another technique is molding in which the polymer is poured into a mold.

**Stamping**   In stamping, a flexible rubber stamp is used to apply small quantities of a specially selected reagent solution as "ink" onto a surface. Since only the top of the pattern will contact the substrate, these are the only regions where the reagent can react with the substrate. The stamp is created using a master (e.g., a silicon wafer with a resist pattern). A silicon rubber is molded on the master and peeled off, thus forming the stamp. Typically, a SAM is used as ink (see also Section 3.7.5). SAMs offer chemically selective processes at surfaces and interfaces. A typical example of a SAM is the formation of a 2 nm thick thiol monolayer on gold, silver, or copper. Stable SAMs are only formed when reagent, substrate, and reaction conditions are carefully selected. For example, the substrate should be without contaminants and a long hydrocarbon chain in the reagent is needed to obtain a well-ordered monolayer. The height and width of the pattern on the stamp are crucial for a reproducible printing process. If the stamp structures are too high, too narrow, or too close, they might collapse under the pressure during stamping. If they are too low or spaced too far apart, extra (unwanted) contacts of the stamp with the surface are the result. Typically, lateral details of 20 nm up to 150 micrometers are possible and the height of the structures varies between 0.6 and 4 micrometers depending on the pattern. Due to the flexibility of the stamp, curved surfaces can also be printed.

**Imprinting**   The essence of imprinting is that a reusable mold is pressed hard into a thin thermoplastic polymer film, so that polymeric material is pushed away from the imprinted regions. The tiny patterns are created on the surface of a material using a "pattern transfer element" or mold that has a three-dimensional structure formed onto its surface. These pattern-transfer elements are always made from an elastomer—a polymer network that deforms under the

influence of a force and regains its shape when the force is released. This elasticity is why these techniques are also called "soft" lithography. The achievable critical dimensions depend only on the mold dimensions that can be prepared with one of the techniques found in this chapter.

***Molding*** The essence of molding is identical with imprinting and is normally used to duplicate high-aspect-ratio structures. One of the following molding techniques is suitable: injection molding or compression molding. During reaction injection molding, the polymer components (e.g., polyurethane or PMMA) are mixed shortly before injection into a mold and the polymerization takes place in the mold itself. Thermoplastic injection molding means heating the polymer (e.g., PVC, ABS, or PMMA) above the glass transition temperature and introducing it in a more or less viscous form into the mold, where it hardens by cooling. Compression molding or hot embossing means heating the mold material above its glass transition temperature and patterning it in vacuum by impression of the molding tool. Hot embossing is typically performed at a pressure of 4 bar and a temperature of 200 °C. The embossing pressure should be sufficiently high to provide filling of the mold insert. High-aspect-ratio metal structures can be molded and demolded with polymers quite easily, as long as a polymer with a small adhesive power and rubber-elastic properties, such as silicone rubber, is used. However, those plastics have low shape stability and would not be adequate. Shape-preserving polymers on the other hand, after hardening, require a mold with extremely smooth inner surfaces to prevent form-locking between the mold and the hardened polymer. A mold release agent may be required for demolding.

### 4.2.4. Screen Printing

Screen printing includes silk screening and has special applications in the printing industry. Silk-screen printing is a form of stencil printing (i.e., printing where the ink is applied to the back of the image carrier and pushed through porous or open areas).

### 4.2.5. Optical Printing

Optical lithography comprises the formation of images with visible or near-UV radiation ($\lambda = 300$–380 nm) in a resist (e.g., Novolac) using shadow or projection printing. Shadow printing may be employed where the gap between mask and wafer is small. In case of projection printing, some sort of image-forming system (e.g., a 4:1 demagnification lens) is interposed between mask and wafer. The linewidth limit of optical printing lies near 0.4 $\mu$m, although 0.2 $\mu$m features may eventually be printed under carefully controlled conditions. Optical printing spans almost the entire current lithographic processing and will continue to occupy the primary position for the foreseeable future.

***Shadow Printing*** Shadow printing is a general name for contact printing and proximity printing. In shadow printing, the minimum linewidth that can be printed is roughly $l_{\min} \approx \sqrt{(\lambda g)}$ when $\lambda$ is the wavelength of the exposure radiation and $g$ is the gap between the mask and the wafer and includes the thickness of the resist. For $\lambda = 0.4$ micrometer and $g = 50$ micrometers, the minimum linewidth is

4.5 micrometers. If we reduce $\lambda$ to 0.25 micrometer (i.e., inside the deep-UV spectral region) and $g$ to 15 micrometers, $l_{\min}$ becomes 2 micrometers. Thus, there is an advantage in reducing both $g$ and $\lambda$. However, for a given distance $g$, any dust particle with a diameter larger than $g$ potentially can cause mask damage.

In contact printing a typically chromium or emulsion covered photomask is pressed against the resist-covered wafer and exposed by light of wavelength near 400 nm. Depending on the contact pressure between mask and substrate, we can distinguish between hard contact (with pressures in the range of 0.05 to 0.3 atm), soft contact (no additional pressure), and vacuum contact. With an Hg source the strong lines at 436, 405, and 365 nm provide exposure flux. The intimate contact between resists and mask provides high resolution ($<1\ \mu$m linewidth). However, a dust particle or a speck of silicon dust on the wafer can be imbedded into the mask when the mask makes contact with the wafer. The imbedded particle causes permanent damage to the mask and results in (pattern transfer) defects in the wafer with each succeeding exposure. Moreover, because of spatial nonuniformity of the contact, resolution may vary considerably across the wafer (Newton rings). To provide better contact over the whole wafer, a thin (0.2 mm) flexible mask has been used; 0.4 $\mu$m lines have been formed in a 1 $\mu$m resist. Loss of resolution can be reduced by use of $Fe_2O_3$ or $Cr_2O_3$–Cr masks ($Cr_2O_3$ means that the chromium is covered with a thin chromium oxide layer to reduce reflectivity), which have much lower reflectivity than chromium and reduce scattered light under the opaque parts of the mask. The contact printing produces defects in both the mask and the wafer so that the mask may have to be discarded after a short period of use. Defects include pinholes in the chromium film, scratches, intrusions, and star fractures. Mask defect densities increase typically with 3 defects/cm$^2$ after every exposure. Contact printing nevertheless continues to be widely used.

Proximity printing has the advantage of longer mask life because there is no contact between the mask and the wafer. It is similar to the contact printing method except that there is a small gap. Typical separations between mask and wafer are in the range of 20 to 50 micrometers. The small gap, however, results in optical diffraction at feature edges on the photomask (i.e., when light passes by the edges of an opaque mask feature, fringes are formed, and some light penetrates into the shadow region) and the resolution is degraded to the 2- to 5-micrometer range. Linewidth control is in general more difficult in proximity printing than in contact printing. Linewidth is influenced by variations in light intensity, mask–wafer gap, and resist properties.

***Projection Printing*** To avoid the mask damage problem associated with shadow printing, projection printing exposure tools have been developed to project an image of the mask patterns onto a resist-coated wafer with higher resolution than proximity printing together with large separation of many centimeters between mask and wafer. There are two types of projection printers with respect to the image forming system used: reflective and refractive. In reflective optics, a curved lamp source illuminates an arc on the mask, and this arc is imaged onto the wafer with unity magnification. In this arrangement only a small zone of the spherical

primary mirror is used, providing nearly diffraction-limited imaging. Mask and wafer are swept through the arc to form an image of the whole mask. The other printers use refractive optics: high quality lenses with many elements. They project a 5 times reduced image onto the wafer. To increase resolution, only a small portion of the mask is exposed at a time. The small image area is scanned or stepped over the wafer to cover the entire wafer surface (see the section on stepper lithography).

Usually the mask is fabricated with pattern dimensions 4X to 5X larger than the features actually desired on the wafer because the wafer exposure system reduces the image by the same factor. Demagnification in the wafer exposure system makes the mask easier to fabricate and easier to check for imperfections. Once the mask is checked, it is usually protected from later contamination by dust particles with a thin transparent membrane (pellicle) stretched over a metal frame above the chrome side of the mask. Pellicles are usually made from nitrocellulose a few micrometers thick. Since the pellicles are offset from the mask, dust particles that fall on the pellicle during use will be out of focus on the wafer and therefore will usually not print. Typically the pellicle might be mounted a few mm above the mask. Since the DOF of modern exposure systems is only a few micrometers, dust particles as large as 100 micrometers will not print on the wafer during exposure.

### 4.2.6. Deep Ultraviolet Printing

Deep ultraviolet printing (DUVP) with wavelength between 200 and 300 nm is basically identical to optical printing. However, the UV line at 365 nm of the Hg source is in the process of being replaced by a Xe–Hg source with an enhanced output in the 200–300 nm spectral region. Alternatively, a krypton fluoride laser radiating at a wavelength of 248 nm is possible. This improves the resolution and the DOF sufficiently to enable imaging of features down to 200 and 600 nm respectively. Further gain is possible by utilizing an argon fluoride excimer laser operating at 193 nm or a fluoride laser radiating at 157 nm as the next DUVP sources. The most favorable resists nowadays are based on a polyhydroxy-styrene backbone and a photoacid generator and PMMA. DUV exposure tools today are capable of 80 nm registration, a throughput of ca. 1 wafer per minute, and defect densities of roughly 50 particles per layer/$m^2$ @ 40 nm defect size. Quartz or alumina mask substrates must be used to pass these shorter wavelengths, since the usual borosilicate glass strongly absorbs wavelength less than 300 nm.

### 4.2.7. Extreme Ultraviolet Printing

To extend the ongoing technological trends to wavelengths below 100 nm, processes of a short-wavelength imaging method are explored, which includes "reduction optics" analogs to optical projection printing. Such a reduction scheme with the ability of making diffraction-limited images would take full advantage of the short wavelength. The method, initially called soft X-ray projection lithography but later named extreme-ultraviolet printing (EUVP with wavelength between 4 and 200 nm), uses reflecting optics and masks with special multilayer coatings. The preferred wavelength in EUVP is 13 nm, just below an absorption edge

of silicon, which is one of the components in the multilayer reflective coating. The EUV radiation requires optical elements fabricated with a surface accuracy and roughness in the subnanometer range. The optimal radiation source in EUVP is commonly believed to be a laser-produced plasma source, although compact synchrotron sources are also an option. A laser-plasma is created by focusing the laser onto a metal target. The plasma thus produced emits an intense burst of photons, including the desired EUV. Before EUVP can be successful, a method must be developed to mitigate pollution by plasma debris created by the focused laser beam.

### 4.2.8. X-ray Printing

Röntgen or X-ray printing (XRP) uses a one-to-one shadow printing method similar to optical proximity printing, because for this wavelength no suitable optics is available. The soft X-ray wavelength (0.4 to 4 nm) is much shorter than that of the ultraviolet light (4 to 400 nm) used for optical, DUV, and EUV lithography. Diffraction effects are reduced and resolution is improved by reducing the wavelength; however, optical materials become opaque because of the fundamental absorption and mask materials might become transparent. For an X-ray wavelength of 0.5 nm and a gap of 40 micrometers, the minimum line width obtained is less than 0.2 micrometer. XRP required the development of an application-specific X-ray source, for which so-called compact synchrotron radiation sources are currently employed. These bright sources are basically scaled down versions of the large synchrotron facilities used for fundamental research. Although costly ($\sim$25 MEuro), one synchrotron source can have several exposure beam lines and serve up to 20 wafer steppers. The utilization of the cheaper and smaller laser plasma X-ray sources turned out to be limited, due to their pointlike source nature. In another XRP system, a 25 keV, 5 kW electron beam is incident upon a palladium target that emits X-rays with a wavelength of 0.44 nm. The X-rays pass through a beryllium window into a helium-filled chamber (air is a strong X-ray absorber) to illuminate a mask, which casts shadows into a resist-covered wafer. Materials useful for the absorptive and transmissive parts of the mask, the atmosphere in the exposure chamber, and the resist are in large part determined by the absorption spectra of these materials in the X-ray region. Over a wide range of wavelength the absorption coefficient of an elemental material of density $\rho$ and atomic number $Z$ is proportional to $\rho Z^4 \lambda^3$. As $\lambda$ increases, the proportionality constant decreases in step-function fashion at the "absorption-edge" wavelengths corresponding to the ionization energies of the inner electrons of the $K$, $L$, and other shells. An X-ray mask consists of an absorber on a transmissive membrane substrate. Of the heavy metals with larger $\rho Z^4$ absorbers, gold has been widely used because it is easily patterned. In general, in order to have large enough absorption, the gold metal is considerably thicker (600 nm) than chromium layers used in optical printing.

Electron beam resists can be used as X-ray resists. This is because when an X-ray photon is absorbed by an atom, the atom goes to an excited state with the emission of an

electron. The excited atom returns to its ground state by emitting an X-ray having a different wavelength than the incident X-ray. This X-ray is absorbed by another atom and the process repeats. Since all the processes result in the emission of electrons, a resist film under X-ray irradiation is equivalent to one being irradiated by a large number of secondary electrons from any of the processes. One of the most attractive X-ray resists is dichloropropyl acrylate (DCOPA) and glycidyl methacrylate-co-ethyl acrylate, because it has a very low threshold ($\sim$10 mJ/cm$^2$). Structures well below 100 nm have been reproduced faithfully in various laboratories. The domain of dimensions down to 70 nm can be covered using traditional (optimized) masks, and 30 nm lines were achieved using phase-shifting techniques (see section on phase-shift lithography). XRP has the advantage of being insensible to particle or dust contamination, explained by the large penetration power of the X-rays used. The XRP does not take advantage of the short wavelength due to the lack of suitable optics. In contrast to optical lithography, in which a resolution comparable to the wavelength of the light can be obtained, the (Fresnel) diffraction over the finite gap between mask and wafer limits the resolution to about 100 nm, whereas the physical limit for an imaging system would be several nanometers. In principle the practical resolution could be improved by reducing the gap, but the delicate mask requires a minimal distance (about 10 micrometers) to protect it from damage due to dust particles. Occasionally, alternative X-ray schemes involving novel types of optics are proposed. For instance, a scheme involving "zone plate arrays" has been devised to focus parts of the beam through MEMS shutters onto the surface. This would allow 25 nm resolutions. The question remains if the technique is suitable for commercial mass manufacturing. Due to the one-to-one reproduction method, the mask features should be made to at least the same tolerance as the final structure, while the support membrane cannot be thicker than a few micrometers to ensure sufficient transmission and contrast. Consequently, X-ray masks are delicate and costly.

### 4.2.9. Holographic Printing

In holographic printing, a holographically constructed photomask replaces the standard photomask. In the recording or construction phase of the hologram, one uses the interference of two mutually coherent beams: an object beam and a reference beam. A well collimated, flood laser (object beam) passes through the photomask and is diffracted by the mask features. This signal beam contains the amplitude and phase information of the photomask. When this diffracted object beam passes through the holographic recording layer, it interacts with another beam, the reference beam, to create the interference pattern. The reference beam converts the amplitude and phase information into intensity information, which is stored in the photosensitive holographic resist polymer as variations in the refractive index. Pattern printing or image reconstruction is accomplished by scanning a collimated laser illumination beam—the phase conjugate of the reference beam—to create the hologram. By interaction with the recorded hologram, the latter beam generates an image of the original photomask at precisely its original position in space. When a photoresist-coated substrate

resides in this plane, a copy of the original mask can be printed. The image is only diffraction limited, and because the holographic mask and the wafer can be very close, a high numerical aperture—and thus a very good resolution down to 300 nm—is possible.

### 4.3. Stepper Lithography

There are two basic types of wafer stepper machines, which are routinely used to produce structures as small as 250 nm in a layer of resist on the wafer surface and utilizing reducing projection printing with complex lens systems: "step-and-repeat" and "step-and-scan." In step-and-repeat lithography, the complete pattern of a circuit (die) is imaged at once and then the wafer is moved ("stepped") and the next die is imaged. In step-and-scan lithography, each die is imaged line-by-line by synchronized movements or "scanning" of the mask and the wafer.

A typical step-and-repeat system is illustrated in Figure 69. Radiation from a high-intensity source is collimated and passed through the mask. Each transparent area on the mask transmits the radiation, which is then collected and focused by a second lens system. This second lens system also serves to reduce the image size by 4X–5X. The field of view of such systems is typically only a few cm on a side. Therefore, the wafer is physically moved to the next exposure field and the process repeated so these systems are commonly called step-and-repeat tools or simply steppers.

In step-and-scan lithography, a narrow slit of radiation is produced by the source system and the mask and wafer are simultaneously scanned mechanically so that the mask image is scanned line-by-line across the wafer. Note that in systems of this type, the mechanical system must scan the mask 4X–5X times faster than the wafer, corresponding to the optical reduction factor. Scanners greatly increase the field size up to the limit of the mask dimension, at least in the scanning direction.

**Figure 69.** Schematic overview of stepper lithography.

## 4.4. Alternative and Related Lithography

Resolution enhancement techniques based on the use of the phase of light, such as the use of laser interference, atomic laser interference, stereo techniques, phase-shifting masks which improve contrast and thus resolution, or mask illumination improvements, are increasingly being employed to extend the scope of optical lithography to its limits. Additionally, add-on techniques are found such as edge lithography and combinatorial techniques, which "combine" two or more of the other lithographic techniques to enhance throughput. Optical lithographers expect that the optical techniques will ultimately enable a resolution of 120 nm using argon fluoride lasers. For wavelengths below 120 nm, no optical materials are transparent and the development of diffraction-limited lenses is improbable. Nevertheless, it has recently been shown that it is possible to fabricate 40 nm lines using optical lithography with 193 nm wavelength in combination with a technique called top surface imaging. But the inherent physical limitations become more and more evident.

Several technologies that potentially could be used for nanolithography are described. Independent of the lithography used—write, print, or stepper lithography—the exact lithographic process scheme can be altered to improve certain aspects. The next processes are related to lithography, "resist lithography," "direct lithography" as opposed to resist lithography, "lift-off lithography" which is a complementary method to resist lithography, "trilevel lithography" which is able to enhance resolution for patterned surfaces, and "LIGA."

### 4.4.1. Laser Interference Lithography

In laser interference lithography (LIL), the interference pattern of two intersecting laser beams is used to expose a thin resist. Of course, one can only create gratings (and arrays by multiple exposure), but the grating period can be as small as half the laser wavelength. In case of an argon fluoride eximer laser radiating at 193 nm this would produce 100 nm patterns. This is smaller than what is achievable by conventional photolithography and complete wafers can be exposed in a matter of minutes. This gives this technique a big advantage over for instance electron-beam lithography, if gratings or arrays are the only patterns needed (e.g., data storage media). Patterns with an even smaller periodicity are possible using special period doubling techniques. For example, in achromatic LIL, an interference pattern is produced by diffraction of incoherent (achromatic) light on two identical parallel gratings, which produces an interference pattern with half the periodicity of the gratings. By this technique 100 nm patterns have been realized using gratings with 200 nm periodicity.

### 4.4.2. Atom Lithography

Recently, atom lithography (AL) has emerged as a promising method of massively parallel patterning with nanometer-scale resolution. In AL, a beam of atoms is projected onto a surface through a laser interference pattern. AL relies on fundamental interaction processes between atoms and photons. An atom moving in a near-resonant laser field exhibits

a dipole force, which can be derived from an optical potential, which, to the first approximation, is linear in the light intensity. Atoms moving in such an optical potential tend to oscillate around their minima. The focusing of atoms can be qualitatively understood from the analogy with the focusing property of a lens with a parabolic refractive index profile in conventional optics. The period of the resulting structure is equal to half of the wavelength. Because the dipole potential is weak compared to typical transversal thermal kinetic energies of atoms, the atomic beam needs to be collimated before focusing. This cannot be met by mechanical collimation, since it would result in a high loss of flux. Therefore, optical collimation methods based on the dissipative light forces on atoms are used such as Doppler cooling schemes. The diffraction limit of this approach is lower than that of optical lithography, down to a few nm, due to the short de Broglie wavelength (Planck's constant over the atomic momentum) of thermal atoms. By using atoms that stick well on surfaces, AL can be applied to write structures directly onto substrates. On the other hand, metastable rare gases or chemically aggressive atoms can be used to pattern surfaces in an indirect way: the pattern is first imaged on a special resist and then transferred to the substrate using other methods, such as selective etching.

### 4.4.3. Stereolithography

In stereolithography light exposure solidifies a special liquid resin into a desired shape. The liquid resin is kept either in the free surface or in the fixed surface mode. The latter has a resin container with a transparent window plate for exposure. The solidification always happens at the stable window/resin interface. An elevator is pulled over the thickness of one additional layer above the window for each new exposure. In the case of free surface, solidification occurs at the resin/air interface and more care needs to be taken to avoid waves or a slant of the liquid surface. A 3D structure can be made of a UV polymer by exposing the polymer with a set of 2D cross-sectional shapes (masks) of the final structure or the sliced shapes can be written directly from a CAD-controlled (laser) beam. In this way a complicated 3D shape can be constructed by stacking thin films of hardened polymer layer upon layer. The position accuracy for the 5 micrometers in diameter laser beam spot is 1 micrometer in the $z$-axis and 250 nm in the $x$- and $y$-directions. The plastic shapes made by stereolithography may be used as a cast for electroplating metals or for other materials, which can be molded into the polymer structures.

### 4.4.4. Phase-Shift Lithography

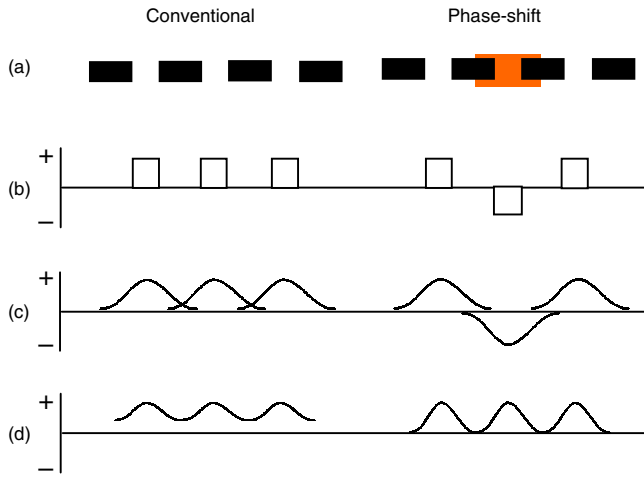
The use of phase-shifting masks allows further improvement of the photolithographic resolution at a given wavelength and numerical aperture by carefully controlling light diffraction using constructive and destructive interference. Using these masks, one controls both amplitude and phase of the light and, in particular, one arranges the mask so that with opposite phase emerges from adjoining mask features. In that case, destructive interference can be used to cancel some of the image-spreading effects of diffraction. In Figure 70 we illustrate the effect for three nearby mask apertures; a conventional transmission mask is added


**Figure 70.** Schematic overview of phase-shift lithography. (a) Conventional and phase-shift transmission mask. (b) Light amplitude distribution on a mask. (c) Light amplitude distribution on a wafer. (d) Light intensity distribution on a wafer.

for comparison. The amplitude profile at the plane of the classical mask consists of three square-cornered features with positive amplitude. The amplitude at the wafer level is broadened and rounded but does not change sign. With a phase-shifting mask, a shifter layer results in a reversal of the phase of the light at the mask. As the photoresist only shows sensitivity toward the intensity of the light and not the sign, the three bright features develop identically and the areas where the light of opposite phases causes destructive interference form very dark contrast lines. Phase-shifting masks can easily improve resolution by a factor of two.

### 4.4.5. Edge Lithography

Edge lithography is a form of lithography in which the edges of the original pattern become the features of the final pattern (see Fig. 71). It is an add-on technology for existing lithography in which the sidewalls of prefabricated steps are used to produce truly 2D and 3D nanoscale structures. The resolution of these nanopatterns is basically controlled only by the thickness of the deposited film and the accuracy of this thickness is believed to be controllable down to the atomic level. This gives this technique a big advantage over, for instance, traditional lithography, employing visible and

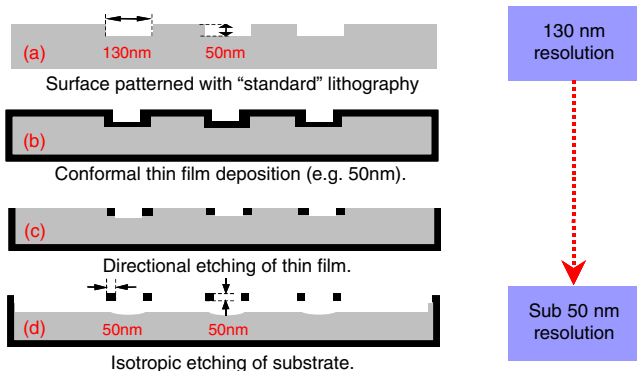

**Figure 71.** Schematic overview of edge lithography.

ultraviolet light, which is confronted with a serious barrier due to far-field limitation of the wavelength of light. Edge lithography is an add-on technology (it uses the pattern of a different lithographic process) that might be comparable to the best in the world. This technology can even be enhanced by incorporation of standard microsystem technologies to enable connection ports with the macroworld.

### 4.4.6. Hybrid Lithography

In order to improve resolution and keeping throughput high, sometimes write lithography is combined with print lithography. For example, the combination of imprinting with scanning probe lithography for the mold preparation may possibly provide an important breakthrough for a low-cost mass preparation of nanometer scale devices. At this point, the local oxidation of semiconductor or metal surfaces seems to offer the most reliable method to produce the required molds. It is important to note that the scanning probe microscopes can at the same time also be used to inspect the mold quality down to atomic scale. As a second example, the use of electron-sensitive deep UV resists opens up the possibility to expose the same resist layer both in a deep UV stepper and an electron-beam writer before development—the so-called "mix-and-match" technology. In this way, large surface areas are being exposed with medium-to-low resolution by the fast stepper, whereas the high-resolution details are being exposed by the accurate but slowly scanning writer. The overall result is an on-average acceptable replication time with higher resolution details in the most critical areas. Another example is the combination of SAMs with surfaces having a pre-etched regular pattern. Some SAMs have the tendency to form hexagonal patterns with a periodicity as small as 20 nm and have a high resistance against plasma etching. This can be used to form nanopatterned surfaces in a one-step film-formation and film-etching process. However, the regularity of these patterns (domains) extends over a few 100 nm only, which limits the application of this technique. The regularity can be improved by using prepatterned surfaces smaller than the size of the domains to extend the nanoregularity into the microdomain. Other examples, and without going into more detail, are to combine LIL with edge lithography, to combine "micro" lithography with "nano" e-beam or ion-beam, or to create first a photonic crystal by LIL and then machine waveguides inside the photonic crystal.

### 4.4.7. Resist Lithography

In resist lithography, a chemically amplified resist is composed of a polymer with groups reactive to protons and a photoacid generator. A photoacid generator is a chemical compound supplying a proton upon irradiation. This proton catalyzes reactions at the polymer, resulting in solubility differences between the exposed and unexposed regions. In resist lithography, a wafer is placed in a cleanroom, which typically is illuminated with yellow light, since photoresists are not sensitive to wavelength greater than 0.5 micrometer. Typical resists today are carbon-based organic materials, such as Novolacs, that have been engineered for optimum performance in micro- and nanotechnology. Radiation-sensitive resists can be classified as positive and negative

tone resist, depending on how they respond to radiation. A negative tone resist on exposure to radiation becomes less soluble in a developer solution, while a positive tone resist becomes more soluble. The net result is that the patterns or images formed in the positive resist are the same as those on the mask. For the negative resist, they are the inverse.

Commercial negative resists consist of two parts: a chemically inert polyisoprene rubber, which is the film-forming component, and a photoactive agent. The photoactive agent on exposure to light reacts with the rubber to form cross-links between rubber molecules, making the rubber less soluble in an organic developer solvent. The reactive species formed during the exposure can react with oxygen and be rendered ineffective for cross-linking. Therefore the resist is usually exposed in a nitrogen atmosphere. The developer solvent dissolves the unexposed resist. One major drawback of a negative photoresist is that in the development process the exposed resist swells by absorbing developer solvent as the un-cross-linked molecules are dissolved. The swelling distorts the pattern features and limits resolution to 2 to 3 times the initial film thickness. However, the swelling is an advantage when the so-called lift-off lithography is used (see next section).

Positive resists consist of three components: a base resin, a photoactive compound, and an organic solvent. Prior to exposure, the photosensitive compound is insoluble in the developer solution. The photoactive compound is a dissolution inhibitor. When it is destroyed by exposure to light, the resin becomes more soluble in an aqueous developer solution and upon development the exposed areas are removed. The unexposed regions do not swell much in the developer solution, so higher resolution is possible with positive resists. The sensitivity of most standard resists peaks in the 300 to 400 nm spectral range. Photoresists are being developed for exposure at shorter wavelengths where higher resolution is possible. A few such deep UV resists, sensitive for $\lambda < 250$ nm, are PMMA and polybutene sulfone. At these shorter wavelengths, the radiation quantum is large enough to produce scission (breakage) of the molecular chain.

Besides the wet-developed methods described, dry-developed resist chemistry forms another important strategy toward nanolithography. An important advantage of dry development is that the swelling found in wet development is prevented. In one approach, plasma-polymerized methylsilane is transformed by deep UV radiation in the presence of oxygen into a poly-methyl-siloxane. By subsequent plasma development with chlorine, and a plasma treatment with oxygen to transfer the poly-methyl-siloxane into silicon oxide, images with sub-180 nm features can be transferred.

With respect to step coverage we have to note that lithographic process latitude can become severely limited, even for a perfectly planarized topography. Resist films crossing over steps have their local thickness altered; thinning occurs over high features and pile-up in low-lying regions. During exposure the thin resist region may get overexposed and the thick resist region underexposed. Moreover, resist pile-up at step corners may exhibit standing wave effects, leading to reduction of resolution. Reflective notching on buried topographical features and the swelling of negative tone resist during development could decrease resolution even further. Practical DOF should encompass device topography, resist

thickness, wafer flatness, focus, and tilt errors in order for the projected image to remain sharp over the whole wafer.

The light intensity, which is effective in exposing a volume element of resist at a certain height above the substrate, depends on the reflectivity of the substrate, the thickness of the resist, and the convolution of the absorption spectrum of the resist with the spectrum of the incident light. The refractive index of most resists is about 1.6, leading to an optical mismatch at the air/resist interface. If the substrate is highly reflective, the interference pattern of standing waves that are set up has a node at the substrate and a peak amplitude that depends on resist thickness. This variation in peak intensity with resist thickness becomes less with decreasing substrate reflectivity and increasing absorption by the resist. Since resist thickness varies at a step in substrate topology, the resulting difference in effective exposure leads to size variations in the resist image. To circumvent this problem, various trilevel lithographic techniques have been used (see next section). Because of the high resolution of positive resists, the standing wave patterns are often well resolved, and the resulting corrugations are seen in the resist edge profile. The edge of a feature in developed resist occurs at the position where the product of light intensity and exposure time equals the resist threshold dose: typically around 10 mJ/cm$^2$.

Other properties of resists, being quite important, are good adhesion to the substrate and resistance to wet and dry etch processes. In general, the commercially available optical resists are compatible with such processes. The unwanted variation of feature size in the resist image is due to many effects, some related to resist properties (e.g., scattering) and resist processing (e.g., reflections) and others to the exposure tool (e.g., coherence).

### 4.4.8. Direct Lithography

Although lithography normally uses an intermediate radiation-sensitive resist layer to transfer a pattern into or onto a film or substrate (i.e., the process known as *resist lithography*), to enhance resolution it might be beneficial to directly transfer a pattern into or onto the film without the use of a resist film (i.e., the technique called *direct lithography*). This enhancement—by a factor of two or even more—is possible because scattering of the exposure flux in the resist and swelling of the resist during development are prevented. For example, it is possible to directly write a pattern in a substrate with a laser, ion, or electron beam, as already found in the sections about beam writing, or it is possible to equip an SEM with high-precision linear and rotary positioning stages inside the vacuum chamber and to construct a metal shape and even a vacuum ball by controlling the stage position and the electron beam direction. This transfer technique is known as *direct write lithography*. Alternatively, the beam could enhance a CVD process to deposit, for example, a dielectric layer only beneath the regions defined by the focused beam. The gases in the reaction chamber are decomposed locally by the focused energy source, and localized film deposition occurs by a pyrolysis or photolysis process. The focused energy sources are also potentially useful to deposit metal films in selected areas to repair devices and a chemical modification of the substrate surface is caused by the beam which could result in etching.

Although direct write lithography can be found already in many applications such as mask fabrication, write lithography has the disadvantage of being "a series technology" making it a rather slow process and "batch-process repellent." But the use of a focused beam is not necessary. By pressing a fused silica mask with etched cavities tidily on top of a H-terminated silicon substrate and meanwhile exposing the stack with UV light, it is possible to oxidize or etch the silicon locally: the process of *direct print lithography*. For example, when $O_2$ molecules are enclosed in the cavities, during exposure with UV light, the molecules are cracked into O-atoms and react with the silicon surface (Fig. 72). The process is self-terminating because only a limited amount of oxygen is present in the cavity and the silicon surface has a well-defined number of reactive sites. Moreover, the wavelength of the UV source does not determine the pattern resolution as long as it is able to create reactive species. Alternatively, it might be possible to deposit a metal-organic compound when the correct wavelength can be found. This is the process of local oxidation or local MOCVD.

A somewhat different approach is the use of radiation-etchable substrate material. For example, photoetchable glass is a very promising material for the production of components for a wide variety of microsystems. The glass is illuminated with 310 nm radiation and an energy density of ca. 2 J/cm$^2$, which is sufficient to structure a 1 mm thick wafer. After exposure to ultraviolet radiation and subsequent heat treatment (1 hour at 500 °C), these glasses will partially crystallize. The crystalline phase is lithium silicate, which is 20 times more soluble in hydrofluoric acid than the surrounding unexposed amorphous glass. High aspect ratio microstructures (up to 20) can be realized by using slightly modified semiconductor equipment and relatively low fabrication costs are achievable already in small-scale production. A typical photoetchable glass is FOTURAN of Schott and similar glasses are produced by Corning (FOTOFORM) and Hoya (PEG3).

### 4.4.9. Lift-off Lithography

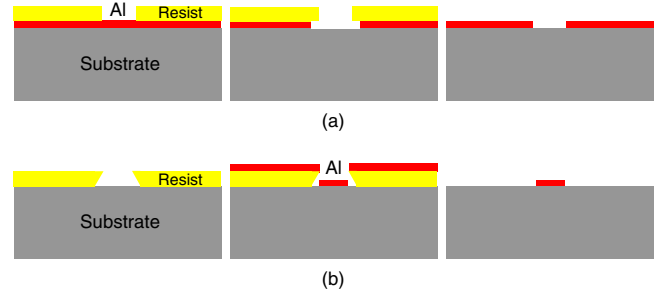
A related pattern transfer process to the conventional resist lithography is the lift-off technique. It uses the shadowing by surface topography of the resist layer as will be clarified next. For example, a positive resist can be used to form a resist pattern on a substrate (Fig. 73b). The film (e.g., aluminum) is deposited over the resist and the substrate, where the film thickness must be smaller than that of the resist. Those portions of the film on the resist are removed by


**Figure 73.** Schematic of resist pattern transfer. (a) Conventional lithography. (b) Lift-off lithography.

selectively dissolving the resist layer in an appropriate liquid etchant (e.g., aceton) so that the overlying film is lifted off and removed. This process leaves only material on the sites where no resist was present after resist development. The lift-off technique is capable of high-resolution pattern transfer. This is because in case of conventional resist lithography, the underlying film has to be etched in a subsequent process step. This etching generally produces underetch and roughness of the film edges (for example, the different crystals of polycrystalline material such as aluminum etch with a different speed).

Because of the finite size of, for example, an electron beam evaporator (with diameter $d_{evap}$), and a finite resist thickness $t_{res}$, a penumbral effect results. The penumbral blur $d$ on the edge of the resist image is $d = d_{evap}t_{res}/L$ where $L$ is the distance from the source to the wafer. If $d_{evap} = 2.5$ cm, $t_{res} = 2$ micrometers, and $L = 50$ cm, the penumbral blur is of the order of 0.1 micrometer. In case of sputter equipment, $d_{sput} = 25$ cm and $L = 5$ cm and the blur is of the order of 10 micrometers. This is why sputter equipment is in general not suited for the lift-off technique. Another geometrical effect is the lateral magnification error, due to the finite resist thickness and the nonvertical incidence of the evaporated material. The projected images of the resist mask are shifted laterally by an amount $d = rt_{res}/L$ where $r$ is the radial distance from the center of the wafer. The shift is zero at the center of the wafer but increases linearly toward the wafer edge. For a 10 cm (4 inch) wafer, the shift can be as large as 1 micrometer. Lift-off procedures have many appearances. In Figure 74 we singled out the schematic for deposition of a buried conductor. The process can be followed by an electroless deposition.

### 4.4.10. Trilevel Lithography

To minimize step coverage problems on patterned surfaces, trilevel lithography might be beneficial. In this technique, first a polymeric layer with a sufficient planarization effect
**Figure 74.** Schematic of a buried conductor process. (a) Pattern lift-off resist. (b) Etch substrate. (c) Deposit PVD metal. (d) Lift-off.

**Figure 72.** Direct print lithography.

is coated on top of the irregular surface (Fig. 75). On top of this polymer a thin layer of, for example, aluminum is deposited and photoresist is applied and patterned in the usual way. After the aluminum has been etched, the planarization polymer is dry etched with oxygen plasma.

## 4.5. Conclusion and Nanoperspective

This section has shown that there are numerous ways to achieve nanostructures of surfaces using lithography and new developments in lithography will largely determine which direction the ICT and MST will take the coming years. Top-down nanofabrication involves other techniques as well, such as etching and forming, but the lithography process will play a key role because it defines the critical dimensions of the structures (with the exception of the edge lithography) that are finally the basis for operation of the circuits to their ultimate specifications. Therefore, different lithography techniques have been discussed extensively in this chapter and we have tried to define the optimum lithography for the near future, which may be different for NST than for MST or ICT. Whereas finer linewidths are the main quest in NST and standardized materials in the ICT, MST seeks high features and high aspect ratios and the introduction of new materials. For example, wafer topography poses a significant challenge for the lithographic definition of "high rise" structures typical for MST.

The main characteristics of the most prominent lithography techniques discussed in this section are listed in Tables 11 and 12. The listed resolutions have been obtained or are considered achievable (bracketed). The techniques labelled "option" are candidates for the mass manufacturing of chips with features below 100 nm. Various other approaches are still in the "research" phase but may be applicable in the future. Writing lithography is too slow for the mass manufacturing of chips, but it is a very useful tool for mask fabrication and special low-volume application. However, a possible route toward mass production of nanoscale devices may rely on the fabrication of many mechanical probes in parallel. In the end, the choice will depend on the critical factors and the application rather than on the achievable resolution.

Fabrication of the newest generations of semiconductor devices continuously imposes higher demands on lithography. Most likely, optical lithography will be the system of choice for many years to come because of its relative simplicity, convenience, and reasonable high throughput.

**Figure 75.** Trilevel lithography.

It will continue to improve with wavelength approaching 120 nm using 193 nm UV radiation. But, although optical lithography is the most prominent lithographic tool, it is not likely that it will be extendible to the sub-100 nm generation. Development of nanotechnology makes it necessary to replace the current lithography technology by higher resolution replication techniques. Beyond that limit several options exist including the use of ions, electrons, and short wavelength photons and potential candidates to replace optical lithography include EUV, X-ray, e-beam direct write, and projection e-beam, each of which is being explored in a variety of approaches. Each method has its limitations: diffraction effects in optical lithography, proximity effects in electron beam lithography, mask fabrication complexities in X-ray lithography, and beam deflection difficulties in ion beam lithography.

Most methods have found their one special place in the lithographic process; electron beam lithography is used to generate the mask set with the help of CAD programs where high resolution is essential, the masks are checked and eventually repaired with the help of ion beam lithography because only ions are energetic enough to repair (i.e., etch or deposit) the mask locally, and finally the mask set is used in mask or stepper lithography to manufacture chips with large throughput. EUV is currently the most likely "winner" in stepper lithography and sub-50 nm EUV is already foreseen to become operational before 2008 and 15 nm resolution has already been demonstrated. Custom circuits, masks, and experimental devices for which high throughput is not needed will continue to be patterned by scanning electron-beam systems. In these applications, fine definition, good overlay, flexibility, and quick turnaround are requested.

In microtechnology, many mask levels are involved but it is not necessary to use the same lithographic methods for all levels. Even within the same level we might combine lithographic methods. This hybrid lithographic approach can take advantage of the unique features of each lithographic process to maximize throughput with a certain requested resolution. Also, the transition from microtechnology toward nanotechnology requires the introduction of totally new production techniques. Besides self-organization of molecular structures on microstructured surfaces, nanoscale patterning of surfaces with SPL may play an important role for achieving this transition. SPL allows one to prepare the individual devices which are needed to evaluate the downscaling of existing devices or to develop totally new quantum devices. When combined with a parallel processing technique such as imprinting—or alternatively, if integrated arrays of probes can be developed—SPL may even allow the mass production of nanoscale devices. Finally, SPL is suited to interconnect, modify, and repair nanostructures during inspection.

Typically, the lithographic process uses a temporally, intermediate, resist layer to transfer a pattern. Resist lithography is the process of transferring patterns of geometric shapes on a mask to a thin layer of radiation-sensitive material (called resist) covering the surface of a wafer. These patterns define the various regions in microdevices such as anchor points for cantilevers, implantation regions, contact windows, and bonding-pad areas. In general, the resist patterns defined by the lithographic process are not permanent

**Table 11.** Schematic overview of lithographic methods and phenomena.

elements of the final device but only replicas of device features. Due to scattering of the energetic particles of the exposure system in the resist layer, resist lithography is generally much less accurate than direct lithography. But it is still the prime technique because of higher selectivity and throughput than possible with direct lithography. To produce device features, these resist patterns must be transferred once more into the underlying layers comprising the device. The pattern transfer is accomplished by an etching process which selectively removes unmasked portions of a layer. This etching process is considered in the next section.

## 5. FILM ETCHING

In general, a lithographically patterned resist layer by itself is not interesting enough for micro- or nanotechnology. Other materials—such as the substrate itself or deposited layers or films—are needed having specific patterns, such as wires, vias, or channels, and with appropriate characteristics such as electrical isolation or conductivity, chemical resistance, or mechanical strength. Resist patterns, formed in the lithographic process, can be transferred to such materials by physical or chemical etching techniques as shown in Figure 76. The mechanism for physical etching

(Fig. 76a) is straightforward; the reactants—usually ionic species—approach the substrate with high velocity where they erode the surface due to impulse transfer. However, chemical etching (Fig. 76b) involves three essential steps, which are quite identical to chemical film formation—only the direction of transport is reversed. The reactants are transported to the reacting surface (e.g., by diffusion) and adsorb, then reactions occur at the surface (e.g., electrochemical), and finally the products from the surface are desorbed and transported away from the surface (e.g., again by diffusion). Basic requirements for a good etch process are that the reactants used for the etching must be able to be transported to the wafer surface, and the products of the etch process must be transported away easily. The latter means that soluble, gaseous, or volatile products are produced in etching. The etch process should be uniform, should be safe to use, and should cause minimal damage to structures on the chip. Finally, the etching process should be clean, with low particulate production and little film contamination, and should be cost effective. Unarguably, many parameters, such as temperature and etchant composition, will influence the etch rate depending on the etch mechanism involved and surface and bulk impurities most often play an important role and might produce unreliable results. This makes etching a very difficult subject. In this

chapter the major film-etching methods will be described and two basic concepts that should be considered in all etch techniques—profile and selectivity.

## 5.1. Etch Profile

The profile of an etched film is a direct consequence of the etch directionality. Etch directionality is a measure of the relative etch rates in different directions, usually normal versus lateral. We can distinguish between four special

cases of material etching: isotropic etching, and orientation-dependent-, tapered-, and vertical-anisotropic etching. The isotropic etch profile is shown in Figure 77a. Ideal isotropic etching occurs in pure chemical processes where etch rates are the same in all directions (i.e., the underetch equals the etch depth). The etch profile would approach a perfect semicircle, forming an ideal isotropic profile. For example, amorphous materials of uniform composition etch isotropically in chemical processes. A special case of anisotropic (i.e., nonisotropic) etching is found when etching monocrystalline material in Figure 77b. For example, silicon is generally etching faster in the $\langle 110 \rangle$ and $\langle 100 \rangle$ direction than in the $\langle 111 \rangle$ direction in many alkaline-based etch solutions. This kind of profile is called the orientation-dependent profile. Physical "bombardment-driven" processes usually give rise to tapered profiles as shown in Figure 77c. Finally, when

**Figure 76.** Processes involved in film etching. (a) Physical. (b) Chemical.

**Figure 77.** Ideal etch profiles: (a) Isotropic. (b) Crystal-dependent anisotropic. (c) Tapered anisotropic. (d) Vertical anisotropic.

combining both chemical and physical processes (i.e., synergistic), vertical etching is possible. The ideal vertical etch profile in Figure 77d has perfectly straight sidewalls exactly under the edge of the mask and the etching under the mask approaches zero.

Mostly, the profile is in between one of the ideal profiles, where the normal etching proceeds faster than the lateral one, as illustrated in Figure 78. The amount of undercutting of the mask leads to nonvertical sidewalls in the film. On the one hand, the more chemical an etch process is, the more selective (see next section) and the more isotropic it generally is. The exception to this are those which are sensitive to crystallographic orientation. On the other hand, the more physical an etch process is, the more tapered and the less selective it generally is.

The ideal vertical profile is seldom found in pure physical processes and tapering (or facetting) is found instead. Two prime reasons for tapered profiles are the mask erosion and the angular dependence of the etch rate (or sputter yield $S$, i.e., the number of atoms removed per incoming ion). Figure 79 is a generalization of the angular dependence effect due to ion impact. Sputter ejection due to normal ion incidence (in the angular sense) requires 180° reversal of the momentum; this is not very likely and accounts for the low yield of the sputter process at normal incidence. As the angle of incidence ($\theta$) increases, so does the sputter yield, again for momentum considerations. This is accompanied by the sputter ejection angular distribution becoming pronounced in the direction of specular reflection. Ultimately the yield goes to zero at 90° incidence, resulting in a maximum yield at $\theta = \theta_m$ somewhat between 0° and 90° depending on the target material, and the ion identity and energy. This angular dependence has several consequences. For example, the polymeric materials used for photoresist tend to sputter rather easily and also degrade under ion bombardment. Sometimes heating of the resist induced by the ion impact or glow causes resist reflow, so that its profile changes. These effects combine to make resist masks prone to etch back and causing tapering during physical etching. The phenomenon of anisotropic tapering, which is illustrated in Figure 80, usually starts on corners, which always have some rounding and therefore present a variety of incidence angles to the incoming ions. A facet will develop for the plane which has the highest etch rate ($\theta = \theta_m$ in Fig. 79), as the more slowly etching planes are consumed. The effect is then transferred to the film but at a different angle corresponding to $\theta_m$ for the film material and the difference in etch rate between the mask and the film. Due to the formation of a tapered-anisotropic profile—or just tapered profile—and because the mask itself is also etched, the final dimension of the opening in the mask will be greater than the initial dimension (Fig. 80d). Consequently, the influence

**Figure 79.** Variation of sputter yield with angle of incidence (with respect to the target normal).

of the mask on the etch profile of the film can be quite pronounced and depends on its initial thickness and profile.

A vertical profile is often desired in an etch process because it maintains lithographically defined feature sizes as they are transferred by etching into underlying films. However, vertical structures that result from vertical etching may also cause problems in subsequent processing. Depositing another layer on top of a structure with vertical steps may cause step coverage problems, as discussed in the section on film formation. Less steep steps, obtained with less vertical etching, would make it easier to obtain good step coverage and would allow easier filling in later formed layers. Because of shrinking feature sizes, however, modern fabrication methods tend to employ vertical etching with little undercutting and use formation techniques that achieve good filling and step coverage even for near-vertical structures. To obtain the perfect vertical profile, usually the synergetic action of both chemical and physical etching is necessary as will be shown in the section on synergistic etching.

## 5.2. Etch Selectivity

Etch selectivity is the ratio of the etch rates of the different materials in an etch process. When the etch rates of the mask and the underlying substrate are near zero, while the etch rate of the thin film is appreciable, then the etch selectivity of the film with respect to both the mask and the substrate is high. Selectivity in the range of 25 or higher is usually considered reasonable. Different materials have

**Figure 78.** Etch directionality.

**Figure 80.** A tapered profile in physical etching: (a) The mask cross-section prior to etching. (b) The onset of facet formation in the mask. (c) The mask facet intersects the original substrate surface plane. (d) The facet propagates laterally in the film thereby exposing additional film to physical etching and consequent facetting.

different etch rates usually because of the chemical effects involved with etching, as opposed to the physical effects. Therefore, chemical reactions can be very selective whereas physical processes tend to be similar for most materials.

In many cases, resist is not enough as a masking layer to transfer a pattern into the underlying material, and generally an intermediate layer is needed. These intermediate masks stand up better to certain etching conditions (i.e., having a higher selectivity) than resist and are often called hard masks. Of course, these hard masks themselves must be selectively etched usually with lithographically defined resist as the soft-masking layer. In Figure 81 a typical procedure to pattern a silicon substrate in an alkaline solution (e.g., KOH) is shown. Resist is attacked in KOH solutions and therefore an intermediate silicon dioxide layer is used. (a) First the oxide is formed (e.g., thermally grown) and coated with a resist pattern. (b) Subsequently, the oxide is (isotropically) etched in an acidic solution (e.g., HF) with the help of the resist pattern (resist can fairly withstand most acidic solutions). (c) Finally, after the resist is removed, the oxide is used as a KOH resistant hard mask to (anisotropically) etch the silicon.

Achieving good selectivity and vertical etching at the same time is important and sometimes quite difficult—with the exception of crystal-dependent etching—for a number of reasons. These reasons are indicated with numbers in Figure 82, where a thin film on top of a substrate is etched. (1) The edge rate of the mask is usually nonzero, and the mask itself is etched. The selectivity for the material to be etched with respect to the mask determines how thick the mask material must be so that the mask is not completely removed during the etching process. Moreover, the mask itself is not perfectly rectangular with rounded top corners and sloped sides due to, for example, postbake procedures of resist (to improve etch selectivity of the resist with respect to the film to be etched). This effect will widen the trench opening during etching (see also Fig. 80). (2) The film structure is an important issue to be considered in film etching. For example, a pinhole will etch the film at places not intended by the designer. (3) Bad adhesion—many times in conjunction with film stress—might curl the mask from the film at the etching corners of structures and might even lift off the whole mask during etching. (4) All etch processes generally employ some amount of overetching in order to ensure that the desired etching process has gone to completion. For example, differences in thickness or etch rate of the thin film between wafer center and wafer edge make extra etch time necessary (typically 10% of the total time). Thus underlying films or the substrate are normally subjected to the etchant for some period of time toward the end of the etch period. The selectivity for the material

**Figure 81.** Typical etch procedure: (a) Resist patterning (first pattern transfer with developer). (b) Silicon dioxide etching (second pattern transfer with HF). (c) Silicon etching (third pattern transfer with KOH).

**Figure 82.** Real etch profile.

being etched with respect to the underlying material determines how much etching of the underlying materials occurs. Clearly, if the substrate beneath the thin film is attacked by the etchant, then the profile of the film will be affected even further.
## 5.3. Film-Etching Methods

Etching can be done either in a plasma- or gas-phase ("dry etching"), liquid-phase ("wet etching"), or solid-phase "abrasive etching" environment. Wet etching involves the use of liquid etchants and is most often a purely chemical process. The wafers are usually immersed in the etchant or spray-etched (e.g., developer solutions) and etching proceeds by dissolution of a material in a solvent or by conversion of a material into a soluble compound, which subsequently dissolves in the etching medium. In the early days of the industry, wet etching was used exclusively. It was a well-established, simple, and inexpensive technology with a high selectivity possible between the masking material and the thin film to be etched due to the chemical nature of the process. Eventually, however, the need for smaller linewidths and more vertical structures required new techniques such as plasma etching. Plasma etching involves the use of reactive etchants from a discharge. Here the etching usually takes place by a combination of chemical and physical processes and forms gaseous or volatile products. The creation of plasma is not always necessary. For example, silicon is etched with $XeF_2$ gas and silicon oxide etches readily in HF vapors. This type of dry etching is beneficial in manufacturing devices where plasma damage would distort the device performance drastically. Solid-phase etching such as powder blasting is not often found in microstructuring. It is a pure physical process and involves the bombardment of particles (typically a few tens of $\mu$m in diameter), which removes material due to physical momentum transfer.

Film etching generally means the complete local removal of a film as given in by the mask pattern on top of the film. However, in some cases the film is not removed but only changes structure. A well-known example of the latter process is the etch formation of porous silicon from single-crystal silicon. This subdivision of film etching into film removal and porous film formation is quite identical with the subdivision of film formation into film deposition and film growing. Therefore this section is organized in more or less the same way as the section on film-formation—it is split into plasma-phase, gas-phase, liquid-phase, and solid-phase etching. Nevertheless, mostly the plasma etching is treated due to its prominent position in current microsystem manufacturing.

### 5.3.1. Plasma-Phase Etching

While wet chemical etching was successfully used in the early days of integrated circuit manufacturing, it has been largely replaced by plasma, or dry, etching due to two main reasons. The first reason is that very reactive chemical species are produced in plasma, which can often etch more vigorously than species in a nonplasma environment. The second reason is that vertical etching—to minimize underetching—is possible with plasma etch systems. This allows smaller and more tightly packed structures. The vertical etching is due to the presence of ionic species in the plasma and the electric fields that direct them normal (i.e., vertical) to the equipotential wafer surface. One of the first widespread uses of plasma etching was in the early 1970s to etch PECVD silicon nitride. Boiling phosphoric acid was commonly used, but this etchant often lifted off photoresist masks so that a mask of silicon oxide had to be used, requiring its own masking and etching steps. It was found that by using $CF_4/O_2$ gas mixture in a plasma atmosphere, atomic fluorine is produced which can etch the nitride film much more easily. In addition, a photoresist mask is not lifted off in this process, making the process simpler and more reliable.

***Principle of Plasma Etching***   The principle of plasma-assisted etching is simple; use a gas glow discharge to dissociate and ionize relatively stable molecules forming chemically reactive and ionic species, and choose the chemistry such that these species react with the solid to be etched to form volatile or gaseous products. Electrical discharges have commonly been used to generate plasma in the laboratory using a glass tube in which two metal electrodes are installed (Fig. 83). The plasma is accomplished by evacuating the discharge tube to a pressure range between $10^{-5}$ to $10^{-3}$ atmosphere and applying a voltage between the two electrodes. As the voltage gradually increases, only a very small electrical current flows. However, when the voltage has reached a few hundred volts, electric current through the tube shows an abrupt increase, and the tube begins to emit visible orange–red light. This condition in the discharge tube is called plasma and is caused by the relaxation of excited particles, which are created by electron impact. The gas becomes electrically conductive due to ionization; the process is also caused by electron impact in which an atom

is fragmented into an ion while liberating an extra electron. Because the extra electrons formed by ionization will also convert electrical energy into kinetic energy—which will produce even more electrons—the electrical fields are quite effective in creating plasma. Generally in such plasma, positively charged ions and negatively charged electrons drift in opposite direction according to the electrical field. The moment when the strength of the electrical field is high enough to increase the number of electrons rapidly is called breakdown, and at this moment the gas ashes and becomes a plasma. This moment depends on the pressure and it is expressed with the help of the so-called Paschen curve, which also is found in Figure 83. Typically, the electrode separation is 10 cm and the gas is turned into plasma at pressures ranging from 10 mTorr up to 1 Torr. At higher pressures, the electrons make too many collisions to be able to gain enough energy necessary for ionization, and only the lower excitation processes take place without an increase in electrons. At the lower pressures, the electrons do not make any collisions with gas particles and they will hit the anode with high energy, again without an increase in electrons.

Wafers are most frequently located directly in the plasma, separated from it only by the natural boundaries of the sheath, where they are bombarded by all of the energetic species of the discharge. These include positive and negative ions, electrons, photons created by electron bombardment of surfaces or from decaying excited atoms or radicals, short-lived radicals, and hot and metastable atoms. It is possible to protect the wafers from some of these particles by appropriate shields or by removing the wafers from the region where the plasma is created. So, while increasing the distance between the sample and the plasma, particles which deteriorate the etch process can be filtered out. In this way it is possible to operate at much lower pressures than when the sample would be mounted directly in the plasma glow region. Therefore, an important classification is to distinguish between a contact plasma, where the sample is in direct contact with the plasma, and a remote plasma, where the sample is located at a distance from the plasma (Fig. 84). In contact plasma etching, samples will be bombarded by all kinds of plasma particles. Members of this important group are the barrel reactors and planar reactors. In barrel etchers or volume-loaded reactors, wafers are simply stacked in a notched quartz support stand that is inserted into a reactor without any attempt to specify the directions of the exciting fields. The planar reactor group can be split up into

**Figure 83.** A direct current (dc) plasma reactor showing ionization by electrons accelerated by the electric field between two electrodes (i.e., anode and cathode) together with the Paschen curve showing the breakdown voltage of a gas between the two electrodes separated by a distance $d$ at a pressure $p$; 1 atm $\sim$ 1 bar $= 10^5$ Pa $\sim$ 760 Torr.

**Figure 84.** Plasma etching at different distances between the plasma and the sample to filter out specific particles from reaching the surface of the sample: Contact and remote plasma etching.

(1) diode reactors with horizontal target plates for single-wafer processing, (2) triodes with an extra electrode used for increased ion bombardment, and (3) hexodes designed for batch processing in which the vertically arranged cathode has the shape of a hexagon surrounded by the cylindrical chamber walls forming the anode. A disadvantage of the contact plasma reactors is that the flux of all the impinging species at the sample surface is difficult to control. A way to improve this is by way of the remote plasma reactors, such as the tunnel-barrel and downstream reactors, which exclude the ionic species by way of a Faraday cage, and ion mill reactors, which subtract the ions from the plasma by way of high-voltage driven grids.

*CCP Reactor* Plasma, such as can be obtained by a dc glow discharge, can also be generated at low pressure (1 mTorr–1 Torr) by a rf discharge with powers of several tens up to hundreds of watts. A basic capacitively coupled plasma (CCP) reactor—currently the most important configuration—is illustrated in Figure 85. The reactor is also known as a plan-parallel plate, planar or diode reactor, and is similar to the PECVD and sputter PVD systems shown earlier (Section 3.7). The energy is supplied by an rf generator—usually operating at 13.56 MHz—and a voltage bias develops between the plasma and the electrodes. This is due to the difference in mobility of the electrons and the ions. Initially, the more mobile electrons are lost to the electrodes at a faster rate than the slower ions. This results in the plasma being biased positively with respect to the electrodes. In CCP reactors, the degree of ionization is typically only $10^{-4}$, so the gas consists mostly of neutral but excited species. A characteristic of this plasma is the lack of thermal equilibrium between the electron temperature and the gas temperature. The rf field is able to effectively convert electrical energy into kinetic energy for the electrons only. In turn, the electrons convert their kinetic energy into inelastic energy for the neutrals to produce ions, radicals, and excited species or they bounce with the neutrals elastically without energy transfer. Thus, the mean neutral velocity is not changed a lot. Hence, this type of plasma is called a nonequilibrium plasma or cold plasma.

For a symmetric CCP reactor (equal electrode areas), the voltage distribution that develops is shown by the solid curve in Figure 86. The sheaths are the regions next to

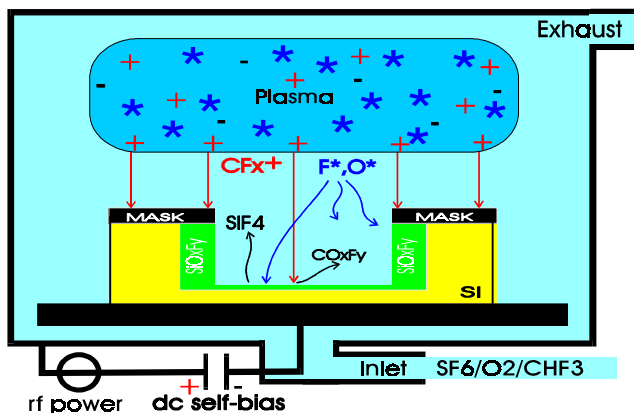

**Figure 85.** A capacitively coupled plasma (CCP) reactor.

**Figure 86.** Potentials inside a CCP reactor.

each electrode where the voltage drops occur. The sheaths form to slow down the electron loss so that it is equal to the ion loss per rf cycle and so that the average current to the electrodes is zero. Whereas the heavy ions respond to the average sheath voltage, the light electrons respond to the instantaneous rf voltage. During most of the rf cycle, the electrons are turned back at the sheath edge, resulting in the sheaths—on the average—being depleted of electrons. This depletion of electrons in the sheath results in the sheath being dark because of the lack of electron/atom collisions and subsequent relaxation by light emission. In the bulk of the plasma, both ionization and excitation events occur, the latter producing the characteristic glow of the plasma. The lack of electrons in the sheath also increases the impedance of the sheath compared to the plasma bulk resulting in the main voltage drop being across the sheaths. If one of the electrodes is made much smaller in area, then the voltage distribution becomes asymmetric with a much larger voltage drop occurring from the plasma to the smaller electrode in order to maintain current continuity throughout the system, as shown by the dashed curve in Figure 86. At low pressure, these reactors develop still higher potentials and bias. The external circuit usually has a blocking capacitor (Fig. 85) so that the negative dc self-bias voltage will appear between the small electrode and the ground (the rf power generator would otherwise shorten the bias voltage).

*ICP, ECR, MIE and Arc Reactors* In the CCP reactors as discussed thus far, the rf generator is capacitively coupled with the plasma. This means that, in order to create high-density plasma, the rf power and thus the dc bias will be high. To lower the bias while keeping the plasma density high it is possible to use an inductively coupled plasma, electron cyclotron resonance (ECR), or magnetron ion etching (MIE) reactor. Unlike the CCP reactors, ICP reactors make use of an inductive coupling in which the electric fields are generated by a coil wrapped around the discharge chamber. These systems commonly operate at a frequency of 13.56 MHz, with powers of several hundreds to thousands of watts. The chamber is typically made of Pyrex, quartz, or alumna. The inductive coupling has the advantage above capacitive coupling that there will be no large or high-voltage sheaths present in the chamber, and as a result no sputtering of the wall. Therefore, these reactors are often used for fast isotropic etching. In ECR, a discharge is produced by microwave excitation (commonly 2.45 GHz).

When a magnetic field of $B = 875$ Gauss is applied, resonance between the cyclotron motion of the electrons in the magnetic and microwave field occurs. Electrons at resonance efficiently convert microwave energy into dissociation of gas species at pressures much lower than possible in CCP or ICP reactors. In MIE, magnetic fields from magnets are used to enhance ionization by confining a discharge. Arrangements similar to those used for magnetron sputtering have been incorporated into etching hardware. Magnetic field lines parallel and electric field lines normal to the cathode surface (self-bias) confine electrons on cycloidal trajectories near the cathode. The probability of an electron undergoing collisions with gas phase species is thus enhanced, and the ion/neutral ratio can be 50 times greater in MIE reactors than in CCP reactors. The mobility of electrons toward the cathode is decreased because of this confinement, causing the self-bias to be lower than conventional CCP. A large flux of low-energy ions is thus produced in MIE reactors at low pressure, whereas in CCP reactors a small flux of high-energy ions is produced for the same input power. There are more types of plasmas, such as thermal arc plasmas, which are used for fusing metal and are generated at near atmospheric pressure or above, microwave multipolar plasma reactors equipped with confinement magnets which surround the etching chamber and use ECR sources, distributed ECR reactors, rf driven double cathode etchers, hallow cathode systems, and magnetically controlled reactive ion (MCRIE) etchers, to name only a few.

*Kaufman Reactors*   In 1961 H. R. Kaufman invented the ion source. In the first instance, the source was used as an ion thruster for space propulsion, but later on it was used for milling (i.e., etching) purposes too. It can generate a collimated ion beam from a wide choice of gas species. The low-pressure (<1 mTorr), line-of-sight nature of beam techniques prevents ion scattering and redeposition of sputtered material due to gas-phase collisions. This possibility of separately controlling ion energy and flux provides a flexibility of directional bombardment not available in other plasma processes. Because it is difficult to start plasma at such low pressure, it is created in a remote, small, higher pressure chamber (Fig. 87). In this so-called Kaufman-source chamber, a high density of electrons is created by way of a heated cathode wire. These electrons are forced to the anode by way of an external voltage source (ca. 40 V). Moreover, their lifetime is increased with the help of permanent magnets surrounding the chamber. The ions are extracted from this plasma with electrostatically controlled grids (up to 1000 V and more) and are directed to the substrate to be etched.

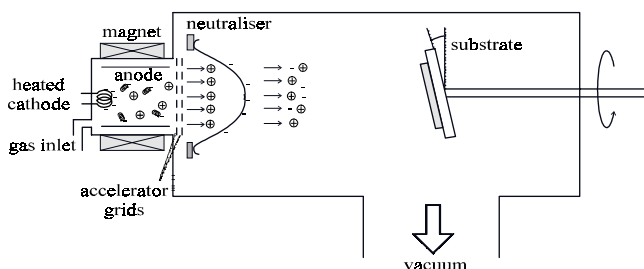

**Figure 87.** Basic schematic for ion beam etching.

A neutralizer is used to prevent charging of the (insulating) substrate, which could cause a nondesirable deflection of incoming ions.

In the previous sections, a few important plasma reactor systems have been treated. These systems can be used for film formation and film etching. As a typical example, the processes which take place in a planar CCP reactor (Fig. 85) are now given:

- *Generation:* An rf generator is used to supply energy for a discharge. This glow discharge is used to generate from a suitable feed gas (e.g., $SF_6$ for Si etching) by electron-impact dissociation/ionization the gas-phase etching environment, which consists of neutrals, electrons, photons, radicals (F), and positive ($SF_5^+$) and negative ($F^-$) ions.

- *Dc-bias formation:* The sample or wafer is placed on an rf driven capacitively coupled electrode. Since the electron mobility is much greater than the ion mobility, after ignition of the plasma the electrode acquires a negative charge with respect to the plasma glow region resulting in the creation of the so-called dc self-bias voltage.

- *Diffusion/forced convection:* The transport of reactive intermediates from the bulk of the plasma to the wafer occurs by diffusion. Positive ions from the glow region are forced to the wafer by way of the dc self-bias and will assist the etching.

- *Adsorption:* Reactive radicals adsorb on the wafer surface. This step can be strongly enhanced by concurrent ion bombardment, which serves to produce "active sites" since it aids in the removal of, for example, an $SiO_xF_y$ layer, which otherwise passivates the surface.

- *Reaction:* A reaction between the adsorbed species and the wafer must take place. In the case of fluorine-based etching of silicon, chemical reactions between the F atoms and the surface spontaneously produce either volatile species, $SiF_4$, or their precursors, $SiF_x$ ($x < 4$). However, in Cl-based etching, Cl atoms are known to adsorb readily on Si surfaces, but the spontaneous etch rate is very slow. Ion bombardment makes it possible for adsorbed Cl atoms to attack the backbones of Si more efficiently and form a volatile $SiCl_4$ molecule. This mechanism is called ion-induced etching.

- *Desorption:* The desorption of the reaction product into the gas phase requires that the reaction product is volatile; thus it should have a high vapor pressure at the substrate temperature. Additionally, there should be no deposited blocking film at the surface. The removal of these films can be greatly accelerated by ion bombardment via sputtering. This mechanism is known as ion-inhibitor etching.

- *Exhaust:* The desorbed species diffuse from the etching surface into the bulk of the plasma and should be pumped out; otherwise plasma-induced dissociation of product molecules will occur and redeposition can take place.

Thus, the two main types of species involved in plasma etching are the reactive neutral chemical species (radicals) and the "physical" ions. It is the free radicals and sometimes other species such as $Cl_2$ or $XeF_2$-, which are primarily responsible for the chemical component in plasma

etch processes creating isotropic or crystal-oriented profiles. It is the ions that are responsible for the physical component creating tapered profiles. Plasma etch systems can be designed such that either the radicals (i.e., chemical plasma etching) or the ions (i.e., physical plasma etching) dominate. The radicals and ions can also work together in a synergistic manner; this is called ion-enhanced or synergistic plasma etching creating various profiles including the ideal vertical profile while maintaining an acceptable degree of selectivity. In Figure 88 the results of the interaction between ionic and radical species with a surface facing plasma are shown, that is, (a) the chemical radical etching (RE), which uses predominantly radicals but not depending on the crystallography, (b) the synergetic ion beam assisted orientation-dependent etching, which depends on crystallography, (c) the synergetic ion beam assisted radical etching (IBARE), which uses both radicals and ions, and (d) the physical sputter etching (SE) or ion beam etching (IBE), which uses only ions. Generally, IBE shows only positively tapered profiles, low selectivity, and low etch rates, whereas RE gives rise to isotropic profiles, high etch rates, and high selectivity.

**Figure 88.** Typical products of the four basic mechanisms of dry plasma etching: (a) Chemical radical etching (isotropic RE). (b) Synergetic ion beam assisted orientation-dependent etching (anisotropic IBA-ODE). (c) Synergetic ion beam assisted radical etching (anisotropic vertical IBARE or RIE). (d) Physical sputter etching or ion beam etching (anisotropic taper IBE).

IBARE enables the achievement of profile control due to the synergetic combination of physical sputtering with chemical activity of reactive species with high etch rates and high selectivity. Next, each of these etching mechanisms will be described more in detail.

***Chemical Plasma Etching*** Radical etching is characterized by almost entirely chemical etching and a minimum of ion bombardment (Fig. 88a). Unfortunately, these chemical plasma systems are also called plasma etchers (PE). Of course, the IBARE and IBE systems are plasma etchers as well. Typical reactor types for RE include the barrel etchers (no ions) and downstream etchers (no ions and photons) in which, generally, the plasma is excited using microwaves (Fig. 84). Such systems are often used for photoresist stripping and other applications where high selectivity and low radiation damage are key requirements and where the isotropic nature of the etching is not a problem or even an advantage (think about plasma-assisted releasing in surface micromachining; Section 6.2). Sometimes symmetrical planar CCP reactors are used. Because of the equal area of both electrodes, there is no bias created between the two electrodes. When the pressure in the reactor is high (say 1 Torr), then the plasma potential and bombardment of ions will be low. Generally, it is more convenient to use an asymmetrical system in which the rf powered electrode (where the wafers are situated) is large relative to the grounded surface area. This is the so-called PE mode. In these cases the plasma potential will be high with respect to the grounded electrode but will almost equal the target electrode potential. Hence, no highly energetic ion bombardment will occur at the substrates. Unfortunately, the wafer can easily be contaminated by material sputtered off the grounded counterelectrode. As a matter of fact, this mode is often found in sputter deposition reactors! Because the grounded surface is more negatively charged than the target electrode, this type of system is also referred to as an "anode-loaded PE system," as opposed to the cathode-loaded IBARE systems for synergistic plasma etching.

***Physical Plasma Etching*** It is often hardly possible to etch a specific substrate material because there is no chemical etchant available. In these cases the patterning is fulfilled by sputtering the layer with a directed energetic ion flux (Fig. 88d). When the ion bombardment takes place at higher pressures in contact with the plasma, it is called sputter etching. In contradiction, at low pressures in remote plasmas, it is known as ion milling or ion beam etching. In SE, a sample is mounted on top of the cathode electrode of, for example, a CCP reactor (Fig. 85). The sample is in contact with the plasma where it is bombarded by highly energetic ions (e.g., $Ar^+$ from the plasma glow region), which pass the plasma sheath region. In sputter processes, radicals and photons are not important enough to influence the overall etch rate, and the ions control the etch rate by way of their impact on the sample surface. However, due to the relatively high pressure, redeposition is often found because of gaseous particles, just sputtered from the surface, which are reflected back from the plasma due to collisions with plasma particles. Moreover, due to collisions of the ions with plasma particles while passing the sheath (i.e., ion scattering), the impact angle of the ions with respect to the surface

is not fully normal anymore, resulting in an undercut. The collisional problems of SE are less pronounced in IBE systems (Fig. 87). This is because the operating pressure in IBE can be much lower (<0.1 mTorr) and, thus, there is less chance of sputtered material (from the target or more importantly from the mask or target support) colliding in the gas phase and being backscattered onto the target. Nevertheless, sputtered material from the mask or the target will be redeposited directly and is responsible for the typical phenomenon of "ears" in IBE (Fig. 89). In IBE, the ions are accelerated toward the sample with the help of a high-voltage source. Because pure physical etching is a slow process, typically 1–30 nm/min, sometimes an extra reactive feed gas is led into the reactor. Such processes are known as chemical-assisted (reactive) ion beam etching (CAIBE, RIBE, and CARIBE). In RIBE, and more in particular CAIBE, it is possible to manipulate important parameters in plasma-assisted etching (e.g., temperature and electron or photon impact). For this reason, basic studies of the surface science aspects of plasma etching were initiated using CAIBE at the beginning of the 1980s in laboratories all over the world.

***Synergistic Plasma Etching*** In applications where, besides radicals, ion bombardment is required, planar reactors can be employed (Figs. 88c and 85). As for the chemical plasma etching, the name for this synergistic plasma etching system is not always straightforward. Trade jargon often refers to low-pressure asymmetric planar reactors as reactive ion etchers, distinguishing higher pressure operation (>100 mTorr) with the term plasma etchers. Of course plasma etching is taking place in both regimes and ions are almost never the primary etchants. We prefer the name of ion beam assisted radical etching instead of reactive ion etching. In IBARE it is difficult to independently control the temperature and fluxes of species. This is one of the reasons for the lack of consistency in the reports concerning the fluorine-based IBARE of silicon. Nevertheless, IBARE is the most important plasma techniques in use today. Popular types of IBARE systems are the planar reactors. As in the case of the radical etch equipment, planar reactors for IBARE processes can be either symmetric, where the cathode area equals the anode area, or asymmetric, where these areas are different in size. In symmetrical low-pressure systems, the plasma potential is high and both electrodes are bombarded by energetic ions. Due to the zero bias caused by the equal electrode areas, this type of etcher is often confused with real RE (i.e., no bombardment). More commonly, in asymmetrical systems, the wafer-loaded rf-powered electrode is small relative to the grounded surface area. These systems are characterized by a low plasma potential (10–50 V) and a large bias on the

**Figure 89.** Resputtering of material in physical plasma etching.

rf-driven electrode (10–1000 V), which increases ion energy and improves the directionality of the etch process. Because of the low plasma potential, relatively little sputter contamination from the grounded surface occurs. Nevertheless, due to the sometimes large bias voltage created in these systems, one should be aware of resputtered mask material toward the etching regions. Because the target electrode is more negatively charged than the grounded surface, this type of system is also referred to as a "cathode-loaded IBARE system," as opposed the anode-loaded PE systems for chemical plasma etching.

An important credit of IBARE is its ability to achieve etch directionality. Etch directionality is due to directed energy input into an etching reaction at a surface and can be accomplished by neutral, ion, electron, or photon bombardment of a surface exposed to a chemical etchant. In the case of IBARE, the achievement of etch directionality is due to energetic ion bombardment. An important clarifying experiment is the exposure of a silicon surface to a well-defined dosage of chemical etchants, $XeF_2$, and energetic ions, argon. It is found that the etch rate obtained for a silicon surface exposed to both particle fluxes simultaneously is much greater than the sum of the etch rates for exposure to the ion beam and chemical etchant separately. Ion-enhanced, ion-assisted, or synergistic plasma etching can be divided in two main groups: ion-induced (reaction controlled etching) and ion-inhibitor (desorption controlled etching) etching.

***Ion-Induced Etching*** Ion-induced etching is used when the surface of the substrate is not reacting spontaneously, such as in the chlorine–silicon, fluorine–silica, or oxygen–polymer system. Ions do modify the surface reactions in one or another way and make it possible for radicals to react with the substrate. Depending on the particular etchant substrate under consideration, a different ion-induced mechanism may be dominant. For instance, it appears that the lattice damage model is important for the oxygen–polymer and chlorine–silicon systems but not for the fluorine–silicon system. Lattice damage produced by ion bombardment increases the reaction rate of etchant species with the substrate relative to undamaged material. For example, when an organic compound like a polymer is exposed to reactive oxygen, the radicals may react spontaneously with the backbones of the long-stretched nonvolatile molecules. However, it is difficult for the oxygen to break such molecules into smaller volatile pieces and thus the etch rate is low. Therefore, an extra energetic ion beam may help to crack these big molecules and will increase the etch rate, because now the oxygen will remove the smaller parts. In Figure 90, typical results of this technique are shown: the directional etching of a polymer and silica with the help of an IBARE system. Note that when the temperature is increased above the so-called glass temperature of the polymer, the reaction of the polymer with the oxygen may become spontaneous, (i.e., no ion bombardment is needed anymore), and the profile will become isotropic. This is not an IBARE process anymore, but a thermally assisted radical etching process.
***Ion-Inhibitor Etching*** In ion-inhibitor etching, the substrate is etched spontaneously and therefore an inhibiting layer is needed to achieve directionality. Sidewalls of trenches
**Figure 90.** Ion-induced etching in an IBARE reactor: (a) Oxygen-based polymer etching ($O_2$ resist). (b) Fluorine-based silica (glass) etching ($SF_6$–$SiO_2$).

are not exposed to ion bombardment and will be covered by the film. However, the bottom of the trench is exposed to ion bombardment and thus free from this deposit and etching can proceed. The passivating layer can be grown by (1) inserting gases which act as a silicon oxidant forming siliconoxy-halogens, as shown in Figure 91, (2) inserting gases which act as polymer precursors forming carbon–halogens, (3) eroding and redepositioning mask material such as metal–halogens, or (4) freezing the normally volatile reaction products of silicon with radicals at the trench walls, such as silicon–halogens. The deposition of a polymeric carbon–halogen film has the disadvantage that this film is thermally less stable than an inorganic silicon–oxyhalogen film. The freezing of reaction products uses expensive cryogenic coolers, and the redeposition of mask material is not acceptable because areas which should stay clean are also contaminated (Fig. 89). Because the passivating film is very thin, the incoming ions should not be highly energetic, so the mask to silicon selectivity will be very high and the substrate damage will be low. Also, because of the low energy of the ions, trenching and faceting (typical IBE problems) are not found, and it is very easy to change

the direction of the impinging ions, thus changing the etched profile (as will be shown in the following). It is exactly these characteristics which make the ion-inhibitor etching such a popular plasma technique.

Because of their high etch rates, normally hydrogen- and halogen-based (i.e., F, Cl, and Br) plasmas are used for the IBARE of silicon and the etch products are volatile $SiH_4$, $SiF_4$, $SiCl_4$, and $SiBr_4$. Whereas F-based plasmas are generally used for isotropic etching, Cl- and Br-based plasmas such as $Cl_2$ are primarily used to achieve anisotropic etch profiles due to ion-induced etching. The latter gases are particularly hazardous ($Br_2$ or Cl compounds) and special precautions are recommended. Therefore, F-based mixes, such as $SF_6/O_2$, are often preferred. In $SF_6/O_2$-based silicon etching in conventional CCP reactors, trenches (up to 200 $\mu$m) with high aspect ratios (up to 10) can be etched at high etch rates (up to several $\mu$m/min) and low ion energies (15–90 eV). The $SF_6/O_2$ mix primarily dissociates in $SF_5$ (little $SF_4$), F, and O radicals. Directionality is achieved by the forming of a passivating $Si_xO_yF_z$ film, which is removed by ion impact at horizontal surfaces but remains at vertical surfaces. In Figure 92 SEM images of Si trenches using various percentages of $O_2$ are displayed. The horizontal etching depends on the thickness of the passivating $Si_xO_yF_z$ layer and the F-atom density trying to etch the Si by penetrating this layer. The thickness of the $Si_xO_yF_z$ layer is a function of, for example, the O-atom density, the ion impact, and the local temperature. The F-atom density is a function of, for example, the $SF_6$ flow, power, and (micro)loading.

*Dual Source Reactors* A disadvantage of CCP systems is that the etch rate is directly controlled by the rf power supply which, in turn, directly controls the bias voltage and, therefore, the ion energy and mask selectivity. Clearly, a

**Figure 91.** Ion-inhibitor etching in an IBARE reactor. Fluorine-based silicon etching ($SF_6/O_2$–Si) using $Si_xO_yF_z$ as inhibitor: (a) Typical nonoptimized profiles. (b) Profiles after proper tuning of the chemistry.

30%          25%

20%
**Figure 92.** The effect of oxygen addition in an $SF_6/O_2$ plasma. With decreasing oxygen content, the thickness of the inhibiting layer decreases and therefore the profile changes from positive to negative: 30% oxygen content resulting in positive-tapered needles, 25% oxygen content resulting in vertical pillars, 20% oxygen content resulting in negative-tapered nails.

low ion-energy prevents substrate damage (electronics) and mask erosion and makes it easy to change the profile of the trench. For this reason it would be convenient to have independent control of the bias voltage with respect to the rf power. Currently, plasma systems are available aiming especially at the micro- and nanoengineering market, which fulfill this demand and come with double powered plasma sources. One is an ICP or ECR source to create a high radical and ion density (i.e. high-density plasma) into a quartz dome. The other is a CCP or dc source to direct the ions from the plasma glow region toward the wafer surface with a specific ion energy controlled by the dc self-bias as developed by the CCP source. In this way it is possible to control independently the energy flux of radicals and ionic species. High etch rates, needed for production of single-wafer etch in microsystem technology, usually require substantially higher power density than batch systems. Special techniques are necessary to handle the resultant thermal loads and enhanced helium backside cooling may require hardware features like wafer clamping (mechanically or electrostatically) and special gas control features to permit adding high-pressure gas behind the wafer, so-called helium chucks. In all cases, coolant fluids need to be circulated to the electrodes in sufficient quantities to remove the heat created by the discharge. Electrode temperatures from $-150$ to $300\,°C$ may be needed for different processes. In addition, it is desirable to control the temperature of all electrodes, because they may affect process performance, so refrigerated cooling systems are common. To control the anisotropy, different ion-inhibitor schemes are in use. A few systems are using cryogenic wafer cooling for profile control and an $SF_6/O_2$-based chemistry for a high etch rate. Others have incorporated the Bosch patent in their system to control the anisotropy (Fig. 93).

*Cryogenic Reactors*    Etching at extremely low substrate temperatures, down to $-150\,°C$, has gained more and more interest in the past years. Advantages seem to be a better control of the undercut during directional etching and an increased selectivity with respect to polymer mask materials. Commonly in CCP reactors, the substrate is cooled by circulating a coolant through the platen on which the substrate rests. However, this technique is insufficient for cryogenic cooling, because the heat transfer between the wafer and the platen is inadequate at such low temperatures and at the pressures normally used for plasma etching. Therefore, helium backside cooling is generally utilized. After optimization of the cryogenic system, etch rates of silicon up
to 15 $\mu$m/min can be obtained at relatively high pressure (4 Pa = 30 mTorr) and ICP power (2 kW) while keeping the anisotropy high (Fig. 93a). At the same time, the erosion rates of thermal silicon dioxide and ordinary photoresist (Shipley S1805) are as low as 7 nm/min (i.e., selectivity up to 2000). Increasing the pressure to 20 Pa, the selectivity increases to 10,000. The high etch rate and high selectivity are especially important in case of microengineering, where wafer through etching with the help of plasmas will become a standard in the near future. In case of nanoengineering, however, profile control is the main concern. To prevent undercut in such cases, in particular bottling due to a broad ion angular distribution, the pressure should be sufficiently low. The best results were found at pressures down to 0.2 Pa = $1\frac{1}{2}$ mTorr and at a low ICP power of 350 W to prevent a too strong mask erosion caused by the low pressure. The silicon etch rate decreased to 1 $\mu$m/min and the erosion rate of the oxide and resist were both approximately 20 nm/min giving a selectivity of 50.

A remarkable effect is observed when the normally isotropic etch chemistry is operated at cryogenic temperatures ($-150\,°C$) with little additional ion bombardment (low bias and plasma potentials—i.e., high pressure). The etch rate turns out to be dependent on the crystallographic structure of the silicon; that is, orientation-dependent etching (ODE) is found. Figure 88b clearly shows the {111} planes probably created due to the difference in activation energy of the crystal orientation (More about this subject is found in Section 5.3.3). Figure 94 shows two related phenomena. The originally circular masks (both opening and dot) have turned into squares! The sidewalls are found to be {110} planes. So the etching at extremely low temperature changes from ion bombardment anisotropy into ion-enhanced crystal anisotropy.

*Bosch Reactors*    In some cases it is possible to switch a plasma chemistry continuously between the isotropic etching with a highly reactive gas (e.g., $SF_6$) and the directional deposition of an inhibiting layer (e.g., $C_4F_8$). Figure 95 shows the basic idea behind this Bosch patent. During the etching of trenches, an intrinsic roughness at the sidewalls is developed (Fig. 93b). This roughness is caused by the isotropic etch and depends on the frequency in which the equipment is switched between etching and depositing and is in the order of the etched depth during one isotropic etch run. However, the etch and deposit runs are using different gases, so the switch frequency is limited by the time

**Figure 93.** Dual-source high-speed etch processes. (a) Cryo process, $SF_6/O_2$ continuous. (b) Bosch process, $SF_6/C_4F_8$ cycle.

**Figure 94.** Ion-enhanced ODE forming {110}-planes- at cryogenic temperature.

Figure 96. Vapor HF $SiO_2$. Etch rate versus temperature.

needed to change the reactor volume between these two gas chemistries: the residence time. Another method to control the directionality is to switch the frequency or power and leave the gases undisturbed. This is feasible because plasma deposition rates are depending on the ion energy. So at high power or low excitation frequency, the reactor is in the etch mode. In contrast, at low power or high frequency, the reactor switches over to deposition. The advantage of this method is the higher switch frequency possible with respect to gas switching.

### 5.3.2. Gas-Phase Etching

Major limitations of wet chemical etching of silicon (dioxide) with hydrofluoric acid (HF) include the necessity for a subsequent rinse and dry step after each etch step, which is critical when dealing with fragile structures. Moreover, the hydrophobic silicon surface strongly attracts particles and other bath contaminations. Another drawback is the inability of wet chemicals to penetrate small geometries with high aspect ratios due to surface tension. Moreover, as wafer size continues to increase beyond 300 mm, single wafer processing becomes a necessity and the clustering ability of dry cleaning or etching processes becomes advantageous. It has been known that the $HF/H_2O$ mixture in the vapor state etches silicon dioxide. In vapor HF or VHF, a vapor from an aqueous solution is delivered to an oxidized surface via carrier gas (Ar or $N_2$) and a condensed phase on the wafer surface is formed to initiate etching. The VHF etch rate peaks between 20 and 30 °C and drops to zero at temperatures above 40 °C, where the condensed phase cannot be maintained (Fig. 96). In VHF etching, first the $HF/H_2O$ is introduced onto the oxide surface. When the partial pressures of HF and $H_2O$ are sufficient, a condensed film forms on the oxide surface. This film is analogous to a thin wet HF layer on the oxide. Etching of the oxide occurs after the aqueous film is present forming $H_2SiF_6$ acid [Eq. (73)] with some liberation of $SiF_4$ [Eq. (74)]. After the oxide is completely removed, the wafer surface becomes hydrophobic, while leaving the silicon surface H-passivated [Eq. (75)]. Reactant species and products desorb from the surface but $H_2SiF_6$ is not a readily volatile species. Therefore, a high-temperature anneal (>100 °C) might be necessary [Eq. (76)]:

$$SiO_2 + 6HF \rightarrow 2H^+ + SiF_6^{2-} + 2H_2O \qquad (73)$$

$$SiO_2 + 4HF \rightarrow SiF_4 + 2H_2O \qquad (74)$$

$$Si_{bulk}:SiO + 4HF \rightarrow Si_{(bulk-1)}:SiH_2 + SiF_4 + H_2O \qquad (75)$$

$$H_2SiF_6 \rightarrow SiF_4 + 2HF \qquad (76)$$
VHF is now a proven technique for removal of native, thermal, and chemical oxides. Given the chemical activity of VHF, the chambers of the various available systems range from Teflon, to SiC, to dense alumna, to stainless steel. Processing pressures range from 10 Torr to atmosphere. The HF is delivered with anhydrous HF gas, or by bubbling a carrier gas through an HF containing solution. Water or IPA is supplied to the chamber via the bubbler or a vaporizer.

Gas-phase silicon etching without the use of a plasma discharge usually contains halide atoms, typically fluorine or chlorine, which form volatile etch products such as $SiF_4$, $SiF_2$, or $SiCl_4$. Silicon can be etched in several fluorine-containing gases, including $XeF_2$, $BrF_3$, $IF_5$, and $F_2$, as well as $HF + H_2O + O_3$, at room temperature and etching in these gases is isotropic (at cryogenic temperatures the etch might show crystal-dependent behavior). Commercial $XeF_2$ etchers are available with adequate gas delivery, which can etch silicon at 0.3 to over 10 $\mu$m/min but etched surfaces tend to be rough. $XeF_2$ etching of silicon has the unusual characteristic of etching more slowly as the temperature rises above room temperature, presumably due to decreased precursor surface coverage. Because the reaction is exothermic, the etch rate may be slowed with time as the substrate is self-heated unless cooling elements are in place. $XeF_2$ is supplied in crystalline form and has a vapor pressure at room temperature of about 4 Torr. It can be masked with photoresist, $SiO_2$, $Si_3N_4$, or Al. Because native oxide can block $XeF_2$–silicon etching, it should first be removed (vapor or wet HF dip). An undissociated molecule $F_2$ etches silicon, but many orders of magnitude slower than $XeF_2$. Therefore high-temperature gas-phase etching (from 220 °C for $F_2$ gas up to 1500 °C for $Cl_2$ gas) is useful for *in-situ* removal of a surface layer of silicon (and native oxide) prior to epitaxial silicon growth to reduce the density of defects such as stacking faults. The $HCl/H_2$ system results in ODE (see Section 5.3.3) forming {111}-plane family facets in openings defined by $SiO_2$ or $Si_3N_4$ windows. A different silicon-etch technique uses a jet from a $SF_6$ gas thermally decomposed at very high temperature (2000–3200 °C).

### 5.3.3. *Liquid-Phase Etching*

The first etchants used in microtechnology were simple wet chemical etchants which were developed for all steps in the fabrication process. By spraying or immersing the wafers into baths of liquid chemicals, the exposed films could be etched away, leaving unetched those regions of the film that were masked with resist or other films. The limiting steps in wet etch processes are usually the chemical reactions in which the etch species react with the film, forming the soluble or gaseous products. Most wet chemical etches result in isotropic profiles—isotropic chemical etching (ICE)—but when etching single-crystalline material, ODE is often found. Wet etches can be very selective because they often depend on chemistry rather than physical processes. The exception for this is the spraying of a high-velocity "water jet," sometimes enriched with powder, which removes material due to physical impact. Moreover, when applying a voltage between the liquid and the substrate, i.e. electrochemical etching (ECE), it is possible to manipulate the etch result and create non-isotropic profile.

***Isotropic Chemical Etching***   A common wet ICE of silicon dioxide is HF acid. It removes (native) oxide while changing HF acid into hexafluoride ($H_2SiF_6$) acid:

$$SiO_2 + 6HF \rightarrow 2H^+ + SiF_6^{2-} + 2H_2O \qquad (77)$$
As an example, 50% HF etches $SiO_2$ at a rate of ca. 2 $\mu$m/min, silicon-rich nitride at ca. 4 nm/min, and silicon at a speed of 0.01 nm/min. Buffering agents are often added to the etch solution to keep the etchants at strength over use and time. For example, ammonium fluoride ($NH_4F$) is added to HF to help prevent depletion of the fluoride ions in the oxide etch. This is called "buffered HF" or BHF. The addition of ammonium fluoride also decreases the etch rate of resist and helps to minimize lifting of the resist during oxide etching.

In some cases the ICE occurs in two steps by first oxidizing the surface of the film or material and then dissolving the oxide. For example, a common etchant for isotropic silicon etching is a mixture of nitric acid ($HNO_3$), HF, and water. The nitric acid oxidizes the surface of the silicon [Eq. (78)] followed by dissolving the oxidation product by HF [Eq. (79)]. Alternatively, oxidants such as oxygen (dissolved in water) or peroxide ($H_2O_2$) can be used:

$$Si + 2HNO_3 \rightarrow SiO_2 + 2HNO_2 \qquad (78)$$

$$SiO_2 + 6HF \rightarrow 2H^+ + SiF_6^{2-} + 2H_2O \qquad (79)$$
Acetic acid, $CH_3COOH$, is often added to the nitric/hydrofluoric acid mix to limit the dissociation of the nitric acid (undissociated $HNO_3$ is the primary oxidant) and to improve wetting and therefore smoother etched surfaces. Any combination of these reagents is commonly referred to as "HNA" for hydrofluoric-nitric-acetic. The etch rate in HNA peaks at over 200 $\mu$m/min at a concentration in the ratio of 2:1:0 (no added diluent). For a range of HNA solutions (e.g., in a ratio of 1:3:8), the silicon etch rate is reduced by more than an order of magnitude for doping levels (whether *n*- or *p*-type) below $10^{17}$/cm$^3$. This is related to the charge-carrier concentration available for charge transfer as part of the reaction. At low HF and high $HNO_3$ concentrations, the etch surface is usually smooth, but the etch rate drops with use as HF is consumed. These etchants can be masked with photoresist, silicon nitride, or gold. At low $HNO_3$ concentrations, the etch rate is limited by the oxidation step—which is a function of crystal orientation, defects, and doping—and therefore, the orientation-dependent etching is found. Etching, however, tends to be difficult to initiate but is aided by a catalyst such as $NaNO_3$. HNA etches are not used as much commercially as alkaline etches due to difficulty of controlling the etch rate but are useful in rounding sharp corners in microstructures to reduce stress concentration. Aside from the HNA system, several HF-based solutions (e.g., concentrated HF and BHF) have been used to etch silicon very slowly.
***Crystal-Dependent Anisotropic Etching***   Wet ODEs are aqueous alkaline solutions that anisotropically etch SCS at rates that vary with crystallographic direction. ODEs etch rapidly in $\langle 110 \rangle$, $\langle 100 \rangle$, and some higher-order crystal directions, effectively terminating at {111} planes as the etch rate drops by over an order of magnitude. The rate of ODE is limited under most conditions by the surface reaction rate rather than mass transport, resulting in more uniform etching than isotropic HNA etchants. Slower etching is observed, however, in the centers of larger exposed areas and deep grooves in $\langle 110 \rangle$ silicon and stratification of etchant concentration has been observed in some unstirred solutions, resulting in etch-rate variation with depth in a solution. In this section some typical ODEs will be discussed. However, before continuing, some definitions concerning the crystal structure will be discussed.

The periodic arrangement of atoms in a crystal is called the lattice. The unit cell in a lattice is a segment representative of the entire lattice. For each unit cell, basis vectors ([100], [010], and [001]) can be defined such that if that cell is translated by integral multiples of these vectors, one arrives at a new unit cell identical to the original. In case of silicon, a simple (face-centred) cubic crystal unit cell is sufficient to describe the silicon lattice with a dimension of 0.543 nm. To identify a plane or a direction, a set of integers *h*, *k*, and *l* called the Miller indices are used. For a specific crystal face, the resulting set of numbers is written down as the (*hkl*) plane and the vector perpendicular with this plane is the [*hkl*] direction. The family of faces which bear like relationships to the crystallographic axes—for example, the planes (001) and (010)—are all equivalent and they are marked as the set of {100} planes. Identically, the family of identical directions—such as [110] and [101]—is marked as $\langle 011 \rangle$ orientations. When ordering silicon wafers, the crystal orientation must be specified. The most common orientations used in microelectronics are the $\langle 100 \rangle$- and $\langle 111 \rangle$ orientation and in micromachining, $\langle 011 \rangle$ orientation is used as well. As found in the section on wafer fabrication, some standards have been formed to identify the crystal orientation with respect to the wafer flat. For example, on a $\langle 100 \rangle$-oriented wafer (commonly just called a $\langle 100 \rangle$ wafer), the {011} plane is often made evident by a flat segment, also called an orientation flat. The precision on the flat typically is about a few degrees. Unfortunately, the standard for the

⟨011⟩ wafer flat is not generally accepted but often parallels a {111} plane. However, it is possible to find the crystal orientation by breaking or cleaving the wafer. If properly done, the wafer will break along one of the {011} planes in case of ⟨100⟩ wafers. In Figure 97a, a "close-up" of the {100} plane in a silicon crystal is shown. In Figure 97b some pictures of a plastic model of three important crystal are shown taken under different angles.

The order of directional etch rates varies considerably with conditions and etchant. A representative order from

(a)

(b)

(c)

fastest to slowest etching planes is {411}, {011}, {311}, {144}, {211}, {100}, {133}, {122}, and {111}. Etch-rate ratios for the primary directions ⟨011⟩:⟨100⟩:⟨111⟩ range from 20:12:1 up to 400:200:1. These ratios are found by using a so-called wagon wheel oxide pattern on top of a silicon wafer. Figure 98 shows such a mask and the "etch-flower" pattern emerging on a wagon-wheel-masked ⟨100⟩ wafer. When {111} planes meet at concave corners of a mask, etching effectively halts. At convex ("sharp") corners, however, undercutting of the mask occurs, with the fastest undercutting planes being {411}. Shaping the undercutting of masks by adding mask structures to convex corners (known as corner compensation) will slow down these corners from etching.

To explain the difference in etch rate ratio between the different oriented planes—it usually follows the sequence {011} > {100} > {111}—some models were proposed based on the reaction kinetics of the collection of surface atoms. For example, the {111} planes present a higher density of surface atoms per $cm^2$ to the etchant than the {100} planes. Due to the subsequent increase in shielding by surface-bonded OH or oxygen, the etch rate would become slower. However, the {011} planes have an even higher density. Another suggestion is that the etch rate correlates with available density of surface bonds, the surface with the highest bond density etching faster. However, the available bond densities follow the sequence 1.41:2:1.15 for the {011}:{100}:{111} surfaces. Alternatively, the {111} planes oxidize faster during etching and, therefore, they are better protected against etching. However, now the oxidation rate follows the sequence {011} > {111} > {100}. In a more consistent model based on the reaction kinetics of the individual surface atoms, it is assumed that the anisotropy is due to differences in activation energy, backbond geometry, and reaction probability. For example, the available bonds per silicon surface atom follow the sequence 1:2:1 for the {011}:{100}:{111} planes, but the backbonds follows the sequence 1:2:3 (the ⟨011⟩ wafer has two in-plane bonds per silicon atom). So, in order to liberate a single silicon atom from a {111} surface, three backbonds have to be broken at the same time and for a {100} surface only two backbonds. If the change that one backbond is broken would be, for example, 1%, then the change that two backbonds are broken at the same time will be 100 times smaller, and for three backbonds this change is still 100 times smaller. This difference will be even larger because occupied bonds will lower the bond energy of the backbonds left.

In the silicon crystal {111} planes form an octahedron and the orientation of the silicon defines how the octahedron is located in the wafer (with respect to the wafer

**Figure 97.** (a) Silicon crystal lattice showing the {100} plane. The silicon atoms at the surface (red-dark) have two bonds available for etching. flats), and therefore the shapes which can be achieved by ODE. Figure 99 shows the octahedron of {111} planes and the way in which it is positioned in $\langle 011 \rangle$, $\langle 111 \rangle$, and $\langle 100 \rangle$ SCS wafers. In the most common application of ODE, a {100}-silicon surface is etched through a rectangular mask window whose sides are parallel to $\langle 011 \rangle$ directions (Fig. 100a). The etch proceeds downward until {111} planes are reached, forming a V-shaped pit in which the {111} planes intersect the {100} surface at a 54.7° angle. However, with silicon wafers this angle will vary slightly as the etch rate of the {111} planes is nonzero and the alignment of the wafer surface and wafer flat with crystal direction is rarely perfect. In such cases, undercutting of the mask is observed as shown in Figure 100b. When the sides of the rectangular are parallel to $\langle 100 \rangle$ directions, the etch process is not halted by the {111} planes (Fig. 100c). In such cases $\langle 100 \rangle$ planes—having a local etch rate minimum—will develop and undercutting of the mask is found with the same amount as the etch depth. Alternatively, high aspect ratio trenches with vertical sidewalls (90° angle)—and V-grooves which intersect the {011} surface at a 35.3° angle—can be formed in a {011} surface using a parallelogram-shaped mask window with sides parallel to $\langle 111 \rangle$ directions (Fig. 99).

*KOH Etching*   Alkali hydroxides such as KOH, NaOH, and LiOH in water etch silicon at about the same rate for the same molarity—almost independent of the cation. KOH is the most popular ODE, having been in industrial use for decades. It can produce a fast etch rate of several micrometers per minute at 100 °C. In the hydroxide etching of silicon both hydroxide ($OH^-$) and $H_2O$ are involved, which explains the initial increase in etch rate with KOH concentration (up to 18% by weight at 80 °C), followed by a decrease at higher KOH (and therefore lower $H_2O$) concentration. Although the reaction kinetics is quite unclear a very

**Figure 100.** Influence of mask rotation on the etch profiles in $\langle 100 \rangle$ silicon ODE: (a) Etch stop on {111} planes intersecting the surface at a 54.7° angle. (b) Influence of small rotation (5°) of the mask with respect to the wafer surface. (c) Influence of 45° rotation. Etch stop on {100} planes caused by the local etch minimum of the {100} plane.
basic reaction is the etching of silicon in pure water from which the oxygen molecules has been removed. The $\langle 100 \rangle$ surface is terminated by OH molecules, which enables etching [Eq. (80)] and the reaction product $Si(OH)_4$ is removed by diffusion. For pH values above 12 the product dissolves [Eq. (81)]. If this production is too fast, for solutions with a high water concentration, this product leads to the formation of a $SiO_2$-like complex (white residue). In contradiction, it has been found with infrared spectroscopy that $\langle 111 \rangle$ silicon is terminated by H-atoms, which effectively blocks etching [Eq. (82)]. In the presence of oxygen, both surfaces immediately oxidize and block further etching [Eq. (83)]:

$$Si_{bulk}:Si(OH)_2 + 4H_2O \rightarrow Si_{(bulk-1)}:Si(OH)_2$$
$$+ Si(OH)_4 + 2H_2 \quad (80)$$

$$Si(OH)_4 \rightarrow SiO_2(OH)_2^{2-} + 2H^+ \quad (81)$$

$$Si_{bulk} \equiv SiH + xH_2O \rightarrow \text{No reaction} \quad (82)$$

$$Si_{bulk}:Si: + O_2 \rightarrow Si_{bulk}:SiO_2 \quad (83)$$

The etch mechanism in strong basic solutions is still quite unclear and one model needs silicate production [Eqs. (84) and (85)]. Another possible mechanism involves the catalytic action of the alkali ion [Eqs. (86) and (87)] and could explain the (small) difference in etch behaviour for different types of alkali ions but the silicon–potassium intermediate is doubtful:

$$Si_{bulk}:Si(OH)_2 + 4OH^- \rightarrow Si_{(bulk-1)}:Si(OH)_2$$
$$+ Si(OH)_4 + 4e^- \quad (84)$$

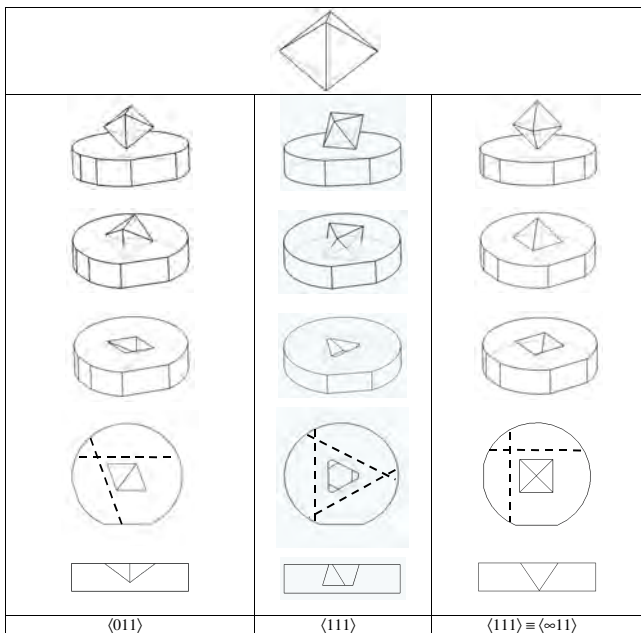

**Figure 99.** Position of the octahedron limited by {111} planes in differently oriented silicon wafers. The bold dashed lines in the lower figures indicate the plane along which the wafer will break.

| $\langle 011 \rangle$ | $\langle 111 \rangle$ | $\langle 111 \rangle \equiv \langle \infty 11 \rangle$ |

$$Si(OH)_4 + 4H_2O + 4e^- \rightarrow Si(OH)_6^{2-} + 2H_2 \quad (85)$$

$$Si_{bulk}:SiK_2 + 4H_2O \rightarrow Si_{bulk}:Si(OH)_2 + 2K^+$$
$$+ 2OH^- + 2H_2 \quad (86)$$

$$Si_{bulk}:Si(OH)_2 + 2K^+ + 2OH^- \rightarrow Si_{(bulk-1)}:SiK_2$$
$$+ Si(OH)_4 \quad (87)$$

Etch-surface smoothness tends to improve as the concentration is increased, especially above 30% KOH. The concentration of maximum etch rate is therefore usually not used because of the rough surfaces and because of the formation of insoluble residues below 15% KOH. A concentration of 30% KOH by weight at 80 °C is a representative etch. Higher temperatures give a faster etch, with an activation energy $E_A$ of 0.595 eV used in the curve-fit equation (where the concentrations are in mol/liter). The density and molecular weight of KOH are 2.055 g/cm$^3$ and 56.11 g/mol, respectively (and 1.00 g/cm$^3$ and 18.02 g/mol for water):

KOH-{100}silicon etch rate

$$= 413[H_2O]^4[KOH]^{1/4} \exp(-E_A/kT)\mu m/min \quad (88)$$

KOH etching has several disadvantages. Hydrogen gas bubbles are evolved during etching which can locally block the transport of reactants to the surface, increasing roughness, and can also damage delicate microstructures. All of the alkali hydroxides, of course, contain alkali ions, which are not compatible with MOS circuitry (and therefore not allowed in many semiconductor facilities). Also of concern for on-chip circuitry, KOH etches aluminum. KOH–silicon etching can be masked by, for example, gold, silicon nitride, and silicon dioxide for short etches due to a non-negligible oxide etch rate (several nm/min). Photoresist is rapidly removed. Boron doping can be used as an etch stop for KOH concentrations below 10%; it is not as effective as in ethylenediamine (EDP) etching. Adding isopropyl alcohol to KOH solutions reduces convex-corner undercutting and also improves uniformity but slows etching by about 20% and lowers the {100}:{111} etch-rate ratio.

*EDP Etching*   EDP in water, sometimes with the addition of pyrazine, is a classic ODE that exhibits etch rates roughly half those of KOH. EDP and water are the primary etchants. EDP has the preferable properties over KOH of halting etching at boron etch stops more effectively, leaving generally smooth surfaces, having a much better selectivity over silicon dioxide, and not containing alkali ions. Because the etch rate of silicon dioxide is so low, native oxide should be removed just before EDP etching. EDP is not used as much as KOH, however, because it is considered to be too toxic and ages quickly with oxygen exposure, giving a faster etch rate and turning the solution opaque.

*TMAH Etching*   Several quaternary ammonium hydroxides—tetramethylammonium hydroxide ($N(C_2H_5)_4 \cdot OH$), or TMAH, tetraethylammonium hydroxide (TEAH), choline (each in water)—came into use for ODE in the early 1990s. TMAH has the advantage over KOH of etching silicon dioxide very slowly, not containing alkali ions, and not attacking aluminum when properly "doped," all of which make TMAH

IC compatible. It has the advantage over EDP of not being considered as toxic. TMAH solutions, however, have a lower etch-rate ratio of {011}:{100}:{111} planes of—typically—60:20:1, and etch silicon about half the rate of KOH at the same concentration and temperature, and tend to yield rougher surfaces. The maximum {100} etch rate is at 2% by weight for TMAH and 20% for TEAH over the temperature range of 60–90 °C. Smooth surfaces are obtained above 20% TMAH. The {100}:{111} etch-rate ratio rises continuously as the TMAH concentration is reduced. By adding 1–2 mol/l of $NH_4HPO_4$ acid and/or dissolving 2–4 mol/l of silicon in a 20% TMAH solution, the pH can be raised sufficiently to reduce the etch rate of aluminum by several orders of magnitude. TMAH with several percent surfactant (30 wt% polyoxythene alkyl phenyl ether) added has the unusual property of etching ⟨100⟩ directions faster than ⟨110⟩ directions, leaving {110} planes exposed after short etches.

*Hydrazine Etching*   Hydrazine and water is an ODE that has been used to a limited degree, because it is toxic and is explosive. It has maximum practical etch rate similar to KOH, stops etching on oxide and heavy *p*-type doping, and can be masked by most metals (but not Al), but has a lower {100}:{111} selectivity than KOH.

*Other ODEs*   Gallic acid + etanolamine + pyrazine + water is found to be most useful. It has etch rates similar to KOH, stops on heavily boron-doped regions better than EDP, etches silicon dioxide slowly, does not contain alkali ions, and is nontoxic. $NH_4OH$ has also been used but was slower than KOH and resulted in rough surfaces. The addition of $H_2O_2$ gave smoother surfaces and faster etch rates. Preferential etches are used to delineate crystal defects such as dislocations or stacking faults and are sometimes sensitive to orientation. All of these etches use a two-step etch process similar to the HNA etchants—silicon is first oxidized and then the resulting oxidized material is etched by HF. A few preferential etches use $HNO_3$ as an oxidizing agent such as the dash etch ($HF_{49\%}/HNO_{3\,70\%}/CH_3COOH_{100\%} = 1/3/10$), which etches ⟨100⟩ silicon at a rate of 130 nm/min and has a {100}:{111} etch-rate ratio of 26:1.

***Electrochemical Anisotropic Etching***   Electrically conducting or semiconducting materials are sometimes etched by application of an external voltage: the process of electrochemical etching. ECE is considerably more complicated than other techniques but can yield results not otherwise attainable. The etch rate and selectivity can be controlled by the potential and/or the current density applied. Electropolishing of metals is a good example of this technique, but a more instructive example is the ECE of silicon (Fig. 101). The silicon substrate is immersed in highly concentrated hydrofluoric acid and a voltage is applied between the silicon and a platinum counterelectrode. Etching can be divided into two types: cathodic and anodic. In the cathodic overpotential, where the silicon is negatively biased, neither *n*- nor *p*-type silicon dissolves into the electrolyte. On the other hand—when anodic overpotential is applied—in both *n*- and *p*-type silicon electronic holes trigger the ECE reaction of silicon dissolution. Since the electronic hole is the majority carrier in *p*-type silicon, there is minor difference between the anodic *I–V* curves of the substrate
**Figure 101.** Basic ECE setup.

with and without illumination and the curves present two peaks, characterized by $I_{crit}$ and $I_{max}$. In case of $n$-type silicon, the electronic hole is the minority carrier and the $I$–$V$ curves with and without illumination are now completely different. In the case of intense illumination of the silicon substrate with photons having energy larger than the bandgap of silicon, electron–hole pairs are generated and the $I$–$V$ curve of $n$-type silicon is roughly similar to that of $p$-type silicon. In the ECE for $n$-type silicon in the dark at a lower overpotential, virtually no reaction takes place but—if the overpotential is greater than breakdown energy—electronic holes are generated and electropolishing occurs.

There are two regions for anodic silicon dissolution. One is porous silicon formation, which occurs at a lower overpotential and at a current below $I_{crit}$, consuming two electronic holes. The other is electropolishing, which uses four electronic holes to dissolve silicon via silicon dioxide and occurs at currents above $I_{crit}$. The first peak in the $I$–$V$ curve shown in Figure 101 (roughly at 1 V and 50 mA/cm$^2$) marks this change from the potential range where the etching results in the formation of porous silicon (charge-supply-limited) to the potential range where polishing occurs (mass-transport-limited). First the chemical reaction of porous silicon formation is given. Silicon, which is immersed in the HF electrolyte, is terminated by hydrogen. The silicon consumes two electronic holes (coming from the inside of the substrate to the surface) and reacts with two F$^-$ ions to become SiF$_2$ with the emission of a hydrogen bubble, H$_2$ [Eq. (89)]. The silicon backbond between silicon atoms is weakened due to large electronegatives of fluorine. Therefore, SiF$_2$ reacts with 2HF and becomes SiF$_4$ [Eq. (90)]. At this stage the silicon atom has been removed from the substrate. SiF$_4$ reacts with 2HF and

becomes H$_2$SiF$_6$. This product is easy to solve in HF as SiF$_6^{2-}$ [Eq. (91)]:

$$Si_{bulk}:SiH_2 + 2F^- + 2h^+ \rightarrow Si_{bulk}:SiF_2 + H_2 \quad (89)$$

$$Si_{bulk}:SiF_2 + 2HF \rightarrow Si_{bulk}:SiH_2 + SiF_4 \quad (90)$$

$$SiF_4 + 2HF \rightarrow 2H^+ + SiF_6^{2-} \quad (91)$$

On the other hand, four electronic holes are consumed by electropolishing, and in the course of silicon dissolution, silicon dioxide is formed. Finally, silicon dioxide dissolves in HF as SiF$_6^{2-}$. During this chemical reaction, hydrogen bubbles are not evolved:

$$Si_{bulk}:SiH_2 + 2H_2O + 4h^+ \rightarrow Si_{bulk}:Si(OH)_2 + 4H^+ \quad (92)$$

$$Si_{bulk}:Si(OH)_2 + 2H_2O \rightarrow Si_{bulk}:SiH_2 + Si(OH)_4 \quad (93)$$

$$Si(OH)_4 \rightarrow SiO_2 + 2H_2O \quad (94)$$

$$SiO_2 + 6HF \rightarrow SiF_6^{2-} + 2H^+ + 2H_2O \quad (95)$$

The porous film delaminates and bright electropolishing occurs at current densities above $I_{max}$. With dissolution of chemical reactants, HF is depleted at the electrode surface and a charge of holes builds up at the interface. Hills on the surface dissolve faster than depressions because the current density is higher on high spots. As a result, the surface becomes smoother (i.e., electropolishing takes place). So the basic technique to make porous silicon is by electrochemical etching in hydrofluoric acid. This technique produces a three-dimensional silicon nanostructure with a very high aspect ratio (depth/width or height/width) above 250 in a single step, which cannot be achieved by the other conventional silicon etching techniques. It also leads to all types of new devices from quantum structures, permeable membranes, photoluminescent and electroluminescent devices, to a basis for making thick silicon dioxide or silicon nitride films. Porous silicon is classified by the pore diameter: pores with a diameter of less than 2 nm are called—how inconvenient—microporous silicon, and those with a diameter of between 2 and 20 nm are mesoporous silicon. These two types of silicon have pores which are highly interconnected and which form network structures (Fig. 102a). Thus etched structures cannot be controlled precisely. Porous silicon with pore diameters larger than 20 nm is called macroporous silicon. The location of the macropores can be controlled by small initial pits to EC etching as proposed by Lehman and is applied, for example, to make photonic crystals and large 3D capacitors (Fig. 102b). Porosity varies with the current density and HF concentration and might follow crystallographic orientation. Porous silicon is highly reactive, oxidizes, and etches at a very high rate.

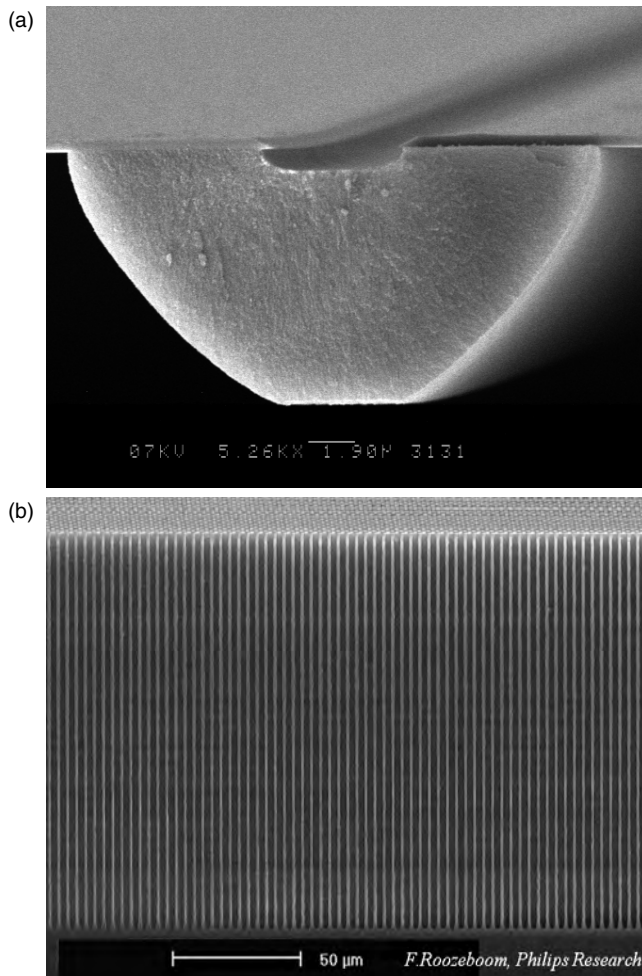
ODEs also slow or stop etching at heavily doped $p$-type regions ($>2 \times 10^{19}$/cm$^3$ boron). At intermediate steps in the EC reaction, four free electrons are generated that reside in the silicon near the etch surface before being exchanged. $p$-Type doping reduces this surface supply of electrons. The drop in etch rate varies with etchant. While $p+$-silicon is used as an etch stop without the application of an external bias, it is possible to etch through a $p$-type layer and stop on $n$-type silicon with the use of an EC etch stop by protecting


Figure 102. Porous silicon patterns. (a) Irregular. (b) Regular. Figure courtesy of Fred Roozeboom, Philips Research.

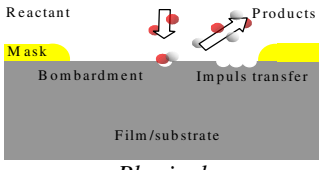
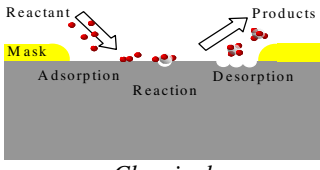
the *n*-type silicon from the solution (e.g., layer of silicon nitride) and reverse-biasing the *p–n* diode that is formed. Electrodeless EC etching can also be performed by way of generating a potential from gold contacting both the *n*-type silicon and the etchant.

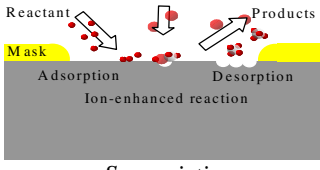
### 5.3.4. Solid-Phase Etching

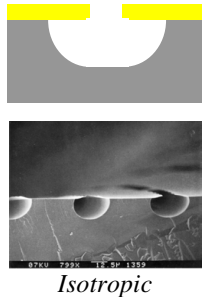
Chemical–mechanical polishing is used in wafer preparation when a relatively defect-free and smooth surface is required. The combination of slow liquid chemical surface etching with gentle mechanical abrasion to continuously remove products from the etching reaction can result in a high-quality surface polish. More details about wafer polishing can be found in Section 2.3.8.

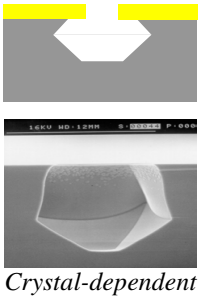
The development of flat panel displays in the 1990s caused powder blasting to be developed to an accurate machining tool. Powder blasting is an old technique in which a particle jet is directed toward a target for mechanical material removal. The particles (typically 30 micrometers in size) are accelerated toward the target with a high-pressure airflow through a circular nozzle with a diameter of 1.5 mm. The particles hit the target with a speed up to 300 m/s (depending on the air pressure and the particle size) in

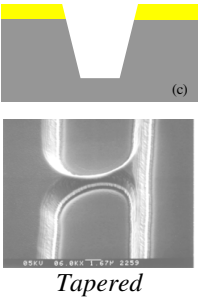
a ventilated box. A lateral movement ensures an evenly eroded surface while a patterned mask covers the target. Powder blasting can be used to erode any type of brittle material such as glass, silicon, and ceramics. Ductile metals and elastomers have high resistance against powder blasting, which allows them to be used as mask materials. Due to the large particle sizes, powder blasting is not suitable in conjunction with high-resolution lithography. Powder blasting creates rough surfaces and is not suitable to selectively remove material for, for example, surface micromachining since it attacks all brittle materials; it is a truly bulk micromachining technique. Figure 103 shows a typical example of an etch-trough hole in a silicon substrate to enable fluid from a "macro" tube to be connected with micromachined channels.


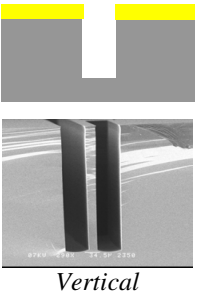


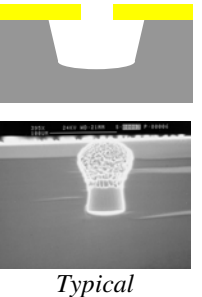


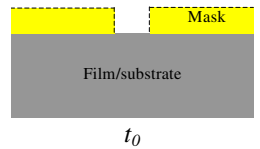


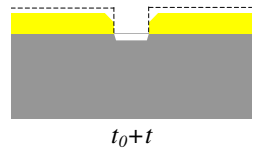


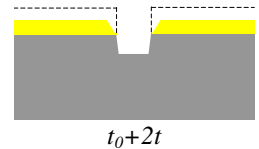


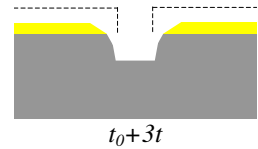


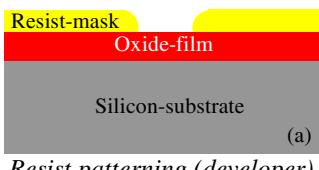












### 5.4. Conclusion and Nanoperspective

Table 13 summarizes this section with a schematic overview of film etching methods and phenomena in micromachining. In etching nanostructures, several aspects are different from micromanufacturing. In case of microelectronic devices, the etch depth is typically less than 1 micrometer and therefore moderate—but accurate—etch rates are requested to ensure a precise etch depth and a smooth surface finish. On the other hand, in case of micromechanical devices, many times high etch rates are needed and nonstandard materials are used to construct high aspect ratio devices with specific properties (e.g., piezoelectric or electro-optic systems). In nanotechnology where the surface interactions play a dominant role, etch processes of different materials having a low etch rate (typically a few nm per minute or slower to control the etch depth using a time stop) and leaving a clean surface finish are of prime concern. So, with respect to nanomachining, the etch rate of the film is not as demanding as in case of microtechnology and the etch depth is fairly identical with semiconductor manufacturing. In addition, the materials from micromachining are requested. Etching nanometer instead of micrometer structures does not significantly alter the etch result, as long as layer thickness are scaled down with lateral dimensions: a process yielding a 5 micrometer deep trench at 1 micrometer width—at best—cannot be

Figure 103. Etch through hole by way of powder blasting.

**Table 13.** Schematic overview of film etching methods and phenomena.

| Etching | Physical | Chemical | Synergistic |

expected to do better than 50 nm depth at 10 nm width. Therefore, in nanotechnology the etching should fulfill the following characteristics:

(i) It should be slow enough to ensure a precise etch-depth in the film.
(ii) It should leave an "atomic-level" smooth surface.
(iii) It should be able to shape diverse materials.

The control in etch depth and surface finish of all kinds of materials can be achieved with two different techniques (Fig. 104). In the first method (Fig. 104a), the substrate or

film is shaped directly with a low-speed etch recipe. The main task is to find a process having the ability to etch slow enough to be able to etch only a few atomic layers up to several tens of nanometers. Additionally, the surface should be smooth enough to ensure proper functioning of the finished product. In the second approach (Fig. 103b), first a film is formed on top of the substrate with a well-defined thickness. After this, it is selectively etched with a chemical that stops accurately when the underlying substrate is reached. So, in the first approach, the film etching is critical whereas in the second approach the film formation defines
**Figure 104.** Typical accurate etch procedures: (a) Accurate etching. (b) Accurate film formation and selective etching.

the surface topography. In both cases, the nanostep can be covered eventually with an additional (nonstandard) layer having specific characteristics (Fig. 104, bottom).

The successful application of etching to new materials in the nanoscale regime mainly depends on the ability to find a chemistry which yields volatile etch products only. The most straightforward way to control etch depth and surface finish is the use of wet chemicals, which are easy to dilute to lower the etch rate. For example, a standard TMAH-based etchant for photoresist (OPD developer) etches silicon approximately at a speed of 3 nm/min at room temperature and a 1% HF solution etches silicon dioxide roughly at 5 nm/min. Clearly, we have to bear this in mind when processing silicon wafers in the lithography step and native oxide should be included to protect the silicon during resist development. Also, it is a well-known effect that silicon etches in oxygen-free water, so rinsing steps in demiwater without controlling the oxygen atmosphere might produce unexpected results.

In microtechnology, low-pressure plasma reactors are much more demanding in terms of pumping equipment and wafer cooling than conventional systems, because moderate gas flows at these low pressures demand very high pumping speeds. However, in nanotechnology the etch rate is not as stringent as in microtechnology and, therefore, ultralow vacuum etch equipment such as ion beam etching ($p <$ 0.1 mTorr) reactors or dual source systems ($p <$ 10 mTorr) equipped with conventional pumping systems are of interest. IBE is a slow and clean plasma process enabling atomic level etches with smooth surface finish. However, the physical nature of the process generally creates tapered profiles, which might be a disadvantage for some applications. With dual-source plasma etchers, the profile can be altered and vertical etching is possible. However, the etch rate is normally too fast to be useful for nanoetch applications. Nevertheless, it might be possible to slow down the etch process by optimizing the equipment. Vertical etching is easier to achieve in low-pressure reactors because of a high ion-to-neutral flux ratio and the reduced probability of ion-neutral collisions in the sheath region at low pressure. Wafer cooling is a critical issue because of significant ion bombardment and low-pressure operation. Backside helium cooling using a wafer clamp or an electrostatic chuck is necessary in order to control the etching process. Process integration is

introduced to effectively integrate plasma etch systems into the overall fabrication sequence (e.g., by connecting deposition and etching chambers by clean, evacuated transport chambers, i.e., cluster tools).

Finally, if proper etch chemistries are unknown, other structuring procedures should be investigated such as ultrathin photoresist layers or films formed using stamping, implantation, plating, or lift-off lithography.

## 6. MICROMACHINING

Micromachining is the underlying foundation of MST fabrication; it is the tool of MST to make high performance microdevices and is suitable for the creation of a range of transducers including pressure sensors, accelerometers, gyros, thermal flow sensors, optical and rf switches, and bio/chemical devices [21–41, 99–127, 631–795]. Furthermore, a great number of conferences are held showing the popularity of MST [79–98]. Of course, material properties play a crucial role in the success of a micromachined device and detailed studies are found in literature [42–78, 145–186]. Arguably, the birth of the first micromachined components dates back many decades, but it was the well-established integrated circuit industry that indirectly played an indispensable role in fostering an environment suitable for the development and growth of micromachining technologies [1–20, 128–144]. Therefore, in order to make these three-dimensional structures—often freestanding and on top of a substrate—a specific sequence of lithographically based techniques such as film formation, lithography, and film etching techniques is required as schematically shown in Figure 105 and which have been treated more extensively in the first sections. These techniques, useful in micro- and nanomachining, have been greatly improved as device dimensions have been reduced and can be boiled down to four basic concepts: bulk, surface, mold, and bond micromachining. In bulk micromachining features are formed out of the bulk of substrate material. In contrast, surface micromachined features are built up—layer by layer—on top

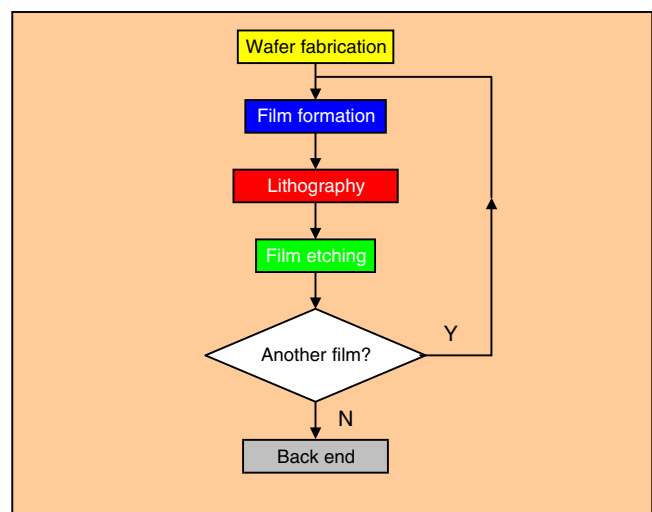

**Figure 105.** An abstract representation of a typical process flow found in micromachining.

of the surface of a substrate. In mold micromachining, a (metal) structure serves as a mold insert to form many plastic replicas. The advantage of mold micromachining is the economically favorable replication characteristic, but truly three-dimensional structures are not possible with replicating. In many cases, the micromachining process is ended with a bonding step to seal the device. However, in bond micromachining, the structure is formed at the interface of two patterned wafers, which enables *in-situ* sealing of the device. In the following sections these basic technologies will be discussed.

## 6.1. Bulk Micromachining

Bulk micromachining is one of the earliest processes in the field of microsystem technology [187–276]. While there are many different types of bulk micromachining, the basic concept is to create features out of a substrate. In general, a silicon, SOI, or glass wafer serves as the substrate material and the structures are created by way of removing (etching) the parts of the wafer that are not wanted, leaving the desired structure behind. Typically, this is done through a sequence of photopatterning steps on the surface of a silicon substrate followed by wet or dry etching of the silicon. Wet orientation dependent etching with alkaline solutions such as potassium hydroxide is often used to create thin membranes with sensor elements on top of it. Dry vertical etching with plasma environments ($SF_6/O_2$) or xenon difluoride ($XeF_2$) gases are found to construct high aspect ratio freestanding actuator elements. Since these two methods have their own advantages and disadvantages, the bulk etching technique should be chosen according to which application is requested such as sensors or actuators.

Figure 106 shows two basic process sequences for a flow sensor fabricated by wet bulk micromachining using ODE of silicon. In this thermal flow sensor, a platinum resistor is heated up, and an airflow removes heat from the resistor. The flow rate can be measured by the change in resistance. In order to improve the sensitivity of the sensor, the resistor is formed on a thin silicon nitride membrane, which is thermally isolated from the silicon substrate. In the first step, silicon nitride is formed on both sides of a silicon wafer and patterned. Next, platinum is deposited and patterned on the frontside to make resistive elements. Finally, the
membrane is fabricated by removing the silicon by alkaline etching with the silicon nitride used as a hard mask. A disadvantage of the method depicted in Figure 106a is that double-sided alignment is necessary to align the patterns at the backside with those at the frontside. This complicates the lithographic equipment. This problem can be solved when micromachining from one side only as shown in Figure 106b. However, the mask design to construct a freestanding structure is somewhat more complicated due to blocking {111} planes.

Figure 107a shows an example of a thin structured membrane (photo taken from the backside), fabricated with the help of through-the-wafer wet etching. Figure 107b shows a so-called shadow mask to be used as a technique to pattern irregular surfaces. Figure 107c shows a force sensor bridging a flow channel, which is wet bulk micromachined from a single side.

Bulk micromaching using wet alkaline ODE solutions has many advantages. The equipment is cheap and a high throughput can be obtained due to a batch process. Also, the etching stops on a crystal plane, such as the {111} plane and, thus, the etched surface is smooth and lateral dimensions are well defined. On the other hand, the silicon structural shape is also restricted by the crystal {111} planes. Moreover, the stopping plane is slanted with respect to the surface of the substrate, as is shown in Figure 106, and therefore the membrane area on the surface is smaller than the open area of the masking material on the other side of the wafer. This results in relatively large chips. Furthermore, misalignment between the crystal orientation and the mask in lithography (Fig. 100) or due to misorientation of the wafer flat can lead to an error in the etched dimension. Therefore, a pretreatment is necessary to ascertain the crystal orientation precisely (Fig. 98). To enable dimensional control and to realize more complicated structures, plasma-etching

(c)
**Figure 107.** Some typical structures created by means of wet ODE bulk micromachining: (a, b) Double-sided lithography. (c) Single-side lithography.

(a)

(b)

**Figure 106.** Typical schemes for wet ODE bulk micromachining: (a) Double-side litho. (b) Single-side litho.
techniques have been developed. This technique generally does not depend on crystal orientation and, therefore, high aspect ratio structures are possible. In Figure 108a, freestanding single-crystal structures of silicon are fabricated by combining anisotropic and isotropic dry etching. First, trenches are etched using vertical plasma etching. Next, a passivation layer is deposited on the etched surface and subsequently removed on the bottom using directional plasma etching after which an isotropic plasma etch follows. Finally, a metallic layer is deposited to enable electrical contacting of the freestanding structure as shown in Figure 108a. Alternatively, if the trenches etched in the first step are narrow enough, it is possible to seal the trench with a uniform film. In this way, subsurface or buried channels are created as shown in Figure 108b. Figure 109 shows a comb-drive actuator fabricated with the help of dry bulk micromachining and some buried channels.

It is possible to explore the ODE of silicon when using specific mask designs or to combine it with plasma etching to extend the range of microdevices possible with bulk micromachining. In Figure 110 just three of the many possible examples are shown. In Figure 110a, full advantage is taken from the development of {111} planes during ODE of silicon to construct thin single-crystal silicon blades. In the first step, silicon nitride is formed on both sides of a silicon wafer and patterned. Next, the silicon is anisotropically etched. The etch process continues until etched trenches from both sides meet in the middle the wafer and the initially stable {111} planes are broken. Finally, the etching will halt at some other {111} planes, which are stable due to the silicon nitride mask restriction. In Figure 110b, dry and wet etching is combined to achieve needles with various shapes. Such needles can subsequently be plated to form a nickel mold to make many single-use plastic replicas useful in medical instrumentation (drug delivery and invasive penetration). A third example (found in Fig. 110c) is the construction of special fluidic channels with atomically smooth walls. It is primarily a question of smart thinking, and not of the limitation of bulk micromachining, which limits the range of devices possible.

Figure 111a shows how {111} plates can be etched to form a kind of silicon "fan" or a single-crystal valve. Combining both wet and dry bulk micromachining increases the range of structures possible even further. For example, in

Figure 109. Some typical structures created by means of dry plasma bulk micromachining: (a) Single-crystal silicon freestanding structures. (b) Open and closed buried channels. (c) Micropipette.

Figure 111b, a beautiful example of a needle structure created using wet bulk micromachining and stopping on {111} planes is shown. The last example, found in Figure 111c, is the construction of microchannels with extremely smooth walls and micropipettes for fluid injection.

## 6.2. Surface Micromachining

Surface micromachining is a technique to make freestanding structures on the surface of a wafer by the successive deposition, photopatterning, and etching of a sacrificial layer and a structural layer [277–450]. Figure 112 shows the basic process flow. First, a film—the sacrificial layer—is formed on top of a wafer and patterned to make anchors where the freestanding structures will be fixed to the substrate. The

Figure 108. Typical schemes for dry plasma bulk micromachining: (a) Single-crystal structures. (b) Buried channels.

Figure 110. Special schemes for bulk micromachining: (a) Single-crystal blades. (b) Single-crystal needles. (c) Buried channels.
**Figure 111.** Some special structures created by means of bulk micromachining: (a) {111} plates after special ODE. (b) Microneedles after combining ODE and plasma etching. (c) Micropipette as in (b).

sacrificial film serves as a spacer layer between the structural layer and the substrate. Next, another layer—the structural layer—is formed and patterned with, for example, irrigation holes, thus providing access to the sacrificial layer. Finally, the sacrificial layer is etched away, leaving the structural

**Figure 112.** Typical scheme for surface micromachining.

levels free to move and operate. Eventually, small access holes to speed up sacrificial layer etching and large holes to allow for, for example, fluid exchange in fluidic applications are etched and the small holes can be reclosed using a conformal deposited layer. Typically in surface micromachining, polycrystalline silicon (polysilicon) is used as the structural material, and silicon dioxide is used as the sacrificial material. At the end of the process, wafers are immerged in wet hydrofluoric acid, which removes the silicon dioxide layers, leaving the polysilicon and single-crystal silicon substrate untouched. Figure 113 (top) gives some typical examples of this technique.

A key process sequence in surface micromachining is "sacrificial layer etching," the process o etch selectively the sacrificial layer underlying the structural layer. A notorious problem in this process is the release of stress in the structural layer when the underlying sacrificial layer is removed, which causes deformation in the released microstructure. To avoid this, it is necessary to measure the strain and a controlled deposition process is required. Another problem in this process is bubble and rinse-damage of the surface micromachined structures (due to drag forces during wafer handling in liquids) and the phenomenon of sticking or stiction (i.e., the permanent attachment of slender structures to the underlying substrate after drying). To avoid this damage, it is possible to use other structural/sacrificial material combinations, such as a structural metal layer in which a sacrificial resist layer is removed in dry oxygen plasma. Figure 113 (bottom) shows some golden mirrors, surface micromachined with this combination. Such a device could

**Figure 113.** Some typical structures created by means of surface micromachining. Top: Polysilicon structures with silicon dioxide as sacrificial layer. Bottom: Gold structures with photoresist as a sacrificial layer.

be useful to measure rf power along a transmission line by way of monitoring the deflection of the mirror.

## 6.3. Mold Micromachining

Although a variety of three-dimensional structures have been fabricated in silicon and silicon nitride such as nozzles, diaphragms, bridges, and beams, inexpensive fabrication processes for microstructuring of different materials are desirable as well. For certain applications the availability of such materials is a necessity, as in the case of optical devices or single-use plastic devices useful in surgery. This is accomplished with mold micromachining, which forms mechanical features by first creating a mold [451–464]. This mold, which is in the shape of the desired structure, is filled with a structural material and then the mold can be etched away or removed to leave the desired device as shown in Figure 114a. Alternatively, the mold can be filled with an electroplated material such as nickel and then the mold is partially etched away as shown in Figure 114b to form a freestanding metal structure.

Recently, many mold technologies have been developed that are compatible with the traditional semiconductor infrastructure. For example, in dry etching, electroplating, and molding, structures with variable tapering and high aspect ratios can be fabricated in silicon. The silicon is etched with, for example, a plasma system and can be used either directly for molding (described in the section on lithography) or indirectly by first electroplating a metal mold and subsequent molding with this metal structure. The advantage of direct molding with silicon is that the fabrication process of a polymer structure is reduced to silicon etching and molding, facilitating fast prototyping of plastic microstructures. However, the difference of the thermal expansion coefficient of polymer and silicon is larger with respect to, for example, nickel. Therefore, higher shear forces are created when releasing the structure. In order to shape the silicon mold, $SF_6/O_2$ plasma allows elegant control of the tapering as shown in Figure 115. High aspect ratio vertical or slightly positive tapered profiles are feasible, as has been mentioned before in Section 5.3.1 and the roughness of the silicon is well below 100 nm, which facilitates separating the mold from the mold insert (i.e., demolding).

Figure 115. Optimization of the $SF_6/O_2$ plasma chemistry and mask profile to facilitate demolding. For explanation see text.

When silicon structures are etched in a $SF_6/O_2$ plasma system with a highly selective mask, purely straight sidewalls or a positive tapering usually correlate with roughness (so-called "grass") in the valleys of the trenches. In Figure 115a this grass is clearly visible. This grass can be prevented by settling the plasma process into a chemistry where a slightly negative tapering occurs. However, this negative tapering, like the grass, is undesirable for most molding purposes because it is difficult to demold such a structure without destroying (parts of) the feature. Therefore, in molding applications, a slightly positive tapering without grass is highly preferable. In order to achieve this, it is possible to use a slowly withdrawing mask to create a positive sidewall angle, although the plasma etch process itself is settled to create a otherwise slightly negative tapering to prevent roughness. In Figure 115, features are etched with photoresist as a mask. In Figure 115a, the profile is shown after 10 (top) and 20 minutes (bottom) of silicon etching with photoresist baked at 90 °C and the plasma system settled with a gas mixture where a slightly positive taper occurs. The resist has an almost straight slope, which does not facilitate a withdrawing of the mask during plasma etching and roughness is observed. On the other hand, Figure 115b shows the profile using the same plasma setting but now the resist is baked at 130 °C in order to spread (reflow) the resist a little, forming a spherical-like resist pattern. Due to the low selectivity of the resist with respect to the silicon plasma etching and the positive slope of the

Figure 114. Typical schemes for mold micromachining. (a) Replicating. (b) Electroplating.

resist, the mask will repeal during etching and a much more positive tapered profile is transferred into the silicon while preserving the same amount of grass. It is observed that the withdrawing resist has its up influence halfway the structure height, creating a much more positive taper. Now when this process is optimized, it is possible to create features with smooth and positive tapered profiles, as found in the Figure 115c. This is achieved by giving the resist a bake at 130 °C and a pre-etch in an oxygen plasma to remove any remaining vertical slope in the resist and settling the plasma at a recipe, which normally would result in negative tapering but—due to the withdrawing of the positive-sloped mask—the profile becomes slightly positive tapered too. In Figure 116 a glass structure is shown before (a) and after (b) demolding. An important consideration is the prevention of gas inclusions as observed in Figure 116b.

In recent years there has been considerable interest in high aspect ratio processing. The most famous technology to accomplish this is the LIGA technology. LIGA is an acronym for the German words lithography (lithographie), electroforming (galvanic), and molding (abformung). In the LIGA process, masks are created containing the shape of the desired structure. Then, a synchrotron radiation source of 2 Å wavelength is used to expose a thick PMMA resist layer. The irradiated area of the resist is then dissolved with a developer. Subsequent electroplating copper or nickel into the resist pattern and dissolving the remaining resist leaves the mold insert for molding as shown in Fig. 116c. While the LIGA technology enables the fabrication of high-aspect-ratio micromachines and creates extremely precisely dimensioned devices, the technology is limited in that it requires a high-energy synchrotron radiation source. Such a source is not part of the standard semiconductor infrastructure, making this technology not widely available and therefore economically less attractive.
## 6.4. Bond Micromachining

Bond micromachining is a two-wafer process in which a structure is formed at the interface of two bonded wafers [465–630]. Figure 117 shows the basic scheme and it is very straightforward; trenches are etched in one of the wafers and bonded with another wafer to seal the trench. Two variations are possible. In the first method (top), the substrate itself is etched. In the second approach (bottom), first a film is formed on top of the substrate with a well-defined thickness and, then, it is etched with a chemical that stops when the underlying substrate is reached. Alternatively, the cavities can be made accessible by way of through-wafer holes in one or both of the wafers.

In Figure 118a an example of the first method is found. First, a silicon wafer is etched to a depth of 50 nm. Then, a 1% HF dip and an additional Piranha step are performed to clean the silicon surface and to grow a well controlled layer of native oxide on the silicon surface. Finally, the wafer is fusion bonded (2 hours at 1100 °C) to a second silicon wafer. The high temperature needed in silicon-to-silicon fusion bonding can be prevented by using different bonding schemes as described in the section on film formation such as anodic or adhesive bonding. For example, the same etched silicon wafer is also bondable (4 hour annealing at 400 °C) with a borofloat glass wafer as shown in Figure 118b. This annealing temperature of the silicon-to-glass bond is sufficiently low to prevent plastic deformation of the glass (and thereby possibly closing of the nanochannels) and interference of the bonding process with previous micromachining steps. Finally, in Figure 118c an example is found of the second approach. A silicon wafer with a patterned 10 nm thin oxide film is bonded with a second silicon wafer. Other bonding candidates are two patterned borofloat wafers, two oxidized silicon wafers, or wafers coated with for example, a BCB polymer.

The range of structures possible with bond micromachining can be increased enormously when one of the two wafers—a "capping wafer"—is dissolved in the process sequence. Figure 119 (top) shows such an "extended"

**Figure 116.** Some typical structures created by means of mold micromachining. (a) Silicon mold with deposited glass. (b) Glass structure after demolding. Nickle LIGA structure after demolding.

**Figure 117.** Typical scheme for bond micromachining. Top: Substrate etching. Bottom: Film etching.
Figure 118. Some typical structures created at the interface of two wafers by means of bond micromachining: (a) 50 nm nanochannel Si–Si bond, (b) Si–glass bond, (c) 10 nm nanochannel $(Si + SiO_2)$-to-Si bond.

scheme. In the first step, trenches are etched in the capping wafer and covered with a conformal capping film. Then, the wafer is bonded with a structure wafer, which forms channels in between both wafers. Finally, the capping wafer is dissolved to make the capped structures accessible for measuring or further processing. Alternatively, the trenches can be etched in the structure wafer as shown in Figure 119 (bottom), in order to leave a flat wafer surface after wafer dissolving. This enables easier further lithographic processing. Figure 120 gives some typical examples of this "dissolved-wafer" bond micromachining technique.

In addition, the structure wafer and capping layer can be patterned on one or both sides with additional patterned (metal) layers for sensing (e.g., flow) or actuation (e.g., switch) purposes. In this way, it is possible to integrate

Figure 119. Extended schemes for bond micromachining.

Figure 120. Some typical structures created by means of bond micromachining. (a) Enclosed microchannels after silicon-to-silicon wafer bonding. (b) Idem after wafer dissolving. (c) Silicon nitride channels. Figure courtesy of Stefan Schlautmann.

electrodes on top of a channel wall for sensing purposes. Figure 121 shows an artist impression of such "smart" channels. Many variations on this scheme are imaginable such as the use of an additional wafer, which "encapsulates" the encapsulated structures, and so on. Therefore, bond micromachining is an excellent technique to construct nano- or microchannels for many fluidic or rf-MEMS applications. Moreover, the technique exhibits an *in-situ* sealing of structures. A disadvantage is that in bond micromachining surfaces should be reasonably smooth to ensure a successful bond.

## 6.5. Conclusion and Nanoperspective

The four most important micromachining techniques as discussed in this section are summarized; bulk, surface, mold, and bond micromachining. In order to sculpture nanostructures (i.e., nanomachining), several aspects are different from micromanufacturing, especially in relation to etching techniques. In Table 14 the four basic micromachining techniques to construct 1D nanostructures are summarized. While using clever design rules in micromachining, it is possible to realize truly nanostructures (at least

Figure 121. Smart scheme for bond micromachining.

two dimensions below the 100 nm) without using expensive sub-100 nm lithography. In order to fabricate such 2D nanostructures (or nanonanostructures) in Table 15 a few "nanonanoschemes" are outlined based on the edge lithography. Finally, the fabrication of nanostructures is one thing, but how does one connect these structures with the macroworld (i.e., packaging) and how does one control them?

**Nanomachining** In *bulk micromachining*, many times the substrate is etched some tens of micrometers in depth—and in some cases even through the wafer—to make high-aspect-ratio structural parts (generally with the help of plasma systems) or thin membranes (using wet etches). Therefore, there is a strong demand for high-speed directional etch processes. Moreover, in order to construct *in-situ* freestanding microstructures, high-speed isotropic etch processes are requested as well. On the other hand, in case of bulk nanomachining, the etch depth is fairly identical to semiconductor manufacturing and, thus, typically less than 1 micrometer. Therefore moderate—but accurate—etch rates are requested to ensure a precise etch depth and a smooth surface finish. In *surface nanomachining*, isotropic sacrificial layer etching techniques from

**Table 15.** Schematic overview of micromachining techniques to create 2D nanostructures (in short: nanonanostructures).

| | Step 1 | Step 2 | Step 3 | Remarks |
|---|---|---|---|---|
| Channel | | | | *substrate etching* |

| | | | | *lateral growing* |

the micromachining are requested to sculpt nanodevices such as nanobeams or enclosed nanochannels. Isotropic sacrificial etching is even more demanding in nanotechnology with respect to microtechnology, because the delicate sculptured nanostructures are more easy to damage due to drag forces during wafer handling in wet chemicals and the probability of sticking of slender nanostructures during drying after wet etching. To avoid damage of sculptured nanostructures or sticking of the nanostructures, dry release techniques are favorable. In *mold micromachining*, lithography seems to be the most prominent step and advances will probably take place in soft lithography and related technologies. *Bond micromachining* seems to be well suited for nanomachining, at least where it concerns the manufacturing of 1D nanochannels as was found in Figure 118.

***Nanonanomachining*** In order to construct nanodevices with at least two dimensions in the nanometer range, it is still possible to use micromachining techniques (i.e., without the use of expensive nanolithographic techniques). In Table 15 a few basic schemes are found to fabricate nanonanochannels or nanonanobeams.

***Nanopackaging*** System packaging is much more difficult and complex than electronics packaging and will frequently be the prime determinant in success or failure. This is because system packaging is customer specific and not only embraces electronic connections but also fluidic and mechanical coupling. For nanotechnology, it is essential to have a direct control of matter—either between two nano-objects or between a micro (or macro) object and a nano-object. In the bottom-up molecular engineering strategies, this is certainly a nontrivial issue. However, top-down microtechnology seems to be ideally suited to perform this task and seems to be a logical technique to bridge the

gap between the nano and macro world. For example, the scanning probes are in fact micromachined microcantilevers mechanically coupled with integrated nanotips. The fluidic coupling of nanochannels with the outer world is not very well known, but in fact not at all troublesome. Currently, already a few options exist to connect microchannels with the macrochannels (e.g., http://www.upchurch.com/). The only problem left to solve is how to couple the nanochannels with microchannels or reservoirs. An option is to first machine nanochannels in a wafer. This is followed by machining microchannels in the same wafer. The through-wafer holes are constructed (powder blasted) in a second wafer. Finally, the wafers are bonded to seal the channels. Figure 122 shows an artist's impression and pictures of such a system.

**Figure 122.** Artist's impression and pictures of a fluidic packaging system to connect nanochannels with macrocapillaries.

## ABBREVATIONS

**AFM**   Atomic-force microscopy.

**AL**   Atom lithography.

**APCVD**   Atmospheric-pressure CVD.

**CAIBE**   Chemical-assisted IBE.

**CARIBE**   Chemical-assisted RIBE.

**CCP**   Capacitively coupled plasma.

**CLD**   Chemical liquid deposition.

**CLG**   Chemical liquid growth.

**CMP**   Chemical–mechanical polishing.

**CSG**   Chemical solid growth.

**CVD**   Chemical vapor deposition.

**CVG**   Chemical vapor growth.

**CZ**   Czochralski.

**DC**   Direct current.

**DOF**   Depth of focus.

**DOP**   Degree of planarization.

**DPL**   Direct print lithography.

**DUVP**   Deep-UV printing.

**EBP**   Electron-beam printing.

**EBW**   Electron-beam writing.

**ECE**   Electrochemical etching.

**ECR**   Electron cyclotron resonance.

**EL**   Edge lithography.

**EPI**   Epitaxial.

**EUVP**   Extreme-UV printing.

**FIBE**   Focussed IBE.

**FZ**   Float zone.

**HC**   Hallow cathode.

**IBARE**   Ion-beam assisted radical etching.

**IBE**   Ion-beam etching.

**IBP**   Ion-beam printing.

**IBW**   Ion-beam writing.

**ICE**   Isotropic chemical etching.

**ICP**   Inductively coupled plasma.

**ICT**   Integrated circuit technology.

**LIL**   Laser-interference lithography.

**LPCVD**   Low-pressure CVD.

**LPE**   Liquid-phase epitaxy.

**MBE**   Molecular-beam epitaxy.

**MCRIE**   Magnetically controlled RIE.

**MEMS**   Microelectromechanical systems.

**MESA**   Microelectronics sensors and actuators.

**MIE**   Magnetron ion etching.

**MM**   Micromachining.

**MOCVD**   Metal-organic CVD.

**MST**   Microsystem technology.

**NEMS**   Nanoelectromechanical systems.

**NST**   Nanosystem technology.

**ODE**   Orientation-dependent etching.

**PE**   Plasma etching.

**PECVD**   Plasma-enhanced CVD.

**PLD**   Physical liquid deposition.

**PVD**   Physical vapor deposition.

**PVG**   Physical vapor growth.

**PSD**   Physical solid deposition.

**RF**   Radio frequency.

**RIBE**   Reactive IBE.

**RIE**   Reactive ion etching.

**SAM**   Self-assembled monolayer.

**SCALPEL**   Scattering with angular limitation projection electron-beam lithography.

**SCS**   Single crystal silicon.

**SE**   Sputter etching.

**SNOM**   Scanning near-field optical microscopy.

**SNOW**   Scanning near-field optical writing.

**SOI**   Silicon on insulator.

**SOG**   Spin-on-glass.

**SPE**   Solid-phase epitaxy.

**SPL**   Scanning-probe lithography.

**STM**   Scanning tunnel microscopy.

**TARE**   Thermal-assisted radical etching.

**UV**   Ultraviolet.

**VPE**   Vapor-phase epitaxy.

**XRP**   X-ray printing.

## GLOSSARY

**Adhesive bonding**   A bonding method, which uses organic (polymer) or inorganic (ceramic) intermediate layers. The adhesive material deforms and flows so it can make sufficient close contact with the wafer surface to promote adhesion.

**Amorphous film**   A material showing short-range (atomic) order and only the average distance between neighboring atoms or molecules can be used to the determine film density.

**Anodic bonding**   A bonding method based on joining a conducting material and a material with ion conductivity, such as Pyrex, by applying a high voltage at sufficient high temperature to mobilize the ions.

**Anodization**   A film deposition method for obtaining amorphous, highly-insulating, pinhole-free and low-stress films. It is an oxidation process performed in an electrolytic cell and using a voltage source. When electric current is passed, the substrate surface at the positive electrode is converted to an oxide.

**Atmospheric pressure chemical vapour deposition**   A chemical vapour deposition technique performed at atmospheric pressure to increase deposition rate.

**Atomic-force microscopy**   A way to image surface forces to the nanometer level by moving a sharp tip within a distance of the order of 1 nm from the surface.

**Atom lithography**   An alternative technique of print lithography with nanometer-scale resolution in which a beam of atoms is projected onto a surface through a laser interference pattern.

**Bond micromachining** A micromachining technique in which features are formed at the interface of two patterned wafers meanwhile enabling *in-situ* sealing of a device.

**Bottom-up nanotechnology** The area of nano system technology, which applies to building organic or inorganic structures atom-by-atom, or molecule-by-molecule, and having its origin in the (bio)chemical industry.

**Bulk micromachining** A micromachining technique in which features are formed out of the bulk of substrate material.

**Capacitively-coupled plasma** A form of plasma making use of a capacitively coupling in which electric fields are generated by two isolated platens at both sides of a discharge chamber. These systems commonly operate at a frequency of 13.56 MHz and powers up to several hundreds of watts.

**Casting** A film deposition method where a rim structure is fashioned around the substrate, providing a "flat beaker" for the drying solution.

**Chemical deposition** A form of film deposition that involves three essential steps, which are identical to chemical film etching except the direction of transport is reversed: the reactants are transported to the surface and adsorb, then surface reactions occur, finally the products are desorbed and transported away from the surface while leaving the desired film.

**Chemical etching** A film etching process involving three essential steps, the reactants are transported to the reacting surface and adsorb, then reactions occur at the surface, and finally the products from the surface are desorbed and transported away from the surface. It usually results in an isotropic or orientation-dependent profile.

**Chemical growth** A form of film growth in which reactants adsorb first at a substrate surface and then they diffuse into the substrate and react.

**Chemical vapour deposition** A film deposition method where the constituents of a vapour phase, often diluted with an inert carrier gas, are introduced into a reaction chamber and adsorbed on a heated surface. The adatoms undergo migration and film-forming reactions to form the desired film.

**Cleanroom** A facility to perform micro- and nano-technology where the total number of dust particles per unit volume is minimized and tightly controlled along with temperature and humidity in order to maximize device yield.

**Cluster beam deposition** A film deposition method where ionized atom clusters are deposited in a high vacuum.

**Compression bonding** A bonding method where the two surfaces are brought in close contact by applying high pressure (continuous hydraulic or instantaneous explosive). It is sometimes called solid-state welding.

**Czochralski technique** A wafer fabrication technique to enable single crystal growth by pulling a single crystal seed from a melt and forming a single crystal ingot. Afterward, the seed is removed to be reused. See also float zone.

**Deep ultraviolet printing** A kind of print lithography, basically identical with optical lithography, in which an image is transferred in a resist through a mask using deep-ultraviolet radiation ($\lambda = 200–300$ nm).

**Defect density** A measure in lithography, which translates directly transfer mistakes into loss.

**Depth of focus** The maximum feature height in lithography that can be transferred with high fidelity to a film or substrate.

**Dip coating** A film deposition method where a substrate is dipped into a solution containing a polymer and a solvent. After evaporation of the solvent on a hotplate, a thin layer is formed.

**Direct bonding** A bonding method, which relies on the tendency for very smooth and flat surfaces to adhere to each other, it is also known as fusion bonding.

**Direct lithography** A form of lithography in which a pattern is transferred without the use of an intermediate resist layer in order to enhance resolution.

**Dry etching** A form of etching without using any liquids. It is usually synonymous for plasma-phase etching, but includes the less common gas-phase and solid-phase etching too. Due to the physical nature of dry etching it enables smaller linewidth and more vertical profiles than possible in wet etching, but usually lacks high selectivity.

**Edge lithography** An alternative form of print lithography in which the edges of the original pattern become the features of the final pattern.

**Electrochemical etching** A film etching process in which an electrically (semi)conducting material is etched by application of an external voltage. The etch rate and selectivity can be controlled by the potential or the current density applied. Electroless electrochemical etching is possible by way of generating a potential from e.g., gold contacting both the material and the etchant.

**Electroless plating** A film deposition method related to electroplating and also using an electrolytic solution but without the need for external electrodes.

**Electron beam printing** A kind of print lithography in which a wide parallel beam of electrons is forced through a thin film (silicon nitride) mask containing a (tungsten) pattern, which selectively scatters the electrons for the pattern transfer.

**Electron beam writing** A kind of write lithography in which an electron gun is used for the patterning.

**Electroplating** A film deposition method where the substrate is immersed into a liquid plating solution that contains metal ions. A voltage is applied between the substrate and a counter electrode forcing the metal ions toward the wafer forming a metal deposit.

**Epitaxial deposition** A technology involving the deposition of a single crystal layer upon a single crystal substrate so, that the lattice of the newly formed film duplicates that of the substrate.

**Etch directionality** A measure of the relative etch rate in different directions, usually normal versus lateral.

**Etch profile** The profile or shape of an etched film as a direct consequence of the etch directionality.

**Etch selectivity** The ratio of the etch rate of different materials in an etch process.

**Eutectic bonding**   A bonding method like the solder bonding where the eutectic property of metal alloy is used to lower the melting temperature.

**Evaporation**   A film deposition method based on the boiling off or sublimation of a heated material onto a substrate in a high vacuum.

**Exposure field**   The maximum exposure area in lithography. The requirements result from ever-increasing chip sizes and the need to expose at least one full chip with each exposure.

**Extreme ultraviolet printing**   A kind of print lithography in which an image is transferred in a resist with atomically smooth reflecting optics and through a mask with multilayer coatings using extreme-ultraviolet or soft X-ray radiation ($\lambda = 4$–$200$ nm).

**Film adhesion**   An important film property to be considered in film formation. Due to insufficient adhesion, freshly applied films can locally detach or even delaminate from the surface.

**Film deposition**   A form of film formation in which a new layer is deposited on top of a substrate surface.

**Film etching**   The process of transferring a pattern from one layer into another one. It is one of the basic steps in a micromachining process flow.

**Film formation**   The collection of techniques to form a layer on top of or into a substrate. It is one of the basic steps in a micromachining process flow.

**Film growing**   A form of film formation in which substrate surface material is consumed while forming a layer with different properties.

**Film step coverage**   Film property, which relates the surface topography of a deposited or grown film to the previous wafer irregularities.

**Film stress**   Film property showing the emergence of film tension during film formation, which can greatly affect physical integrity and long-term stability and might result in failures such as cracking, blistering, and loss of adhesion (delamination or peeling), shape problems such as bending, shrinking, curling, or buckling of structures, as well as reliability problems such as void and hillock formation and long-term shifts in material properties due to creep.

**Film uniformity**   Global film property, which relates the changes of other film properties across the wafer surface.

**Float glass**   The production of atomically smooth glass by flowing glass into a float furnace onto molten tin (tin bath).

**Float zone technique**   Wafer fabrication technique to purify a single crystal ingot using a moving molten zone. See also Czochralski.

**Focused ion beam etching**   A form of ion beam etching in which the ion beam is focused to a single spot.

**Gas-phase etching**   A form of dry etching using solely gaseous reactants.

**Gas-phase formation**   The formation of a film out of the vapour or gas phase.

**Holographic printing**   A kind of print lithography in which a laser reference is used to interfere with a holographically constructed mask to form a hologram to transfer a pattern.

**Hybrid lithography**   A form of lithography combining two or more of the other lithographic techniques to improve resolution and keeping throughput high.

**Immersion plating**   A film deposition method where a metal displacement reaction occurs between relatively noble metal ions in a solution and less noble metal ions at a wafer surface forming a surface layer of noble metal.

**Imprinting**   A kind of mechanical printing in which a reusable mould is pressed hard into a thin thermoplastic polymer film so that polymeric material is pushed away from the imprinted regions.

**Inductively-coupled plasma**   A form of plasma making use of an inductively coupling where magnetic fields are generated by a coil wrapped around the discharge chamber. These systems commonly operate with powers of several hundreds to thousands of watts. The inductive coupling has the advantage above capacitive coupling that there will be no large or high-voltage sheaths present in the chamber, and as a result, no sputtering of the wall.

**Ingot grinding**   The machining of the single crystal silicon ingot to define the wafer diameter and one or more flat regions along the length of the ingot to mark the specific orientation.

**Integrated circuit technology**   The ability to fabricate tens of millions of individual semiconductor components on a silicon chip with an area of a few square cm using lithographic techniques.

**Intrinsic stress**   A form of film stress caused by several mechanisms such as incorporation of atoms (e.g., residual gases, precipitation inclusion, or energetic ion bombardment), chemical reaction as in thermal oxidation, recrystallization, dislocation rearrangements, lattice mismatch between film and substrate, excess vacancy annihilation, grain boundary relaxation, or phase transformations.

**Ion beam assisted radical etching**   A form of plasma etching, which makes use of the synergetical action of both radicals and ionic species.

**Ion beam etching**   A form of plasma etching in which a broad collimated ion beam is produced in a remote plasma reactor. The possibility of separately controlling ion energy and flux at very low pressure provides a flexibility of directional bombardment not available in other plasma processes, but limits selectivity severely.

**Ion beam printing**   Print lithography in which a wide parallel beam of ions is directed through a set of stencil masks for the patterning.

**Ion beam writing**   Write lithography in which a focused ion beam is used for the patterning.

**Ion implantation**   Film growth method where a dopant is implanted into a material by means of a high-energy ion beam.

**Ion plating**   Film deposition method where the evaporation of a material is combined with ionization of the atom flux by an electron filament or plasma.

**Isotropic profile**   A typical result of chemical etching where the etch rate is the same in all directions, i.e., the under etch equals the etch depth.

**Laser ablation**  A film deposition method, which uses intense laser radiation to erode a target and subsequently deposits the eroded material onto a substrate.

**Laser-interference lithography**  An alternative technique of print lithography in which the interference pattern of two intersecting laser beams is used to expose a resist layer.

**Lift-off lithography**  A form of resist lithography, which uses the shadowing by surface topography of a resist pattern. The film to be patterned is deposited after a resist pattern is applied—and not before as is the case in conventional resist lithography—and subsequently selectively removed by dissolving the resist with the film on top of it leaving the inverse pattern on top of the substrate.

**Liquid-phase etching**  A form of wet etching in which wafers are immersed in an etchant and etching proceeds by dissolution of a material in a solvent or by conversion of a material into a soluble compound, which subsequently dissolves in the etching medium.

**Liquid-phase formation**  The formation of a film out of the liquid phase.

**Lithography**  A technique used in the micro- and nanotechnology to shape (pattern) a thin film or substrate. It is one of the basic steps in a micromachining process flow.

**Low pressure chemical vapour deposition**  A chemical vapour deposition technique at low pressure to increase film uniformity.

**Mechanical beam writing**  Write lithography in which a sharp atomic-force microscopy probe is used for the patterning.

**Mechanical printing**  Print lithography in which a stamp or mould is used for patterning.

**Melting**  Film deposition method just like casting but now the liquid is formed by melted granules of material in a nitrogen-purged furnace.

**Micro system technology**  A portfolio of techniques and processes usually having its foundation in the integrated circuit technology to design and create miniature systems. It is suitable for the creation of a range of transducers including pressure and flow sensors, accelerometers, gyros, optical, and radio frequency switches, and (bio)chemical devices. These systems merge the functions of sensing and actuation with computation and communication to locally control physical parameters at the microscale, yet cause effects at much grander scales.

**Molecular beam epitaxy**  Film deposition method involving the reaction under ultrahigh vacuum conditions.

**Molding**  Mechanical printing used for high-aspect-ratio structures in which a polymeric film is poured into a mold where it hardens.

**Mould micromachining**  A micromachining technique in which a (metal) structure serves as a mold insert to form many (plastic) replicas.

**Nanosystem technology**  The area of science and technology where dimensions in the range of 100 nm play a critical role. It encompasses precision engineering as well as lithographic technology, but also (bio)chemical synthesis and biomedical multiplication techniques in areas as diverse as semiconductor electronics, scanning probe microscopy analysis, microsystems, telecommunication, information technology, protein duplication, gene therapy, and drug delivery.

**Optical printing**  Print lithography in which an image is transferred in a photosensitive resist through a mask using visible ($\lambda = 380$–$780$ nm) or near-ultraviolet radiation ($\lambda = 300$–$380$ nm).

**Orientation-dependent profile**  A specific result of chemical etching found when etching single crystal material where the etch rate depends on the crystallographic direction.

**Phase-shift lithography**  An alternative technique of print lithography which controls both amplitude and phase of the light to enable destructive interference to cancel some of the image spreading effects of diffraction generally found in optical printing.

**Photon beam writing**  Write lithography in which a laser or optical beam is used for the patterning.

**Physical deposition**  A form of film deposition in which reactants are transported to a surface and adsorb.

**Physical etching**  Film etching process in which reactants, usually ionic species, approach a substrate with high velocity where they erode the surface due to impulse transfer. It usually results in a tapered profile.

**Physical growth**  A form of film growth possible due to sub-surface implantation of high-velocity particles—most often ionic species.

**Plasma bonding**  A bonding method where the surfaces to be bonded are first treated with plasma.

**Plasma enhanced chemical vapour deposition**  A chemical vapour deposition technique using an additional plasma source to lower the deposition temperature.

**Plasma-phase etching**  A form of dry etching which involves the use of very reactive species or etchants from a discharge. It usually takes place by a combination of chemical (radicals) and physical (ionic) processes and forms gaseous or volatile products. Vertical profiles are possible due to the presence of ionic species in the plasma and the electric fields that direct them normal (i.e. vertical) to the wafer surface.

**Poly crystal film**  A material having a collection of single crystals with different orientations and showing structural variation (morphology) on a micron scale (microstructured films) or decrease to nanoscale dimensions (nanostructured films).

**Print lithography**  A parallel lithographic technique in which an intermediate radiation-sensitive resist is selectively exposed by shining radiation through a mask, which contains the pattern information for the particular layer being fabricated.

**Projection printing**  Optical printing in which an image-forming system (e.g., a 4:1 demagnification lens) is interposed between the mask and wafer with large separation of many centimeters to avoid mask damage associated with shadow printing.

**Pyrex**  A material often used for bonding purposes in the microsystem technology due to its identical coefficient of thermal expansion with respect to silicon.

**Registration**   A measure in lithography of how accurately patterns on successive masks can be aligned with respect to previously defined patterns on a substrate.

**Resist lithography**   A form of lithography in which a chemically amplified resist is used composed of a photoacid proton generator and a polymer with groups reactive to protons. The photoacid generator is a chemical compound supplying a proton upon irradiation. This proton catalyses reactions at the polymer, resulting in solubility differences between the exposed and unexposed regions.

**Resolution**   The minimum lateral feature dimension in lithography that can be transferred with high fidelity to a film or substrate.

**Scanning near-field optical microscopy**   A way to image a surface to the nanometer level by moving a sharp optical fiber tip within a distance of the order of a few nm from the surface.

**Scanning tunnel microscopy**   A way to image surface conduction to the atomic level by moving a sharp tip within a distance of the order of 1 nm from the surface.

**Screen printing**   A kind of print lithography in which ink is applied to the back of an image carrier or stencil and pushed through porous or open areas.

**Self-assembled monolayer**   A film deposition method of a close-packed monolayer of molecules—just like soap molecules—with a (polar) head attached to the underlying substrate and a (non-polar) tail pointing upwards.

**Shadow printing**   A kind of optical printing in which the gap between the mask and the resist is zero (contact printing) or near zero (proximity printing).

**Silicon**   The most dominant element in integrated circuit technology.

**Silicon-on-insulator wafer**   Wafers having an oxide film under the electronically active single crystal top later.

**Single crystal film**   A material having a perfect arrangement of atoms, a lattice virtually without defects or impurities and this order extends to macroscopic dimensions.

**Single crystal ingot**   A single crystal rod having electronic grade purity.

**Single crystal seed**   A piece of single crystal material used to initialise crystal growth in the Czochralski technique.

**Solder bonding**   An adhesive bonding method using a temporally molten metal as the adhesive.

**Solid-phase etching**   A pure physical etch process, which involves the bombardment of particles (typically a few tens of micrometer in diameter), that remove material due to physical momentum transfer.

**Solid-phase formation**   The formation of a film out of the solid phase.

**Spin coating**   A film deposition method where a substrate is held on a vacuum spindle and a droplet of liquid (resist) is applied to the center of the wafer. The wafer is then rapidly accelerated up to a constant rotational speed to give a uniform film.

**Spraying**   A film deposition method on a substrate involving pressurization by compressed air or pushing liquid mechanically through tiny orifices forming a spray.

**Sputter deposition**   A film deposition method in which positive ions from a plasma source, usually Ar+, are accelerated to bombard a target and subsequently deposits the bombarded material onto a substrate.

**Sputter etching**   A form of plasma etching making use of the ionic species in the plasma only. Like ion beam etching it is a purely physical process but the pressure during etching is much higher.

**Sputter yield**   The number of atoms removed per incoming ion in physical etching.

**Stamping**   A kind of mechanical printing in which a flexible (rubber) stamp is used to apply selectively small quantities of a specially selected reagent solution as ink onto a surface.

**Stepper lithography**   A lithographic technique combining both writing and reduction projection printing to enhance throughput.

**Stereo lithography**   An alternative technique of write lithography where a resist is hardened into a 3 dimensional shape by way of two intersecting scanning laser beams.

**Surface micromachining**   A micromachining technique in which features are built up layer-by-layer on top of a surface or substrate.

**Synergetical etching**   A film etching process involving both physical as well as chemical etching. It preferably results in a vertical-anisotropic profile.

**Tapered profile**   A common result of physical etching resulting in facets caused by mask erosion and the angle dependency of the etch rate or sputter yield.

**Thermal bonding**   A bonding method, just like direct bonding but using a high-temperature annealing step to improve adhesion.

**Thermal diffusion**   A film growth method where a dopant is driven into a material at high temperature.

**Thermal oxidation**   A film growth method where a material is oxidized at high temperature.

**Thermal stress**   A form of film stress caused by differences in thermal expansion between two layers, which are tightly connected.

**Throughput**   The number of wafers that can be exposed per hour for a given mask level.

**Top-down nanotechnology**   The area of nanosystem technology, which refers to making miniature (or "nanoture") structures by lithographic printing and non-lithographic machining techniques.

**Tri-level lithography**   A form of lithography to minimize step coverage problems on patterned surfaces.

**Vertical-anisotropic profile**   A typical result of synergetical etching having perfectly straight sidewalls exactly under the edge of the masking layer and the etching under the mask approaches zero. A vertical profile is often desired in an etch process because it maintains lithographically defined feature sizes as they are transferred by etching into underlying films.

**Wafer bonding**   A deposition method where two solid materials fuse and adhere to each other if they are brought in sufficient close contact. The cohesion of atoms and molecules between the two (different) materials is ensured by a number of basic bond types and based on Coulombic forces, which are covalent, metallic, ionic, or Van der Waals.

**Wafer edge profiling** The rounding of sharp, fragile edges of wafers in order to provide strength to the wafer after wafer slicing.

**Wafer etching** A process following wafer lapping to remove remaining microcracks or surface damage introduced by the alumna abrasive in the previous lap-stage.

**Wafer fabrication** The first basic step in a micromachining process flow. It generally means the preparation of an atomically smooth and particle free surface.

**Wafer lapping** A wafer fabrication process following wafer edge profiling to increase symmetry and remove surface roughness from saw cuts and process damage using a mixture of alumna powder and glycerine.

**Wafer orientation flat** Regions in a wafer to mark the specific crystal orientation and conductivity type of the material.

**Wafer polishing** A technique following wafer etching to provide an atomically smooth, specular surface where device features can be defined by lithographic processes or to improve bondability.

**Wafer slicing** The machining of the single crystal ingot into wafers using a saw after ingot grinding.

**Wet etching** A form of etching that involves the use of liquid etchants and is often a pure chemical process. It is a well-established, simple, and inexpensive technology with a possible high selectivity between the mask material and the thin film to be etched due to the chemical nature of the process.

**Write lithography** A serial lithographic technique in which a narrow (focused) beam or probe is scanned in a XY-pattern across a substrate to transfer a pattern.

**X-ray printing** A kind of print lithography in which an image is transferred through a mask in a resist using X-ray radiation ($\lambda = 0.4$–4 nm). It uses a one-to-one method, similar to optical shadow printing, because for this wavelength no suitable optics is available.

# Mesoscopic Organizations of Metal Nanocrystals

## G. U. Kulkarni, P. John Thomas, C. N. R. Rao

*Jawaharlal Nehru Center for Advanced Scientific Research,
Jakkur, Bangalore, India*

## CONTENTS

## 1. INTRODUCTION

A metal nanocrystal is a tiny chunk of the bulk measuring a few nanometers with a finite number of metal atoms in it. Nanocrystals in the size range of 1–50 nm are considered important and are obtainable as metal sols—a dispersion of a solid in a liquid, also called a colloidal sol. Metal sols possess fascinating colors and have long been used as dyes. The fact that such dyes indeed consist of tiny metal chunks was established as early as 1857 by Faraday [1]. Modern techniques of synthesis have enabled us to obtain sols that can be dried and redissolved like water colors. The colloidal particles display a remarkable tendency to remain single-crystalline and are hence named nanocrystals. However, the nanoparticles, depending on the method of synthesis, may exhibit multiply twinned domains sometimes even with a fivefold symmetry. Metal nanocrystals possess high surface area—a great fraction of the atoms in a nanocrystal is on its surface. A small nanocrystal of 1 nm diameter will have almost all of its atoms ($\sim$30) on the surface, while a larger nanocrystal of 10 nm ($\sim$1000 atoms) will have around 15% of its atoms on the surface [2].

An added dimension to research on nanocrystals is their size-dependent properties. The electronic, magnetic, and optical properties of a nanocrystal depend on its size [2]. In small nanocrystals, the electronic energy levels are not continuous as in the bulk metal but are discrete, due to the confinement of the electron wavefunction to the physical dimensions of the particles [3]. This phenomenon is called quantum confinement and therefore, nanocrystals are also known as quantum dots. The spacing between successive energy levels varies inversely as the diameter of the nanocrystal is changed; hence the observed changes in the properties. In fact, metal nanocrystals with volume less than 1 nm$^3$ have been shown to exhibit a definitive bandgap (few tens of meV) at room temperature. In other words, a small nanocrystal could be a very bad conductor although it is a tiny silhouette of the conducting bulk. Likewise, a tiny nanocrystal of a ferromagnetic metal can be paramagnetic in nature. In several respects, small nanocrystals behave like molecules. The nanocrystals can be discretely charged with electrons with characteristic charging energies. It means that a nanocrystal carrying an extra electron can exhibit properties different from a neutral species.

The electronic absorption spectrum of metal nanocrystals in the visible region is dominated by the plasmon band. This absorption is due to the collective excitation of the itinerant electron gas on the particle surface and is characteristic of a metal nanocrystal of a given size. In colloids, surface plasmon excitations impart characteristic colors to the metal sols, the beautiful wine-red color of gold sols being well known [4–10]. The theory of optical absorption in small metal particles was proposed at the turn of the last century by Mie [7, 10], who predicted the dependence of the plasmon peak on the dielectric constant of the surrounding medium and the diameter of the nanocrystal. Further, it was also predicted that the optical properties of metal nanocrystals would be highly anisotropic with a change in shape [8, 9]. The dependence of the absorption band of thiol-capped Au nanocrystals on solvent refractive index was recently verified by Templeton et al. [11]. Link and El-Sayed found that the absorption band splits into a longitudinal and a transverse band in Au nanorods [4, 5]. The positions of the two bands agree well with the theoretical prediction of Gans [8, 9].

The shrinking dimensions of the current microelectronic devices and the realization that current lithographic processes cannot extend to the nanoworld [12] have lent

tremendous thrust to research aimed at ordering nanocrystals into functional networks [13–18]. The nanocrystals akin to covalent systems self-assemble into ordered arrays in one, two, and three dimensions under the right conditions. Lattices of nanocrystals consist of interacting nanocrystals and may exhibit novel properties arising out of such interactions. The ability to engineer such assemblies, thus, extends the reach of current lithographic techniques and holds promise for a new generation of electronics of the nanoworld [13]. In this context, synthesis and programmed assembly of metal nanocrystals assume significance.

In this chapter, we discuss the structure and stability of mesoscopic organizations of nanocrystals in one, two, and three dimensions obtained by using a variety of surfactants. Some discussion is also devoted to unusual organizations such as clusters of nanocrystals and microcolloidal crystals. Though much of what is said holds good for semiconductor nanocrystals as well, we restrict ourselves only to metal nanocrystals for the sake of brevity.

## 2. SYNTHETIC STRATEGIES FOR METAL NANOCRYSTALS

### 2.1. General Methods

Bare metal nanocrystals of varying sizes are prepared by employing physical methods such as evaporation of metal in a vacuum by resistive heating or laser ablation. The nanocrystals are usually deposited on a solid substrate in a vacuum. Although the size of the nanocrystals cannot be exactly controlled during evaporation, it is possible to narrow the size distribution by controlling the rate of evaporation, varying the distance between the substrate and the evaporator, as well as by using nucleating inert gases. Complete control over size requires mass selection using a cluster beam apparatus. In the soft-landing method, nanoparticles generated in a stream of argon are made to land gently on a cold substrate covered with a bed of argon. The morphology of soft-landed clusters is quite different from that obtained from direct deposition, the former being more spherical and uniform.

Chemical reduction of metal salts dissolved in appropriate solvents yields small metal particles of varying size distributions [19–22]. The stabilizing agents employed include surfactants such as long-chain thiols or amines or polymeric ligands such as polyvinylpyrrolidone (PVP). A variety of reducing agents have been employed for reduction. These include electrides, alcohols, glycols, metal borohydrides, and certain specialized reagents such as tetrakis(hydroxymethyl) phosphonium chloride. The last reagent has enabled the preparation of gold hydrosols (down to ~2 nm) with a narrow size distribution. The polyol method has been quite popular in producing particles of Ag, Au, Pd, Ru, Co, Ni, and variety of other metals from nanometric to micron dimensions. Reverse micellar methods exploit the "water pools" in water-in-oil mixtures to synthesize nanocrystals and have been successful in the preparation of Ag, Au, Co, Pt, and Co nanocrystals [23, 24]. Microorganisms such as bacteria and fungi have also been harnessed to synthesize nanocrystals [25]. The synthesis of metal nanocrystals at the air-water interface as in Langmuir–Blodgett films or at a liquid-liquid

interface is currently attracting wide attention [14, 26, 27]. One such preparation involved a water-toluene interface, across which a film of Au nanocrystals was grown as shown in Figure 1 [28]. Other chemical techniques for the preparation of nanocrystals involve radiolytic, sonochemical, or electrochemical reactions [29, 30] or templates such as channels of zeolites [31]. Sonochemical reactions sometimes yield amorphous nanocrystals. Traditionally, clusters of controlled sizes have been generated by ablation of a metal target in vacuum followed by mass selection of the plume to yield cluster beams [32, 33]. Such cluster beams could be subject to *in-situ* studies or be directed on to solid substrates. In order to obtain nanocrystals in solution, Harfenist et al. [34] steered a mass-selected Ag cluster beam through a toluene solution of thiol and capped the vacuum-prepared particles. Alternatively, sols of Au and Ag have also been obtained by simply irradiating [35, 36] a strip of metal immersed in a solution containing the capping agent with laser light.

### 2.2. Size Control

The successful synthesis of metal nanocrystals involves three steps: nucleation, growth, and termination by the capping agent or ligand [19–21]. Though the reaction temperature and reagent concentrations provide a rudimentary control of the three steps, it is often impossible to independently control them and so the obtained nanocrystals usually exhibit a distribution in size. Typically, the distribution is log-normal with a standard deviation of 20% [21]. Given the fact that properties of the nanocrystals are size-dependent, it is significant to be able to synthesize nanocrystals of precise dimensions with minimal size distributions. This can be accomplished to a limited extent by size-selective precipitation either by centrifugation or by use of a miscible solvent-nonsolvent liquid mixture to precipitate nanocrystals. Lasers have also been used to alter the size distribution of nanocrystalline sols [37–41]. A breakthrough of sorts was achieved independently by two groups, led by Schmid [42] and Zamaraev [43], who succeeded in preparing truly monodisperse nanocrystals which they called "cluster compounds." They are like macromolecules with a core containing metal-metal bonds yet

**Figure 1.** Nanocrystalline film of Au formed at the toluene-water interface (middle). Gold is introduced as a toluene solution of Au(PPh$_3$)Cl while partially hydrolyzed THPC (tetrakishydromethylphosphonium-chloride) in water acts as a reducing agent. The film is obtained when the two layers are allowed to stand for several hours. When dodecanethiol is added to the toluene layer, the film breaks up forming an organosol (left) while mercaptoundecanoic acid added to water produces a hydrosol (right).

obtainable in definite stoichiometries, typical examples being $[Pt_{38}(CO)_{44}H_2]^{2-}$, $Au_{55}(PPh_3)_{12}Cl_6$. The enhanced stability of $Au_{55}$ was recently demonstrated clearly by Boyen et al. [44], who exposed a series of $Au_n$ nanocrystals to oxidation. These nanocrystals are bequeathed with special stability because they consist of a magic number of metal atoms which enables the complete closure of successive shells of atoms in a cubic close-packed arrangement. The magic numbers 13, 55, 147, 309, and 561 correspond to the closure of 1, 2, 3, 4, and 5 shells, respectively [45]. A schematic illustration of magic nuclearity nanocrystals is shown in Figure 2. Since the breakthrough, several magic nuclearity nanocrystals have been prepared including PVP-stabilized $Pd_{561}$ nanocrystals [46]. In Figure 3 are shown scanning tunneling and transmission electron micrographs of polymer-protected $Pd_{561}$ nanocrystals.

## 2.3. Shape Control

Since the properties of the nanocrystals follow from the confinement of the electrons to the physical dimensions of the nanocrystals, it would be interesting to vary the shape of the nanocrystals and study the effect of confinement of electrons in such artificial shapes [47]. This has led to the revival of interest in synthetic strategies yielding nonspherical nanocrystals. Conventional methods such as due to Turkevich [20] yield, in addition to spherical particles, a mixture of shapes—triangular, teardrop, etc.—which were once thought of as undesirable. Today, smarter synthetic schemes have been designed which yield selectively nanocrystals in the form of rods, elongated spheres, cubes, and hexagons. Au nanorods were first electrochemically synthesized by Yu et al. [48] and their optical properties were studied by Link et al. [47]. Murphy's group has pioneered a solution state method to obtain long nanorods of Au and Ag [49–51]. Their method involves a seed-mediated growth of nanocrystals into nanorods and is an easy method to produce large quantities of nanorods. Besides the above, channels of cationic micelles [52] and the polyol process [53] have been adapted to yield nanorods of Au or Ag. Puntes et al. [54] have obtained nanorods of Co by carefully decomposing cobalt carbonyl in high boiling organic solvent.

**Figure 2.** Metal nanocrystals in closed-shell configurations with magic number of atoms.

**Figure 3.** STM image of polymer-coated $Pd_{561}$ nanocrystals. The nanocrystals are seen as fluffy balls against plane background of the graphite substrate. The inset shows a high-resolution electron micrograph (HRTEM) of an individual nanocrystal. We see the characteristic 11 [111] fringes in the icosahedral shape measuring 2.5 nm. The diameter estimated from STM is ~3.4 nm, the difference being due to the ligand shell.

## 2.4. Tailoring the Ligand Shell

Nanocrystals in their native form are dominated by the surface species; the capping agents employed play a role in determining the properties of the nanocrystals [55]. Hence, in addition to controlling the size and the shape of the nanocrystal, it is also necessary to tailor its surface with the right capping agent. In addition to traditional capping agents that include ions, surfactants, and polymers, a new breed of ligands—dendrimers, hydrogen-bonding fragments of protein, DNA, and dyes—with pendent thiol groups as well as silica layers have been used as capping agents [56–58]. In some cases, a layer of a noble metal is used as a buffer between the core nanocrystal and the ligand shell [59]. Thus, a layer of gold lends special stability to Fe nanocrystals and helps in preventing oxidation and in preserving the magnetic properties of Fe (see Fig. 4).

Of special interest in this regard are reactions that enable the total replacement of one set of ligands with another [60–64]. These reactions also typically enable the transfer of nanocrystals from one phase to another. A novel method of thiol-derivatizing hydrosols of metals has been developed by Sarathy et al. [61, 62]. The procedure involves mixing vigorously a hydrosol containing metal particles of the desired size distribution with a toluene solution of an alkane thiol in the presence of a strong acid or reducing agent. The completion of the derivatization is marked by a vivid interchange of the colors from the aqueous layer to the hydrocarbon layer. The advantage of this method is that well-characterized metal particles can be easily thiol-derivatized in a nonaqueous medium. A variety of hydrosols of Au, Ag, and Pt has been thiolized by this procedure.

## 2.5. Alloy Nanocrystals

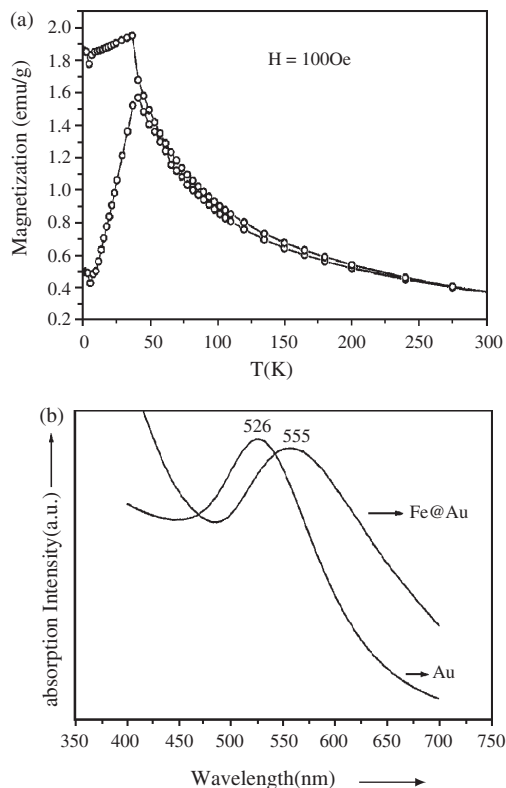
Bimetallic or alloy colloids have been made by the chemical reduction of the appropriate salt mixture in the solution phase. Thus, Ag-Pd and Cu-Pd colloids of varying composition have been prepared by alcohol reduction of mixtures of silver nitrate or copper oxide with palladium oxide [65].


**Figure 4.** (a) Zero field cooled and field cooled magnetization curves for Fe-Au core-shell nanocrystals. The blocking temperature is 42 K. (b) Absorption spectrum showing the Au surface plasmon. For comparison, the spectrum of Au hydrosol is also shown. Reprinted with permission from [59], J. Lin et al., *J. Solid State Chem.* 159, 26 (2001). © 2001, Elsevier.

Fe-Pt alloy nanocrystals have been made by thermal decomposition of the Fe and Pt acetylacetonates in high boiling organic solvents [66]. Au-Ag alloy nanocrystals have been made by co-reduction of silver nitrate and chloroauric acid with sodium borohydride [67, 68]. Bare alloy nanocrystals have been made by thermal evaporation of alloy ingots in vacuum, typical examples being Ni-Cu, Ag-Au, Cu-Pd [69]. Lasers are being increasingly used to bring about alloying of nanocrystals. Au nanocrystals with their plasmon bands centered around 530 nm are ideal for laser irradiation studies. Au-Ag alloying and segregation have been brought about by the use of lasers on Au-Ag layered particles [70, 71].

## 3. METAL NANOCRYSTAL ASSEMBLIES

Like molecular systems, nanocrystals capped with suitable ligands spontaneously assemble into ordered aggregates. That such self-assembly can occur through a variety of weak forces is being recognized. Cooperative assemblies of ligated metal [13] as well as of colloidal polymer spheres seem to occur through the mediation of electrostatic and capillary forces [72–74]. The forces that govern the nanocrystal assembly, however, are different in many ways. Surface tension, for example, plays an important role [21] because in a nanocrystal, a large fraction of atoms is present at the surface. Surfactant molecules which self-assemble on

metal surfaces have proved to be the best means of obtaining ordered arrays of nanocrystals [74]. The way in which the nanocrystals organize themselves depends critically on the metal core diameter, the nature of the ligand, substrate, and even the dispersive medium used [75]. Thiolized nanocrystals readily arrange into two-dimensional arrays on removal of the solvent [13]. Using suitable methods, they can also be put into one-dimensional organization in the form of strings or assembled in a stepwise fashion in a three-dimensional superlattice (see Fig. 5).

### 3.1. One-Dimensional Arrangements

Hornayak and co-workers [76] used the ordered channels of porous alumina as templates to obtain linear arrangements of Au nanocrystals. By varying the pore size, the diameter of the nanowire could be controlled. A linear arrangement has also been obtained by coordinating Au particles (∼1.4 nm) stabilized with phosphine ligands to single-stranded DNA oligonucleotide of the desired length and specific sequence [77, 78]. Organization of particles in a 1D lattice has met with limited success. Heath and co-workers [79] have fabricated wires of Ag nanocrystals by compressing a dispersion of Ag (4.5 nm) nanocrystals in toluene (Fig. 6). The wires were one nanocrystal thick, a few nanocrystals wide, and extended in length from 20 to 300 nm. The interwire separation distance as well as the alignment of the wires could be controlled by compressing the film of nanocrystals.

**Figure 5.** Schematic illustration of the various metal nanocrystal organizations.
## 3.2. Two-Dimensional Arrays

Ligands based on long-chain thiols have served as good candidates for assembling nanocrystals on a flat substrate. Gold organosols using alkane thiols as surfactants were first prepared by Schiffrin and co-workers [80] by phase transferring gold ions and carrying out reduction in the presence of thiols. Several workers have adopted this procedure to obtain thiolized metal nanocrystals [81–84]. Whetten et al. [82] have centrifuged and separated out fractions containing particles of different mean sizes, to prepare 2D arrays of size-selected Au nanocrystals. A two-dimensional array of dodecanethiol-covered Ag nanocrystals obtained by Fitzmaurice and co-workers [83] is shown in Figure 7. Similarly, well-ordered arrays of magic nuclearity nanocrystals, $Pd_{561}$ and $Pd_{1415}$, have been successfully obtained after replacing their polymer coating by alkanethiols (Fig. 8) [85]. Harfenist et al. [34] found that Ag nanocrystals prepared by using a cluster beam were stable in air and formed extended 2D arrays. Ordered 2D lattices containing thiolized Au particles of two different sizes have been reported by Kiely et al. (see Fig. 9) [84]. They found that the

**Figure 8.** TEM micrographs showing hexagonal arrays of thiolized Pd nanocrystals: (a) $Pd_{561}$ octanethiol, (b) $Pd_{1415}$ octanethiol. Organized arrays of these nanocrystals extend to lengths over several microns.

nanocrystals of different radii follow the radius ratio rules formulated for alloying of different metals. Alloy arrays consisting of Au and Ag nanocrystals of different sizes have been made [86]. Similarly, arrays consisting of a mixture of $Fe_3O_4$ and Fe-Pt nanocrystals of several different sizes have been obtained [87]. Long-chain fatty acids have also been used for ligating metal nanocrystals. Colloidal dispersion of Co nanocrystals capped with fatty acids were found to self-assemble to yield hexagonally ordered arrays similar to those obtained with alkanethiols [88, 89]. Similarly, Ag nanocrystals capped with fatty acids of appropriate lengths yield cubic or hexagonal close-packed structures [90, 91]. It is possible to obtain micrometer-sized rings and hexagonal arrays of monodisperse nanocrystals instead of extended arrays by varying the solvent evaporation rate and exploiting the resulting fluid instabilities (the Marangoni effect) that occur during evaporation [92–96].

Schmid et al. [97] have reported an ordered two-dimensional array of small $Au_{55}$ nanocrystals (diameter ~1.4 nm) on a polymer film (see Fig. 10). At the other end of the size regime, big Au nanocrystals of 15–90 nm dimensions have also been organized into two-dimensional arrays [98]. Arrays of Au-Ag [67, 68] and Fe-Pt alloy nanocrystals [66] have been obtained. Magic nuclearity $Pd_{561}$ nanocrystals have been exploited to make Pd-Ni core-shell particles with variable Ni loadings [99]. The nanocrystals so obtained possess a core-shell structure, with the Pd seed in the middle and a Ni layer covering it. The magic nuclearity $Pd_{561}$ nanocrystals act as high-quality seeds and promote the formation of monodisperse Pd-Ni core-shell
**Figure 10.** TEM images of Au$_{55}$ monolayers showing a hexagonal (a) and a cubic (b) structure. The monolayers were prepared on a polyethyleneimine functionalized carbon grid. The magnified inset in (a) shows single clusters in the hexagonal form. Reprinted with permission from [92], M. Maillard et al., *J. Phys. Chem.* B104, 11871 (2000). © 2000, American Chemical Society.

nanocrystals. Arrays of Pd$_{561}$Ni$_n$ ($n$ up to 10,000 atoms) have been prepared after thiolizing the core-shell nanocrystals (see Fig. 11) [100]. By a simple extension of this technique, arrays of triple-layer nanocrystals of the form Pd$_{561}$Ni$_{3000}$Pd$_{1500}$ were also obtained. Methods to organize nonspherical metal nanocrystals into two-dimensional arrays have met with limited success. A TEM image of an array of thiol-derivatized hexagonal Pt nanocrystals ($\sim$8 nm diameter) is shown in Figure 12. These were first prepared using an inverse micellar method, and thiol-derivatized without altering the shape or size. Elongated silver nanocrystals have been organized into ordered nanowire arrays [101].

The nanocrystal organizations mentioned are mainly entropy-driven. The two lengths involved—the nanocrystal diameter ($d$) and the ligand chain length ($\ell$)—play an important role in deciding the nature of the organization, that is, its orderliness. It has been observed experimentally that for a given diameter of the nanocrystal, the packing changes swiftly as the length of the thiol ligand is increased. The stability diagram in terms of $d$ and $\ell$ shown in Figure 13 illustrates that extended close-packed organizations of nanocrystals are found for $d/\ell$ values $\sim$2. Although entropy-driven, the above can not be treated as hard sphere organizations. Based on a study of the effect of the solvent polarity on the self-assembly of ligated nanocrystals, Korgel et al. [75, 83] proposed a soft sphere model taking the interparticle interaction into consideration.

**Figure 11.** TEM image of an ordered array of octanethiol capped (a) Pd$_{561}$Ni$_{561}$ and (b) Pd$_{561}$Ni$_{3000}$ nanocrystals.

**Figure 12.** TEM image of thiol-derivatized Pt nanocrystals. The hexagonal nanocrystals form close-packed structures resembling a honeycomb pattern. The wiggly pattern in the TEM image is due to the second layer of the honeycomb structure sitting directly over the first layer in a AB-type packing.

Accordingly, a ligated nanocrystal allows for penetration of the ligand shell up to its hard sphere limit. In this model, the total potential energy, $E$, is considered to be a result of two types of forces between the nanocrystals,

$$E = E_{\text{steric}} + E_{v\,dW} \tag{1}$$

$$E_{v\,dW} = \frac{A}{12}\left\{ \frac{d^2}{\tau^2 - d^2} + \frac{d^2}{\tau^2} + 2\,\ln\left[\frac{\tau^2 - d^2}{t^2}\right] \right\} \tag{2}$$

$$E_{\text{steric}} = \frac{50 d \ell^2}{(\tau - d)\pi \sigma_a^3} kTe^{-\pi(\tau - d)} \tag{3}$$

The van der Waals interaction due to the polarization of the metal cores constitutes the attractive term and the steric interaction between the thiol molecules on the two surfaces forms the repulsive term, where $\tau$ is the interparticle distance. The Hamaker constant, $A$, for Pd nanocrystals in

**Figure 13.** The $d - \ell$ phase diagram for Pd nanocrystals thiolized with different alkanethiols. The mean diameter, $d$, was obtained from the TEM measurements on as-prepared sols. The length of the thiol, $\ell$, is estimated by assuming an all-*trans* conformation of the alkane chain. The thiol is indicated by the number of carbon atoms, C$_n$. The bright area in the middle encompasses systems that form close-packed organizations of nanocrystals. The surrounding darker area includes disordered or low-order arrangements of nanocrystals. The area enclosed by the dashed line is derived from calculations from the soft sphere model. Reprinted with permission from [85], P. J. Thomas et al., *J. Phys. Chem.* B104, 8138 (2000). © 2000, American Chemical Society.

toluene has been estimated to be 1.95 eV [102]. The calculated diameter of the area occupied by the thiol molecule (sa) on the particle surface is 4.3 Å [83]. The total energy is attractive over a range of interparticle distances, the magnitude increasing with fall in distance. There could be a range of interparticle distances where the attractive energy from the van der Waals term exceeds the repulsive energy due to the steric factor, giving rise to net stabilization of the two-particle system. This is illustrated in Figure 14 in the case of 4.5-nm Pd particles. Stabilization energies of 17 and 2 meV are obtained from the calculation for particles coated with octanethiol and dodecanethiol, respectively. When the stabilization energies have moderate values, comparable to the thermal energy of the nanocrystals, ordered organizations can be expected (see the regime shown by dashed line in Fig. 13). If the $d/\ell$ and hence the stabilization energy is not favorable, collapsed monolayers of nanocrystals or loosely packed structures are seen. Clearly, the interdigitation of thiol molecules plays a major role in attributing hardness to the ligated nanocrystal, which in turn decides the nature of the two-dimensional organization.

## 3.3. Three-Dimensional Superlattices

Multilayer assemblies using monothiols are generally fragile. Multilayer deposition of nanocrystals is best achieved by exploiting bifunctional molecular spacers (see Fig. 15) [13, 14]. One end of the bifunctional molecule is tethered to the surface by chemisorption and the exposed amine or thiol moiety at the tail can now be used to anchor nanocrystals. Subsequent layers can be introduced by dipping the substrate sequentially into the respective spacer molecule solutions and the nanocrystal dispersion, with intermediate steps involving washing and drying. The formation of the multilayer assembly can be monitored using a variety of spectroscopy and microscopy tools. Thus, employing Au substrates and dithiols as spacers, multilayer assemblies of several metal nanocrystals have been accomplished [103]. One such example of layer-by-layer deposition of Pt (5 nm) nanocrystals is shown in Figure 14. Brust et al. [104] have reported the formation of multilayers of Au nanoparticles using dithiols. These workers have confirmed the layer-by-layer deposition of particle arrays by employing UV-vis spectroscopy and ellipsometry. Such assemblies

**Figure 15.** Multilayer deposition of Pt (5 nm) nanocrystals on a polycrystalline Au substrate. After each deposition, the structure was characterized by STM, X-ray diffraction, as well as by XPS. (a) STM image obtained after the second deposition showing the presence of regular arrays of nanoparticles with a interparticle spacing of 2 nm, extending over 300 nm, corresponding to the size of a typical flat terrace on the substrate. (b) X-ray diffraction pattern of the arrays after the first, third, and fifth depositions exhibiting low-angle reflections with the d-spacings reflecting the particle diameter and the interparticle distance. (c) X-ray photoelectron spectra in the Pt(4f) and Au(4f) regions for the 5 nm Pt/Au system. The intensity of the Pt(4f) feature increases with the number of depositions, accompanied by a decrease in the Au(4f) intensity as the substrate gets increasingly shadowed due to the limited escape depth of the photoelectrons.

can be made with ionic spacer molecules as well [105, 106]. Three-dimensional superlattices involving nanocrystals of different metals (e.g., Pt, Au) and of metals and semiconductors (e.g., Au, CdS) have also been prepared and characterized [103].
## 3.4. Superclusters

It has been proposed that self-similarity in metal nanocrystal organization would manifest in the form of a giant cluster whose shape and size are direct consequences of the nanocrystals themselves [107]. The invariance of the shell effects in metal nanocrystals with scaling is shown schematically in Figure 16. Thus, $Pd_{561}$ nanocrystals would be expected to self-aggregate into a giant cluster of the type $(Pd_{561})_{561}$ under suitable conditions. The monodisperse nature of the nanocrystals is thought to be important in assisting the self-aggregation process. Formation of such clusters was observed in the mass spectra of magic nuclearity $Au_{55}$ nanocrystals. Secondary ion mass spectrometry indicated the presence of species with large m/z values and these were attributed to $(Au_{13})_{55}$ giant clusters [108]. The giant clusters so obtained have, however, not been isolated

or imaged. One such observation was made in the case of $Pd_{561}$ nanocrystals where the PVP covered nanocrystals aggregated to form giant clusters [109]. The TEM image in Figure 17 is revealing. There are regions where the nanocrystals are densely packed in the form of giant aggregates with estimated nanocrystal nuclearities corresponding to various magic numbers. It is possible that the formation of the giant clusters is facilitated by the polymer shell that encases them. Unlike in case of Pd nanocrystals coated with alkanethiols, which self-assemble to form ordered arrays, the polymer shell effectively magnifies the facets of the metallic core, thereby aiding a giant assembly of the nanocrystals.
## 3.5. Colloidal Crystals

The tendency of monodisperse nanocrystals to arrange into ordered three-dimensional arrays extending to a few microns has been noticed [110]. Careful tuning of crystallization conditions has yielded crystallites of micrometer dimensions consisting of $Au_{55}$ nanocrystals and Fe-Pt alloy nanocrystals (4.5 nm) as shown in Figure 18 [111, 112]. However, it was observed that the nanocrystal arrangement in the crystallites was polymorphous. It is believed that such crystallites, consisting of ordered nanocrystals, could prove to be the best candidates to study the collective properties of an ensemble of nanocrystals.

# 4. APPLICATIONS OF METAL NANOCRYSTALS

Several applications have been envisaged for metal nanocrystals, ranging from simple dyes to magnetic-resonance-imaging contrast agents [113], as components of electronic circuitry [17, 114] and magnetic media [88], as ingredients in catalyst and sensors, and so on. The properties of a nanocrystal, however, depend critically on its size [2].
## 4.1. Isolated Nanocrystals

A nanocrystal undergoes a size-induced metal-insulator transition when the diameter of the particles is decreased to below a few nanometers [3, 115, 116]. Scanning tunneling spectroscopy measurements of nanocrystals of various metals have revealed that the nanocrystals of dimensions $\sim 1$ $nm^3$ exhibit a definitive bandgap (up to 70 meV) that decreases gradually as the volume of the nanocrystal increases [115]. Beyond 2 nm, the nanocrystal becomes essentially metallic. Photoelectron spectroscopic measurements on mass-selected $Hg_n$ nanoparticles ($n = 3$ to 250) in

**Figure 17.** TEM micrograph showing the giant clusters comprising $Pd_{561}$ nanocrystals. Sample for TEM was prepared by the slow evaporation of a $PVP - Pd_{561}$ hydrosol. Giant clusters are enclosed in circles whose diameters correspond to magic numbers. The $n$ and $L$ values indicate the number of nanocrystals and closed shells, respectively.

**Figure 18.** (a, b) Optical and (c, d, e) SEM images of Fe-Pt microcrystals. (f) Schematic illustration of a $Au_{55}$ nanocrystal arrangement in a microcrystal. (g) Small-angle X-ray diffraction pattern obtained from a $Au_{55}$ microcrystal. Reprinted with permission from [111], G. Schmid et al., *Chem. Commun.* 1303 (1999). © 1999, RSC Journals.

the gas phase reveal that the characteristic HOMO–LUMO ($s$–$p$) energy gap decreases gradually from ~3.5 eV for $n < 3$ to ~0.2 eV for $n < 250$, as shown in Figure 19. The bandgap closure is predicted at $n \sim 400$. The metal-to-nonmetal transition in gaseous Hg nanoparticles was examined by Rademann and co-workers [117] by measuring the ionization energies (IE). For $n < 13$, the dependence of IE on $n$ suggested a different type of bonding. A small Hg particle with atoms in the $6s^26p^0$ configuration held together by relatively weak van der Waals forces, is essentially nonmetallic. As the nanoparticle grows in size, the atomic $6s$ and $6p$ levels broaden into bands and an insulator-to-metal transition appears to occur driven by the physical dimensions of the individual particle. Note that this is the same element, Hg, behaving as either a metal or a nonmetal, depending upon its physical size! The change in the electronic structure of the nanocrystal manifests itself in many ways, one example being reactivity. Nanocrystals of the noble metal gold, in contact with an oxidic support such as silica, act as efficient catalysts for the oxidation of CO to $CO_2$, the activity depending on the size (see Fig. 20); maximum activity was observed for nanocrystals of ~3 nm diameter [118]. Sometimes, the reactivity is so specific to the nanocrystal size that literally "every atom counts" in determining the chemical reactivity [119]. A few studies have sought to exploit dependence of the plasmon absorption band on the dielectric constant of the surrounding medium in metal nanocrystals to detect binding events taking place at the ligand shell. Thus, Au nanocrystals could colorimetrically determine the successful hybridization of oligonucleotide strands bound to their surface [73, 77]. It has been proposed that colorimetric sensing of heavy metal ions could be obtained by the use of carboxylic acid terminated bifunctional thiols bound to metal nanocrystals [120, 121]. The changes in the electronic absorption spectra of ~5-nm Ag nanocrystals capped with lipoic acid, following the addition of the heavy ions, $Cu^{2+}$ and $Fe^{2+}$, is shown in Figure 21. Such a dampening also brings about a change in color. It is apparent that $Cu^{2+}$ ions dampen the plasmon band more effectively than $Fe^{2+}$. Nanocrystals are thought of as important in single-electron devices such as supersensitive electrometers and memory devices [114, 122]. Capped nanocrystals, by virtue of their

**Figure 20.** The activity (CO atoms/total Au atoms) for CO oxidation at 350 K as a function of the Au cluster diameter supported on a $TiO_2$ surface. Valden et al., *Science* 281, 1647 (1998). © 1998, American Association for the Advancement of Science.

size, possess capacitance in the range of attofarad ($10^{-18}$ F). Charging a nanocrystal with an extra electron perturbs it to such an extent that the next electron requires an appreciable change in the charging potential. This is often seen as a "Coulomb staircase" in the current-voltage tunneling spectra. Indeed, the charging energy varies linearly with the inverse of the diameter of the nanocrystal [123, 124]. The sensitivity of a nanocrystal to single-electron charging makes it an ideal candidate for use in single-electron transistors and memory devices.

Size effects were perhaps first noticed in magnetic clusters [88]. Magnetic properties of nanoparticles of transition metals such as Co and Ni show marked variations with size. It is well known that in the nanometric domain, the coercivity of the particles tends to zero [125]. Thus, the nanocrystals behave as superparamagnets with no associated coercivity or retentivity. The blocking temperature which marks the onset of this superparamagnetism increases with the nanocrystal size. This scenario, however, changes in the case of interacting nanocrystals, where the interparticle interaction and hence their magnetic properties can be tuned by varying the interparticle distance. Thus, lattices of interacting magnetic nanocrystals are considered important in the future magnetic storage devices. Further, the magnetic

**Figure 19.** Photoelectron spectra of Hg clusters of varying nuclearity. The $6p$ feature moves gradually towards the Fermi level, emphasizing that the bandgap shrinks with increase in cluster size. Reprinted with permission from [117], K. Rademann et al., *Phys. Rev. moment per atom is seen to increase as the size of a particle decreases [126].

Creating patterns of nanocrystals on surfaces has attracted wide attention. Such patterned substrates can act as templates to grow nanowires, and etch masks to grow nanopillars and quantum dots [127–129]. Other than the layer-by-layer technique mentioned before, simple techniques such as spin-coating have been employed to create a nanocrystalline pattern on surfaces [130]. We have utilized dip-pen nanolithography, a direct write lithographic technique [131, 132], which relies on a cantilever used for atomic force microscopy (AFM) to write on a substrate to create patterns of Au nanocrystals on mica substrates. Figure 22 shows a contact AFM picture of nanocrystals patterned in rectangles of varying aspect ratios.

## 4.2. Collective Properties

The fact that the physical properties of metal nanocrystal organizations could be different from those of the isolated particles is being realized. Pellets of monodisperse nanocrystals, obtained by the use of bifunctional ligand that binds to more than one nanocrystal or by applying pressure on dried nanocrystalline matter, have been used for electrical transport measurements [133–136]. Pellets made of small Au and Pd nanocrystals exhibit nonmetallic behavior with specific conductivities in the range of $10^6 \ \Omega^{-1} \mathrm{cm}^{-1}$ [133–135]. The conductivity, however, increases dramatically with an increase in the diameter of the nanocrystals. An insulator-metal transition has indeed been reported from pellets made of ∼12.5 nm Au and Ag nanocrystals [136]. Electrical transport measurements on layer-by-layer assemblies of nanocrystals on conducting substrates have been carried out by adoption of a sandwich configuration [137–139]. Nanocrystalline films with bulk metallic conductivity have been realized with Au nanocrystals of 5 and 11 nm diameter spaced with ionic and covalent spacers [138, 139].

**Figure 22.** Contact AFM scan of a 9 $\mu$m$^2$ area on mica substrate showing rectangles of various aspect ratios filled with Au nanocrystals. The inset shows a TEM image of a similar pattern on a holey carbon copper grid. The scale bar in the inset corresponds to 50 nm.

The conductivity of monolayered two-dimensional arrays of metal nanocrystals have been studied with patterned electrodes [140–145]. Structural disorder and interparticle separation distance have been identified as key factors that determine the conductivity of such layers [140–143]. The conductivity of such layers has been enhanced by replacing alkane thiol with an aromatic thiol *in-situ* [144, 145]. That the interaction energy of nanocrystals in such organizations can be continually varied by changing the interparticle distance was exploited by Heath and co-workers [146, 147], who prepared a monolayer of Ag (∼3 nm) nanocrystals at air-water interface in a LB trough and varied the interparticle distance by applying pressure. A host of measurements including reflectivity and nonlinear optical spectroscopic techniques were carried out *in-situ*. This study led to the observation of a reversible Mott–Hubbard metal-insulator transition in the nanocrystal ensemble wherein the coulomb gap closes at a critical distance between the particles. Tunneling spectroscopic measurements on films of 2.6-nm Ag nanocrystals capped with dodecanethiol reveal a coulomb blockade behavior attributable to isolated nanocrystals [147]. On the other hand, nanocrystals capped with hexane and pentane thiol exhibit characteristics of strong interparticle quantum-mechanical exchange. Similar behavior was observed in the case of self-assembled two-dimensional arrays of Co nanocrystals and Au nanocrystals [148, 149].

Co nanocrystals when organized into two-dimensional arrays exhibit a higher superparamagnetic blocking temperature compared to isolated nanocrystals; that is, they display a higher resistance to thermal reversal of their spins than when they are isolated [150]. Sun et al. reported a lattice of nanocrystals each consisting of a Fe core and a Pt shell prepared by heating Fe-Pt alloy nanocrystals [66]. Following phase segregation, the interaction between the nanocrystals increased, leading to a ferromagnetic film. Exchange spring magnets—nanocomposites that consist of magnetically hard and soft phases interacting by magnetic exchange coupling—have been made by carefully annealing the mixed nanocrystal array consisting of Fe-Pt and Fe$_3$O$_4$ [87].

## 4.3. Nanocomputing

Ordered arrays of nanocrystals, in principle, could be thought of as arrays of SETs, where the electrostatic interaction between neighboring SETs acts as wireless communication means. It has been suggested by Korotkov [151] and Lent and co-workers [152] that simple logical operations can be performed on a circuitry consisting of arrays of SETs in the form of chains or cells with suitable insulating spacers. An electric field applied in one direction polarizes the strings into either the 1 or 0 state. Lent's scheme, named quantum cellular automata, instead uses a square cell consisting of five nanocrystals to denote the state of polarization. Preliminary experiments to evaluate the schemes are currently being pursued.

The realization that self-assembly driven fabrication process is not capable of producing defect-free structures has fuelled a search for algorithms that can compute even with defective circuitry. Heath and co-workers [153] have developed Teramac, a computer that works despite a high concentration of defects in its bank of microprocessors.

A more radical solution called amorphous computing aims to "engineer pre-specified, coherent behavior from cooperation of large numbers of unreliable parts interconnected in unknown, irregular and time varying ways" [154–156].

## 5. CONCLUSIONS

Nanocrystals of metals with diameters in the range 1 to 50 nm form a new class of materials with unusual properties which are size-dependent. Excellent electrical conductivity that primarily characterizes a metallic state becomes a rare entity in small nanocrystals (<2 nm) due to quantum confinement of the electronic states. Similarly, magnetic metals lose much of the coercivity with diminishing size. On the other hand, chemical properties such as reactivity may show up better at smaller sizes due to a greater number of surface bonding sites and other electronic effects. Considering the importance of nanocrystals in technological applications, a large number of synthesis methods have evolved in recent years which include reverse micelle and sonochemical methods besides laser ablation. Control over size and shape as well as encasing the nanocrystals with ligands of specialized functionalities have become subjects of urgent enquiry. While isolated metal nanocrystals are interesting by themselves, their organizations, especially those which are capable of self-assembling into well-ordered arrays, have attracted greater attention. Nanocrystals anchored to fragments of DNA or similar molecules essentially form one-dimensional organizations. When coated with long-chain alkane thiols, nanocrystals exhibit a tendency to assemble into hexagonal arrays on flat substrates. The stability of such a two-dimensional organization depends on the diameter of the nanocrystals and the length of the ligand. Multilayers of nanocrystal arrays can also be made in a programmed way by selecting suitable spacer molecules. Patterns of nanocrystals can be obtained using scanning probe techniques. Another mesoscalar aggregation known is the formation of giant clusters of nanocrystals with definite nuclearities. It would be ideal to grow crystals of nanocrystals, but such efforts have met with only a limited success to date, giving micron-sized crystals. Nanocrystal organizations may exhibit properties very different from those of the individual. They are amenable to unprecedented control over the lattice, the size of the nanocrystal and interparticle separation being continuously variable over a range. Exploratory experiments for measuring such collective properties are currently underway.

## GLOSSARY

**Atomic force microscopy**   A scanning probe microscopic technique which utilizes the weak forces between a sharp cantilever and the specimen to obtain a topographic image.

**Mesoscale**   A scale of higher order than the constituents.

**Metal-insulator transition**   A transition from a conducting to a nonconducting state induced by external stimuli or the size of the object.

**Nanocrystal**   A single crystal of a material with dimensions in the nanometer range.

**Scanning tunneling microscopy**   A scanning probe microscopic technique which uses the tunneling current between a metal tip and the conducting specimen to obtain a topographic image.

**Self-assembly**   Spontaneous assembly of objects under the influence of weak forces.

**Transmission electron microscopy**   An electron microscopic technique relying on electrons transmitted through the specimen to obtain atomic scale images.

## CONTENTS

## 1. INTRODUCTION

Evolution of recent nanotechnology is brilliant. It has made possible experimental observation of the nanoworld, leading to evolution of nanoscience. A variety of novel phenomena have been found in quantum and mesoscopic physics in the past decade. The mainstream of the nanotechnology is of course semiconductor nanotechnology, such as nanolithography using electron beams, dry etching with low damage, and two-dimensional electron gas formed in compound semiconductors. Besides, scanning probe microscopy also realized observation of nanoworld and manipulation of nanoscale materials. These methods are called top-down methods, because one artificially reproduces macroscopic-size materials down to nanosize. Using this way, one can reproduce materials mostly as one wants, while this method may accompany difficulties in its precise reproducibility and uniformity in nanostructure parameters because of the artificial method.

In contrast, self-organization is the other way relevant to produce nanostructures. Because this is not artificial but a natural method depending on automatic organization of molecules, this is called the bottom-up method. Since nanomaterials are naturally organized, this method brings high reproducibility and uniformity in nanoparameters.

Porous alumina membrane is one of the typical self-organized materials. This membrane consists of a honeycomb structure with nanosized diameter pores on the top view. Besides, these pores have straight shape vertical to the aluminum substrate without crossing each other. In this chapter, we report on a variety of quantum and mesoscopic phenomena observed in nanostructures realized by utilizing this alumina membrane as a template. We deposit nickel (Ni) and carbon nanotubes (CNT) into the pores of alumina template. These lead to successful study of nanoscience as follows.

In Section 3, we report on Coulomb blockade (CB), a typical phenomenon in single electron tunneling, observed in a single tunnel junction (STJ) attached to the bottom ends of Ni-nanowires and multiwalled carbon nanotubes (MWNTs). The first aim of this study was to confirm that CB could take place even in a STJ. The second aim was to investigate association of the CB with its external electromagnetic environment (EME). Many theoretical works reported that CB was very sensitive to its external EME in STJ systems (e.g., the so-called phase correlation theory), whereas only some researchers reported on this experimentally. In particular, we focused on identification of mesoscopic phenomena in Ni-nanowires and MWNTs. We reveal that Ni-nanowire has quasi-one-dimensional electron–electron interaction following Altshuler's theory and MWNT possesses weak localization (WL) resulting from phase interference of electron waves in the diffusive regime. We investigate how these electron interactions and WL contribute to the CB in STJ, as its external EME.

In Section 4, we focus on quantum phenomena observed in MWNTs, without the tunnel junction presented in Section 3, synthesized in the nanopores of alumina membranes (i.e., spintronics, superconductivity, and Y-junctions with nano-hetero-band junction). In Section 4.1.1, we found that phase interference in the MWNTs was sensitive to the materials slightly diffused into the top ends of MWNTs from the metal electrodes. We clarified that diffusion of heavy mass electrodes (e.g., gold and platinum) with the volume ratio of only about 5% yielded spin flipping due

to its spin–orbit interaction, changing the WL to antilocalization in bulk MWNTs. We propose a novel spintronics device, which operates like a CMOS transistor, using these MWNTs. In Section 4.1.2, we report how excess volume of cobalt, deposited into the bottom of the pores as catalyst for MWNT growth, changed structures of the MWNTs and spin interference in those. We found three anomalous behaviors. These phenomena imply strong spin coherence, which is maintained even with ferromagnetic impurities, of the MWNTs.

In Section 4.2, we report proximity-induced superconductivity (PIS) in niobium (Nb)/MWNT junctions. It is difficult to observe superconductivity in CNTs, because (1) the interface transparency of the metal electrode/CNT junction is poor due to misalignment of chemical potential and (2) strong one-dimensional repulsive electron interaction prevents Cooper pairs from those existences in the case of single walled CNTs. We realized a highly transparent interface by evaporating Nb electrodes on the top ends of our MWNTs with annealing. We found for the first time that conductance increases, on temperature decrease, due to PIS in the MWNTs. We also reveal that the increased conductance starts to decrease at lower temperature due to Thouless energy yielded by diffusion of Cooper pairs (i.e, reentrant effect).

In Section 4.3, we report electronic properties of Y-junction CNTs, consisting of a large diameter stem divided into two small diameter branches. This result implies automatic formation of a molecular heteroband junction controllable by a gate terminal utilizing one of the branches.

In Section 5, we report on quantum phenomena in ferromagnetic nanowire (Ni-nanowire). In Section 5.1, we report on abrupt magnetoresistance (MR) jump and reveal a possibility that this is due to macroscopic quantum tunneling of magnetic domain wall, which includes a large number of electron spins. In Section 5.2, we report on possible coexistence of phase coherence and ferromagnetism. We discuss whether ferromagnetism destroys phase coherence of electron waves based on our observation. Because these phenomena are quite strange, one may feel many open questions. We just present the observed results and one example for interpretation.
## 2. POROUS ALUMINA MEMBRANE

Porous alumina membrane was studied in early times. It shows extremely high uniformity of structure parameters in comparison with other many porous materials. For instance, it was studied as a magnetic recording media by depositing ferromagnetic materials into the pores. As mentioned in Section 1, porous alumina membrane has a honeycomb structure consisting of nanosized diameter pores on the top view (Fig. 1a). Besides, these pores have a straight shape vertical to the aluminum substrate without crossing each other (Fig. 1b). One can easily synthesize this membrane just only by anodizing pure aluminum substrate in some solutions (e.g., $H_2SO_4$, $H_3PO_4$) with applied voltage.

Figure 2 shows schematic cross-sectional view, which indicates how this alumina membrane with pores is formed. First, aluminum substrate starts to be anodized at random leading to pits (a). Because the distance between the top

**Figure 1.** (a) SEM top view image of a porous alumina membrane. This looks like a honeycomb. (b) AFM top view image of a porous alumina membrane. This implies the presence of cell structures and defects. Lower part of the figure shows cross-sectional image, along the blue solid line in the top view, around the top portion of pores. This emphasizes a periodic location of nanopores with highly uniform diameter. (c) Cross-sectional SEM image of Ni-nanowire array deposited into (a) and (b). (d) SEM overview image of an exposed carbon nanotube array synthesized into (a) and (b). After the synthesis of nanotubes, alumina membrane was etched out. This implies that an alumina membrane with nanopores can be a template favorite to produce nanowire arrays consisting of a variety of materials.

**Figure 2.** Schematic views showing how to synthesize a porous alumina membrane.

part of the pit and the other electrode becomes smaller than the plane places without pits, electrical field concentrates on this part. This induces further anodization of the pits (b). Consequently, the parts where pits did not exist remain as pores, whereas the pits become alumina film (c). As this procedure goes ahead, alignment of the pores becomes highly regular to avoid energy loss (i.e., the distance between the pores becomes equal). This is the so-called self-organization. This leads to alumina membrane with high uniformity which looks like honeycomb on its top view (d). However, why alumina membrane has the highest uniformity is still an open question.

We developed successfully how to control the structure parameters of this alumina membrane down to nanoscale by optimizing anodization conditions, such as current density, applied voltage, and anodizing temperature, with relevant solutions. We can reduce pore diameter down to 5 nm now. We also realized deposition of a variety of materials into the nanopores (e.g., metals; gold, copper, cobalt, nickel, ferrite, semiconductors; CdS, CdTe, molecules; carbon nanotubes), leading to a variety of nanowires or nanotubes. In addition, those combinations are possible.

In this chapter, we evaporated electrodes on the top parts of arrays of nanowires or nanotubes and measured electric features by applying bias voltage between the top electrode and the Al substrate. Hence, the observed characteristics are the averaged features of the nanowires or nanotubes with numbers as large as $10^3$–$10^5$. Nevertheless, we find that even averaged results exhibit unique and interesting phenomena in quantum and mesoscopic regimes. From the next section, we show some such examples.

# 3. COULOMB BLOCKADE IN SINGLE TUNNEL JUNCTION ATTACHED TO NANOWIRE

## 3.1. Correlation with Electron–Electron Interaction in Metal Nanowire

### 3.1.1. Introduction

In this section, Coulomb blockade depending on mutual Coulomb interaction (MCI) in external electromagnetic environments is reported in an array system of single tunnel junctions connected directly to disordered Ni-nanowires (i.e., an array of disordered Ni-nanowire/$Al_2O_3$/Al located in parallel), fabricated using a nanoporous Al film template. Observed zero-bias conductance ($G_0$) anomaly and its linear $G_0$ vs temperature relation qualitatively agree with Zeller and Cleland's observations of CB. CB is also quantitatively confirmed from the extended Zeller's model in a tunnel-junction array. In the high voltage region, only one-dimensional (1D) MCI following Altshuler's formula in a disordered Ni-wire dominates the conductance mechanism with the absence of CB. In contrast, in the lower voltage region, the CB mentioned previously emerges at the temperatures below a phase transition temperature ($T_c$), accompanied by the 1D MCI in the Ni-wire. The MCI plays the key roles of high impedance EME and transmission line following phase correlation theory of CB. It is found that CB is very sensitive to the diffusion coefficient ($D$) of the MCI,

resulting in the linear $T_c$ vs $D^{1/2}$ relation. For this relation, we propose as one possible model that the charging energy of CB competes with the energy quantum of fluctuation of Nyquist phase breaking caused by multiple Coulomb scattering in the Ni-nanowire. This linear $T_c$ vs $D^{1/2}$ relation is reconfirmed by the Ni-wire diameter dependence of $T_c$. Magnetic field dependence of the $G_0$ vs temperature relation obviously supports the actual presence of $T_c$ with different conductance mechanisms between the temperatures above and below $T_c$.

Coulomb blockade has been experimentally reported in a variety of nanotunnel junction systems (e.g., metal nanoparticle array systems, quantum dots, and other nanojunction systems fabricated by semiconductor nanotechnologies and scanning probe microscopes). It is also successfully understood by many theoretical works (e.g., the orthodox theory proposed by Averin et al. [1]). Most of experiments have been basically performed in multi-tunnel-junction (MTJ) systems. For instance, Zeller et al. first reported a zero-bias conductance ($G_0$) anomaly and its linear $G_0$ vs temperature relation in the array of Sn nanoparticles located in parallel [1, 5]. They explained the $G_0$ anomaly by introducing the charging effect of the nanoparticle (i.e., capacitance model). The linear $G_0$ vs temperature relation was also interpreted by the contribution of many nanoparticles with distributed charging energy ($E_C$). In contrast, only a few reports have successfully reported on CB in a STJ system, because it is difficult to fabricate EME satisfying phase correlation (PC) theory of CB in a single junction system. In PC theory, unless the real part of the total impedance of EME ($\text{Re}[Z_t(\omega)]$) is larger than the resistance quantum $R_Q \sim h/e^2 = 25.8$ k$\Omega$, the tunneling electron cannot transfer its energy to the EME. In addition, unless the high impedance transmission line ($R_L > R_Q$) is more closely connected to a single junction, zero-point oscillations caused by the EME fluctuation fluctuate the surface charges on the junction. They easily smear out the CB [2, 3]. Furthermore, the geometry of the high $\text{Re}[Z_t(\omega)]$ including the high $R_L$ region also must have enough small parasitic capacitance to observe clear CB [1, 8]. Cleland et al. successfully reported on the $G_0$ anomaly and CB in one single junction system, turning out the PC theory [3]. The first goal of this work is to report on the $G_0$ anomaly and its linear $G_0$ vs temperature relation in an array of single junctions located in parallel, which was never fabricated in the past works, and to identify it as the CB. They are actually consistent with Zeller and Cleland's reports in some viewpoints, suggesting the presence of CB.

Here, since Coulomb blockade (CB) is very sensitive to the external environment (EME) as mentioned above, correlation of CB with the mesoscopic phenomena in EME has recently attracted much attention [4–9]. In multijunction systems, some works successfully revealed the correlation of CB with the phase interference of electron waves [4], the spin interaction of electrons [6], and the fluctuation (e.g., (1) electron phase coherence is never destroyed even in quantum dots inserted in an Aharonov–Borm ring except for the case of spin coherence [4]; (2) many body effects in artificial atoms [6]). On the other hand, in single junction systems, only our past work has experimentally reported on the CB associated with the repulsive MCI in the EME and

with the extended PC theory proposed by previously [10–12]. The second goal of this work is to clarify the detailed correlation of the CB with MCI in external environment, based on the confirmation of CB mentioned previously.

In our past works, we briefly discussed the CB and its correlation with MCI in the same system as that in this work [i.e., an array of Al/Al$_2$O$_3$/Ni-nanowire (STJs)] [10–12], from the following two viewpoints.

***From the Viewpoint of Nazarov's Theory* [11, 13]**
In PC theory, EME plays two key roles for CB in STJ. (1) Tunneling electron transfers its energy to the EME, leading to CB. (2) EME phase fluctuations ($\Delta\varphi$) cause a charge fluctuation ($\Delta Q$) on the junction surface by coupling with zero-point oscillation (or by commutation relation [$\Delta\varphi, \Delta Q$] = $ie$), smearing CB out. To cause the first process, Re[$Z_t(\omega)$] must be larger than $R_Q$, and to avoid the second process, high $R_L$ must be closely connected to a single junction. Since this connection of the high $R_L$ automatically results in the high Re[$Z_t(\omega)$], the first process can also occur in the $R_L$. Nazarov applied this PC theory to the CB depending on the MCI in the external environment [13]. We fit the second derivative of measured current ($d^2I/dV^2$) in our samples with different wire diameters by his theory at the fixed temperature ($T = 1.5$ K) and identified the tunnel structure parameters [11]. Since they were in good agreement and reasonable values, we concluded the results of CB related to the MCI following Nazarov's theory.

***From the Comparison with the Past Reports of CB and the Theory for MCI in Disordered Conductors* [10, 14]**
The linear $G_0$ vs temperature relation observed was very roughly compared with the past two experimental results [3, 15] and identified as the CB [10]. The presence of MCI in the Ni nanowire was also identified from the $G$ vs $V^{1/2}$ curve fitting by Altshuler's theory. We pointed out a possibility that the MCI plays the role of high $R_L$ for the CB. Altshuler's theory basically employs calculation of the density of states in which MCI was treated as its quantum correction [14]. Hence, it is very different from Nazarov's theory, because the charging effect $E_C$ of tunnel-junction capacitance was never considered. In this viewpoint, the CB and MCI were separately discussed. Also, other necessary conditions for CB were discussed (e.g., influence of many STJs located in parallel and the parasitic capacitance of the long resistive Ni-wire on the CB) [10].

Although they discussed the presence of CB related to the MCI, no detailed features of the CB, MCI, and their correlation were clarified. In particular, the correlation in the temperature dependence was never reported. In this work, we clarify them focusing on the temperature dependence of resistance (conductance), taking into account Altshuler's and CB theories. In Section 3.1.2, the experimental results are at first presented. $G_0$ anomaly and the linear $G_0$ vs temperature relation are discussed based on Zeller and Cleland's observations of CB. Based on the extended Zeller's capacitance model, it is quantitatively confirmed that the $G_0$ anomaly originated from CB in the array of junctions located in parallel with distributed $E_C$. The high resistance Ni-wire ($>R_Q$) plays the roles of the high Re[$Z_t(\omega)$] and $R_L$ for the CB. One-dimensional MCI following Altshuler's theory is discussed based on the temperature dependence of

the normalized resistance in the high voltage region. In contrast, that at the low voltages is discussed. The appearance of CB at the temperatures below a phase transition temperature ($T_c$) is identified with the 1D MCI at the high temperatures ($>T_c$). The MCI is the origin of the high resistance of the Ni-wire. Correlation of the CB with the 1D MCI is discussed. The CB is sensitive to a diffusion coefficient ($D$) of the MCI, resulting in the linear $T_c$ vs $D^{1/2}$ relation. The origin of the linear $T_c$ vs $D^{1/2}$ relation is interpreted from the comparison of $E_c$ with an energy quantum of phase fluctuation caused by the MCI. The linear $T_c$ vs $D^{1/2}$ relation is reconfirmed by the linear wire diameter dependence of $T_c$. The presence of $T_c$ and different conductance mechanisms classified at the $T_c$ are obviously reconfirmed by the magnetic field dependence of the $G_0$ vs temperature relation.

### 3.1.2. Experimental Results

***Sample Structure and Measurement Method*** Figure 3a shows a schematic overview of the sample structure fabricated by using novel nanomaterial (i.e., nanoporous alumina film template, NAT) [10–12]. The NAT with high packing density of nanosized diameter pores was simply fabricated by

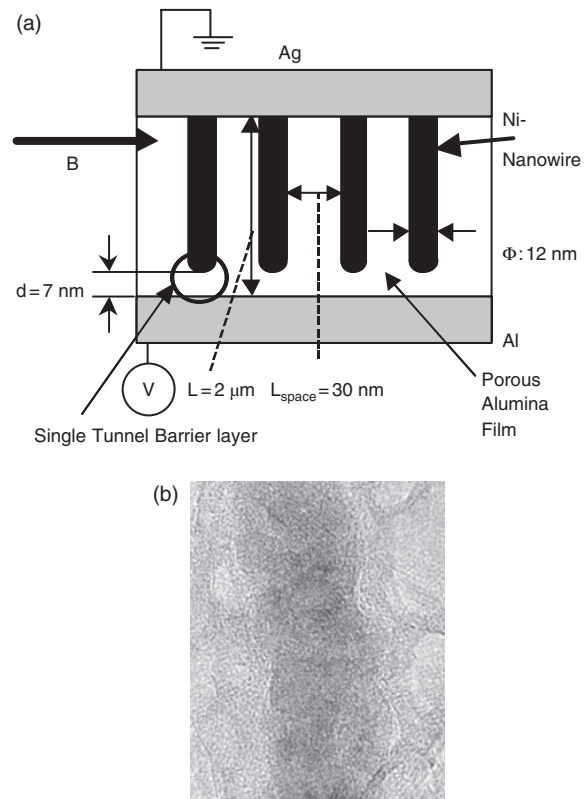

**Figure 3.** (a) Schematic overview of a sample structure, an array system of Ni-nanowire/Al$_2$O$_3$/Al (single tunnel junctions directly connected to Ni-nanowires) located in parallel. It was fabricated using a nanoporous alumina film template, which simply provides unique nanostructures by self-organized growth. (b) High resolution cross-sectional TEM image of one Ni-nanowire. We confirmed the presence of a thin tunnel barrier of 10 nm order thickness at the bottom end of this nanowire in [124]. Reprinted with permission from [124], J. Haruyama et al., *Phys. Rev. B* 62, 8420 (2000). © 2000, American Physical Society.

anodizing a pure Al film in $H_2SO_4$. Each pore automatically has a single tunnel barrier layer between its bottom and the Al substrate. Because of the self-organized growth, this NAT exhibits high uniformity, high repeatability, and high controllability of the nanostructure parameters (e.g., pore diameter and thickness of the tunnel barrier layer). In this work, Ni was electrochemically deposited into the nanopores. Thus, this system is an array structure of Ni-nanowire/$Al_2O_3$/Al (single junctions connected directly to Ni-nanowires) located in parallel. The structure parameters of the Ni-wire and the tunnel junction were confirmed by atomic force microscopy (AFM), scanning electron microscopy (SEM), and high resolution cross-sectional transmission electron microscopy (TEM) [10–12].

Figure 3b shows a typical high resolution cross-sectional TEM image of one Ni-wire including the bottom part. One can actually observe the tunnel barrier layer and Ni-nanowire with the order of 10 nm in the thickness and the diameter, respectively. In addition, very small interference patterns with the order of sub-nm diameter are visible in the Ni-wire. It suggests that the Ni-wire is in a disordered structure. This, however, never means the presence of electrical discontinuity grains, because the thickness of a grain boundary is as thin as sub-nm and any insulator layers cannot be introduced in our electrochemical deposition process. It also never indicates subnanoparticle arrays with charging effect like Zeller's system, because such thin boundary layers in the Ni cannot quantitatively have a tunnel resistance larger than $R_Q$. Furthermore, no Coulomb staircase (conductance oscillation) is observable in any current vs voltage (conductance vs voltage) curves unlike the many past reports of metal nanoparticle arrays [10], as mentioned in the next section. These strongly support that Ni-wire is electrically continuous in spite of a disordered structure, and our system is purely a single junction/Ni-nanowire array system. It is the key for our argument.

All electrical measurements were carried out by applying dc voltage between the Al substrate and the top of all Ni wires as shown in Figure 3a. The number of electrically active wire/junctions is estimated from the observed current order to be at most on the order of $10^4$. Magnetic field ($B$) was applied perpendicular to the axis of Ni-wire.

***Measurement Results and Analyses*** Figure 4 shows the temperature ($T$) dependence of conductance ($G$) vs $V^{1/2}$ curve in the plus voltage region. They obviously exhibit the $G_0$ anomalies. One corner voltage noted as $V_{1D}$ is observed around 0.3 V at each temperature, whereas the other corner voltage noted as $V_{CB}$ emerges around 0.12 V only at $T = 1.5$ K. No conductance oscillation is observable in any curves as mentioned. Although small conductance oscillations are observed at some voltage points, they originate from the simple measurement noise because they are independent of temperature. The inset of Figure 4 shows the temperature ($T$) dependence of $G_0$. The relation is mostly linear at temperatures below about 4 K. It is because this low temperature region could not be fit by any functions related to CB, electron transport in disordered conductors, and hopping conductance (e.g., $G$ vs $T^{1/2}$, $G$ vs $T^{1/4}$, $G$ vs $\log(T)$, $R$ vs $T^{-1/4}$) [1, 14, 16] and only the linear relation gave the best fit. The interpretation of this linear $G_0$ vs $T$ relation as the CB is discussed.

**Figure 4.** Temperature dependence of conductance ($G$) vs $V^{1/2}$ features in the positive voltage region, exhibiting the $G_0$ anomaly. The corner voltages ($V_{CB}$ and $V_{1D}$) were interpreted as the transition voltages from the one-dimensional mutual Coulomb interaction to the CB regimes and from the 3D to the 1D MCI regimes, respectively. Inset: Temperature dependence of $G_0$. The linear $G_0$ vs temperature relation as shown by the dotted line is interpreted as evidence for CB in the tunnel junction array. Reprinted with permission from [124], J. Haruyama et al., *Phys. Rev. B* 62, 8420 (2000). © 2000, American Physical Society.

Figure 5 shows the temperature dependence of the normalized resistance at each voltage point, which is below and slightly above $V_{CB}$, in Figure 3. Data fitting by the following Eq. (1), Altshuler's formula for 1D MCI in disordered conductors, basically gave the best fit to the linear $\delta R/R_n$ vs $T^{-1/2}$ parts,

$$\delta R(T)/R_n = (\rho e^2/8\hbar A)(4 + 3\lambda/2)(D\hbar/T)^{1/2} \qquad (1)$$

where $R_n, \rho, A, \lambda$, and $D$ are the resistance at the highest temperature, the resistivity (order of $10^{-7}$), the cross-sectional area (order of $10^{-16}$), the effective constant for MCI (order of 10), and the diffusion constant for MCI, respectively. In the data fitting, $D$ was used as only a free parameter, fixing the $R_n$ at the one end.

The temperature dependence can be classified into the following two voltage regions:

(1) **High voltage region:** lower four features (0.144–0.124 V of $V^{1/2}$). The temperature dependence can be fit by Eq. (1) at the entire temperatures measured. This high voltage region exists between $V_{1D}$ and $V_{CB}$.
(2) **Low voltage region:** upper eight features (0.114V–0.032 V). This low voltage region is smaller than $V_{CB}$.

The temperature dependence can be classified into the following two regimes by the $T_c$, defined as the temperature at which the deviation starts to emerge from the linear fitting
**Figure 5.** Temperature dependence of the normalized resistance at each voltage in Figure 4. The lower four and upper eight features were measured at the voltage points above and below $V_{CB}$, respectively. The dotted line shows the best fitting by Altshuler's formula for 1D MCI in disordered conductors. The arrows indicate phase transition temperatures ($T_c$) from the 1D MCI to the CB temperature regimes. Reprinted with permission from [124], J. Haruyama et al., *Phys. Rev. B* 62, 8420 (2000). © 2000, American Physical Society.

by Eq. (1):

(1) **a high temperature region** ($T_c > T$) that can be well fit by Eq. (1) and
(2) **a low temperature region** ($T_c < T$) in which the deviations appear from Eq. (1).

In the high temperature region, it should be noted that the slope value, $\alpha$, of the linear part increases in a decrease of voltage as shown in Figure 5. Figure 6a shows the inverse of the slope value ($\alpha^{-1}$) vs $V^{1/2}$ obtained from Figure 5. The interpretation assuming the linearity shown by the dotted line will be discussed. In addition, $T_c$ interestingly shifts to the lower temperature region in this increase of $\alpha$ in Figure 5. Figure 6b shows the $T_c$ vs $D^{1/2}$ relation. $D$ was determined from the parameter fitting to $\alpha$ by Eq. (1) at each voltage in Figure 5. The $T_c$ vs $D^{1/2}$ relation is mostly linear. Since it is the manifestation of the correlation of the CB with MCI in the Ni-wire, the interpretation is discussed.

Figure 7 shows the dependence of the $G_0$ vs temperature relation on the Ni-wire diameter ($\phi$). In each feature, the linear $G_0$ vs temperature relation and $T_c$ can be clearly observed. They are more obvious than those in the inset of Figure 4. The inset shows the dependence of $T_c$ on $\phi$ with the $T_c$ in the inset of Figure 4. It exhibits a mostly linear $T_c$ vs $\phi$ relation, although the sample number is only three. It is discussed that this linear relation is consistent with the linear $T_c$ vs $D^{1/2}$ relation.

Figure 8a shows the magnetic field ($B$) dependence of the $G_0$ vs temperature relation of the sample with

**Figure 6.** (a) $V^{1/2}$ dependence of the inverse of the slope value ($\alpha$) of the linear $\delta R(T)/R_n$ vs $T^{-1/2}$ parts obtained from Figure 3. $\alpha$ drastically increases within $V_{CB}$. The dotted line means a linear relation possibly assumed. (b) $T_c$ in Figure 3 vs the square root of the thermal diffusion coefficient ($D^{1/2}$) of MCI. $D$ was obtained from $\tilde{\alpha}$. It implies a mostly linear relation as shown by the dotted line. Reprinted with permission from [124], J. Haruyama et al., *Phys. Rev. B* 62, 8420 (2000). © 2000, American Physical Society.
$\phi = 32$ nm in Figure 7. The magnetic field dependence remarkably changes around $T_c$. $G_0$ is mostly independent of the magnetic field at temperatures below $T_c$, whereas positive magnetoconductance emerges at temperatures above $T_c$. This result strongly supports the actual presence of $T_c$ with different mechanisms at the temperatures above and below $T_c$. Figure 8b shows the magnetic field dependence of the $I$–$V$ curves in each temperature region. The change of the $I$–$V$ curve is quite asymmetric at $T = 1.5$ K ($<T_c$). The current is reduced in the plus voltage region, whereas it mostly does not change in the minus voltage
**Figure 7.** Dependence of $G_0$ vs temperature features on the Ni-wire diameters ($\phi$). Only $\phi$ was varied with keeping tunnel-junction parameters constant. Inset: Dependence of $T_C$ on $\phi$ with the $T_C$ of the inset in Figure 4 It supports the linear $T_C$ vs $D^{1/2}$ relation in Figure 6b. Reprinted with permission from [124], J. Haruyama et al., *Phys. Rev. B* 62, 8420 (2000). © 2000, American Physical Society.

region. They lead to mostly independent $G_0$ on the magnetic field. On the other hand, the change of $I$–$V$ is symmetric at $T = 15$ K ($> T_c$). Absolute values of the current are much increased in the entire voltage regions, leading to the

**Figure 8.** (a) Magnetic field ($B$) dependence of $G_0$ vs temperature in the sample with $\phi = 32$ nm shown in Figure 7. The $G_0$ vs temperature relation is mostly independent of $B$ at temperatures below $T_c$ (CB regime), whereas a positive magnetoconductance appears at temperatures above $T_c$ (1D MCI regime). (b) $B$ dependence of $I$–$V$ curves at the temperatures above and below $T_c$. Reprinted with permission from [124], J. Haruyama et al., *Phys. Rev. B* 62, 8420 (2000). © 2000, American Physical Society.

positive magnetoconductance. The possible mechanisms are speculated.

### 3.1.3. Interpretation and Discussion

**Coulomb Blockade in an Array of Single Junctions Located in Parallel** The $G_0$ anomaly with the linear $G_0$ vs temperature relation shown in Figure 4 can be interpreted as a result of CB from the following two viewpoints.

**From the Viewpoint of Zeller's Report of the CB [15]** Zeller et al. experimentally reported on the observation of the $G_0$ anomaly and its linear $G_0$ vs temperature relation. The system was an array of Sn nanoparticles with the surface oxide layers located in parallel (i.e., double nano-tunnel-junction array system). The linear $G_0$ vs temperature relation, which was observed at temperature below about 4 K in the Sn array with the mean radius of 15 nm, is qualitatively similar to our observation, although the quantitative discussion is difficult because the $G_0$ was presented in arbitrary units in their report. They theoretically explained the $G_0$ anomaly by the capacitance model (i.e., charging effect) of one Sn nanoparticle. It has basically the same meaning as the orthodox theory of CB. The linear $G_0$ vs temperature relation was also explained by the contribution of many particles, located in parallel, with distributed charging energy (i.e., $V_c$) as

$$G_0(T) = \int_0^\infty n(V_c) \exp(-eV_c/kT)\, dV_c \qquad (2)$$

where $n(V_c)$ is the area of all particles with activation energy $e^2/2C \pm eV_D = eV_c$. This equation can result in the linear $G_0$ vs temperature relation by assuming $n(V_c)$ as a constant and taking it out of the integral. It is, however, not relevant to directly employ Eq. (2) for explanation of our result, because Eq. (2) includes no consideration about the tunnel probability based on Fermi's golden rule and only Maxwell–Boltzmann statistics are introduced as the number of particles with $V_c$ in it.

Here, extending this model, we try to explain our linear $G_0$ vs temperature relation by using the orthodox theory of CB. Tunneling probability ($\Gamma$) for one STJ is simply given by the following equation including Fermi's golden rule, when the tunnel transition probability is assumed to be $(e^2 R_t)^{-1}$ and the influence of external environment is neglected:

$$\Gamma(V, T) = (1/e^2 R_t) \int_{-\infty}^\infty dE f(E)[1 - f(E + \delta E)]$$

$$= \frac{V - e/2C_j}{eR_t}\{1 - \exp[-(\delta E/kT)]\}^{-1} \qquad (3)$$

where $\delta E$ is the resultant energy change of system by a single electron tunneling (SET) event (i.e., $\delta E = eV - e^2/2C_j$). $C_j$ and $R_t$ are the junction capacitance and the tunnel resistance of single junction, respectively. Equation (3) can be rewritten by placing $V = 0$ and taking into account the $e^2/2C_j(= E_c) \gg kT$ as follows.

$$\Gamma(0, T) = \frac{1}{2C_j R_t} \exp[-(E_c/kT)] \qquad (4)$$

This equation gives the temperature dependence of zero-bias tunnel probability for one single junction. In this process, a thermal-exited electron occasionally causes the SET event. More detailed calculation for tunnel transition probability leads to the temperature dependence of $G_0$ in the orthodox theory. Here, the contribution of many single junctions located in parallel with the distributed $E_c$ can be introduced by integrating $E_c$ in Eq. (4) as

$$\Gamma_{\text{total}}(0, T) = \frac{1}{2C_j R_{t(\text{total})}} \int_0^\infty \exp[-(E_c/kT)] \, dE_c$$

$$= \frac{k}{2C_j R_{t(\text{total})}} T \qquad (5)$$

where $R_{t(\text{total})}$ is the total $R_t$. Equation (5) actually implies the linear $G_0$ vs temperature relation that is qualitatively consistent with our observation.

The coefficient of Eq. (5) also quantitatively agrees with the experimental result (slope value of the linear part of the inset of Fig. 4) as follows. Since we used a simple tunnel transition probability in Eq. (3), $R_t$ in Eq. (4) should be replaced by the total $R_t$ in Eq. (5). In contrast, $C_j$ should not be replaced by the total $C_j$, because the coupling among the neighboring junctions is weak in our system due to the sufficiently large junction spacing (~30 nm). Here, $R_{t(\text{total})}$ can be estimated to be on the order of $10^2\,\Omega$ from the $R_t$ of $10^6\,\Omega$ and the number of junctions of $10^4$. $C_j$ is also estimated to be on the order of $10^{-17}$ F from [10, 11]. Thus coefficient of temperature in Eq. (5) can be estimated to be on the order of $10^{-8}$. This value is in nice agreement with the slope value of the linear part(order of $10^{-8}$/1 K) in the inset of Figure 4. Therefore, one can conclude that the linear $G_0$ vs temperature relation can provide qualitatively and quantitatively strong evidence for the CB in the array of junctions located in parallel.

Although our system is a STJ array biased by voltage, this calculation is relevant, because of the presence of high $\text{Re}[Z_t(\omega)]$ with the high $R_L$ and the zero-bias tunneling probability. For more accurate discussion, both the phase correlation function ($P(E)$) and the actual distribution function of the junction parameters have to be introduced into Eq. (3).

### *From the Viewpoint of Cleland's Report* [3]    There is one large difference between our observation and Zeller's observation. The extrapolation of the linear $G_0$ vs temperature ($T$) relation to $T = 0$ K leads to no $G_0$ in Zeller's, whereas a nonvanishing $G_0$ exists even at $T = 0$ K in our case. From this viewpoint, Cleland's report is comparable with our observation. Cleland et al. reported on the $G_0$ anomaly, which strongly depends on the transmission line resistance $R_L$ and the normalized zero-bias resistance ($R_0/R_t$) vs $1/T$ relation. The relation exhibited a saturation (flattening) at the low temperatures near $T = 0$ K and a linear relation at the high temperatures. Since the $R_0/R_t$ vs $1/T$ relation can be basically replaced by the $G_0$ vs $T$ relation, both the saturation and the linear $R_0/R_t$ vs $1/T$ relation can qualitatively correspond to our observations (i.e., nonvanishing $G_0$ and linear $G_0$ vs T, respectively).

Their system was similar to ours, because the single junction was directly connected to the Ni transmission line with

2 $\mu$m wide. Since they explained the $G_0$ anomaly as CB following a theory like PC theory and successfully turned out environmental effect on CB, our results can be applied also qualitatively to CB. The saturation at the low temperatures was also explained by employing a fluctuation charge, $q$, caused by Nyquist voltage noise in the transmission line, into Eq. (4). It is consistent with our result, because there is a possibility of the presence of a Nyquist phase breaking process also in our Ni-nanowire as discussed later. The only main difference between our observation and Cleland's observation is that his result also indicates that even one single junction can exhibit the linear $G_0$ vs $T$ relation based on $q$.

When it is concluded that the $G_0$ anomaly in Figure 4a is CB from the previous discussion, our single junction system at least must satisfy the following four necessary conditions [10]: (1) $R_t \gg R_Q$, (2) $E_c \gg kT$, (3) $\text{Re}[Z_t(\omega)] \gg R_Q$, (4) half width of distributed tunnel junction parameters $<25\%$. The first and second conditions must be satisfied in any tunnel junction systems. The fourth condition, based on Mullen's calculation [10], is required only for the parallel located junction array system. The third condition is of core importance only for STJ systems. It was already confirmed in [10, 11] that our STJ system satisfied all of these conditions, except for the following one problem about parasitic capacitance ($C_{\text{par}}$). When we defined $L = \tau \times c$ (where $\tau \sim h/eV$, $c$ is the velocity of light in vacuum) as the geometry for an effective $C_{\text{par}}$ like the horizontal model, the $C_{\text{par}}$ in the $L$ was much larger than that estimated from the observed CB [10, 18]. To explain this difference, we may have to select a smaller velocity instead of $c$ in our very disordered Ni-nanowire. This problem is not yet clarified even in this work.

Here, the third condition is the key factor for this work. Measurement of the resistance ($R_{\text{Ni}}$) of one Ni-wire by scanning tunneling microscopy revealed that the $R_{\text{Ni}}$ was near 120 K$\Omega$ which was larger than $R_Q$. The Ni-wire is also directly connected to the single junction. Therefore, one can interpret that the Ni-wire automatically plays the roles of high $\text{Re}[Z_t(\omega)]$ and $R_L$ in our system. The $R_{\text{Ni}}$ of 120 K$\Omega$ is, however, three orders higher than that of bulk Ni. It is discussed in the next section that the origin for this anomalously high $R_{\text{Ni}}$ is in the mutual Coulomb interaction caused by disorder.

### *Mutual Coulomb Interaction in Disordered Ni-Nanowire at High Voltages*    The linear $G$ vs $V^{1/2}$ relation at the voltages above $V_{1D}$ in Figure 4 quantitatively indicated the presence of 3D MCI, in the disordered Ni-nanowire, following Altshuler's formula [10, 14]. In contrast, the temperature dependence in the first high voltage region ($V_{CB} < V < V_{1D}$) of Figure 5 was successfully fit by Eq. (1) in the entire temperature region. It qualitatively implies the presence of a 1D MCI following Altshuler's theory. One can confirm its relevance by comparing the thermal diffusion length $l_T$ with the localization length $\xi_{\text{loc}}$. They can be estimated as follows, by using $D$, which gives the best fit to the linear slope of the high voltages of Figure 5, and the $R_{\text{Ni}}$ of 120 K$\Omega$ for conductivity $\sigma$, respectively:

$$lT = [\hbar D/kT]^{1/2} \sim 10^{-8} \qquad (6)$$

$$\xi_{\text{loc}} = (2\hbar/e^2) A\sigma \sim 10^{-7} \qquad (7)$$

Since $\xi_{loc}$ is actually one order larger than $l_T$, it is reconfirmed that the Ni-wire is in the weak localization regime.

In addition, since this $l_T$ is larger than $\phi$ and smaller than wire length, it quantitatively supports the presence of one dimension of the MCI. Thus, it is concluded that the 1D MCI is the dominant conductance mechanism in the high voltage region and that $V_{1D}$ is the transition voltage from the 3D to the 1D MCI regimes in a decrease of voltage. Since $l_T$ becomes larger than $\phi$ at $V_{1D}$ with decreasing voltage in this transition, the MCI loses the two dimensions at $V_{1D}$ at the same time, because the cross section of Ni-wire has the two dimensions. It results in the direct transition from the 3D to 1D MCI regimes, which is consistent with our observation of the absence of the 2D MCI regime. Since this 1D MCI can lead to impedance higher than that of the 3D MCI because of the stronger scattering rate, it can play the roles of the high $\mathrm{Re}[Z_t(\omega)]$ and $R_L$ for the CB. However, note that any CB related characteristics are not observed in the voltage region higher than $V_{CB}$ in spite of this high impedance EME. The reason is discussed.

Why $l_T$ increases with decreasing voltage can be qualitatively interpreted as follows. In the formula of $l_T$, only diffusion constant $D$ has a voltage dependence because of the equation

$$D = vF^2\tau_{e-e}/d \qquad (8)$$

where $v_F$, $\tau_{e-e}$, and $d$ are the Fermi velocity, the relaxation (collision) time for electron–electron scattering, and the sample dimension, respectively [14]. Although $v_F^2$ decreases with decreasing voltage, $\tau_{e-e}$ can increase by decreasing the electron–electron scattering rate (i.e., $1/\tau_{e-e}$). If the increase of $\tau_{e-e}$ quantitatively exceeds the decrease of $v_F^2$, $D$ can increase with decreasing voltage.

***CB and 1D MCI Temperature Regimes Distinguished at $T_c$ at Low Voltages***    In the low voltage region, $T_c$ classified the temperature dependence into two regions. At low temperatures ($T<T_c$), conductance ($G$) vs temperature features show a mostly linear relation. In particular, it can be well represented by the linear $G_0$ vs temperature regime (below 4 K) shown in the inset of Figure 4. This is the straightforward indication that the temperature region below $T_c$ is the CB temperature regime. This CB temperature regime emerges only at voltages below $V_{CB}$ at $T = 1.5$ K. In this sense, $V_{CB}$ can be the transition voltage from the 1D MCI to the CB voltage regimes. In contrast, the linearity at the high temperatures ($T>T_c$) indicates the possible presence of Altshuler's 1D MCI as well as that of the high voltage region mentioned in the previous section.

There is, however, one large difference that the slope value, $\alpha$, of the linear part drastically increases with reducing voltage, as shown in Figure 6a. If one possibly assumes that this relation is mostly linear except for the saturation around 0 V as shown by the dotted line in Figure 6a, the increase of $\alpha$ can be also qualitatively interpreted by Altshuler's formula for the voltage dependence of $\tau_{e-e}$ (i.e., linear $\tau_{e-e}^{-1/2}$ vs $V^{1/2}$) in the 1D MCI as follows [14]. From Eq. (1) and the discussion in the previous section, $\alpha$ can have the following relation with $D^{1/2}$ and $\tau_{e-e}$:

$$\alpha \propto D^{1/2} \propto \tau_{e-e}^{1/2} \qquad (9)$$

Thus, if the linear $\alpha^{-1}$ vs $V^{1/2}$ relation is assumed, one can attain the following relation:

$$\alpha^{-1} \propto \tau_{e-e}^{-1/2} \propto V^{1/2} \qquad (10)$$

This qualitatively agrees with the linear $\tau_{e-e}^{-1/2}$ vs $V^{1/2}$ relation proposed by Altshuler as mentioned. This relation implies that the scattering rate of MCI (i.e., $\tau_{e-e}^{-1}$) decreases in a decrease of the applied voltage in 1D disorder systems. The reason for the saturation around 0 V, however, is not revealed here. It indicates that $\tau_{e-e}^{-1}$ does not become zero even at $V = 0$. There may exist other interesting mechanisms (e.g., influence of thermal diffusion at finite temperature). In the case, the linearity cannot be assumed and hence novel explanations for this increase of $\alpha$ will have to be introduced. We conclude that the high temperature regime ($T>T_c$) is also the 1D MCI regime as well as that in the first voltage region ($V>V_{CB}$), based on only the presence of the linear $\delta R/R_n$ vs $T^{-1/2}$ relation and the assumption of linearity in Figure 6a.

Consequently, one can conclude that $T_c$ is the phase transition temperature from the 1D MCI to the CB temperature regimes in a decrease of temperature. This means that the $G_0$ anomalies, which are observed at the temperatures above 7 K ($>T_c$) in Figure 4, are simply due to the MCI following Altshuler's theory. In contrast, that at $T = 1.5$ K ($<T_c$) originates from the CB. It is consistent that $V_{CB}$ is distinct only at $T = 1.5$ K in the $G$ vs $V^{1/2}$ curves in Figure 3, because even the largest $T_c$ is 3.2 K as shown in Figure 6b. However, note that the 1D MCI in the Ni-wire never disappears even in this CB temperature regime ($T<T_c$). It plays the key role to yield the CB as the high $\mathrm{Re}[Z_t(\omega)]$ and $R_L$ in the CB temperature regime. As mentioned in the next section, it is supported by the fact that this CB temperature regime is very sensitive to the diffusion constant ($D$) of the MCI. Here, MCI is basically an elastic process. Since, however, the origin of this MCI is the electron–phonon scattering by disordered potential, the tunneling electron may at least transfer the $E_c$ to there, although it is small energy transfer.

***Correlation of CB with 1D MCI in Ni-Wire***    For the correlation between CB and 1D MCI in the Ni-wire, we can find an interesting feature. $T_c$ shifts to the lower temperature region in an increase of $\alpha$ (i.e., $D$) by decreasing voltage as shown in Figure 5. The $T_c$ vs $D^{1/2}$ exhibits a mostly linear relation as shown in Figure 6b. Since $D$ is assumed to be proportional to $\tau_{e-e}$ as shown in Eq. (9), this linearity indicates that $T_c$ strongly depends on $\tau_{e-e}$ in the Ni-wire. Although there may be some interpretations for this linear $T_c$ vs $D^{1/2}$ relation, we propose one possible explanation as follows. All MCI processes yield some kinds of fluctuations. In particular, Altshuler et al. pointed out that multiple quasielastic MCI processes dominate the phase breaking process in 1D and 2D disordered conductors in the absence of other phase breaking mechanisms, the so-called Nyquist phase breaking [17]. According to [17], an energy quantum ($E_N$) of fluctuating field can be given by

$$E_N = h\omega_N \sim h[T/D^{1/2}N(E)]^{2/3} \qquad (11)$$

Where $h$, $\omega_N$, and $N(E)$ are the Planck constant, the frequency of the fluctuating field, and the density of states in a 1D conductor, respectively. Since $V_{CB}$ is in the 1D MCI voltage regime, Eq. (11) can be applied for this discussion. If the charging energy ($E_c$) of CB is smaller than the $E_N$, the CB will be smeared out by the fluctuation even if the temperature satisfies the thermal condition (i.e., $E_C \gg kT$). Hence, when $E_N$ is equal to $E_C$, Eq. (12) is given from Eq. (11):

$$T_c \sim [(E_c/h)^{3/2} N(E)^{-1}] D^{1/2} \qquad (12)$$

When it is assumed that both $E_c$ and $N(E)$ are basically constants, this equation immediately indicates the linear $T_c$ vs $D^{1/2}$ relation. Here, $E_c$ is actually a constant for the same one sample. In contrast, since $N(E)$ in a 1D conductor is generally proportional to the inverse of $E$ and applied voltage, it is not constant. $N(E)$ here, however, can be almost a constant, because this voltage region (i.e., $V < V_{CB}$) is around 0 V. In Figure 6b, the extrapolation to $D^{1/2} = 0$ leads to $T_c = 2.3$ K. This means that the CB temperature regime survives up to 2.3 K, even if the Ni-nanowire is in the strong localization regime.

This explanation implies that the $E_c$ and the $E_N$ compete at the $T_c$, which is characterized by diffusion constant $D$ depending on the $\tau_{e-e}^{-1}$ as shown in Eqs. (9) and (12). As applied voltage is decreased, $D$ becomes larger, because of the decrease of $\tau_{e-e}^{-1}$. It can reduce $E_N$ in Eq. (11). As a result, since $E_c$ exceeds $E_N$, $T_c$ increases in Eq. (12). In the other words, the CB temperature regime can be smeared out by the fluctuation energy quantum $E_N$ of the Nyquist phase breaking process in the EME. Of course, since CB requires essentially no phase coherence, the phase breaking process itself does not directly affect the CB except for the case of spin coherence. This result, however, indicates that the field fluctuation caused by phase breaking in the EME can affect the CB in single junction systems. Here, as discussed, our observation qualitatively agreed with Cleland's observation [3, 10, 18], which was explained by introducing the fluctuation charge, $q$, caused by a Nyquist voltage noise in the external transmission line [3]. This is consistent with the presence of a Nyquist phase breaking process in the Ni-nanowire in our system.

This discussion is also consistent with PC theory [2]. One can simply replace the excitation energy of an environmental mode ($h\omega_S$) in PC theory to the fluctuation energy quantum $h\omega_N$ and compare with $E_C$. In this sense, the tunneling electron can transfer its $E_c$ by exciting $h\omega_N$ in our system. Here, this MCI in the Ni-wire also plays the role of high $R_L$ to avoid the external environmental fluctuation in our system, leading to CB. However, when too large $E_N$ caused by the high $\tau_{e-e}^{-1}$ exists in our Ni-wire, it can excite too large $h\omega_N (h\omega_S)$. In such a case, the Ni-wire can no longer act as a high $R_L$, because the Ni-wire becomes only a large Nyquist noise source. This is also consistent with PC theory, because if $E_C$ is much smaller than the excited energy of environmental mode $h\omega_S$, phase correlation function ($J(t)$) and phase fluctuation $\Delta\varphi$ of the external environment become zero and the charge fluctuation $\Delta Q$ on junction surface diverges through the commutation relation $[\Delta\varphi, \Delta Q] = ie$ in PC theory. It easily smears out CB voltage. Here, since the high $\tau_{e-e}^{-1}$ (i.e., decrease of $\alpha$) is caused by the increasing of

voltage in Figure 4 and 5, it is suggested that the smearing out of the CB temperature regime in $V > V_{CB}$ is due to this too large $\tau_{e-e}^{-1}$ at 1.5 K in Figure 4. This explanation implies the necessity of the optimized $\tau_{e-e}^{-1}$, when the MCI is the origin of the high $R_L$ for the CB in single junction systems.

***Wire Diameter Dependence of $T_c$***   In order to reconfirm this discussion, quantitative comparison of the slope of the value of Figure 6b with the coefficient of Eq. (12) is required. However, since the coefficient has not been exactly fixed in any past works, it will be difficult at this stage. As one of the other works, dependence of $T_c$ on diameter ($\phi$) of Ni-nanowire was measured. In the previous section, decrease of the applied voltage made the diffusion constant $D$ varied. In contrast, since $D$ also strongly depends on $\phi$, it is expected that different $\phi$ also makes $T_c$ shifts. The result exhibited a mostly linear $T_c$ vs $\phi$ relation as shown in the inset of Figure 7. Here, $D$ has the following relation with the electron density, $n$, and the cross-sectional area of Ni-wire $A$:

$$D \propto 1/n \propto A = \pi(\phi/2)^2 \qquad (13)$$

Thus, $T_c$ can have the following relation with $D$, when the linear $T_c$ vs $\phi$ relation actually exists:

$$T_c \propto \phi = 2(A/\pi)^{1/2} \propto D^{1/2} \qquad (14)$$

Therefore, the linear $T_c$ vs $\phi$ relation in Figure 7 qualitatively supports the presence of the linear $T_c$ vs $D^{1/2}$ relation. In Figure 7, the extrapolation to $T_c = 2$ K results in $\phi$ of about 5 nm. It may mean that around the $\phi$, the Ni-nanowire may enter a strong localization regime as discussed.

The $G_0$ vs $T$ relations in Figure 7 have the following two slight differences from that in the inset of Figure 4a. (1) $G_0$ saturates around $T = 1.5$ K with a value of about $10^{-8}$ S. (2) The data fittings by Eq. (1) at temperature above $T_c$ become rougher, although they are still fit with the different slopes. Although these may originate from large wire diameters, the origins are not clear here.

***Magnetic Field Dependence of $G_0$ versus Temperature Relation and $I$–$V$ Curves***   The magnetic field ($B$) dependence of $G_0$ vs temperature ($T$) relation is drastically varied around $T_c$ as shown in Figure 8a. This result obviously supports the actual presence of a $T_c$ with a physical meaning, although $T_c$ was not distinct in the inset of Figures 4a and 5. It also implies the presence of quite different $G_0$ mechanisms between the temperature regions below and above $T_c$. In fact, the symmetry of the $I$–$V$ curves on the $B$ applied was quite different between the two temperature regions as shown in Figure 8b.

Here, applying a positive voltage corresponds to the injection of an electron from the Al substrate side, whereas a negative voltage corresponds to the injection from the Ni-wire side. The origin of Figure 8b may be speculated based on it as follows, although it is not the aim of this work.

The change of the $I$–$V$ curve by the applied $B$ is quite asymmetric in the CB temperature regime [$T = 1.5$ K($< T_c$)]. The most asymmetric part in our structure is the single tunnel barrier layer that exists between the one end of the Ni-nanowire and the Al substrate. When CB is the dominant

mechanism for electron transport in the system, the change in the $I$–$V$ curve with the $B$ will easily reflect this asymmetry from the following speculation. There may exist three effects related to the applied $B$ in the Al/Al$_2$O$_3$/Ni-wire (i.e., in Al and Ni) system: (1) differences in spin flip scattering, (2) different Zeeman energies (spin magnetic moments), (3) difference in spin–orbit interaction. In the first case, the electrons in the $d$ orbit of the Ni-nanowire are strongly spin-polarized by the applied $B$, whereas there is no spin polarization in the Al substrate. Thus, only when the electrons tunnel through from the Al to the Ni-wire is a large spin flip scattering caused at the entrance of the Ni-wire. Consequently, CB is enhanced in this process, because an electron has to get a larger energy to overcome the spin-flip scattering in addition to the $E_c$. In contrast, when the electrons tunnel into the Al, there is basically no influence of the spin polarization. Thus, the $I$–$V$ curve is mostly independent of $B$. These may lead to the asymmetric $I$–$V$ on the applied $B$.

Also, in the second case, when electrons tunnel into the Ni-wire, an additional energy for electrons is required in addition to $E_c$, because of Zeeman energy in the Ni. In contrast, this means that electrons can tunnel into the Al with smaller energies, because of the Zeeman energy of Ni. Therefore $I$–$V$ curves should strongly depend on the $B$ in all the voltage regions in this process. Hence, this case does not seem to explain the $B$ independent feature in the negative voltage region in Figure 8b. The third case may be less possible because Ni has a very small spin–orbit interaction.

On the other hand, the change of $I$–$V$ curve with applied $B$ is quite symmetric in the 1D MCI regime [$T = 15$ K($> T_c$)]. When CB has vanished at this high temperature region, the tunnel barrier becomes a simple tunneling resistance. Thus, the electron transport is dominated by the Ni-nanowire, which has the symmetric structure. It is consistent with the symmetric $I$–$V$ change on the applied $B$. As a typical example, positive magnetoconductances (MC) have been observed in weak localization as a result of phase interference effect of electron waves [e.g., $G = \log(B)$ in 2D weak localization]. Our case, however, may not correspond to it, because Altshuler's formula for MCI, which exists in our Ni-wire, took into account only charge of electrons for quantum correction. In addition, the $B$ dependence of the 1D MCI is not clearly reported, especially in ferromagnetic nanowires. Thus, it is difficult to identify the origin of positive MC and also its correlation with $T_c$ from this $B$ dependence.

Anyway, in order to reveal the mechanisms for magnetoconductance, detailed measurements are indispensable taking into account ferromagnetic nanowire.

### 3.1.4. Conclusion

Coulomb blockade depending on the one-dimensional mutual Coulomb interaction in the external electromagnetic environment was reported for the first time in an array of disordered Ni-nanowire/Al$_2$O$_3$/Al located in parallel, fabricated using nanoporous alumina film. Observed $G_0$ anomaly and its linear $G_0$ vs temperature relation qualitatively agreed with Zeller and Cleland's reports of CB. It was also quantitatively concluded from the extended Zeller's model in the tunnel junction array. At $V > V_{CB}$, only the 1D MCI following Altshuler's formula in the disordered Ni-wire governs the conductance mechanism. In contrast, at $V < V_{CB}$,

CB emerged accompanied with 1D MCI also following Altshuler's formula. The 1D MCI in the Ni-wire played the key roles of high Re[$Z_t(\omega)$] and $R_L$ in phase correlation theory for our CB in the single junction system. It was supported by the fact that CB was very sensitive to the diffusion constant $D$ of the MCI, yielding the linear $T_c$ vs $D^{1/2}$ relation. This relation was interpreted as a result of the correlation between the charging energy $E_c$ of CB and the energy quantum $E_N$ of the fluctuating field in the Ni-wire. Tunneling electrons could transfer $E_c$ to the EME by exciting this energy quantum $E_N$ ($= h\omega_N$), although it was a small energy transfer. It is consistent with PC theory. In contrast, MCI also acted as a high $R_L$. Too large a mutual Coulomb scattering rate, however, yielded large $E_N$, smearing the CB by the commutation relation [$\Delta\varphi, \Delta Q$] $= ie$. This linear $T_c$ vs $D^{1/2}$ relation was reconfirmed by the linear wire diameter dependence of $T_c$. The presence of $T_c$ and different conductance mechanisms classified at $T_c$ was also obviously reconfirmed by the magnetic field dependence of the $G_0$ vs temperature relation.

This work reported on the correlation of CB with the 1D MCI in the external environment in a single junction system. In contrast, when phase coherence of electron waves is conserved in disordered materials, a variety of mesoscopic phenomena emerges (e.g., AB effect, UCF, weak localization). They will bring us novel mesoscopic phenomena associated with single electron tunneling. We will report it in the very near future by utilizing our porous alumina film (e.g., by depositing multiwalled carbon nanotubes into the nanopores).

## 3.2. Correlation with Weak Localization in Carbon Nanotubes

### 3.2.1. Introduction

We report on correlation of Coulomb blockade in a single tunnel junction with phase interference effects of electron waves in its external electromagnetic environment, by utilizing multiwalled carbon nanotubes. Experimental results and analysis suggest that a high impedance external environment caused by weak localization in the MWNT can yield Coulomb blockade, in accordance with phase correlation theory. It is also revealed that the Coulomb blockade is very sensitive to phase modulation in the MWNT, which acts as a high impedance transmission line.

Coulomb blockade, a typical phenomenon associated with single electron tunneling, has been successfully observed in a variety of systems. Recently, the correlation with phase of electron waves and spins that exist in the EME has attracted much attention, because Coulomb blockade is very sensitive to EME. Most such studies have been performed in multijunction systems. For instance, Coulomb blockade was not observed to destroy the phase coherence of electron waves in quantum dots inserted to an Aharonov–Borm ring and did not require phase coherence with the EME [19], whereas it was drastically affected by the spin coherence of the electrons, according to many body effects in quantum dots (i.e., artificial atoms connected to lead) [20]. On the other hand, no work has reported it in single junction systems. It is because correlation between Coulomb blockade

and its external environment in single junction systems has characteristics quite different from those in multijunctions, although it is much more sensitive to the external environment. It has been well known as phase correlation theory [21, 22].

Phase correlation theory implies that the external electromagnetic environment plays the following two key roles. (1) The tunneling electron transfers a charging energy ($E_c$) to the external environment, yielding Coulomb blockade. (2) Fluctuation of the external environment fluctuate the junction surface charge by coupling with the zero-point oscillation, smearing out Coulomb blockade. To realize the first role and avoid the second role, the real part of the total impedance of the external environment ($\mathrm{Re}[Z_t(\omega)]$) must be much larger than resistance quantum ($R_Q = h/e^2 \sim 25.8$ k$\Omega$). This is the key factor in phase correlation theory. A part of $Z_t(\omega)$ also must be closely located to a single junction to avoid the second role as a high impedance transmission line $R_L$ ($\gg R_Q$). Since the connection of this high $R_L$ automatically results in a high $Z_t(\omega)$, the first role can occur also in the $R_L$ region.

Phase correlation theory has been experimentally confirmed [23]. Some works also reported good agreement with the current vs voltage [or conductance ($G$) vs voltage] feature observed in the weak tunneling case [24], and recently even in the strong tunneling case [25, 26].

Here, we focus on the correlation of Coulomb blockade in a single junction with the phase coherence of electron waves in its external environment, based on phase correlation theory. We ask the question, "Can weak localization play two such roles in a single junction system, yielding Coulomb blockade?" It corresponds to the question, "How different are the impedance mechanisms between phase correlation theory and weak localization theory?" The total external environment impedance $Z_t(\omega)$ employed by phase correlation theory is interpreted as a delay of surface electron charge decay in the external environment, because it is described by a set of harmonic oscillators (i.e., a set of $LC$ circuits in a circuit model) with energy quantum $\hbar\omega$ and originates from the commutation relation between phase $\varphi$ of tunneling electron and junction surface charge $Q$ (i.e., $[\varphi, Q] = ie$). Energy transfer is performed by exciting this $LC$ mode in a circuit model and hence it should correspond to electron-charge related phenomena in realistic systems (e.g., electron–phonon scattering). Here, electron–phonon scattering decreases as temperature lowers and phase interference effects of electron waves, which are represented by weak localization, can also yield high impedance ($>R_Q$) at such low temperature [27].

However, since the impedance caused by weak localization is quite different from $Z_t(\omega)$ for the following two points. (1) Since it is a result of phase interference of electron waves in the diffusive regime, electron charge is not basically related. (2) Since it is an elastic process, any energy transfer cannot occur. Therefore, if one follows phase correlation theory (at least from the viewpoint of the role of energy transfer), no Coulomb blockade may be observed under a high impedance external environment caused by weak localization. We try to examine this hypothesis by directly connecting multiwalled carbons (MWNTs) with weak localization to single tunnel junctions by utilizing a nanoporous alumina film

template. Although Coulomb oscillation has been already reported in single-walled carbon nanotube systems with multitunnel junctions [28], it should be noticed that this work has a quite different meaning from those.

### 3.2.2. Experiments and Discussion

We measured averaged static electric characteristics of the sample shown in Figure 9a. Figure 10a clearly exhibits a zero-bias $G$ ($G_0$) anomaly.

The shape of the $G_0$ anomaly is drastically varied near $T = 5$ K and the shape at 2 K is quite different from the inset shown as a reference [29]. It is evidence that the nanomaterials connected to single-tunnel junctions strongly

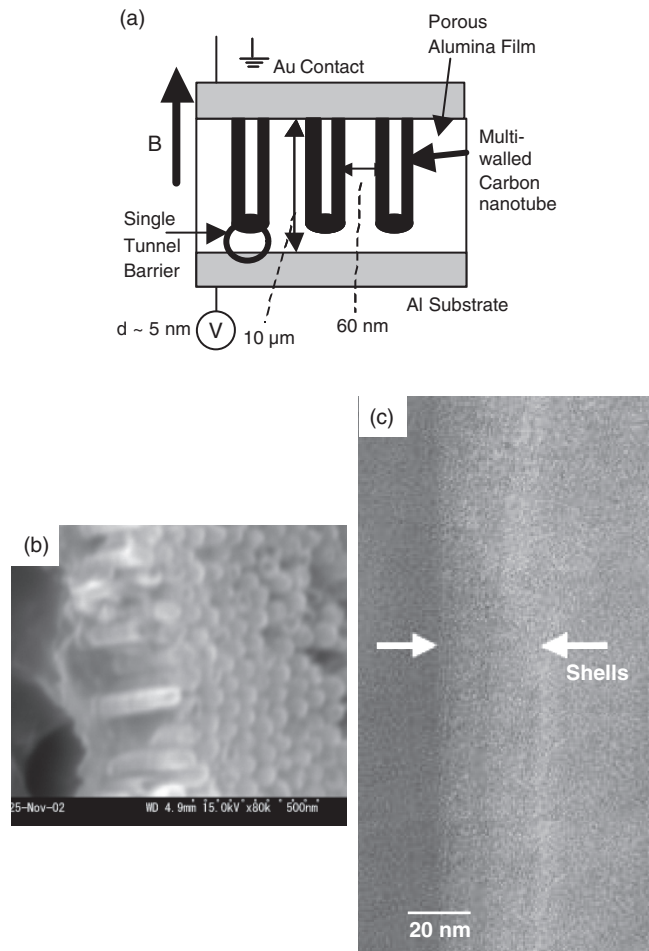

**Figure 9.** (a) Schematic cross-section of the sample, an array of single-tunnel junctions connected to multiwalled carbon nanotubes (i.e., array of Al/Al$_2$O$_3$/MWNTs). Nanoporous alumina film easily allows us to realize this structure, because single tunnel junctions are automatically formed at the bottom part of each nanopore filled by MWNTs. The absence of a tunnel barrier at the Au/MWNT interface was actually confirmed by high resolution cross-sectional TEM imaging and X-ray analysis. It is the key for this work. (b) SEM image of the exposed MWNT array, after the Al$_2$O$_3$ layer was etched out. (c) High resolution cross-sectional TEM image of one-side shells of MWNT with about 26 shells and the mean radius of 17.5 nm. Reprinted with permission from [40], J. Haruyama et al., *Phys. Rev. B* 63, 073406 (2001). © 2001, American Physical Society.
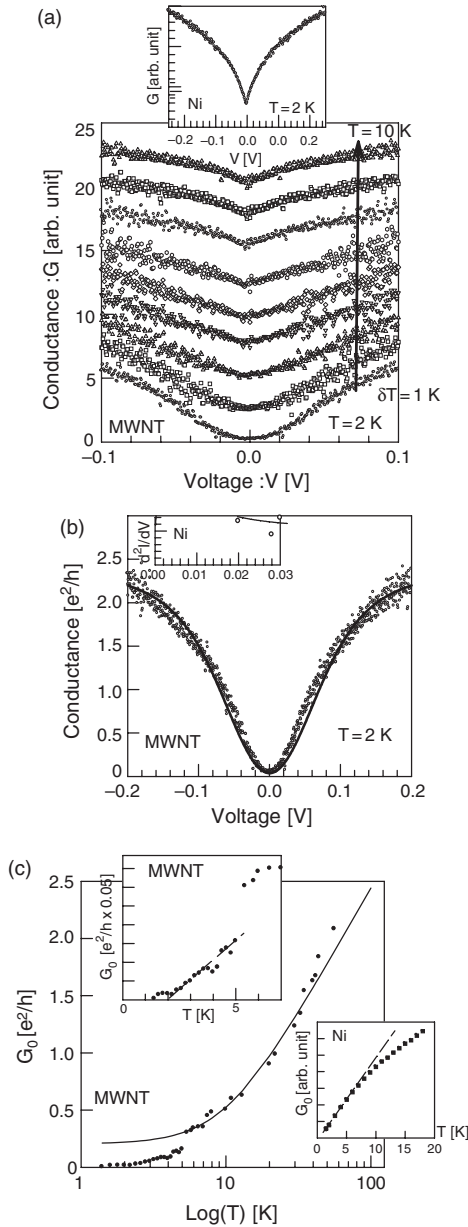

**Figure 10.** (a) Al/Al$_2$O$_3$/MWNT array. Temperature dependence of a typical conductance ($G = dI/dV$) vs voltage ($V$) curve, exhibiting a zero-bias $G$ ($G_0$) anomaly. The shape of the $G_0$ anomaly is drastically varied near $T = 5$ K. Inset: Al/Al$_2$O$_3$/Ni-nanowires array: $G$ vs $V$ curve, exhibiting a different shape of $G_0$ anomaly[29]. The sample was fabricated by depositing nickel into the nanopores of the alumina film with exactly the same nanostructure parameters as in Figure 1a. (b) MWNT system. Data fitting to $G$ vs. $V$ curve of Figure 2a by phase correlation theory. The solid line is the result calculated from Eqs. (1)–(3). The data and calculation results are in nice agreement, implying that the MWNT acts as the high external environment impedance for this Coulomb blockade. (c) MWNT system. Temperature ($T$) dependence of $G_0$ shown in Figure 2a. The solid line is the result calculated by the two-dimensional weak localization formula of MWNT. Upper inset: Linear $G_0$ vs temperature relation at temperatures below 5 K in (c), indicating evidence of Coulomb blockade in an array system[29]. Lower inset: Ni-nanowire system. Temperature dependence of $G_0$, indicating a linear $G_0$ vs temperature relation at low temperatures. Reprinted with permission from [40], J. Haruyama et al., *Phys. Rev. B* 63, 073406 (2001). © 2001, American Physical Society.

contribute to the $G_0$ anomaly. The $G_0$ anomaly in Figure 10a can be well fit by phase correlation theory as shown in Figure 10b and as explained in the next paragraph, whereas that in the inset of Figure 10a cannot be directly fit by phase correlation theory. Its first derivative (i.e., $dG/dV$ vs $V$ curve) is fit by Nazarov's theory introducing a mutual Coulomb interaction to the external environment of Coulomb blockade [30] as shown in the inset of Figure 10b. This large difference is also evidence that Coulomb blockade in the single junction system can be much influenced by mesoscopic phenomena in the nanowires directly connected.

Figure 10c is distinguished by the following three temperature regions; (1) above 10 K: $G_0$ vs $\log(T)$ relation is linear; (2) 5 k–10k: its saturation region; (3) below 5 K: $G_0$ vs temperature relation is linear (see the upper inset). This linear $G_0$ vs temperature relation is also observable in the lower inset. We have argued that it provides strong qualitative and quantitative evidence of Coulomb blockade in an array of single junctions located in parallel (i.e., as a temperature dependence of averaged $G_0$) [29]. The temperature of 5 K also agrees with that at which the shape of the $G_0$ anomaly starts to change in Figure 10a, suggesting that the $G_0$ anomaly below 5 K originates from Coulomb blockade.

In order to confirm Coulomb blockade in an Al/Al$_2$O$_3$/MWNTs array and clarify its connection with phase correlation theory, we first numerically calculate a $G$ vs $V$ curve, normalized by tunneling resistance ($R_t$) and the number of junctions, using Eqs. (1)–(3) from phase correlation theory [21, 22]. We then fit the $G$ vs $V$ curve measured at 2 K in the Coulomb blockade regime in Figure 10a by the calculation result. Since we know the $R_t$ of 300 k Ω (larger than $R_Q$) from the measurement, the fitting parameters are the resistance of the external transmission line ($R_L$) and junction capacitance ($C$) as $\omega_{RC} = 1/(R_L C)$.

$$I(V) = \frac{1 - e^{-\beta eV}}{eR_t} \int_{-\infty}^{+\infty} dE \frac{E}{1 - e^{-\beta E}} P(eV - E) \quad (15)$$

$$P(E) = \frac{1}{2\pi\hbar} \int_{-\infty}^{\infty} dt\, e^{J(t) + i\frac{E}{\hbar}t} \quad (16)$$

$$J(t) = 2 \int_{-\infty}^{\infty} \frac{d\omega}{\omega} \frac{\mathrm{Re}[Z_t(\omega)]}{R_Q} \frac{e^{-i\omega t}}{1 - e^{-\beta\hbar\omega}} \quad (17)$$

where $\beta$ is the $1/kT$ and $Z_t(\omega) = 1/[i\omega C + Z(\omega)^{-1}]$ is the total EME impedance consisting of junction capacitance $C$ in parallel with an external environment impedance $Z(\omega)$ in a circuit model. $J(t)$, $P(E)$, and $I(V)$ are phase correlation function, Fourier transform of $J(t)$, and the tunnel current, respectively.

These three equations well represent the argument of phase correlation theory mentioned in the Introduction. Phase fluctuation of the junction surface charges caused by the tunneling electrons and its time evolution result in Eq. (17) through the commutation relation between charge and phase. Tunneling current (probability) is obtained from Eq. (15) by purterbatively treating the tunneling Hamiltonian using Fermi's golden rule and $P(E)$, which is interpreted as a probability density for the tunneling electrons to transfer $E_c$ by exciting the external environment mode described by $J(t)$. If $\mathrm{Re}[Z_t(\omega)]/R_Q$ is much smaller than one in Eq. (17), $P(E)$ becomes delta function $\delta(E)$ and

thus Coulomb blockade disappears in Eq. (15). In addition, phase fluctuation $\varphi$ can be also neglected and thus charge fluctuation $Q$ on the junction surface diverges due to the commutation relation $[\varphi, Q] = ie$, smearing the Coulomb blockade voltage $e/2C$.

As shown by the solid line in Figure 10b, the measurement and calculation results are in excellent agreement in our weak tunneling case (i.e., $R_t$ of 300 k$\Omega > R_Q$). The best fitting gives the $R_L$ of 450 k$\Omega$ and the Re$[Z_t(\omega)]$ with mostly the same order value as $R_L$. This impedance of 450 k$\Omega$ mainly corresponds to the impedance of MWNT ($R_{NT}$) in our system, because the MWNT was directly connected to the single junction and the resistance of the gold contact layer including the gold/MWNT interface was at most on the order of 100 $\Omega$. We cannot find the impedance of 450 k$\Omega$ in any parts of the system other than the MWNT. The value of 450 k$\Omega$ as the resistance of MWNT is also in good agreement with that in a previous report [31]. In addition, note that this 450 k$\Omega$ is actually larger than $R_Q$. Therefore, we conclude that our Coulomb blockade is consistent with phase correlation theory, and that the MWNT acts as both a high $Z_t(\omega)$ for transferring charging energy and a high $R_L$ for avoiding external environment fluctuation, because the MWNT is closely connected to the single junction.

The origin of this high impedance of carbon nanotubes is the key point for this work. As we expected, it can be qualitatively understood as a result of weak localization from the curve fitting shown in Figure 10c. As shown by the solid line, the $G_0$ vs temperature characteristic is in nice agreement with the formula of 2D WL of MWNT [28], except for the Coulomb blockade temperature region,

$$G(T) = G(0) + \frac{e^2}{2\pi^2\hbar} \frac{n\pi d}{L} \ln\left[1 + \left(\frac{T}{T_c(B, \tau_s)}\right)^p\right] \quad (18)$$

where $n$, $d$, $L$, and $\tau_s$ are the number of shells, the diameter of the inner shell of the MWNT, the length of the MWNT, and the relaxation time of spin-flip scattering, respectively. The contribution of number of MWNTs and $R_t$ were taken into account by the term of $G(0)$. The best fitting gives $n = 18$, $p = 2.1$, and $T_c = 10$ K. Here, a main difference from the past reports [31] is the $T_c$ as high as 10 K. This high $T_c$ is understandable by the presence of magnetic impurities (cobalt), which was deposited into the nanopores as a reactant for carbon nanotube growth, in the MWNT with a very small volume [29]. In addition, the localization length $\xi_{loc}$ can be estimated to be on the order of 1 $\mu$m ($<$ the MWNT length of 10 $\mu$m) from the carbon nanotube impedance of 450 k $\Omega$. It also supports that our MWNT is in the weak localization regime.

Based on these confirmations [i.e., (1) Coulomb blockade following phase correlation theory with near 450 k$\Omega$ of the external impedance, (2) the impedance of 450 k$\Omega$ existing only in the MWNT in our system, (3) the origin of the highly resistive MWNT being weak localization], we finally conclude that the weak localization in the multiwalled carbon nanotube plays the roles of both high $Z_t(\omega)$ and high $R_L$ for the Coulomb blockade. This conclusion is controversial to our hypothesis mentioned in the Introduction. The reason may be interpreted as follows at this stage. Of course, even apart from this interpretation, observed facts and analyses strongly support our conclusion.

Unless the tunneling electrons cannot transfer their energy to the environment, a tunneling event is allowed and, hence, Coulomb blockade cannot be caused in any case, if one follows PC theory [i.e., Eqs. (4)–(6)]. This is of core importance also for MQC (MQT) following the spirit of Caldeira and Leggett. MQT is much smeared by energy dissipation in its external environment. There may exist, however, the following two exceptions [30]; (1) the Debye–Waller factor exp$(-\rho)$ in Mössbauer effect in $LC$ mode and (2) infrared divergence in $RC$ mode at finite temperature.

The latter comes from the analogy between the motion of free Brownian particle and the $RC$ environmental effect with the impedance $Z_t(\omega) = R$ and is relevant for the $RC$ environment with the impedance much larger than $R_Q$. With $Z_t(\omega) = R$, Re$[Z_t(\omega)]$ is given by $R/(1 + (\omega RC)^2)$ and then $(\pi/C)\delta(\omega)$ for very large $R$ at finite temperature. Hence, energy transfer is carried out only around $\omega = 0$ in accordance with $P(E) = \delta(E - E_c)$. This is the so-called infrared divergence. In this case, only thermal fluctuation yields a time evolution of phase $J(t)$ (i.e., diffuse the free Brownian particles), leading to $J(t) \propto t$ for long time, because the $RC$ mode at very low frequency has basically no time-fluctuated electromagnetic factor. Therefore, the tunneling electrons can have a chance to transfer the charging energy $E_c$ by exciting the $RC$ mode through thermal fluctuation even in the nondissipative electromagnetic environment, particularly in the environment sensitive to electron phase fluctuations like localization. This new interpretation means a possibility that thermal environment is taken into account as $P(E)$ in Eq. (4), if it is coupled with the electromagnetic environment. Our result may be qualitatively interpreted by this case at least from the following three points, (1) Re$[Z_t(\omega)]$ of about 450 k$\Omega$ is much larger than $R_Q$, (2) Resistance of MWNT is basically frequency independent. (3) The measurement temperature is 2 K.

Otherwise, $P(E)$ in Eqs. (4) and (5) may have to be reinterpreted as "*the other probability*," not associated with the energy transfer probability of the tunneling electrons to the EME. Here, $P(E)$ is the Fourier transform of $J(T) = \langle[\tilde{\varphi}(t) - \tilde{\varphi}(0)]\tilde{\varphi}(t)\rangle$, a time evolution of phase fluctuation $\tilde{\varphi}$ in the EME, and the origin of the phase was defined as $\varphi(t) = e/\hbar \int dt V(t)$, where $V(t) = Q(t)/C_j$ is the voltage across the tunnel junction. The phase interference effect in localization also originates from this definition. Hence, $J(t)$ is a time evolution of $\tilde{\varphi}$ but should be attached to the localization effect so as not to destroy phase coherence in the MWNT. In this sense, $P(E)$ may be reinterpreted as a transmission probability of electrons, associated with $J(t)$ in the localization regime, in the MWNT. This does not deny the energy dissipation in external environment. In this case, energy transfer may take place in the contact metal electrodes with lower impedances.

In addition, we may have to perform more careful data fitting from the following points.

(1) Junction capacitance $C$: We used $C$ obtained in our past report [28]. Since the $C$ was estimated from data fitting by Nazarov's theory, it is not yet experimentally confirmed.

(2) Parasitic capacitance $C_p$: We did not take into consideration the influence of the $C_p$ of MWNT. When we

define $L = \tau \times c$ (where $\tau \sim h/eV$, $c$ is the velocity of light in vacuum) as the geometry for an effective $C_p$ based on the horizontal model [33] and included the $C_p$ in the data fitting, it does not exhibit perfect agreement. $C_p$ for better agreement should be smaller than that calculated from $L = \tau \times c$. To explain this difference, a smaller velocity instead of $c$ may have to be employed, because our MWNT has very disordered surface.

(3) LCR model: We also have employed the *RC* mode as a lumped circuit model in PC theory here. Since, however, MWT has distributed *L*, *R*, and *C* including this $C_p$ in the actual system, the *LCR* transmission line model will have to be introduced.

However, even apart from these data fitting problems, the linear $G_0$ vs temperature dependence, the high impedance EME only in the MWNT directly connected to the junction, and its dependence on the localization effect will support our conclusion.

Here, why Coulomb blockade disappears near 5 K in Figure 10c is also not obvious with the $G_0$ discontinuity. In the Ni-nanowire system shown in Figure 10c, inset, Coulomb blockade also disappeared around 6 K due to the phase fluctuation caused by mutual Coulomb interaction in the Ni-wire [29]. Based on this result, we modulate the phase of electron waves in the MWNT by applying a magnetic field also in this case and observe its influence on the Coulomb blockade. As shown in Figure 11, the $G_0$ vs magnetic field ($B$) relation exhibits oscillation. Such oscillation

**Figure 11.** Magnetic field ($B$) dependence of $G_0$ in the CB temperature regime. Magnetic field was applied parallel to the tube axis within a few degrees as shown in Figure 1a. The radius of the AAS cylinder calculated from the first oscillation peak ($\Delta B = 2.2$ T) is in excellent agreement with the mean radius of the actual MWNT, although we did not take into account the contribution of the tube length, the misalignment angle of B to the tube axis, and the number of many MWNTs for the oscillation magnitude. It also indicates that the electron wave flows either in all of the shells or only in the midshells. Reprinted with permission from [40], J. Haruyama et al., *Phys. Rev. B* 63, 073406 (2001). © 2001, American Physical Society.

in MWNT has been understood as the Altshuler–Aronov–Spivak (AAS) effect in a graphite cylinder [32], which originates from phase interference of the electron waves encircling the cylinder in opposite directions and modulated by magnetic flux enclosed, with an oscillation period $\Delta B = (h/2e)/(\pi r^2)$ where $r$ is the radius of the cylinder. Here, the radius can be estimated to be 17.3 nm from the first oscillation peak. This radius is in excellent agreement with the mean radius of our actual MWNT of 17.5 nm. It is a straightforward indication that this conductance oscillation originates from AAS effect.

This result implies that the Coulomb blockade is very sensitive to the electron phase fluctuation of the MWNT even under a high $R_L$ ($>R_Q$) directly connected to a single junction. Since the high $R_L$ is caused by weak localization in the MWNT, this result may be relevant. It also suggests the possibility that the elimination of Coulomb blockade near $T = 5$ K in Figure 10c may be attributed to the dephasing process by strong spin-flip scattering in the MWNT, as well as that in the Ni-nanowire system.

# 4. MULTIWALLED CARBON NANOTUBES

## 4.1. Spintronics

### 4.1.1. Antilocalization Due to Spin–Orbit Interaction in Metal-Doped Nanotubes

***Introduction*** Electrode atoms are slightly diffused, with only about 5% volume-ratio, into the top end of MWNTs, standing in nanopores of porous alumina membranes. Diffusion of light-mass materials (carbon and aluminum) leads to weak localization in the AAS oscillations, which is qualitatively consistent with previous works on MWNTs. In contrast, we find that diffusion of heavy materials (gold and platinum) changes this weak localization into an antilocalization in the MWNT bulk. This effect is only observable when electrons are injected through the diffusion region and undergo a $\pi$-phase shift in their electron waves, caused by polarized injection of spin-flipped electrons due to spin–orbit interaction in the diffusion region of the MWNT bulk.

Single-walled carbon nanotubes are conducting molecular nanowires that exhibit a variety of mesoscopic phenomena. There is a renewed interest in these nanostructures because their characteristics are very sensitive to materials deposited onto the tube inner space [34]. In contrast, the physical properties of MWNTs have been interpreted only in terms of quantum phase interference effects of electron waves in the diffusive regime at the single-molecular level (e.g., WL [35–37], AAS oscillations [38–42], universal conductance fluctuation [35], possible metal–insulator transition [43], and strong spin coherence [44]). The investigation of correlation of such interference phenomena with dopant materials in the tube inner space or the MWNT itself has so far received no attention.

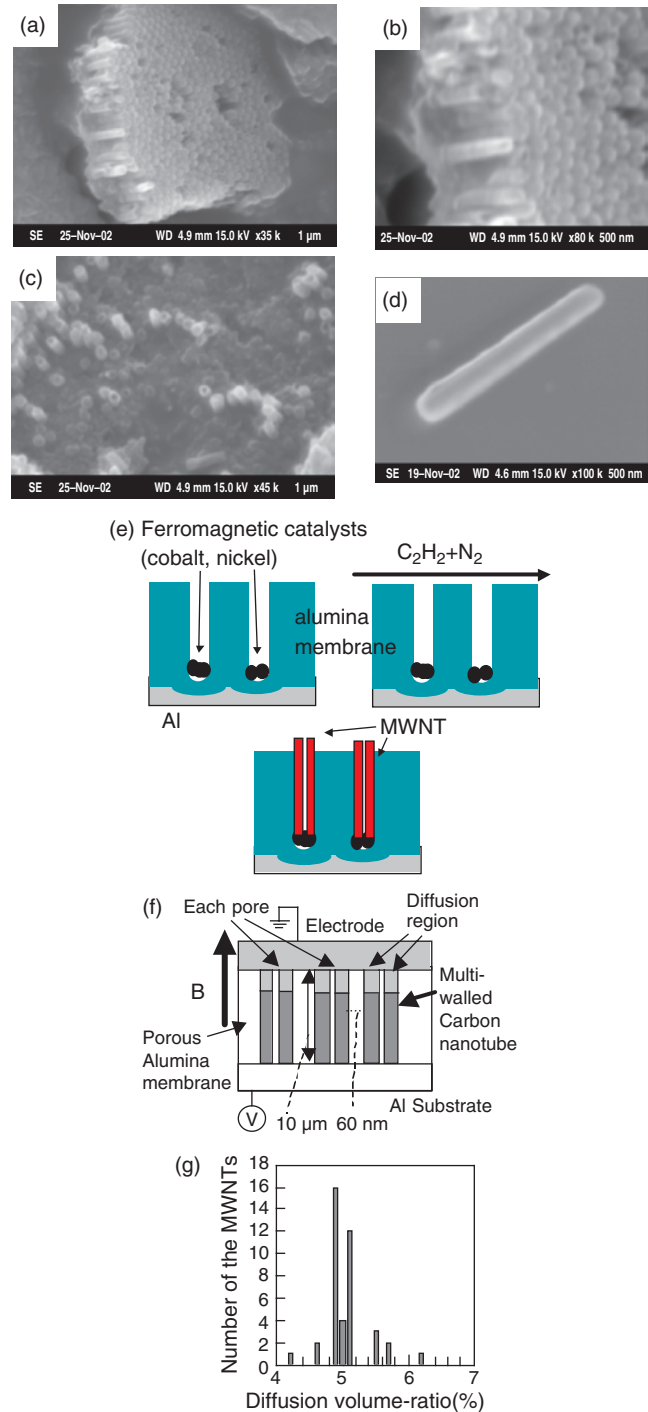
AAS oscillations and WL are the typical phase interference effects of electron waves observed in MWNTs. Constructive phase interference in current paths encircling MWNTs with time-reversal symmetry leads to WL, when the sample size is smaller than both the phase coherence length and the localization length [45–47]. The presence

of a resistance maximum and a negative magnetoresistance (MR) around zero-magnetic field reflect WL in the AAS oscillations [48]. Previous works on MWNTs reported only this type of AAS oscillation. On the other hand, the presence of a strong spin–orbit interaction (SOI) in thin metallic cylinders formed by heavy mass atoms leads to antilocalization (AL), reflected by a resistance minimum and a positive MR around zero-magnetic field, in the AAS oscillations [49]. This is because the SOI causes electron-spin flipping, thereby leading to change of the electron phase by $\pi$ [50–52]. No group, however, has yet successfully observed this electron-spin flipping and AL in the AAS oscillations in MWNTs.

In this chapter we find that diffusion of heavy-mass atoms, deposited onto the top end of MWNT electrodes *with only about 5% in volume-ratio* drastically changes this WL to AL in the bulk of the MWNTs. Based on a revised Altshuler's theory, we show that SOI, depending on the diffused atom mass and the diffusion volume-ratio, is the key for understanding the WL to AL change. We find that this phenomenon is observable only when electrons are injected through the diffusion region and is understood as spin flipping of electron waves (i.e., phase shift by $\pi$), caused by SOI in the diffusion region of the bulk of MWNTs.

***Experiments and Discussion*** In electrical measurements of MWNTs performed in previous works, an individual MWNT was deposited on a substrate [38, 39], and gold (Au) fingerlike electrodes were fabricated by lithography over the MWNT. Only the upper half-part of the MWNT that did not face the substrate, had an interface with the electrodes. Hence, it was difficult to diffuse by annealing the electrode-atoms into one entire end of the MWNT along the circumference of the NT (including the lower half-part facing the substrate). In contrast, we reported earlier on a different method to obtain the characteristics of MWNT arrays standing in nanosized diameter pores of porous Alumina membranes [40–42]. In this method, after the deposition of MWNTs into the nanopores (Fig. 12e), the top ends of the standing MWNTs were exposed from the surface of alumina membranes (Fig. 12a–d) and, then, a thick electrode was directly deposited on all of the top ends (Fig. 12f). Hence, diffusion of electrode-atoms takes places into the entire end of the standing MWNTs. For this reason, the diffusion region of the electrode-atoms forms the other nanotubelike structure on the top end of MWNTs (Fig. 12f). In fact, we confirmed that our sample clearly exhibited the diffusion of Au atoms, deposited as an electrode material, into the top end of MWNT, in [81].

Figure 13 shows typical MR oscillation characteristics observed in the samples with four different electrode materials. In this work, we measured a large number of MWNTs in one array sample at the same time. However, although this smears MR oscillation in some cases, we assumed that the observed characteristics were the simple superposition of the characteristic of each MWNT from the following three reasons: (1) The uniformity of the tube diameter was extremely high (e.g., half-width of distribution was less than 13). (2) The spacing between the MWNTs was relatively large. (3) According to [53], the characteristics of the individual MWNTs and the MWNT arrays fabricated by this method were basically consistent.



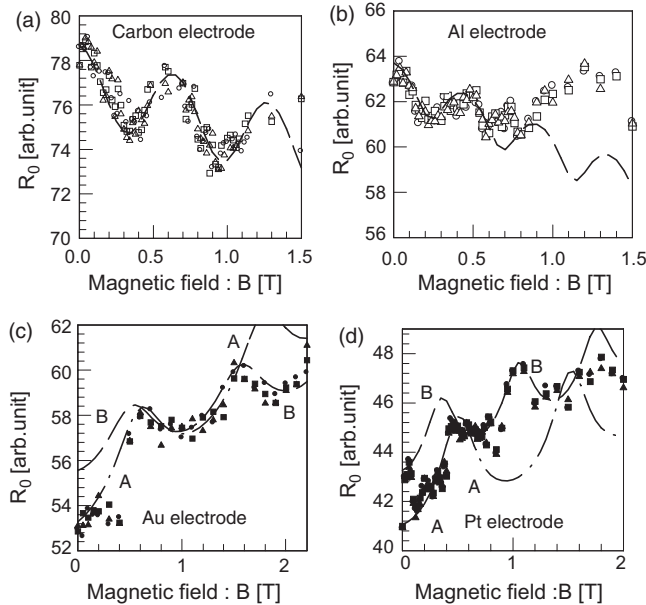


**Figure 12.** (a) SEM overview image of the exposed top part of a MWNT array, exhibiting a high regularity like a honeycomb. (b) High resolution image of (a). (c) SEM top view of (b), implying the opened top portion. (d) SEM image of one MWNT. (e) How to synthesize MWNTs in nanopores of alumina membrane by chemical vapor deposition. (f) Schematic cross-section of the MWNT array sample for this section. Thin tunnel barriers attached to the bottom end of MWNTs, used for Section 3, were basically deleted in the experiments of this section. Hence, MWNTs have direct contact to Al substrate. (g) Distribution of the diffusion volume ratio of Au electrode, obtained from CSTEM images of one array. The total number of MWNTs investigated is 41. Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.
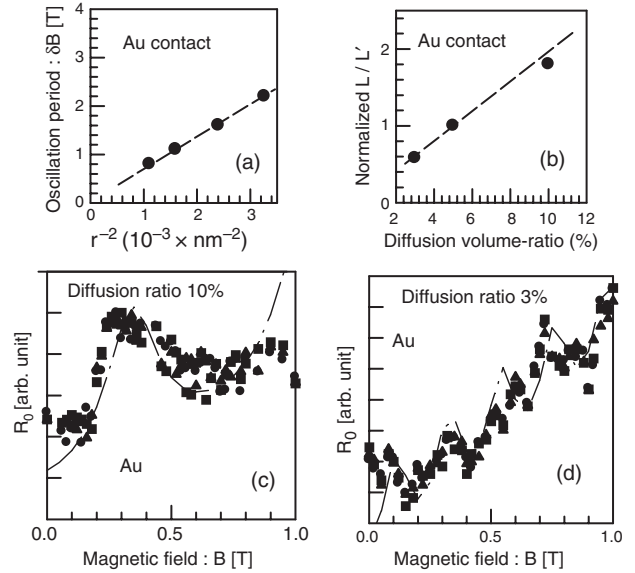


Since Figure 13a exhibits the MR maximum at $B = 0$ T and negative MR, the localization type is WL. This is qualitatively consistent with the previous works on AAS oscillations in MWNTs. Figure 13b also exhibits a MR oscillation with WL, although the decrease of MR saturates around $B = 0.5$ T. On the contrary, the MR oscillations shown in Figure 13c and d clearly reveal the MR minimums at $B = 0$ T and positive MRs which imply the presence of AL, although the oscillations themselves are not clear in comparison with (a) and (b). The positive MR is in contradiction with previous works [38–42].

In order to confirm the correlation between the observed MR oscillations and the AAS effect, we investigated the dependence of the oscillation period, $\Delta B$, on the MWNT radius, $r$. Figure 14a shows the result, which is a linear $\Delta B$ vs $r^{-2}$ relation with the slope value of $2.5 \times 10^{-16}$ (J•S/C). This is quantitatively in good agreement with the relation $\Delta B = (h/2e)/(\pi r^2)$ given by the AAS oscillation theory, with $(h/2e)/\pi \sim 6.5 \times 10^{-16}$.

Next, we discuss the influence of the electrode materials on the type of localization observed in the AAS oscillations as suggested by the results in Figure 13. The atomic numbers of Pt and Au are 78 and 79, respectively, whereas those of C and Al are 6 and 13. This indicates that the emergence of WL or AL strongly depends on the mass of the electrode-material atoms. Since AL is observable only in the samples with heavy-mass electrode materials (Pt and Au), this is qualitatively consistent with the previous works on thin Mg and Li cylinders [48, 49], which emphasizes the contribution of SOI. However, it should be noticed that the

**Figure 14.** (a) MR oscillation period vs square of mean tube radii. Mean tube radii of the array samples are confirmed by TEM and SEM images. (b) Normalized $L_\varphi/L'_\varphi$ vs diffusion volume ratio of Au atom to the MWNT. Each $L_\varphi/L'_\varphi$ was obtained from the best data fitting to Figure 3c and d by Eqs. (15)–(18) and then normalized by that for line A of the Figure 2c sample with 5% ratio. (c) MR oscillation in the sample with the diffusion volume ratio two times higher than the Figure 2c sample. Dotted line means the calculation result from Eqs. (15)–(18). (d) That with the diffusion volume ratio 0.6 times smaller than the Figure 2c sample. The smaller oscillation period is due to the larger tube radius caused by the fabrication process to get the longer tune length. Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.

diffusion region of our electrode materials is only about 5% of the volume-ratio in our MWNTs. Hence, one deals with a qualitatively different phenomenon from any previous observations in thin metallic film systems, although nothing of this kind has been reported in MWNT systems.

In order to resolve this issue, we carry out a data fitting procedure based on Altshuler's equations for AAS oscillations [48]. In [48], the equations for AAS oscillations including the contribution of SOI can be rewritten as

$$\delta G = -(e^2/\pi h)(2\pi r/L_s)[(1/2 + \beta)Z_\phi(L_\varphi(H)) \\ - 3/2 Z_\phi(L'_\varphi(H))] + \alpha(H) \quad (19)$$

$$Z_\phi(L_\varphi(H)) = \ln(L_\varphi/\ell) + 2\sum_{n=1}^{\infty} k_0(n(2\pi r/L_\varphi)) \\ \times \cos[2\pi n(\Phi/(hc/2e))] \quad (20)$$

$$1/L_\varphi^2 = 1/D\tau_\varphi \quad (21)$$

$$1/L_\varphi'^2 = 1/L_\varphi^2 + 2/D\tau_{so} \quad (22)$$

where $L_s$, $\beta$, $L_\varphi$, and $L'_\varphi$ in Eq. (19) are the tube length, the constant depending on electron–electron interaction, and the phase coherent length without and with SOI, respectively. $\ell$, $k_0$, and $\Phi$ in Eq. (21) are the mean free path, the Macdonald function, and the magnetic flux ($\pi r^2 H$), respectively. $D$, $\tau_\varphi$, and $\tau_{so}$ in Eqs. (21) and (22) are the diffusion constant,

**Figure 13.** Dependence of magnetoresistance oscillations on the top electrode materials. Four samples with different electrode materials [i.e., (a) carbon, (b) aluminum, (c) gold, and (d) platinum] were measured. Magnetic field was applied parallel to the tube axis. We basically plot the three times measurement results at each magnetic field. Dashed and dotted lines are the calculation results by Eqs. (15)–(18). Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.

the relaxation time for inelastic scattering, and the relaxation time for SOI, respectively. Here, $\alpha(H)$ in Eq. (19) represents the increase or decrease of the mean value of conductance, depending on magnetic field $H$. We also neglected the contribution of magnetic field on $L_\varphi$ in Eq. (21).

Equation (19) has very simple physical meaning: The first term related to $Z_\phi(L_\varphi(H))$ basically represents the AAS oscillations without SOI (i.e., WL), whereas the second term with $Z_\phi(L'_\varphi(H))$ reveals the influence of SOI (i.e., AL) on the AAS oscillations, using Eq. (22). Equation (22) includes the term $1/D\tau_{so}$ as the contribution of SOI. If SOI is very weak, $\tau_{so}$ diverges to an infinite value and, hence, $L_\varphi/L'_\varphi$ becomes "1" because of $(L_\varphi/L'_\varphi)^2 = 1 + 2(L_\varphi^2)/D\tau_{so}$, leading to WL. On the contrary, if $\tau_{so}$ has a finite value, $L_\varphi/L'_\varphi$ becomes larger than "1" because of $2(L_\varphi^2)D\tau_{so} > 0$, leading to the increase of the oscillation amplitude of the second term of Eq. (19) and thus AL. Therefore, the contribution of $\tau_{so}$ can be represented by $L_\varphi/L'_\varphi$. We selected this $L_\varphi/L'_\varphi$ as the fitting parameter.

As shown by the dashed line in Figure 13, the measurement and calculation results are in good agreement in all the samples. This is interpreted as strong evidence for AAS oscillations. The best fittings to Figure 13a and b give $L_\varphi/L'_\varphi = 1$, assuming $L_\varphi = 10^{-5}$ m and $\beta = 2$. This strongly supports the absence of SOI and the presence of WL for the reason mentioned previously. In particular, the measurement and calculation results are in excellent agreement in Figure 13a. On the other hand, both Figure 13c and d are fitted by two independent oscillation modes depending on magnetic field (i.e., bimodal behavior) as shown by lines A and B, assuming finite values for $\tau_{so}$. Compared with the value of $L_\varphi/L'_\varphi$ of the carbon electrode sample, the best fittings give $L_\varphi/L'_\varphi = 9.18$ and $L_\varphi/L'_\varphi = 9.3$ for lines A and B in Figure 13c and $L_\varphi/L'_\varphi = 9.28$ and $L_\varphi/L'_\varphi = 9.4$ for lines A and B in Figure 13d, respectively. These values of $L_\varphi/L'_\varphi \sim 9$ ($> 1$) are strong evidence for the contribution of SOI and, hence, the emergence of AL, also for the reason explained. The comment for the bimodal behavior is mentioned in the later part of this chapter.

The central issue of this chapter is the physical relevance of $L_\varphi/L'_\varphi$, as obtained from the best fit shown in Figure 13, because Eqs. (19)–(22) do not relate to actual material parameters. Two facts make it possible to physically identify this $L_\varphi/L'_\varphi$: There is a correlation (1) with the atomic numbers of the electrode materials (i.e., mass of the atoms) and (2) also with the volume-ratio of the diffusion region to the MWNT.

From the viewpoint of correlation (1), the atomic numbers ($Z$) of C and Pt are 6 and 78. Reference [48] indicates that $\tau_\varphi/\tau_{so}$ is given by $(3L_\varphi^2/\ell a)(aZ)^4$, where $a$ is the fine structure constant ($\approx 1/137$). In the case of carbon, $\tau_\varphi/\tau_{so}$ can be estimated to be on the order of $10^{-6}$ in our system from this equation. This is nearly consistent with $\tau_{so} = \infty$ (i.e., $L_\varphi/L'_\varphi = 1$) obtained from the best fits in Figure 13a and b. In contrast, in the case of Pt, $\tau_\varphi/\tau_{so}$ can be estimated to be on the order of $10^{-2}$. This does not quantitatively agree with $\tau_\varphi/\tau_{so} \approx 5$ estimated from $L_\varphi/L'_\varphi \approx 10$ obtained from the data fitting. In this case, only the increase of $\tau_\varphi/\tau_{so}$ with the atomic number is in qualitative agreement. Hence, based only on [48], the physical meanings of $L_\varphi/L'_\varphi$ cannot be quantitatively identified from the atomic numbers.

In order to clarify correlation (2), we varied the diffusion volume-ratio by changing the MWNT length with a constant diffusion length in the same electrode-material samples. $L_\varphi/L'_\varphi$ was obtained from the best fit of the experimental data in Figure 14c and d by Eqs. (19)–(22) by identifying each MWNT length with $L_S$ in Eq. (19). As shown in Figure 14b, the relation between the $L_\varphi/L'_\varphi$ values and the diffusion volume-ratio is mostly linear. This is the strong evidence that factor (2) is the key to determine $L_\varphi/L'_\varphi$ (i.e., the contribution of SOI) and $L_\varphi/L'_\varphi$ has a correlation with actual systems. It implies that the contribution of SOI to AL is linearly proportional to the volume-ratio of the diffused Au atom.

Consequently, the diffusion of heavy-mass atoms, deposited as the electrode materials on MWNTs, at only about 5% in volume-ratio can drastically change WL to AL in the bulk of NTs. This can be shown by a phase shift of the electron waves by $\pi$, caused by spin flipping due to SOI in the diffusion region of MWNT bulk. However, which conjugated conditions are formed between the atom of Au or Pt and the carbon nanotube by annealing and how it leads to SOI is still an open question. Further investigation is indispensable to clarify this issue.

Based on the linear relation mentioned, the bimodal behaviors and the two different $L_\varphi/L'_\varphi$ values obtained in Figure 13c and d suggest the presence of two different distribution peaks in the diffusion volume of Au and Pt atoms in one array sample. The equal ratio of $L_\varphi/L'_\varphi$ from line B to line A ($\sim 1.013$) in both (c) and (d) also supports this conclusion. As a confirmation, we exactly investigated the distribution of diffusion volume-ratio in an array. As shown in Figure 12d, we could actually find two peaks at 4.9% and 5.1% of the volume-ratio. Since the ratio of 5.1%/4.9% is 1.041, this is nearly consistent with the $L_\varphi/L'_\varphi$ ratio between lines A and B ($\sim 1.013$). However, the reason they independently emerge in the different magnetic-field regions is still unclear.

Finally, we show why such a small diffusion region only at the one end of MWNT drastically changes the phase interference in the bulk of MWNT. Figure 15a shows MR oscillations when electrons are injected into the MWNTs from either the Au electrode or Al substrate. It reveals a polarity of AL and WL; that is, only when electrons are injected through the Au diffusion region does a positive MR (i.e., AL) emerge. This strongly supports the contribution of SOI caused in the diffusion region. As shown in Figure 15b, when the electrons are injected through the Au diffusion region, the electron phases are spin-flipped by the strong SOI right after the injection, and then they cause phase interference. Since the spin coherence is strongly conserved in all the phase interference paths of electron waves encircling the MWNT [44], it leads to the AL in the bulk of the MWNTs. In contrast, when the electrons are injected from the Al substrate, they are spin-flipped in the diffusion region, after most of the interference procedure is completed (i.e., after the interference paths were already closed) as shown in (b). Such electrons no longer contribute to the phase interference. These phenomena are the direct evidence of the important role played by the small diffusion region in the phase interference in the bulk of the MWNTs.

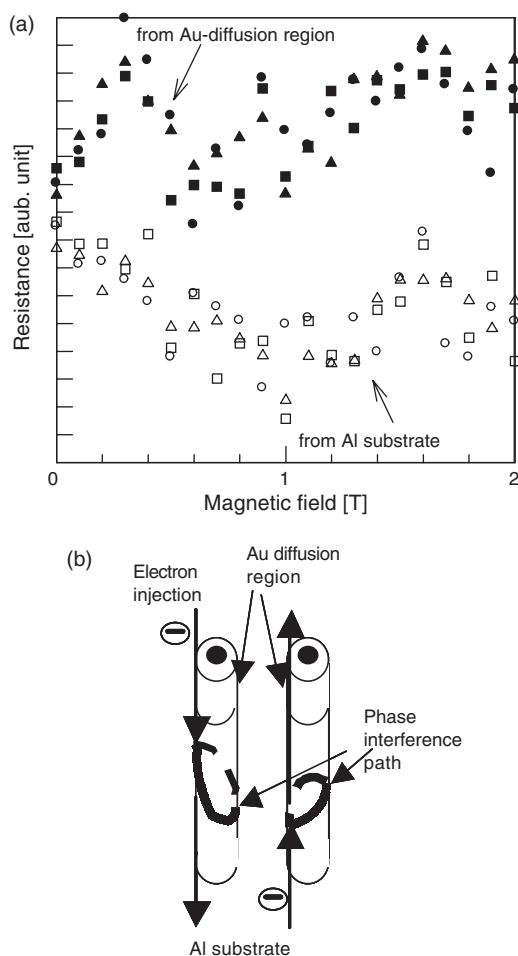
For the application of this effect, we propose a phase switching device like a CMOS circuit, as shown in Figure 16.


**Figure 15.** (a) MR features when electrons are injected from different electrode sides. Open and filled symbols are the MRs for the electron injection from the Al substrate and the Au electrode, respectively. (b) Schematic figures of MWNTs with the phase interference path, encircling the MWNT, for AAS oscillations and the direction of electron injection. Left and right figures mean the electron injections from the Au diffusion region and Al substrate sides, respectively.

When magnetic field is applied, WL is destroyed in the MWNT1 leading to high conductance, whereas AL is destroyed in the MWNT2 leading to low conductance. Hence, the current flows from $V_{DD}$ to $V_{out}$ and, hence, $V_{out}$ becomes "1" as shown in the left figure. In contrast, when magnetic field is not applied, MWNT1 and MWNT2 show WL and AL, respectively. Hence, no current flows between $V_{DD}$ and $V_{out}$. It makes the potential difference between earth and $V_{out}$ equal and, hence, $V_{out}$ becomes "0." This is a quite novel electron-phase switching device, although detailed adjustment of the resistances of MWNTs is of course required.

### 4.1.2. Anomalous Spin Interference Due to Excess Cobalt Catalyst and Strong Spin Coherence

**Introduction** We report on the sensitivity of localization effects, identified in conductance ($G$) versus logarithmic temperature (log [$T$]) relations ($G$ vs log [$T$] relations) and

**Figure 16.** Novel electron-phase switching device utilizing the effect found here. MWNT1 is a general MWNT, exhibiting WL under no magnetic field. MWNT2 is our MWNT with an Au diffusion region, exhibiting AL under no magnetic field. Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.

in MR oscillations, to excess volume of a cobalt catalyst in MWNTs synthesized in nanoporous alumina membranes. These localization effects bring about the following anomalies in bulk MWNTs. (1) A slight increase in the volume of excess cobalt changes AL to WL both in MR oscillations and in the $G$ vs log [$T$] relation. (2) A further increase in excess changes this WL back to the AL, but only in MR oscillation. (3) Even under this AL in MR, neither AL nor WL can be observed in the $G$ vs log [$T$] relation. We carry out data fitting to the MR oscillations by a revised formula for Altshuler–Aronov–Spivak oscillation and find a drastic change of phase coherence length depending on the excess cobalt deposition time. We also carefully observe each MWNT by high resolution cross-sectional transmission electron microscopy and find unique MWNT structures with cobalt particles and wire. Based on these, we propose interpretation for the anomalies. We interpret the first anomaly by the odd-time spin flip due to the cobalt particles remaining in MWNTs and spin polarization due to the short cobalt wires formed at the bottoms of MWNTs; these particles and wires are yielded by the slight increase in excess cobalt. The second and third anomalies are also interpreted by thick and highly disordered MWNT shells, which surround cobalt particle arrays. This is yielded by a further increase of the amount of cobalt. These phenomena can be basically universal in MWNTs that are synthesized by excess ferromagnetic catalysts, by virtue of the strong spin coherence.

Carbon nanotubes (CN), single-level molecular conductors, are attracting much attention, because they exhibit

unique quantum-mesoscopic phenomena and provide a variety of applications to novel molecular-quantum devices. It is well known that such quantum phenomena are very sensitive to the presence of impurities and defects in CNs. Here, one method of synthesizing CNs is a catalytic process of chemical vapor deposition using ferromagnetic catalysts (e.g., cobalt, nickel, and iron) [54]. Because these ferromagnetic catalysts remain in CNs even after synthesis under excess catalyst volume, it is of core importance to clarify how the excess volume of ferromagnetic catalysts contributes to changes in the physical characteristics of CNs.

Excess volume of the ferromagnetic catalysts affects CNs in at least two aspects: (1) During synthesis, excess volume changes CN structures, leading to changes in their physical characteristics, (2). After synthesis, excess volumes remaining in CNs are magnetic impurities, which change the physical characteristics of CNs. No work has been reported on the first of these aspects, whereas the second aspect, the influence of magnetic impurities, has been studied in both single-walled CNs and multiwalled CNs, as follows.

The influence of magnetic impurities in SWNTs has been studied mainly through electron spin resonance [55, 56]. Even a small concentration of magnetic impurities can relax the conducting electrons very efficiently [55], because SWNTs have a large carrier mean free path and a large spin diffusion length, like one-dimensional conductors. Spins and phases of electron waves in this ballistic regime are very sensitive to magnetic impurities. In addition, recently even a novel Kondo effect was reported, in which a SWNT serves as a one-dimensional host for conducting electrons, with magnetic clusters including a localized spin [56].

In contrast, the influence of magnetic impurities in MWNTs has been interpreted to be the origin of dephasing for quantum electron waves, as follows. The electrical properties of MWNTs are basically understood by the phase interference of quantum electron waves in the diffusive regime [54]. A typical example of such a phenomenon is a 2D WL, a constructive phase interference of electron waves. In thin metallic film and 2D electron gas systems, the conductance of 2D WL exhibits linearly logarithmic temperature ($\log[T]$) dependence with a saturation region forming at low temperatures. The Log $[T]$-dependent region is a manifestation of decoherence by electron–phonon scattering, whereas the saturation region implies decoherence by spin-flip scattering due to magnetic impurities.

Also in MWNTs, the conductance ($G$) vs log $[T]$ relation has exhibited such 2D WL behavior [57, 59–61], although the linear $G$ vs log $[T]$ relation survived at higher temperatures. The influence of magnetic impurities on the electrical properties of MWNTs has been reported in regards only to this decoherence for spin relaxation. For our MWNTs utilizing cobalt catalysts, we also reported previously that the transition temperature, $T_c$, between the linear $G$ vs log $[T]$ and its saturation regions was higher than the transition temperatures, $T_c'$, in thin metallic-film samples: about $T_c \sim 6$ K versus, for example, $T_c' \sim 1$ K [59–61].

However, no researchers have clarified how increases in the volume of excess cobalt change such phase interference phenomena in MWNTs. In this work, we reveal for the first time that phase interference, identified by $G$ vs log$[T]$ relations and magnetoresistance oscillations, is very sensitive to

increases in excess cobalt catalysts, based on our previous discovery of antilocalization in our MWNTs [64]. We find three anomalies in this sensitivity, and we interpret them in terms of correlation of AL and WL with complicated MWNT structures, observed by TEM (e.g., cobalt particles remaining in the MWNTs, short cobalt nanowires at the bottoms of the MWNTs, and thick and highly disordered MWNT shells), yielded by the excess cobalt catalyst.

### Experimental Results and Discussion

***Sample Structures and Measurement Methods*** Figure 17a shows the schematic cross section of our MWNT array synthesized into nanopores of an alumina membrane. After the membrane was formed by anodizing an aluminum substrate, a cobalt catalyst was electrochemically deposited

**Figure 17.** (a) Schematic cross-section of an MWNT array synthesized into nanopores of porous alumina membranes. We prepared three samples with three different times for cobalt deposition (i.e., 30, 120, and 360 seconds for samples 1, 2, and 3, respectively). The deposition time of 30 seconds corresponds to the optimal cobalt volume, whereas 120 and 360 seconds lead to the slightly and highly excess cobalt volumes, respectively. (b) Schematic cross-sectional model of the MWNT with the cobalt particles and the short cobalt nanowire accumulated at the bottom of the MWNT. This explains the first anomaly in this work. This model was obtained from the observation of high resolution cross-sectional TEM images (Fig. 20a–c), and the increase of spin scattering due to magnetic impurities obtained from the drastic decrease in $L_\varphi$ (change from Figure 19a to b in Table 1). Slight increase of excess cobalt catalyst yields this original structure. (c) Schematic cross-sectional model of the MWNT with thick and disordered shells surrounding a cobalt particle array. This explains the second and third anomalies. This model was obtained from a TEM image (Fig. 20c), the increase in $L_\varphi$ (change from Fig. 19b to c in Table 1), and the decrease in $T_c$ (change from Figs. 18b to c). High increase of excess cobalt catalyst leads to this original structure. Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.

into the bottom of the nanopores at three different times. As we explain later, the deposition time of 30 seconds is around the optimal point for our parameters of alumina membranes. Hence, 120 and 360 seconds led to the excess deposition times. With this cobalt catalyst, MWNTs were synthesized by chemical vapor deposition of $C_2H_2$ and $N_2$ gases. Although we measured the physical properties of MWNTs as averaging about $10^3$ in the array, it was already confirmed in [65] that the averaged properties of such arrays were mostly the same as those of individual MWNTs because of the extremely high uniformity of the nanostructure parameters of this alumina membrane. It also turned out that even averaged measurement results could exhibit unique quantum-mesoscopic phenomena (see [59, 61–64]).

### Relationship between Conductance vs log [T] and Excess Cobalt Volume

Figure 18 shows the dependence of the zero-bias conductance ($G_0$ vs log [T] relation on the volume of cobalt catalyst in the samples with three different cobalt deposition times. The data reveal drastic changes in the $G_0$ vs log [T] relation, depending strongly on the deposition time. Figure 18a and its inset exhibit a slight decrease of $G_0$ as the temperature increases (i.e., negative $G_0$ behavior) up to $T = 2$ K. In contrast, Figure 18b, in which the cobalt deposition time was slightly increased, surprisingly implies that this decrease of $G_0$ disappears and only a saturation region (flatness) emerges at the lowest temperatures.

The further increase of the cobalt deposition time interestingly leads to the elimination of this saturation region (Fig. 18c). Even negative $G_0$ behavior, like that shown in

**Figure 18.** Dependence of zero-bias conductance ($G_0$) vs logarithmic temperature (log[$T$]) relation on the three different cobalt deposition times. (a), (b), and (c) correspond to the optimized cobalt volume, the slightly excess cobalt volume, and the highly excess cobalt volume, respectively. Solid lines are the calculation results by 2D weak-localization formula for MWNTs [Eq. (19)]. Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.

Figure 18a, is unobservable. At almost all of the temperatures measured, only a linear and positive $G_0$ vs log [T] relation appears.

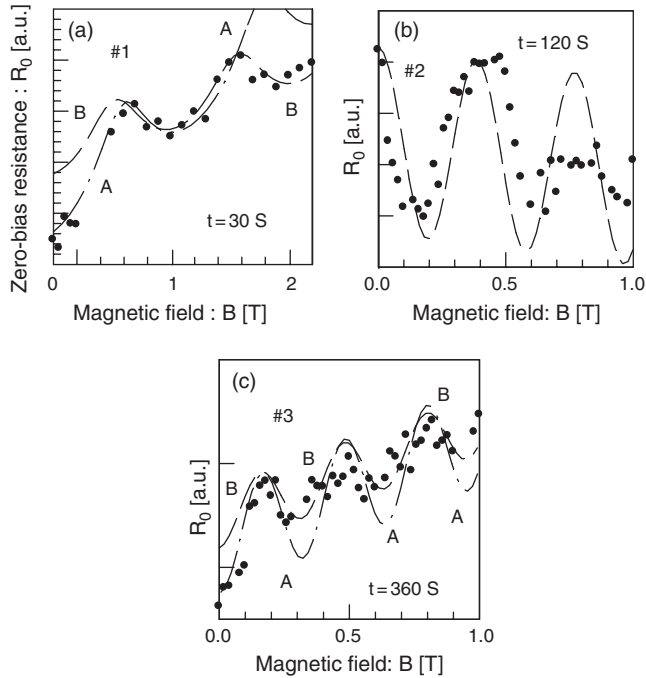
The characteristics in Figure 18 can be understood as follows. Figure 18a results from the presence of AL, a destructive phase interference phenomenon, which we reported previously [64]. In that study, we revealed that the gold-diffusion region at the top end of our MWNTs had SOI and the spins flipped by this SOI were injected into the bulk MWNT (Figs. 17a and b), leading to the phase shift by $\pi$ and, hence, the AL [64]. In this AL regime, decoherence due to the increased temperature leads to a negative $G_0$ vs log [T] relation because the destructive interference is eliminated.

In contrast, qualitatively Figure 18b means the emergence of 2D WL, consistent with previous reports on MWNTs [57], with magnetic-impurity (spin-flip) scattering at low temperatures as mentioned in the Introduction. Quantitatively, the relation was well fitted by the formula of 2D WL, as shown by the solid line in Figure 18b [59],

$$G(T) = G(0) + (e^2/\pi h)(n\pi d/L)\ln[1 + (T/T_c(B, \tau_s))^p] \tag{23}$$

where $n$, $p$, $d$, $L$, and $\tau_s$ are the number of shells, the parameter for dominant inelastic scattering, the diameter of the inner shell of the MWNT, the length of the MWNT, and the relaxation time of spin-flip scattering due to magnetic impurities, respectively. The contribution of the number of MWNTs is taken into account by the term $G(0)$. The good agreement between the data and calculation in Figure 18b supports presence of 2D WL. The best fitting to the experimental result gives $T_c = 5.4$ K, using $n = 18$, $p = 2.1$, $d = 50$ nm, and $L = 10$ mm. This $T_c$ as high as 5.4 K actually implies the presence of strong spin-flip scattering by magnetic impurities. In contrast, the best fitting to Figure 18c gives $T_c$ as low as 1.7 K, which actually emphasizes a mostly linear $G_0$ vs log[$T$] relation in the measured temperature range down to $T = 1.5$ K.

### Relationship between Magnetoresistance Oscillations and Volume of Excess Cobalt

In order to confirm these AL and 2D WL, we measured the MRs in the sample in each figure. Figure 19 shows the results. Figure 19a exhibits a positive MR around $B = 0$ T. This is actually consistent with decoherence in the AL regime shown in Figure 18a, with the bimodal oscillations (i.e., large- and small-magnitude oscillations, depending on the magnetic fields), as we already reported in [64]. In contrast, a negative MR surprisingly emerges around $B = 0$ T in Figure 19b. This is also consistent with the 2D WL regime shown in Figure 18b.


We performed data-fitting for Figure 19a and b by the revised Altshuler's formula for AAS oscillation [64],

$$\delta G = -(e^2/\pi h)(2\pi r/L_s)[(1/2 + \beta)Z_\phi(L_\varphi(H))$$
$$- 3/2Z_\phi(L'_\varphi(H))] + \alpha(H) \tag{24}$$

$$Z_\phi(L_\varphi(H)) = \ln(L_\varphi/\ell) + 2\sum_{n=1}^{\infty} k_0(n(2\pi r/L_\varphi))$$
$$\times \cos[2\pi n(\Phi/(hc/2e))] \tag{25}$$

$$1/L_\varphi^2 = 1/D\tau_\varphi \tag{26}$$

$$1/L_\varphi^2 = 1/L_\varphi^2 + 2/D\tau_{so} \tag{27}$$

**Figure 19.** Dependence of magnetoresistance features, corresponding to each figure in Figure 18. A magnetic field was applied in parallel with the tube axis. Lines A and B in (a) and (c) and the dotted line in (b) are the calculation results by the revised formula of Altshuler–Aronov–Spivak oscillation with and without spin–orbit interaction, respectively [Eqs. (20)–(23)]. Different oscillation periods in (a), (b), and (c) are due to the different tube diameters caused during the anodization procedure. They were also taken into account for the data fitting. Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.

where $L_s$ $\beta$ $L_\varphi$, and $L'_\varphi$ in Eq. (24) are the tube length, the constant depending on electron–electron interaction, and the phase coherent length without and with SOI, respectively. $\ell$, $k_0$, and $\Phi$ in Eq. (25) are the mean free path, the Macdonald function, the magnetic flux ($\pi r^2 H$), respectively. $D$, $\tau_\varphi$, and $\tau_{so}$ in Eqs. (26) and (27) are the diffusion constant, the relaxation time for inelastic scattering, and the relaxation time for SOI, respectively. Here, $\alpha(H)$ in Eq. (24) represents the increase or decrease of the mean value of conductance, depending on magnetic field $H$. We also neglected the contribution of magnetic field on $L_\varphi$ in Eq. (26).

Equation (24) has a very simple physical meaning: The first term related to $Z_\phi(L_\varphi(H))$ basically represents the AAS oscillations without SOI (i.e., WL), whereas the second term with $Z_\phi(L'_\varphi(H))$ reveals the influence of SOI (i.e., AL) on the AAS oscillations, using eq. (27). Equation (27) includes the term $1/D\tau_{so}$ as the contribution of SOI. If SOI is very weak, $\tau_{so}$ diverges to an infinite value and, hence, $L_\varphi/L'_\varphi$ becomes "1" because of $(L_\varphi/L'_\varphi)^2 = 1 + 2(L_\varphi^2)/D\tau_{so}$, leading to WL. On the contrary, if $\tau_{so}$ has a finite value, $L_\varphi/L'_\varphi$ becomes larger than "1" because of $2(L_\varphi^2)/D\tau_{so} > 0$, leading to the increase of the oscillation amplitude of the second term of Eq. (24) and thus AL. Therefore, whether $\tau_{so}$ has infinite or finite values can decide emergence of either

AL or WL. Since this is represented by $L_\varphi/L'_\varphi$, we selected this $L_\varphi/L'_\varphi$ as the fitting parameter.

The results are shown in each figure by the solid and dotted lines. The agreement between data and theory is good in each figure also for the bimodal oscillation modes (i.e., large- and small-magnitude oscillations, depending on the magnetic fields, as we reported in [11]). This bimodal behavior means the presence of two different $L_\varphi/L'_\varphi$. Because $L_\varphi/L'_\varphi$ depended on the diffusion volume of gold atoms (Figure 20a), we clarified that this bimodal behavior was attributable to the presence of two distribution peak of this gold diffusion volume in one array. The best fitting to the

**Figure 20.** Typical high-resolution cross-sectional TEM images of each MWNT. (a) Example of a cobalt particle, without any shells, included in the MWNTs of the samples in Figures 18b and 19b. This sample includes high density of such particles. (b) Short cobalt wires formed at the bottom of MWNTs of the samples in Figures 18b and 19b. This is formed by accumulation of cobalt catalyst at the bottom of a nanopore of alumina membrane and has no diffusion during the synthesis. (c) Cobalt particle arrays surrounded by the disordered and thick shells in the samples in Figures 18c and 19c. Highly disordered shell structures (i.e., coffee-cup structures), which originated from the cobalt particle array, are also observable. Highly excess cobalt catalyst leads to this unique structure. (d) General shell structures of our MWNT, with about 36 shells, observable in the samples in Figures 18b and 19b. Reprinted with permission from [81], J. Haruyama et al., *Phys. Rev. B* 65, 33402 (2002). © 2002, American Physical Society.

line A in Figure 19a gives "$L_\varphi = 10.2$ $\mu$m" and $L'_\varphi = 1.1$ $\mu$m, respectively. Because $L_\varphi/L'_\varphi > 1$, this means the finite value of $\tau_{so}$ and hence quantitatively supports the presence of strong SOI and AL in Figure 18a. In contrast, the best fitting to Figure 19b actually gives "$L_\varphi = 0.13$ $\mu$m" and "$L'_\varphi = 1.02$ $\mu$m." In this case, $L_\varphi$ drastically decreases for reasons explained in the next section (d), whereas $L'_\varphi$ (i.e., the strength of the SOI) is nearly equal to that of Figure 19a. This decrease of $L_\varphi$ leads to $L_\varphi/L'_\varphi \sim 1$ under a constant $\tau_{so}$, because $(L_\varphi/L'_\varphi)^2 = 1 + 2(L^2_\varphi)/D\tau_{so}$. This $L_\varphi/L'_\varphi \sim 1$ is also consistent with the presence of 2D WL.

In Figure 19c, a positive MR emerges again with the bimodal oscillations. The best fitting to line A gives "$L_\varphi = 8.2$ $\mu$m" and $L'_\varphi = 0.75$ $\mu$m, implying the presence of AL, similar to Figure 19a. $L_\varphi$ increased again nearly up to the value found in Figure 19a under mostly the same $L'_\varphi$ as that in Figure 19b and we explain why in the next section. It should be noticed, however, that this is not consistent with the linear $G_0$ vs log$[T]$ relation shown in Figure 18c, because AL should exhibit a negative $G_0$ vs log $[T]$ relation like Figure 18a.

Consequently, Figure 18 and 19 imply that $G_0$ vs log $[T]$ relations and MRs (i.e., AL and WL) are very sensitive to the excess cobalt-deposition time (i.e., the volume of excess cobalt). We find the following three anomalies in these results. (1) A slight increase in the excess cobalt volume causes a transition from the AL to the 2D WL, in both the $G_0$ vs log $[T]$ relations and the MRs [i.e., from (a) to (b) in Figure 18 and 19]. (2) A further increase changes this WL back to the AL only in the MRs (Fig. 19c). (3) Despite that, AL is unobservable in the $G_0$ vs log $[T]$ dependence (Fig. 18c), exhibiting only the linear log $[T]$ relation.

***Proposal of the Models for the Three Anomalies*** What is the origin for these anomalies? In Table 1, we show the summary of the fitting parameters obtained from the best fit to each of Figure 19 and the density of cobalt particles, confirmed by high resolution cross sectional TEM (HRC-STEM) images, in each MWNT corresponding to Figure 19. As we explained, we note that only $L_\varphi$ changes drastically depending on the deposition time of cobalt catalyst, whereas $L'_\varphi$ is mostly constant. In general, $1/L^2_\varphi$ is given by $1/D\tau_{in} + 2/D\tau_s (= 1/L^2_{in} + 2/L^2_s)$, where $\tau_{in}$ is the relaxation times for inelastic scattering, when decoherence due to electron–electron interaction is neglected (e.g., at temperatures above $T = 1.5$ K). We can propose models as the origins for the anomalies, based on these.

In the first anomaly, $L_\varphi$ decreased drastically and we confirmed the increase of cobalt density in the MWNT by the HRCSTEM image (Fig. 20a). Because no change was found in the MWNT shell structure at least by the HRC-STEM image (Fig. 20d, i.e., no change in disorder of the MWNT), we have no reason for the change in $L_{in}$. Hence, the decrease of $L_\varphi$ can be due to the decrease of $L_s$. This $L_s$ decrease and the increased density of cobalt particles strongly suggest that the spin-flip scattering by the cobalt particles is the main reason for the first anomaly. Based on this, we propose a model representable by Figure 17b.

In the second anomaly, $L_\varphi$ increased drastically, whereas we found that the density of cobalt particles also increased further, leading to the arrays of cobalt particles (Fig. 20c), by HRCSTEM. These are not consistent. Besides, we also found the highly disordered shells of the MWNT by the HRTEM (Fig. 20c). This can bring strong electron–phonon interaction and hence decrease of $L_{in}$. This is also not consistent with the increase of $L_\varphi$. We found, however, that the cobalt particle arrays were surprisingly surrounded by the thick shells, by the HRCSTEM (Fig. 20c). If the current flows along the outer part of these thick MWNT shells, this large thickness reduces the influence of the spin scattering due to the cobalt particles, leading to the increase of $L_\varphi$. We propose a model explainable by Figure 17c, based on this.

The third anomaly is at least strongly associated with the strong disorder of the thick MWNT shells mentioned (Fig. 20c), because the linear $G_0$ vs log $[T]$ relation implies the presence of strong electron–phonon interaction caused by the disordered structure. We also propose an interpretation based on Figure 17c.

***Relationship among the First Anomaly, Cobalt Particles, and Short Cobalt Wires*** The AL observable in Figures 18a and 19a was attributed to the polarized injection of the spins, flipped by SOI in the gold-diffusion region at the top end of the MWNTs, into the bulk of MWNTs as we reported in [64]. Since the flipped spins led to the phase shift of electron waves by $\pi$ in the bulk MWNTs, the WL in the bulk MWNTs changed to the AL. This phase shift and AL are well represented by the negative $G_0$ vs log $[T]$ regime at low temperatures and the positive MR in Figures 18a and 19a, respectively. This AL was caused when the volume of the cobalt catalyst was optimal, because no cobalt particles could be detected in the bulk MWNTs.

However, when the volume of excess cobalt is increased slightly, the cobalt particles easily remain in the bulk MWNT even after the synthesis. We explain the first anomaly, based on Figure 17b, taking into consideration these cobalt particles, as we implied.

In general, this influence may lead to simply random flipping and the decoherence of these spins and hence to the elimination of both the negative $G_0$ vs log $[T]$ relation and

**Table 1.** Relation of deposition time of the cobalt catalyst vs magnetoresistance oscillation behavior, confirmed from Figure 19, around zero magnetic field. Phase coherence length without ($L_\varphi$) and with ($L'_\varphi$) spin–orbit interaction obtained from the best fit in Figure 19. Those ratios and density of cobalt particles confirmed by high resolution cross-sectional TEM image of each sample for Figure 3 (see Fig. 20), in MWNT after the synthesis.

| Cobalt deposition time | MR (at $B = 0$) | $L_\varphi$ | $L'_\varphi$ | $L_\varphi/L'_\varphi$) | Averaged density of cobalt particles in a MWNT |
|---|---|---|---|---|---|
| 30 S (Fig. 3a) | positive [AL] | 10.2 | 1.1 | 9.27 | ~0 |
| 120 S (Fig. 3b) | negative [WL] | 0.13 | 1.02 | 0.13 | 27 |
| 360 S (Fig. 3c) | positive [AL] | 8.2 | 0.75 | 10.9 | 55 [particle array] |

the positive MR (i.e., elimination of the AL). This scenario does not agree with Figures 18b and 19b. Here, if the spin, flipped by the SOI at the top of MWNT, is flipped by these cobalt particles in the $n$th time (here, $n$ should be the odd integer) during flowing through the MWNT before AAS interference occurs, the interference is caused by this flipped spin with opposite moment (Fig. 17b). Because this leads to phase shift by $\pi$ in the AAS interference, this changes the AL to the WL. These flipped spins, however, have fluctuation. Here, HRCSTEM detected the presence of cobalt wire as short as about 300 nm at the bottom end of the MWNTs in sample 2 (Fig. 20b). This wire was yielded by an accumulation of excess cobalt catalyst at the bottom part of the nanopores of the alumina membrane due to the excess deposition time, because such excess cobalt can no longer contribute to the growth of the MWNTs and no longer diffuse into the MWNTs as particles. After the AAS interference took place, such spins with fluctuation are injected into the short cobalt wire at the bottom end of the MWNT (Fig. 17b). If this cobalt nanowire plays a role of spin polarization for these spins, all such spins will be aligned reducing the fluctuation as they flow through the cobalt nanowire. This makes the magnitude of the WL increase. Consequently, the WL appears in Figures 18b and 19b, when the magnitude of this WL becomes dominant compared with that for the AL. In fact, it was reported that MWNTs connected to ferromagnetic electrodes exhibited strong spin polarization, characterized by strong spin coherence [63]. Besides, we confirmed that these phenomena could not be observed when electrons were injected from the Al substrate.

Quantitatively, in this case, SOI length ($L_{so}$) $\geq$ spin scattering length ($L_s$) must be satisfied, because the spin-flip scattering due to the cobalt particles has to beat the spin flipping by the SOI. Here, $L_{\varphi}$ in Figure 19b decreased remarkably from that in Figure 19a under the mostly constant $L'_{\varphi}$ (see Table 1). This led to $(L_{\varphi}/L'_{\varphi})^2 = 1 + 2(L_{\varphi}^2)/D\tau_{so} \sim 1$ and hence this WL. This change means $(L_{\varphi}^2)/(D\tau_{so}) = (L_{\varphi}/L_{so})^2 \sim 0$ and hence $L_{so} \geq L_{\varphi}$. As explained, this $L_{\varphi}$ decrease is due to the decrease of $L_s$. Therefore, $L_{so} \geq L_{\varphi}$ implies presence of $L_{so} \geq L_s$. This quantitatively supports our argument discussed. The high $T_c$ of 5.4 K in Figure 18b supports this explanation, because $T_c$ is the transition temperature for decoherence from the spin-flip scattering to the inelastic scattering regimes with increasing temperature.

These structures, that is, the presence of ferromagnetic particles remaining in the MWNTs and ferromagnetic electrodes formed at the bottom ends of MWNTs, can be yielded in any MWNTs, when excess volume of a ferromagnetic catalyst is used. Therefore, this phenomenon can be universal in such MWNTs. The strong spin coherence, which cannot surprisingly be dephased even after the $n$th time flipping, of the MWNTs makes this spin interference phenomenon possible.

***Relationship between the Second and Third Anomalies and Thick and Disordered Shells of MWNTs*** The second anomaly is more complicated, because a further increase in excess of the cobalt volume seems merely to induce further spin-flip scattering, leading to stronger decoherence of the 2D WL and hence the destruction of MR

oscillation in Figure 19b. We also explain this anomaly based on Figure 16c, as we mentioned.

In order to clarify the reason for this anomaly, we carefully observed, by HRCSTEM, the shell structures of the MWNTs around cobalt particles. In Figure 20c, we found the following. (1) There is a larger density of cobalt particles in the Figure 18c sample than in Figure 18b, and such cobalt particles were combined, in most cases, to cobalt-particle arrays. (2) Such cobalt-particle arrays were surrounded by the disordered and thick shells of the MWNTs. These structures can be yielded by a high increase in the excess volume of the cobalt catalyst, far from the optimal condition, because the growth of the MWNTs is very sensitive to the catalyst, especially in chemical vapor deposition. Here, quantum electron waves in our MWNTs flow along the outer portions of the shells [64]. Hence, these thick shells increase the distance ($L$) between the cobalt particles and the wave flow, reducing the influence of spin-flip scattering by the cobalt particle on phase coherence (Fig. 17c). This leads to the elimination of the 2D WL, because the origin for the 2D WL in Figure 19b was this spin-flip scattering. This in turn changes the WL back to the AL, similar to Figure 19a. This phenomenon can be also universal in MWNTs, when the excess volume of a catalyst is too high. Such unoptimized conditions easily lead to MWNTs with thick shells surrounding ferromagnetic catalysts. One should note that even such thick MWNTs can conserve strong spin coherence.

In this case, $L_{\varphi}$ increased up to about 8.2 $\mu$m with mostly constant $L'_{\varphi}$, leading to $L_{\varphi} > L'_{\varphi}$ again (Table 1). This quantitatively supports the explanation mentioned, because only $L_s$ can increase in this structure, along with decreased $L_{in}$ as will be mentioned.

In contrast, the third anomaly stresses decoherence by only strong electron–phonon scattering. The highly disordered shell structure observed in Figure 20c emphasizes the possible presence of strong electron–phonon scattering in this MWNT (i.e., a decrease in $L_{in}$), leading to the elimination of AL. Besides, dephasing by the cobalt particles leading to the low temperature saturation in the WL is also reduced by the thick shells as mentioned. Therefore, only the lineal and positive $G_0$ vs log $[T]$ relation can emerge (Fig. 18c). This behavior, however, can be consistent with the AL in MR (Fig. 19c) because of the following: (1) The positive MR in Figure 19c was yielded by decoherence of SOI due to the increase of magnetic field at the fixed temperature ($T = 1.5$ K), whereas the third anomaly is caused by decoherence of electron–phonon interaction due to the increase of temperature at the fixed magnetic field ($B = 0$). (2) Decoherence of SOI and electron–phonon scattering are very sensitive only to magnetic field and temperature, respectively. These second and third anomalies stress that the thick shell of MWNTs reduces the influence of spin-flip scattering due to the cobalt particles under the magnetic-field change, but its disorder enhances the electron–phonon interaction under the temperature change.

The coexistence of the second and third anomalies may be not universal, because it can be constructed only when there is a highly optimized balance among the thickness of MWNT shells, the strength of their disorder, and the location of

the cobalt particles in the MWNTs. Our system seems to occasionally have included such an optimized structure.

**Conclusion** In conclusion, we found for the first time that the $G_0$ vs log[$T$] relation and MRs were very sensitive to the excess increase of cobalt-catalyst volume in MWNT arrays, synthesized in nanoporous alumina membranes. We found the following three anomalies in these results. (1) A slight increase in the excess cobalt volume caused a transition from the AL to the 2D WL, in both the $G_0$ vs log[$T$] relations and the MRs. (2) A further increase changed this WL back to the AL only in the MRs. (3) Despite that, AL was unobservable in the $G_0$ vs log[$T$] dependence, exhibiting only the linear log[$T$] relation. We found drastic change of $L_\varphi$ in each anomaly, from the data fitting to the MR oscillations by revised AAS oscillation theory. We also performed careful observation of each MWNT by HRCSTEM and found the unique MWNT structures with the cobalt particles. We proposed interpretations for the anomalies, based on those.

Based on the drastic decrease of $L_\varphi$ and the increased density of cobalt particles, we qualitatively attributed the first anomaly to the odd-time flipping of electron spins by the cobalt particles remaining in the MWNTs, leading to the phase shift by $\pi$ and, hence, the change from AL to 2D WL. The polarization of those spins by the short cobalt wires, formed at the bottoms of the MWNTs, induced this. These structures resulted from the slightly excess cobalt volume. Quantitative comparison of change of $L_{so}$ and $L_s$ also supported this interpretation. We explained the second anomaly by the thick shell structures of the MWNTs, based on the increase of $L_\varphi$. The thick shells eliminated the 2D WL by surrounding the cobalt particle array and reducing the spin scattering due to the cobalt particles by detaching the current flow along the outer portion of MWNTs from the cobalt particles. This led to the re-emergence of AL. In contrast, the disordered shells strongly enhanced the decoherence by electron–phonon scattering, leading to the linear $G_0$ vs log[$T$] down to $T = 1.7$ K. We qualitatively attributed this third anomaly to the different sensitivity of decoherence between magnetic field increases and temperature increases. For further quantitative confirmation, estimation of $L_s$ from the $G_0$ vs log[$T$] relations will be at least indispensable.

It has been already reported that diffusive SWNT rings can, interestingly, exhibit WL and AL together with strong localization, depending on the temperature[66]. We also reported that 2D WL in the bulk MWNT was changed to AL by doping gold and platinum on the top end of the MWNT[64]. On the other hand, this chapter implies the possibility that bulk MWNTs themselves can provide AL, 2D WL, and the switching between them. In any case, it is important to note that we can control these by changing the volume of excess ferromagnetic catalyst. We believe that these phenomena are basically universal in MWNTs with excess volume of ferromagnetic catalysts, because these are reproducible. Only the strong spin coherence of MWNTs can make these anomalous spin interference phenomena possible. These phenomena will be also very useful to realize novel spintronics and phase interference devices that utilize MWNT networks synthesized by ferromagnetic catalysts networks.

## 4.2. Superconductivity

Proximity-Induced Superconductivity and Its Reentrance Effect in Niobium/Multiwalled Carbon Nanotube Junctions

### 4.2.1. Introduction

We report on an experimental study of the diffusive transport near interface of niobium(Nb)/multiwalled carbon nanotube junctions. Utilizing MWNTs synthesized in nanopores of alumina membranes makes a highly transparent interface possible. On the magnetic-field dependence of observed conductance increase and the transition temperatures versus nanotube length diagram, we observe proximity-induced superconductivity with an onset temperature of $T = 9$ K at the highest case. We reveal that this conductance decreases due to its reentrance effect at low temperature. These phenomena are the manifestation of the extremely large diffusion constant of Cooper pairs in the MWNTs. The drastic magnetic-field dependence of the reentrant conductance supports the presence of a reentrance effect associated with the Altshuler-Aronov-Spivak effect.

Superconductivity of carbon nanotube, a molecular conductor, is currently of great interest, because it was recently found that hole-doped $C_{60}$ and magnesium diboride that have structures similar to CNs, exhibit high-temperature superconductivity. Until recently, only two groups had reported superconductivity in single-walled carbon nanotubes [67–69]. The first group claimed to have observed superconductivity at $T = 15$ K only from the Meissner effect without actually showing vanishing resistance [67]. The other group reported a transition temperature as low as $T < 1$ K in both proximity-induced and intrinsic superconductivity [68, 69]. However, no other group has been able to reproduce successfully these results. In fact, Morpurgo et al. attribute the absence of proximity-induced superconductivity in niobium(Nb)/SWNT/Nb junctions [70] to the following two reasons: (1) Because charge carriers in SWNTs behave as a Luttinger liquid due to the strong one-dimensional repulsive electron interaction, unusual phonon modes would be capable of producing Cooper pairs with attractive electron interaction [69, 70, 78–80]. (2) High transparency of the metal electrode/CNs interface is hard to achieve because of the misalignment between Fermi levels. Only electrodes made of titanium(Ti), carbide(C), silicon(Si)C, or NbC by a special technique [68, 69] meet this criterion, but Ti and Si are not superconductors. Consequently, only NbC is a suitable candidate for highly transparent superconductor/CN interfaces.

In contrast, nobody has successfully reported superconductivity in multiwalled carbon nanotubes. Because MWNTs exclude the existence of Luttinger liquid (although this issue is debatable, we could not actually find any power law dependence in the conductance versus temperature and voltage characteristics of our samples), one can at least avoid the former handicap of SWNTs. In addition, it is well known that two-dimensional quantum electron waves generated from the molecular band in MWNTs have the longest phase coherence among many materials in the diffusive regime; therefore, it is crucial to show that Cooper pairs can exist with such strong phase coherence.

In this work, we for the first time, investigate "PIS" in Nb/MWNTs junctions. When the superconductor (S)/ normal conductor (N) interface is highly transparent, leakage of the Cooper pair wave function from the S into the N leads to PIS in the N. Recent experimental transport studies near a mesoscopic S/N interface (e.g., S/2D electron gas (2DEG)[71–73] and thin metal S/N junctions [74–77]), have revealed the presence of subtle physics implying the coexistence of Cooper pair wave functions with the 2D electron waves.

In particular, the "reentrance effect" has attracted much attention. This effect emerges when the conductance enhancement due to PIS suddenly decreases at energy below the "Thouless energy $(E_{Th})$" that arises from the uncertainty between the diffusion time of Cooper pair and its energy fluctuation [76]. Furthermore, when an Aharonov–Bohm (AB) ring is inserted on the N channel of such S/N junctions, the AB flux causes drastic changes in the reentrance effect, simultaneously with modifications of the effective channel length and the Andreev reflection at the S/N mirrors [73–77].

How can such phenomena take place in S-electrode/ MWNT junction systems? In this chapter, we report the existence of PIS at a temperature of $T = 9$ K at the highest case and its reentrant effect from the magnetic-field dependence of conductance behaviors and the dependence of the transition temperatures on the nanotube length in a high-transparency Nb/MWNT junctions. This junction is realized by utilizing MWNTs synthesized into the nanopores of alumina membranes. Next, we show that two magnetic-field dependences strongly support the "reentrance effect connected to the AB trajectory," with two anomalous behaviors.

### 4.2.2. Experiments and Discussion

Here, in any case, the low-transparency interface of S/N junctions prevents PIS from occurring. Figure 21a and b shows the schematic views of an array of Nb/MWNTs (S/N) junctions and a single Nb/MWNT junction, respectively. After the synthesis of MWNTs into the nanopores of alumina membranes [81–83], we performed the preannealing. Then, the surface of alumina membrane was etched out so that the top portion of the MWNTs was exposed. Right after we evaporated Nb/gold film (in high vacuum with each 1 $\mu$m thickness, superconducting transition temperature of about 8.1–9 K, and critical magnetic field of about 1500 Gauss) on these top ends of MWNTs, we carried out the annealing in vacuum, again. Hence, the annealing changes only the boundary conditions of the Nb/MWNT interface. We found that annealing at 650 °C for this structure led to high diffusion of Nb atoms into the top ends of all shells in MWNTs, due to the interface area being large enough for diffusion along the circumferential direction (Fig. 21b and d). Because this process leads to the generation of NbC (right panel of Fig. 21d), the interface became highly transparent. In contrast, we could not find any diffusion of Nb and the presence of NbC in the samples annealed at lower temperatures [150 (e) and 400 °C]. The end-bonded MWNT also contributes to the high transparency [85]. We also showed that even the normal metal electrodes, slightly diffusing into the top ends of MWNTs, actually led to a drastic change of phase interference in the bulk of our MWNTs [81].

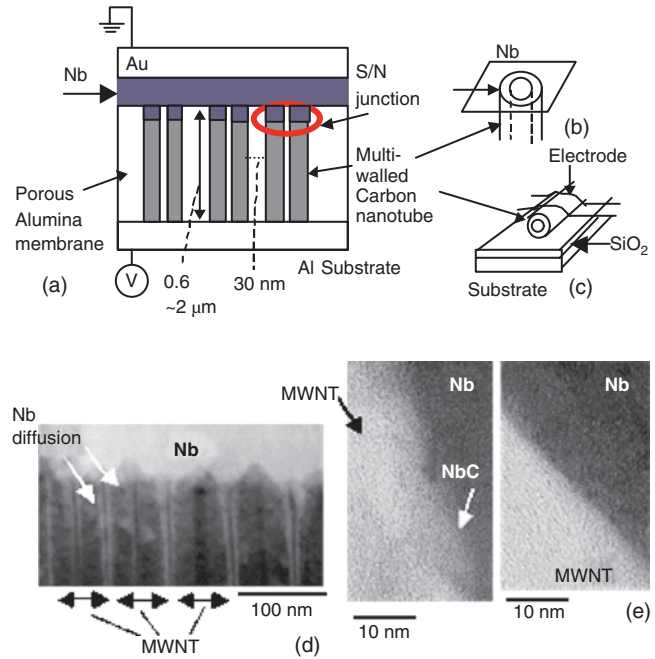

**Figure 21.** The schematic cross-sections of (a) an array of Nb/MWNT junctions and (b) one Nb/MWNT (S/N) junction, synthesized into the nanopores of alumina membranes by chemical vapor deposition. The mean outer and inner diameters of MWNT are 100 and 60 nm, respectively, with the shell thickness of 20 nm. The half width of the distribution of the outer diameter is as small as about 15%. The shell structure proving the MWNT was already reported in [82]. Because this system is not a S/N/S junction, there is no Josephson contribution in the measurement results. Although we measured the average characteristics of Nb/MWNTs junctions with about $10^4$ in one array, it was already confirmed that they could exhibit approximately the same quantum phenomena as those of an individual MWNT [81–83], due to the extremely high uniformity. (c) One of the general methods, much different from ours (b), used to provide electrical contact with the nanotube. It is difficult to provide high-transparency interface by this, because only half of the most outer shell along the circumferential direction has the interface with the electrode. (d) Left: High angle annular dark field image of cross-sectional TEM around the Nb/MWNT junction array [see (a)] annealed at 650 °C, implying the high diffusion of Nb atoms. Right: High resolution CSTEM image of an Nb/MWNT interface. The gray regions blended by the white (MWNTs) and black (Nb) regions are clearly visible at the boundary, implying the presence of NbC with the lattice constant of 0.35 nm. (e) High resolution CSTEM image of an Nb/MWNTs interface annealed at 150 °C, implying no gray region at the border between the MWNTs and Nb and hence the absence of NbC.

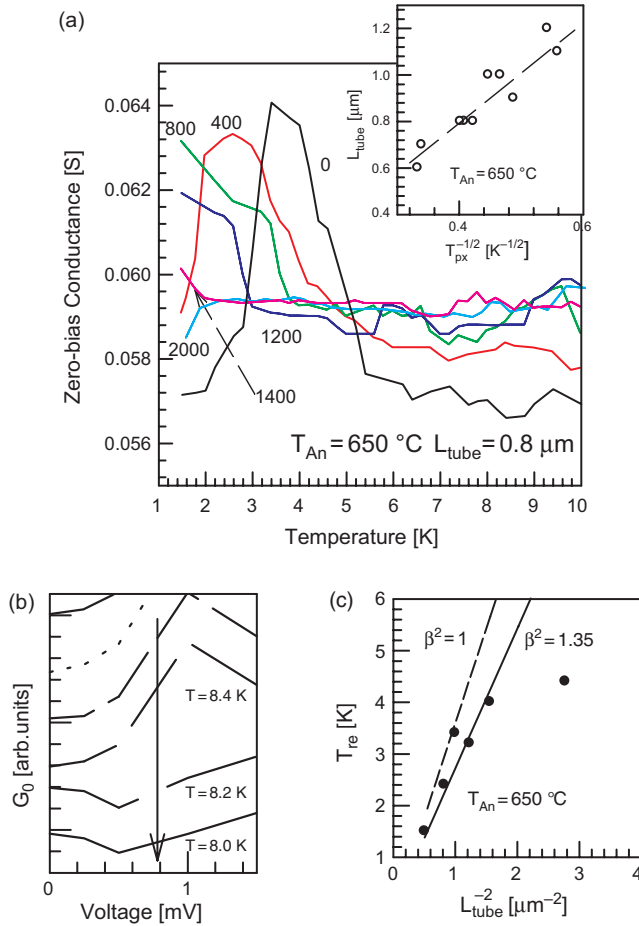
In the main panel of Figure 22a, we show the temperature dependences of zero-bias conductance $(G_0)$ in an Nb/MWNT array annealed at $T_{An} = 650$ °C. We successfully find the gradual but obvious conductance increases with the onset transition temperature ($T_{px}$ of $T_{px} = 5.4$ K under zero magnetic field $(H = 0)$. In contrast, we note that this conductance starts to drop from $T = 3.4$ K (i.e, transition temperature for the conductance decrease, $T_{re} = 3.4$ K). The $T_{px}$ was shifted to lower temperature when a magnetic field $(H)$ was applied in the Nb electrode (i.e., perpendicular to the tube axis). The critical magnetic field $(H_c)$ for the disappearance of the conductance increase was about 1400 Gauss, which is mostly the same as $H_c$ for the vanishing


**Figure 22.** (a) Temperature dependences of zero-bias conductance ($G_0$), in an Nb/MWNT array annealed at $T_{An} = 650$ °C, measured for different values of the magnetic fields perpendicular to the MWNT axis. The labels on the curves correspond to the value of magnetic field in Gauss. The resistance of one MWNT with the interface resistance is around 100 KΩ to 1 MΩ at $H = 0$ Gauss, which is consistent with that of MWNTs with weak localization [81, 82]. Inset: The averaged tube length ($L_{tube}$) vs $T_{px}^{-1/2}$ relation obtained from the measurements of 10 samples, with different $L_{tube}$ annealed at $T_{An} = 650$ °C. The dotted linear line was obtained from the minimum square method. (b) Temperature dependences of conductance vs voltage relation, around the superconducting transition temperature of our Nb film, in an Nb/MWNTs array with $T_{px} = 3.5$ K. Conductance dip is observable above $T = 8.4$ K, whereas this abruptly changes to the conductance peak at $T = 8.2$ K in a decrease of temperature. We qualitatively confirm that this conductance peak originates from the emerging Andreev reflection, due to the superconducting transition of Nb film, at the Nb/MWNT junction, because (1) $T = 8.2$ K mentioned previously is approximately near $T_c$ of our Nb-film and (2) the voltage width of the conductance peak ($\sim$1.2 meV) is nearly equal to the $\Delta$ of Nb (i.e., $\Delta_{Nb} \sim$1.4 meV). (c) Transition temperature for reentrant conductance ($T_{re}$) vs $L_{tube}^{-2}$ relation obtained from the six samples in the inset of (a). We could not find reentrant conductance in other four samples in (a). The dot and solid lines are calculation results from $T_{Th} = \hbar D/kL^2 = (A/\beta)^2/L^2$ with $L = L_{tube}$, $A \sim 1.9 \times 10^{-6}$, and $\beta$ as a fitting parameter.

superconducting transition of our Nb electrode film, in contradiction to [3]. The $T_{re}$ also moved to lower temperature in $H = 400$ Gauss, and the conductance drop vanished above $H = 800$ Gauss. The conductance increase observable

mainly in the change from $H = 0$ to $H = 400$ Gauss at all the temperatures above $T = 5.4$ K is due to destruction of weak localization in the MWNTs [81], because this increase exhibited a linear and positive $G_0$ vs log($H$) relation. We do not discuss this phenomenon in this chapter.

These characteristics for the conductance increase and its $H$ dependence are similar to the behavior of superconducting transition. However, conductance does not increase up to infinite value like in general superconducting transition, due to the conductance drop. Besides, each curve in Figure 22a is inhomogeneous on temperature change unlike in general conductance vs temperature relations. Hence, in order to confirm the correlation of this conductance increase with superconducting transition, we investigated dependence of $T_{px}$ on the MWNT length. We found that $T_{px}$ decreased with increasing the averaged MWNT length ($L_{tube}$), following the linear $L_{tube}$ vs $T_{px}^{-1/2}$ relation (i.e., "$L_{tube} = A \cdot T_{px}^{-1/2}$," where $A$ is a coefficient constant) (inset of Fig. 22a). Besides, we found even $T_{px}$ as high as $T = 9$ K in the junction of Nb/MWNTs with $L_{tube} = 0.6$ $\mu$m. Importantly, this relation qualitatively agrees with the temperature dependence of $L_T$ [i.e., "$L_T = (\hbar D/kT)^{1/2}$," where $D$ is the diffusion constant]. This effect stresses that the "$L_T = (\hbar D/kT)^{1/2}$" relation becomes dominant in the MWNTs below $T_{px}$. This is the straightforward evidence that the conductance increase below $T_{px}$ is strongly associated with the PIS caused by the Nb electrode.

The conductance mechanism follows the smallest of the two parameters, $L_T$ or the phase coherence length ($L_\phi$). Because $L_\phi$ in our MWNTs is on the order of a few $\mu$m [81] around about $T = 10$ K, thereby implying $L_\phi > L_T$ below about $T = 10$ K, we believe that this discussion is relevant. We understand that such a conductance increase was never observed in any of our MWNTs without superconductor electrodes, despite the fact that we measured over 300 samples. They just exhibited monotonic conductance decreases due to weak localization. Besides, one should note that even the highest $T_{px} \sim 9$ K observed is below the superconducting transition temperature ($\sim$9.1 K) of our Nb film. This suggests a strong relation between the conductance increase with superconducting transition of Nb electrode and PIS. PIS can occur even at the N-channel length $\gg L_T$, leading only to the shrinkage of the normal conducting state length (e.g., by Maki–Thompson–Larkin fluctuations of the order parameters)[72]. However, this is not the case because the conductance increase does not exhibit strong dependence on the N-channel length.

We already mentioned that (high-temperature) PIS requires high-transparency interface of S/N junction (see Fig. 21). In fact, we confirmed that the conductance increase in the main panel of Figure 22a is also very sensitive to the interface transparency of Nb/MWNT junctions, as follows. An Nb/MWNT array annealed at $T_{An} = 150$ °C exhibited no conductance increase. This low-temperature annealing results in the low-transparency Nb/MWNTs interface due to absence of NbC by the poor diffusion of Nb into the MWNTs (see Fig. 21d and e). The interface resistance of the 150 °C-annealed Nb/MWNT junction can be estimated to be at least 10 times larger than that in the 650 °C-annealed sample. In addition, no current could be detected in the sample without annealing, indicating zero

transparency. Here, the abrupt onset of a conductance peak, which can be due to Andreev reflection (in which an incident electron coming from the N is converted into the Cooper pair in the S, leaving a reflected hole in the N, at the S/N junction [67, 84]), with decreasing temperature from $T = 8.2$ K (Fig. 22b) also supports the presence of this high-transparency interface in the 650 °C-annealed sample, because Andreev reflection can only take place at a highly transparent S/N interface.

We still need to establish evidence for the existence of PIS. Unlike in general superconductivity, the junction conductance does not reach infinite value but rather starts to drop at $T_{re} = 3.4$ K as temperature decreases. We argue that this is due to the "reentrance effect," which is critical for the manifestation of the PIS regime. The N-channel/N-reservoir (N/N′) junction attached to the other end of the N-channel plays an important role in this context. When the N/N′ interface is highly transparent, the proximity-induced Cooper pair amplitude is suppressed near the N/N′ junction because the Cooper pairs diffuse out of the N-channel, where they feel the $E_{Th}(= \hbar D/L^2)$ gap rather than $\Delta$. Here $\Delta$ and $L$ are the bulk superconducting gap and the N-channel length, respectively, there. This leads to "the spatially averaged normalized density of state $(N_N(E))$ in the N-channel $<$ its normal state value," at $E \leq E_{Th}$. Consequently, the conductance decreases at $E \leq E_{Th}$ (i.e., reentrance effect), whereas the PIS can survive only at $E \geq E_{Th}$.

In Figure 22c, we show the $T_{re}$ vs $L_{tube}^{-2}$ relation obtained from the measurement results for Figure 22b samples. Interestingly, this relation is mostly linear except at $L_{tube} = 0.6$ $\mu$m. This result agrees qualitatively with the Thouless temperature $(T_{Th})$ dependence on the N-channel length, $L$ (i.e., $T_{Th} = \hbar D/kL^2$), and is the first evidence that the conductance decrease from $T_{re}$ is due to the reentrance effect.

We show the second evidence for PIS as follows. As explained, because the "$L_{tube} = A \cdot T_{px}^{-1/2}$" relation in the inset of Figure 22a was qualitatively equivalent to "$L_T = (\hbar D/kT)^{1/2}$," we define $A = \beta(\hbar D/k)^{1/2}$, where $\beta$ is a constant coefficient. Hence, from the asymptotic value of $L_{tube}$ vs $T_{px}^{-1/2}$ ($A = 1.9 \times 10^{-6}$) and the value at which the dotted line crosses to the $Y$-axis ($0.04 \times 10^{-6}$), the data obtained in Figure 22b can be fitted by the expression $L_{tube} = (1.9 \times 10^{-6}) \cdot T_{px}^{-1/2} + 0.04 \times 10^{-6}$. With $T_{Th} = \hbar D/kL^2 = (A/\beta)^2/L^2$, we can derive the $T_{Th}$ vs $L_{tube}^{-2}$ relation, by using $A \sim 1.9 \times 10^{-6}$, $L = L_{tube}$, and $\beta$ as a fitting parameter. From the data shown in Figure 22c, the value $\beta^2 = 1.35$ gives the best fit to the measurements in the linear regime. This $\beta^2 = 1.35$ value establishes the relation $T_{re} = 0.74 \times T_{Th}$." In fact, similar relations were reported in the reentrance effect observed in the Nb/2DEG junction ("$T_{re} = 0.4 \times T_{Th}$")[72] and in the Al/Cu junction ("$T_{re} = 0.5 \times T_{Th}$")[70]. Our coefficient value of 0.74 approximately agrees with those. From this discussion, we conclude that the conductance drop at $T_{re} = 3.4$ K in the main panel of Figure 22a is attributed to the "reentrance effect." The particular "0.74" value is discussed.

The $L_{tube} = 0.6$ $\mu$m value for the departure from the linear regime shown in Figure 22c is associated with a weakening of the reentrance effect due to the decrease of Cooper pair diffusion in the MWNT. Indeed, the density of Cooper pairs is very high even around the MWNT/Al interface in

MWNTs with lengths as short as 0.6 $\mu$m. We speculate that the high-transparency MWNTs/Al (N/N') interface, the key for this reentrance effect, was also realized with the 650 °C annealing, because this temperature is near both the melting point of Al and the synthesis temperature of MWNT. The Al atoms and MWNT are actively connected in such conditions. Nevertheless, the instability and reproducibility of this junction lead to the reproducibility of the reentrant conductance with 60% probability.

The highest $T_{re} = 4.5$ K of the reentrance effect observed in this work is much higher than reported in the Nb/2DEG ($T_{re} = 0.5$ K) [72] and in the Al/Cu junctions ($T_{re} = 60$ mK)[74]. This is a manifestation of the extremely large diffusivity $D = 0.37$ m$^2$/s, estimated from the parameters $A \sim 1.9 \times 10^{-6}$ and $\beta^2 = 1.35$, in our MWNTs (e.g., $D = 0.08$ m$^2$/s at most, in the case of 2DEG and $D = 0.007$ m$^2$/s in the Cu film), resulting in the strong phase coherence. The discovery of the reentrance effect surprisingly implies that the diffusion of Cooper pair even into MWNTs, consisting of $\pi$ and $\sigma$ bands formed by $sp^2$- and $sp^3$-mixed orbitals, can lead to the reduction of $N_N(E)$, which is qualitatively similar to that in Nb/2DEG and metal S/N junctions. We put emphasis on this reentrant conductance as the other evidence for PIS. However, it is interesting to notice that the strong phase coherence did not enhance the critical magnetic field for the vanishing PIS in our MWNTs (main panel in Fig. 22a). This is in contradiction to that in SWNT, which reported the 10 times larger critical field [69].

The magnetic-field dependence [the inset of Fig. 23a and the relation at $\Phi/\Phi_0' = 1/2$ (where $\Phi_0' = \Phi_0/80$ and $\Phi_0$ is

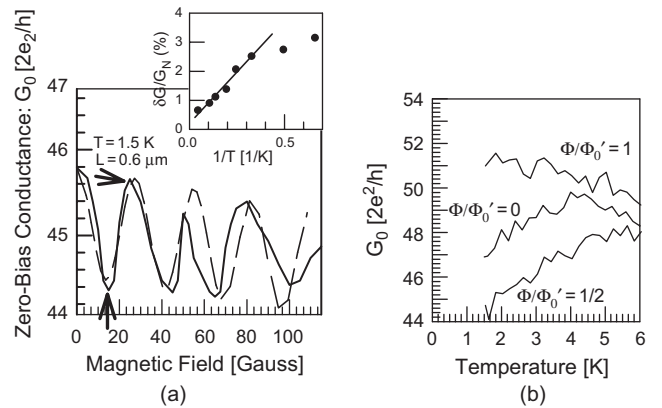

**Figure 23.** (a) Periodic magnetoconductance oscillation (solid line) observed in the reentrant regime. Magnetic flux was applied along the MWNT axis. This can be fitted by the formula of Altshuler-Aronov-Spivak oscillations (dotted line)[81], assuming the anomalous period of $\Delta\Phi = \Phi_0/80 = \Phi_0' = 25$ Gauss and the presence of spin-orbit interaction for the negative MC around zero magnetic field. This period of 25 Gauss corresponds to the magnetic flux $\Delta\Phi = \Phi_0/80 = \Phi_0'$, based on the best fit (dotted line) with the mean MWNT radius of 40 nm[81]. Inset: Power-law relation of the normalized magnitude of this MC oscillation ($\Delta G/G_N$) vs $1/T$ above $T_{re} = 4.5$ K and its saturation below $T_{re}$. $G_N$ is the normal state conductance. The solid line is a guide for the eyes. (b) Magnetic field dependence of the $G_0$ vs temperature relations around $T_{re}$ at the fields shown by the arrows in (a) (i.e., $\Phi/\Phi_0' = 1/2$ and $\Phi/\Phi_0' = 1$, respectively). At $\Phi/\Phi_0' = 1/2$, the $G_0$ maximum shifts up to about $T = 6$ K (enhancement of the reentrance regime). In contrast, at $\Phi/\Phi_0' = 1$, $G_0$ exhibited a monotonic increase (its shrinkage).

the superconducting quantum flux) in Fig. 23b] also supports the presence of reentrance effect, if we assume our Nb/MWNT structure is equivalent to an S/N junction connected to AAS trajectory, like a S/N junction connected to an AB ring [8] (Fig. 24a and b). The reentrance effect in this system has been successfully studied [73–76]. Reference [74] showed the power-law decay of $\Delta G/G_N$ on temperature increase with the ratio between 2.5% and 0.5% and its saturation below the $T_{re}$ ($= 50$ mK). These are quantitatively in precise agreement with the inset of Figure 23a. Besides, the enhancement of reentrance effect at the magnetic flux in the bottom of oscillation ($\Phi/\Phi_0' = 1/2$) in Figure 23b also qualitatively agrees, when we neglect that the magnetic flux was $\Phi/\Phi_0 = 1/2$ in [74]. These two results strongly support the presence of a reentrance effect associated with the AAS effect in our Nb/MWNT system.

The enhancement of the reentrance effect at $\Phi/\Phi_0 = 1/2$ is qualitatively explained by the decrease of the effective N-channel length ($L$), due to the destructive phase interference in the AB ring, for $E_{Th} = \hbar D/L^2$ in [74] (Fig. 24b). The $L$ for $E_{Th}$ consists of the $L'$ and $L''$ regions. Because the destructive phase interference at $\Phi/\Phi_0 = 1/2$ enhances the zero electron–hole pair amplitude at the $\gamma$ point and the $L''$ region, this effect leads to the reduction of $L$ down to $L'$. Consequently the conductance-maximum temperature shifts to higher temperatures. Our results are consistent with this interpretation (Fig. 24). In the following, we explain the "$T_{re} = 0.74 \times T_{Th}$" relation. We point out that in the data fitting for the $T_{Th}$ vs $L_{tube}^{-2}$ relation, we did not include the length of AAS trajectory. By using $\beta = 1$ and assuming a length of 500 nm for this AAS trajectory, we confirmed that it gave the best fit to the measured $T_{re}$ vs $L_{tube}^{-2}$ relation. Hence, the conductance-maximum temperature shifts to $T_{re} = 6$ K, indicating $L = 740$ nm, at $\Phi/\Phi_0' = 1/2$. For a AAS trajectory length of 500 nm, this means $L' = 240$ nm, based on the previous fitting. Interestingly, this implies that the main AAS trajectory is located at a distance of 240 nm from the Nb/MWNT interface (Fig. 24a).

However, (1) the AAS oscillations assuming $\Delta\Phi = \Phi_0/80 = \Phi_0'$ and influence of spin–orbit interaction (SOI) and (2) the "shrinkage" of the reentrance effect at $\Phi/\Phi_0' = 1$ are very anomalous. In (1), SOI is not required if one follows the aforementioned explanation. The negative MC around zero magnetic field in the MC oscillations can be qualitatively understood by the enhancement of the reentrant conductance (Fig. 23b) due to the destructive phase interference at $\Phi/\Phi_0' = 1/2$. When this conductance decrease due to the reentrance effect overcomes the conductance increase due to the destructive phase interference in the AAS effect, the negative MC can emerge However, the MC oscillation with "the period $\ll$ the quantum flux" has never been observed in our N electrode/MWNT junctions before [81]. Besides, only quantum flux should penetrate into the Nb electrode that exists on the inner space of MWNTs in Figure 24a, because the tops of the inner space of MWNTs are capped by the Nb film. In this sense, the small period may indicate that MC oscillations may be not associated with AAS oscillations. This is still in contradiction to the explanation supporting the reentrance effect.

For a possible interpretation, we may have to take into consideration (1) the contribution of the trajectory, which encircles a MWNT in the $n$th time, where $n$ is the integer, which leads to $\Delta\Phi = \Phi_0/n$, (2) the contribution of extra phases resulting from Andreev reflection, which takes place in AAS trajectories facing the Nb/MWNT interface, which leads to $\Delta\Phi = \Phi_0/2$ [75], and (3) multiple Andreev reflections due to the strong electron interaction [67, 77], which may lead to $\Delta\Phi = \Phi_0/2^n$.

Finally, we tried to eliminate the reentrance effect by reducing the interface transparency of the MWNT/Al substrate junction. In order to realize this, a thin tunnel barrier with a thickness of a few nanometers was formed at the bottom end of the pores (i.e., MWNTs) by optimizing the anodization condition of the alumina membrane. Annealing this sample after the synthesis of MWNTs leads to diffusion of this tunnel barrier and the bottom part of the MWNT (we confirmed this by TEM), yielding a lower transparency interface of the MWNT/Al-substrate junction. As explained, because this low transparency reduces diffusion out of Cooper pairs from the MWNT to the Al substrate, the reentrance effect must disappear. The result is shown in the inset of Figure 25. In fact, the $G_0$ increase is only observable from $T = 6$ K down to $T = 1.5$ K as temperature decreases. Because this $T = 6$ K approximately corresponds to $T_{px}$ of MWNTs with $L_{tube} = 0.8\ \mu$m, this conductance increase can be due to PIS. The main panel of Figure 25 also shows the temperature dependence of its $G_0$ vs voltage relationship. A conductance peak around zero voltage starts to grow in the region between $-0.65$ and $+0.65$ mV (i.e., $\Delta = 1.3$ meV) from $T = 6$ K corresponding to $T_{px} = 6$ K, whereas two conductance dips appear between the voltage regions of $\pm 0.6$ and $\pm 2$mV also at $T = 6$ K. This conductance peak monotonically reduces to $T = 1.5$ K with decreasing temperature, while the conductance dips also monotonically deepen. In addition, the very sharp conductance valley observable at a voltage of $+0.2$ mV disappears as the temperature decreases.

This disappearance of reentrant conductance strongly supports the claim that the highly transparent interface of the MWNT/Al substrate junction is the key factor in the reentrance effect. This growth in the conductance peak is also evidence of the high-transparency interface of the Nb/MWNT junction and the consequent PIS. It is already known that Andreev reflection (in which an incident electron coming from the N is converted into a Cooper pair in the S, leaving a reflected hole in the N, at the S/N junction)

**Figure 24.** (a) An Nb/MWNT junction with a trajectory for AAS oscillation. (c) An S/N junction with the AB ring in its N-region [74]. This structure is assumed to be equivalent to (a) just by replacing the AB ring to the AAS trajectory.
**Figure 25.** Temperature dependence of conductance vs voltage relationships in an Nb/MWNT/Al array with $L_{tube}$ of 0.8 $\mu$m and low-transparency interfaces of the MWNT/Al-substrate junctions. Inset: Temperature dependence of $G_0$ of the main panel.

with a highly transparent S/N interface leads to a conductance peak, particularly in one-dimensional N/S junctions [70, 84]. Our Nb/MWNT junction mostly corresponds to this case, because: (1) $T = 6$ K, at which the conductance peak emerges, agrees with $T_{px}$ as mentioned and is below $T_c$ of our Nb film. (2) The value of $\Delta = 1.3$ meV is approximately equal to the $\Delta$ of Nb (i.e., $\Delta_{Nb} \sim 1.4$ meV). (3) The phase coherence length, estimated from $D = 0.37$ m²/s as 523 nm, is larger than the circumferential length of the MWNT which is about 250 nm, so that our MWNT can be a one-dimensional conductor in the diffusive regime.

### 4.2.3. Conclusion

In conclusion, we reported a conductance increase with the onset temperature of $T_{px} = 9$ K as the highest case and its decreasing with decreasing temperature in Nb/MWNTs junctions with high-transparency interface. The junctions have been achieved by utilizing MWNTs synthesized in nanopores of alumina membranes. We argued that the former and the latter originated from the PIS and its reentrance effect, respectively. The estimated large diffusion constant of Cooper pairs in the MWNTs strongly contributed to these two effects, whereas it did not enhance the critical magnetic field for the vanishing PIS. The observed drastic magnetic-field dependences were also consistent with previous works but some questions remain open. Because of the high reproducibility, MWNTs must be a molecular material relevant for the investigation of superconductivity related phenomena.

### 4.3. Y-Junction Carbon Nanotubes

Self-gate Suppressed Rectification Property in Y-Junction Carbon Nanotube with a Large Diameter and Acute Angle of Two Branches.

### 4.3.1. Introduction

We successfully synthesize a variety of Y-junction multi-walled carbon nanotubes with different diameters and angles of two branches by utilizing porous alumina membranes realized by a two-step anodization method and investigate those electrical properties. We find here that even a Y-junction MWNT with a diameter as large as 50 nm in its stem can show a stable rectification property following the Anderson mode for macroscopic heteroband junction with 20 meV of built-in potential, when the two branches form acute angle. In contrast, we clarify the presence of a current-suppression mechanism deviating from the Anderson model, in the forward voltage region. We argue that this is due to a self-gating effect, caused by difference in an electrochemical potential between the two branches.

A carbon nanotube, a molecular conductor, is a strong candidate for nanoelectronics devices. It is theoretically known that the junction at which a larger diameter "stem" of a single-walled carbon nanotubes is divided into two smaller diameter "branches" (Y-junction or T-junction SWNTs) exhibits interesting electrical properties (such as nano-hetero-junctions of different bandgap semiconductors and nano-Schottky junctions) representing a rectifying nanodiode [86–88]. This is because SWNTs can be either metal or semiconductor with different bandgaps, depending on the diameter, chirality, and defects. Multiple connection of such SWNTs with differences in chiralities, diameters, and defects leads to the properties mentioned at the Y-junction [89].

In addition, the presence of the Y-junction implies the connection of one more SWNT to this two-terminal junction as the third terminal. This third terminal can act as a gate electrode which can control the electric features of two-terminal SWNT devices. A three-terminal operation of quantum conductivity, like a metal–oxide–semiconductor transistor, has also been predicted only theoretically [86].

Hence, Y- and T-junction SWNTs are expected to become a key component of carbon nanotube integration circuits, but synthesizing them with high reproducibility has proved to be very difficult. Only recently have some experiments [90–92] reported successful synthesis of Y-junction nanotubes and the presence of asymmetric current versus voltage features only at room temperature, possibly resulting from heteroband junctions. The details of the electrical properties are still ambiguous.

Even apart from carbon nanotube systems, the Y-branch nano-electron-wave guide is attracting large attention as a novel switching device in nanoelectronic junctions [93, 94]. It has been reported that capacitive coupled two branches led to switching of electron-wave flow between the branches up into THz range due to a self-gating effect in new class of gateless mesoscopic devices [93] and to switching gain increasing superlinearly with source–drain voltages due to side-gate voltages applied [94]. Both reports implied that even very small voltages applied on both sides of the branches (i.e., lateral electric field) efficiently switched flow of electron waves between the two branches. A Y-junction carbon nanotube can be a good candidate for such novel nano-electron-wave guides.

Here, in this work, we successfully synthesize a variety of Y-junction multiwalled carbon nanotubes with different

diameters and branch angles by utilizing Y-shaped nanopores of alumina membranes [95, 96] realized by a two-step anodization method. We clarify that even a Y-junction MWNT with a large diameter stem can lead to macroscopic heteroband junction representable by the Anderson model at the Y-junction, when the two branches form an "acute angle." We also find a deviation from the model, implying a self-gating effect due to capacitive coupling of the two branches.

### 4.3.2. Experimental Results and Discussion

We show the structural information of Y-shaped pores, in which Y-junction MWNTs were synthesized, in Figure 26. We have already confirmed that our carbon nanotubes synthesized in porous alumina membrane by chemical vapor deposition were MWNTs, which exhibited diffusive electron-wave transport at low temperature [95, 96]. Besides, nanotubes synthesized by similar methods showed semiconducting behavior at room temperature [91]. Hence, our MWNTs can have semiconducting characteristics in the diffusive regime. We prepared three different types of Y-junction MWNTs with one straight MWNT as a reference for this experiment, and their features are described in Table 2. SEM images of those pores are shown in Figure 26c. These imply that only type B1 has an acute angle between the two branches. In contrast, there is a spacing of 20–30 nm between two branches in types A and B2, due to the large diameter stems.

Figure 27 shows the current versus voltage ($J$ vs $V$) characteristics of each type of MWNT at room temperature. First, we find that only type B1 exhibits a strong asymmetry and rectification property similar to that noted in past reports (Fig. 27b). Because type C, which is not a Y-junction MWNT, exhibited a symmetric $J$ vs $V$ curve (Fig. 27d), we conclude that not the interface of electrode/MWNT junctions but the Y-junction is the origin for this asymmetric $J$ vs $V$ property of type B1. In contrast, second, we note that the $J$ vs $V$ feature of type A is mostly symmetric and shows poor reproducibility (Fig. 27a). Because the ratio of diameters between the stem and branches is the same as that of type B1, the very large diameter around 90 nm in the stem of type A can be the origin for the instability and elimination of the rectification property in Figure 27a. Third, we find that the $J$ vs $V$ feature of type B2 (Fig. 27c) even with a high diameter ratio (above 4) of the stem and branch is also symmetric. This also implies that a large diameter around 70 nm in the stem of type B2 eliminates the rectification property, even under such a high diameter ratio.

Why do the large diameter stems in types A and B2 eliminate the rectification property? Why can only type B1 have the rectification property? One main reason can be the angle between the two branches (i.e., whether the angle is obtuse or acute) as mentioned for Figure 27c, because only type B1 has the acute angle between the two branches. Reference [86] theoretically reported a rectification property in a (14,0) SWNT branching two (7,0) SWNTs with acute angle. The acute angle led to the presence of six heptagons clustered at the Y-junction, leading to the rectification property. In contrast, [86] also showed that a Y-junction SWNT, consisting of three (8,0) SWNTs, with an obtuse angle led

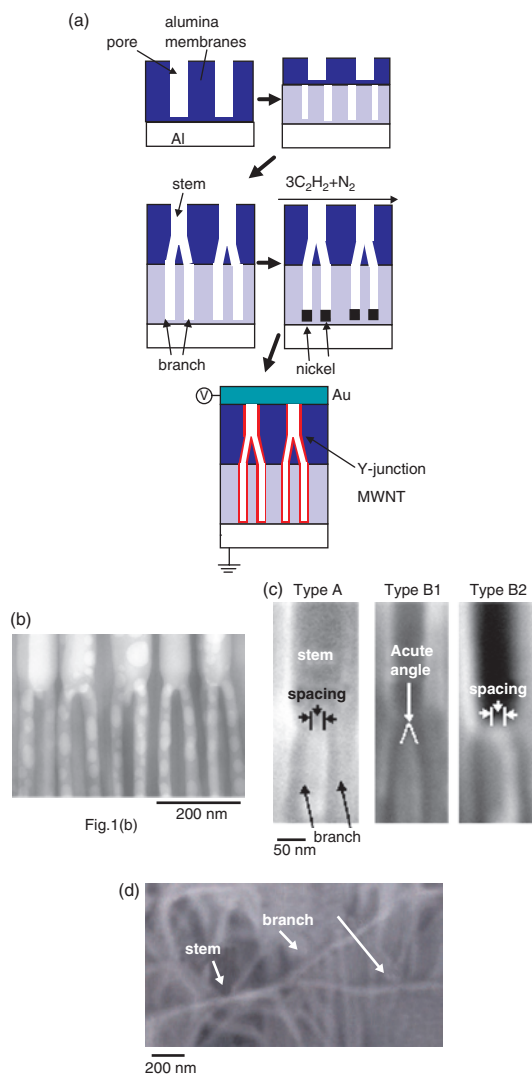

**Figure 26.** Schematic cross-section of alumina membrane with Y-shaped nanopores and its synthesis method. First, aluminum substrate, with applied positive bias voltage (50 V for type A and B1, 60 V for type B2), is anodized in $H_2C_2O_4$ under a current density and temperature of 10 °C (left upper). This leads to large-diameter pores for the stem in the alumina membrane. After this anodization is stopped, second, anodization with reduced bias voltage of 35 V was continuously performed under the same conditions, leading to smaller diameter pores for the branch (right upper). The total thickness of the alumina membrane is 5 $\mu$m in each sample. Y-shaped pores were synthesized by automatic alignment of the interface of the upper and lower membranes, due to self-organization (left lower). We also realized smaller diameter pores in type B by reducing current density for anodization, compared with type A. Consequently, we successfully prepared three types of Y-shaped pores for this experiment (Table 2). After the synthesis of the Y-shaped pores, nickel was electrochemically deposited into the bottom ends of the branch pores and then, Y-junction MWNTs were synthesized by chemical vapor deposition using the nickel as a catalyst (right lower and the lowest). Although we measured the averaged characteristics of Y-junction MWNTs with the number of about $10^4$, it was already confirmed that even this was mostly the same as those in an individual Y-junction nanotube [91]. (b) Cross-sectional TEM image of Y-shaped pore array for type B1 in an alumina membrane. (c) Cross-sectional SEM images of Y-shaped pores, for types A, B1, and B2 (see Table 2), in alumina membranes. (d) SEM overview image of a Y-junction nanotube (shown by an arrow) of type B1.

**Table 2.** Structure parameters for types A, B1, B2, and C of Y-shaped pores.

|            | Type A | Type B1 | Type B2 | Type C |
|------------|--------|---------|---------|--------|
| $\phi 1$ (nm) | 90  | 50  | 69  | 80 |
| $\phi 2$ (nm) | 26  | 15  | 17  | — |
| $\phi 3$ (nm) | 27  | 16  | 19  | — |
| $\phi 1/\phi 2$ | 3.5 | 3.3 | 4.1 | 1 |
| $\theta$   | obtuse | acute | obtuse | — |
*Note:* The diameter corresponds to most outer diameters of MWNTs. We measured about 30 pores in each array to confirm these averaged structure parameters. Types A and B1 have mostly the same ratio of the stem and branch in diameter, but each pore diameter in type A is approximately two times larger than that in type B1. Types B1 and B2 have mostly the same diameter in the branch, but the ratios of the stem and branch in diameter in type B2 were increased from that of type B1 by increasing the stem diameter. These lead to acute angle of two branches only in type B1. Type C has just a straight shape like a general MWNT with a large diameter.

to only two heptagonal defects. These calculation results imply the presence of heptagon defects at the Y-junction parts with the acute angle in our nanotubes (i.e., in type B1), although we failed to observe actual chilarity of our

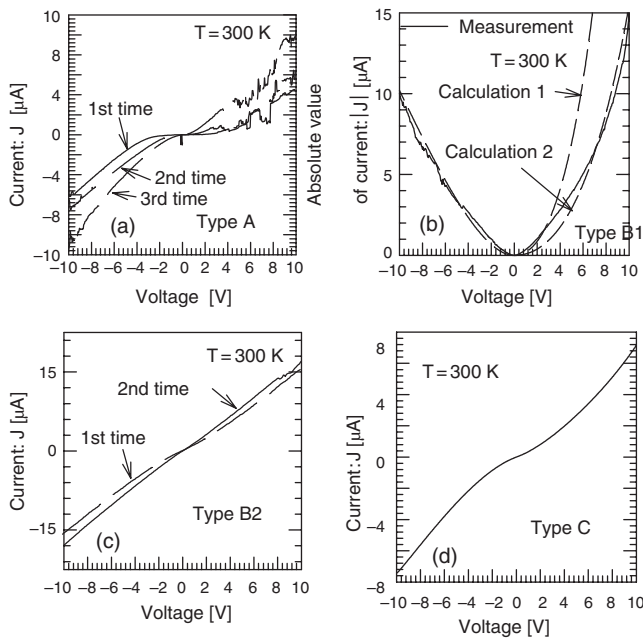

**Figure 27.** Current vs voltage ($J$ vs $V$) curves, measured three times, of type A. The first-time measurement exhibits weak asymmetry, whereas the asymmetry drastically degrades in the second- and third-time measurements, resulting in symmetric features. (b) "Absolute value of the $J$" vs $V$ curve of type B1. Solid line is the measurement result. Calculations 1 and 2 mean the calculation results using only the Anderson model [Eqs. (23) and (24)] and that with the self-gating effect [Eqs. (23)–(27)], respectively. (c) $J$ vs $V$ curves of type B2, implying a mostly symmetric property in the two-time measurements. (d) $J$ vs $V$ curves of type C, implying a perfect symmetric feature.

Y-junction MWNTs here. Besides, because one MWNT consists of many SWNTs, rolled up coaxially, with different chiralities and diameters, the acute angle between the branches in our Y-junction MWNT will introduce defects with the number larger than that of one Y-junction SWNT, at some of shells. Reference [86] implied that heptagonal defect had a positive charge and, hence, asymmetric locations of such defects in Y-junction tube easily led to the rectification property. Y-junction MWNTs can also easily introduce such asymmetric location of defects near the Y-junction parts at some of shells, due to the structural reasons mentioned with a larger number of defects. Therefore, we speculate that the presence of heptagon defects introduced by the acute angle of two branches and the asymmetric location yielded the rectification property in our Y-junction MWNTs. Anyway, these experimental results revealed that even a Y-junction MWNT with diameter as large as 50 nm in its stem could show a stable rectification property when the two branches formed the acute angle. In contrast, the Y-junction MWNTs including the diameters larger than 50 nm with obtuse angle between two branches could not show any rectification properties even if they had the high diameter ratio of the stem and branches.

Based on this result, we focus on detailed features of type B1. Figure 28 shows the logarithmic conductance ($\log[G]$) versus the inverse of temperature ($1/T$) relation, which are the so-called thermal-activation-type characteristics representing the semiconductor-like features, in type B1. We found that the $\log[G]$ vs $1/T$ relationships were very different between the positive (Fig. 28a and b) and negative (Fig. 28c) bias voltage regions. The $\log[G]$ vs $1/T$ relation in the negative bias voltages is linear and hence follows the thermal-activation type at high temperatures (Fig. 28c),

**Figure 28.** Logarithmic current ($\log[J]$) vs inverse of temperature ($1/T$) relation at $V = +1$ V above $T = 285$ K of type B1. (b) Logarithmic conductance ($\log[G]$) vs $1/T$ relation at $V = +1$ V below $T = 285$ K of the type B1. (c) Log [$G$] vs $1/T$ relation at $V = -9$ V of the type B1. The sold line shows the best fit by the thermal-activation relation.

whereas this relation saturates at low temperatures below a transition temperature. In contrast, the $\log[G]$ vs $1/T$ relation in the positive bias voltage regions does not follow the thermal-activation type. It increases as temperature increases above $T \sim 285$ K (Fig. 28a), whereas it decreases with decreasing temperatures below $T \sim 285$ K (Fig. 28b).

Because the asymmetric $J$ vs $V$ curve in Figure 27 (b) means the presence of either a heteroband junction or a Schottky junction, we carry out data fitting by the Anderson model for macroscopic semiconductor heterojunction as follows [97]. The $J$ vs $V$ characteristics are given by the following equation in the Anderson model:

$$J = (qA^*TV_{bi}/k)\exp(-qV_{bi}/kT)$$
$$\times (1 - V_{sd}/V_{bi}[\exp(qV_{sd}/kT) - 1] \quad (28)$$
$$A^* = 4\pi qm^*k^2/h^3 \quad (29)$$

$q$, $A^*$, $V_{bi}$, $V_{sd}$, and $m^*$ are the elementary charge of hole, the effective Richardson constant, the built-in potential at the heterojunction, the source–drain voltage applied between the electrodes for the stem and one branch, and the effective mass of hole, respectively. We used $V_{bi}$ as only a fitting parameter, normalizing the observed current by the number of measured Y-MWNTs in one array. The agreement between the experimental result and the calculation for the $J$ vs $V$ curve is good below $V = 2.4$ V (calculation 1 in Fig. 27b). In particular, the experimental result and the calculation exhibit excellent agreement in the negative bias voltage region. The current in this region does not reach saturation levels but decreases linearly proportional to the bias voltage. This implies the absence of a Schottky junction, because the current through a Schottky junction with reverse bias reaches saturation due to the Schottky barrier. This nonsaturated $J$ vs $V$ feature is a manifestation of a heteroband junction at the Y-junction. In addition, the $\log[G]$ vs $1/T$ relation in the negative voltage region is also in good agreement with the calculation result obtained from Eq. (28) (Fig. 28c). The best fitting in Figures 27b and 28c gives $V_{bi} = 20$ meV as the heterojunction barrier.

These results provide a configuration of a two-terminal macroscopic heteroband junction for the Anderson model at the junction of the stem and one branch (Fig. 29), when we neglect the influence of the other (third) branches. Because the bandgap is proportional to the inverse of the MWNT diameter in semiconducting carbon nanotubes, the branch with 15 (or 16) nm diameter should have a bandgap larger than that of the stem (50 nm diameter). We applied the positive and negative bias voltages to the braches and stems, respectively, in the measurement for Figure 27b. Because the positive and negative bias regions correspond to the forward and reverse bias regions, respectively, in Figure 29, the current carrier can be a hole. Hence, the band discontinuity at the valence band of heterojunction can be 20 meV as $V_{bi}$.

We have confirmed that a Y-junction MWNT even with the diameter as large as 50 nm in its stem, when the acute angle between the branches is formed, can exhibit the electrical properties of a macroscopic heteroband junction, mostly following the Anderson model. This emphasizes an advantage that one does not have to synthesize carbon nanotubes with diameters as small as a few nm,

**Figure 29.** Configuration for a heteroband junction, corresponding to the reverse and forward bias voltage regions in the $J$ vs $V$ curve in Figure 27b, based on the measurement results and Anderson model.

to realize heteroband junction by connection of different carbon nanotubes. However, the following two problems remain in the interpretation of these experimental results: (1) disagreement between the measurement and calculation results above $V = +2.4$ V in Figure 27b and (2) conductance decrease accompanying a temperature decrease in Figure 28b. Because Eq. (28) indicates that there should be a larger current in the forward bias region in Figure 27b and conductance should increase with decreasing temperature in Figure 28b, the presence of a mechanism that prevents the current from increasing in accordance with the Anderson model, in the forward bias region, is implied.

Here, we can understand this current-suppression mechanism in accordance with a side-gating effect reported in [93, 94]. We have taken into consideration only the connection of the stem and one branch (i.e., two-terminal configuration) for the explanation of the rectification property. However, if resistances of the two branches are asymmetric (e.g., $R_{s1} + R_{b1} \ll R_{s2} + R_{b2}$ in Fig. 30), source–drain voltage ($V_{sd}$) applied between the stem and branches leads to difference in an electrochemical potential between the two branches ($\Delta\mu_{12}$). Because alumina film exists between the branches, this $\Delta\mu_{12}$ results in a capacitive coupled two-branch system (Fig. 30). Reference [93, 94] implied that even very small difference in voltages applied on both sides of the branches (i.e., lateral electric field) yielded a large difference in $\Delta\mu_{12}$, leading to efficient switching flow of electron waves between the two branches, in a nano-Y-branch waveguide. This is represented by the following equations taking into account only a self-gating effect.

$$\Delta V - sd = 2R_0J_1 = (1 + \gamma)/(1 - \gamma)$$
$$\times [(\Delta\mu_{12}/-e) - (\mu/-4e)] \quad (30)$$
$$\gamma = \tanh[\eta_{sg}(\Delta\mu_{12}/-e)/V_s] \quad (31)$$
$$\eta_{sg} = C_Q/(C_Q + 2C_{12}) \quad (32)$$

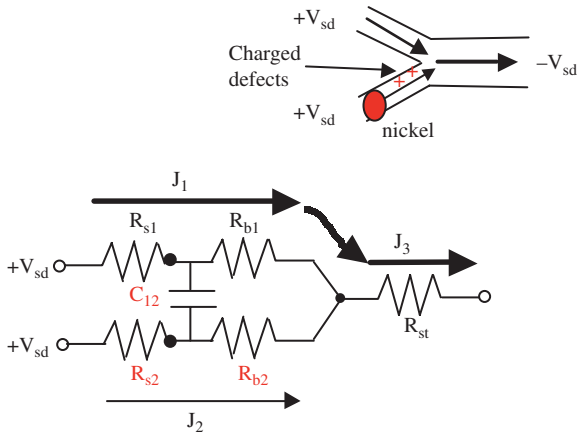
$R_0 = h/2e^2 \sim 13$ k$\Omega$, $J_1$ is the current represented by Anderson model in one branch channel (Fig. 30), $\mu$ is


**Figure 30.** Equivalent circuit of a Y-junction nanotube. $R_s$, $R_b$, and $R_{st}$ are the resistances of the source contact (interface resistance at the Al/MWNT-branches), branches, and stem, respectively. $J_i$ is the hole current in each part of the Y-junction MWNT.

the electrochemical potential in electrode connecting to the stem, $V_s$ is the switching voltage which is a measure of how large a change in $\Delta\mu_{12}$ is required to affect $\gamma$, $C_Q = 2/R_0v_F \sim 2 \times 10^{-10}$ (F) is the quantum capacitance (i.e., $e^2 \times$ density of state), and $C_{12} \sim 10^{-14}$ (F) is the capacitive coupling between the two branches (Fig. 30). $\Delta V_{sd}$ in Eq. (30) means a voltage difference, yielded by $\Delta\mu_{12}$, between the electrodes for the stem and one branch. $\gamma$ in Eq. (31) is the switching parameter between the two branches. $\eta_{sg} \sim 0.95$ in Eq. (32) is the side-gating efficiency which is a measure of how well the $\Delta\mu_{12}$ follows the side-gating voltage which was yielded by $C_Q$ and $C_{12}$. Consequently, these equations imply that even very small $\Delta\mu_{12}$ leads to a large $\Delta V_{sd}$, induced by $C_Q$ and $C_{12}$ with asymmetrical located charges on the two branches, resulting in a large current only in one branch and, hence, efficient switching of current between the two branches. Because this current flow enhances $\Delta\mu_{12}$, this self-gating effect grows self-consistently. When this $\Delta V_{sd}$ plays the role of voltage relaxation for the heteroband junction in Figure 29, the rectified current can be reduced as we found.

We performed data fitting to Figure 27b introducing this $\Delta V_{sd}$ into Eq. (28) as the term of $(V_{sd} - \Delta V_{sd})$. The fitting parameters are $\Delta V_{sd}$, $(\Delta\mu_{12}/-e)$, and $V_s$. The result in a positive bias voltage region is shown in Figure 27b as calculation 2. The agreement between the data and the calculation result is good. The best fitting gives $\Delta V_{sd} = 0.3V_{sd}$, using $(\Delta\mu_{12}/-e) = 0.1V_{sd}$ and $V_s = 0.1$ (V). Therefore, this result implies that the origin for the current reduction deviating from the Anderson model is $\Delta\mu_{23}$. We confirmed that this $\Delta\mu_{12}$ is due to the following origin.

We investigated the structures of Y-junction MWNTs in detail and found that the amount of nickel, which was electrochemically deposited into the bottom of the pore branches as a catalyst, was asymmetric between the two pore branches of alumina membranes, by high-resolution cross-sectional TEM observation. This asymmetry is easily introduced, because the electrochemical deposition is very sensitive to electric field applied (i.e., positive and negative bias voltages applied between the Al substrate and the other electrode, respectively, in our case). Even very small struc-

tural asymmetry in the two branches of a Y-shaped pore leads to a large difference in the electric field and, hence, the asymmetric volume of nickel catalyst between the two pore branches. A larger volume of nickel in one branch still remains at the bottom of pore as particles even after the synthesis of Y-junction MWNTs. These nickel particles diffuse around the interface of the Al substrate/Y-MWNT branch junction by annealing [95], and then lead to high interface resistance (i.e., $R_{s1} \ll R_{s2}$ in Fig. 30) because it is well known that interface resistance of metal/carbon nanotube junction is basically high except for TiC, SiC, and NbC [98]. This asymmetric resistance can yield $\Delta\mu_{12}$.

Besides, [93] reported that the self-gating effect together with heptagon induced positive charge might lead to induction of the self-gating effect. Because it could be assumed that the heptagon induced positive charges located asymmetrically near the Y-junction in our Y-junction MWNT as mentioned, this is consistent with our model.

### 4.3.3. Conclusion

In conclusion, we found that even the Y-junction MWNT with diameter as large as 50 nm in its stem exhibited the rectification properties that were in good agreement with the Anderson model for macroscopic heteroband junctions with a hetero barrier of 20 meV, when the two branches formed the acute angle. The observed deviation from the Anderson model was also interpreted by the self-gating effect caused by $\Delta\mu_{12}$ due to the asymmetric resistance between the two branches. We also pointed out that the heptagonal defects introducible by the acute branch angle were the origin for the rectification property.

However, we failed to find actual chilarities and the presence of heptagons with asymmetric locations in the Y-junction MWNTs. Besides, it was not clarified how the heptagon leads to heteroband junctions. Hence, further investigation is expected to reveal them. In any cases, our results imply that porous alumina membrane is a favorite template for synthesis of a variety of Y-junction nanotubes that can be a strong candidate for a molecular rectification diode and transistor.

## 5. FERROMAGNETIC NANOWIRES

### 5.1. Macroscopic Quantum Tunneling of Magnetic Domain Walls

#### 5.1.1. Introduction

Detailed behavior of abrupt magnetoresistance jumps in Ni-nanowires, imbedded into nanoporous alumina membranes, is reported. Abrupt elimination of the MR hysteresis by the MR jump indicates abrupt motion and emission of magnetic domain walls (DWs) from the wires. We find that temperature dependence of the inverse of the normalized jump magnitude shows behaviors similar to those of thermal escape and macroscopic quantum tunneling (MQT) rates in Josephson junctions. We also find that the MR jump is also sensitive to wire diameters. These can be evidence for MQT of magnetic DWs. We also reveal the possible presence of weak localization in the Ni-wire and find that this MR jump is independent of it.

Macroscopic quantum tunneling is an interesting phenomenon, proving the presence of a single macroscopic degree of freedom governed by quantum mechanics. Since it also leads to macroscopic quantum coherence (MQC), useful for realization of quantum computation, it is currently of great interest. The possibility of MQT has been discussed in some material systems (e.g., Josephson junction systems [99], (anti)ferromagnetic nanomaterials [100–106], and organic nanomaterials with charge density wave [107]).

In particular, MQT has been successfully studied in Josephson junction systems. Clarke et al. observed phase difference across the Josephson junction and precisely measured an escape rate, $\Gamma$, of the particle associated with the phase difference from the washboard potential well as the function of current [99]. They found that the experimental results were in good agreement with the prediction by Caldeila and Leggett both in nondissipative and dissipative environmental cases. Hence, $\Gamma$ at low temperatures was interpretable as MQT. Recent observation of quantum oscillation between two charge states in a single Cooper-pair box, utilizing charging effect by single Cooper-pair tunneling, also exhibited a possible MQT and MQC.

In contrast, experimental identification of MQT in ferromagnetic materials still remains ambiguous, despite many theoretical and experimental papers on the subjects [2–8].

Abrupt MR jumps observed in ferromagnetic nanowires and -particles are such examples. They have been discussed from the viewpoint of MQT of magnetic domain walls, spin transition layers including a large number of electron spins. For instance, Hong et al. experimentally reported on a stochastic behavior of the critical magnetic fields for MR jumps and its dependence on microwave radiation in Ni-nanowires [2–4]. The results were interpreted by MQT of magnetic DWs through a tunnel barrier of a pinning potential well. In their interpretation, since the DW abruptly causes MQT through the tunnel barrier at the critical magnetic field, the total magnetization abruptly changes, leading to the abrupt MR jump. They, however, did not show detailed dependence (e.g., MR jump on hysteresis loop and wirediameter, jump magnitude on temperature), which can be more direct evidence for MQT.

In addition, another interpretation for the MR jump has been presented theoretically. It is a destruction of weak localization, the constructive phase interference effect of electron waves in the diffusive regime [105]. WL is strongly coupled with phase of electron spin in ferromagnetic materials. Hence, it argued that spin-flip scattering in the DW and the fluctuation caused by DW motion lead to the dephasing in WL and, hence, the negative MR. None, however, experimentally investigated this theory, including coexistence of phase-interference effects in ferromagnetic nanostructures.

In this work, we experimentally report on detailed behaviors of abrupt MR jumps observed in Ni-nanowires, imbedded into nanopores of alumina membranes. The observed features of hysteresis loops in MR, the temperature, and wire-diameter dependences of MR jumps can be evidence for MQT of magnetic DWs. We also find that possible WL, independent of the MR jump, exists in the Ni-nanowires.

## 5.1.2. Experiments and Discussion

The array sample of Ni-nanowires for MR measurements has been fabricated by electrochemically depositing Ni into nanopores of porous alumina membranes [106, 108–111]. This method leads to high confinement of only Ni-atoms into the pores and, hence, Ni-nanowires with less defects, impurities, and good morphology, compared with nanowires fabricated by the lithographic method and placed on substrates. In addition, since the aspect ratio between the wire length and the diameter is as high as 100, it provides high anisotropic MR as mentioned later. Wire-nanostructure parameters like diameters also can be easily controlled in this method. Therefore, this method is relevant for this study.

Figure 31a shows the typical MR jumps observed in our sample. It clearly exhibits abrupt MR jumps (MR increases) around $B = 0.7$–$0.9$ T [i.e., critical magnetic fields ($B_c$) for MR jumps]. The MR jumps have the following two characteristics. (1) The emergence of MR jump depends on the measured times at the same $B_c$. (2) $B_c$ are observable not

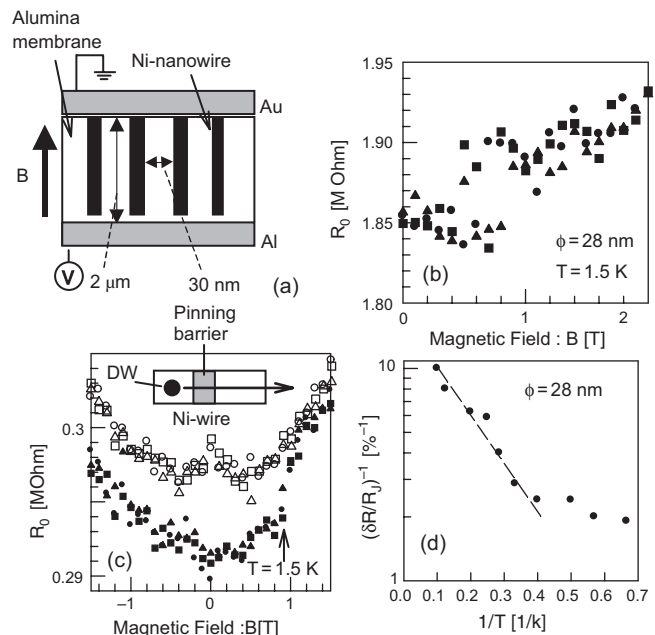

**Figure 31.** Typical magenetoresistance jumps observed in the Ni-nanowire array including the wire number of about $10^4$. Sample structures are mostly the same as those in Section 3, except for elimination of the thin tunnel barrier attached to the bottom ends of the Ni-nanowires. The mean wire diameter ($\phi$), length, and spacing between the wires are about 28 nm, 2 $\mu$m, and 18 nm, respectively. Since the interwire spacing is large enough, the MR value shown here means the superposition of individual wire's characteristics. The half width of the distributed diameter is about 15%, implying high uniformity. Magnetic fields were applied in parallel with the wire axis in all the measurements. (b) Hysteresis loop in the MR and its elimination by the MR jump. Sample-structure parameters are basically the same as those in (a). Arrows mean the MR jumps. Asymmetry of MR jump on the magnetic fields is due to a tunnel junction connected to the one end of the wire as explained elsewhere. (c) Temperature dependence of the inverse of normalized MR jump magnitude in the sample with the same parameters as (a). Dotted line is a guide for the eye. Reprinted with permission from [125], J. Haruyama et al., *Phys. Status Solidi A* 189, 609 (2002). © 2002, Wiley–VCH.

at one magnetic field point but at several field points (i.e., $B = 0.7$, 0.8, and 0.9 T). About the first point, three times we measured MR at each magnetic field and we plot them on Figure 31a. For instance, MR jump is unobservable at the first time measurement at $B = 0.7$ T, whereas it appears at the second and third time measurements at the same $B (= 0.7$ T). This implies that this MR jump is a stochastic phenomenon. In this sense, this is qualitatively consistent with Hong's observation [100–102]. About the second point, we measured a lot of wires ($\sim 10^4$) in one array sample at the same time. Since $B_c$ is sensitive to the wire diameter as revealed in the later part (Fig. 32), this will be due to the distributed wire diameter. When we measured an array sample with the wire number as large as $10^8$, the MR jump was actually smeared out by averaging. It supports this argument.

This MR exhibits a hysteresis loop as shown in Figure 31b. Presence of a hysteresis loop in ferromagnetic materials implies that spin flipping cannot follow the magnetic field in a reversed process in its some geometry parts, leading to geometry parts with different spin orientations (i.e., magnetic domains) and hence magnetic DWs. Therefore, this result suggests that two magnetic domains at least exist in our Ni-wires, although the presence of multidomains is suppressed as the wire diameter is reduced.

However, it should be noticed that this hysteresis loop is very different from that in the past reports in the following very important point; that is, this hysteresis loop is destroyed by MR jump (at magnetic fields higher than the $B_c \sim 1.0$ T) as shown in Figure 31b. This strongly implies that the magnetic DWs are abruptly emitted from the Ni-nanowires by this MR jump, based on the previous discussion.

Here, we investigate the correlation of MR jump with this abrupt motion of the DW by the following two measurements; (1) temperature dependence of the amplitude of MR jump and (2) wire diameter dependence of MR jump behavior.

Initially, Figure 31c shows the temperature dependence of the inverse of the normalized magnitude of MR jump, $(\Delta R/R_J)^{-1}$, where $R_J$ is the MR at the magnetic field right before the MR jump. Above $T \sim 3$ K, it exhibits the thermal-

activation-type characteristic

$$(\Delta R/R_J)^{-1} = A\exp(-\Delta E/kT) \tag{33}$$

where $A$ is the constant and $\Delta E$ is the activation energy. In contrast, it saturates below $T \sim 3$ K. This relation is very similar to the temperature dependence of thermal escape and MQT rates, $\Gamma$, of the particle associated with phase difference in Josephson junction, mentioned in the introduction and given by the equation [1]

$$\Gamma = (\omega_p/2\pi)\exp(-\Delta U/kT - \text{esc}) \tag{34}$$

where $\omega_p$ and $\Delta U$ are the plasma frequency of the particle in the potential well and the tunnel barrier height at the well, respectively. $T_{\text{esc}}$ was nearly equal to temperature at high temperatures (i.e., in classical regime), whereas $T_{\text{esc}}$ took temperature-independent values at temperatures lower than a critical temperature (i.e., in quantum regime) [99]. $\Gamma$ at high temperatures was interpreted as the thermal escape rate, whereas it was interpreted as MQT probability of the phase particle at low temperatures.

This qualitative agreement of $(\Delta R/R_J)^{-1}$ with $\Gamma$ on the temperature dependence implies a possibility that this MR jump, observed at the saturation region (temperatures below $T \sim 3$ K), is strongly associated with MQT in Ni-nanowires. Since the magnetic DWs move abruptly and are emitted from the wires at the MR jump as mentioned, this suggests a possibility that the MR jump is related to MQT of the magnetic DWs.

However, it should be noticed that $(\Delta R/R_J)^{-1}$ itself does not directly correspond to MQT probability in our case unlike the case of Josephson junctions. In Josephson junction systems, the thermal escape rate increased in an increase of temperatures, whereas it decreased at low temperatures, leading to MQT observed as a deviation from the relation. In contrast, although the thermal escape rate of the DW increases with an increase of temperatures like the Josephson junction case, it reduces $\Delta R/R_J$ by thermal smearing, because abrupt MR jumps can be caused only by the abrupt motion of DWs (i.e., MQT at a critical magnetic field). Thus, the $\log(\Delta R/R_J)^{-1}$ vs $1/T$ relation follows the thermal-activation type in this case. Therefore, only the $T_c$ can have a quantitative meaning as the transition temperature, at which the deviation from the thermal-activation relation emerges, indicating the emergence of MQT at lower temperatures. Hence, one cannot quantitatively compare Eq. (33) with Eq. (34).

In order to interpret $\Delta R/R_J$ from the viewpoint of MQT probability, the following relation must be required; $\Delta R/R_J \propto$ "emission rate of the magnetic DW from the entire parts of the nanowire: $\Gamma_{\text{em}}$" $\propto$ "MQT rates of the DW at the pinning potential barrier (i.e., $\Gamma$)." Hence, when $\Gamma_{\text{em}} = \Gamma$ is assumed, $\Delta R/R_J$ should be proportional to MQT probability (i.e., $\Delta R/R_J = A\Gamma$). This coefficient $A$ is the factor representing a sensitivity of DW emission to $\Delta R/R_J$ as follows.

There are the following two cases for the contribution of the presence of the magnetic DW to MR (i.e., representing coefficient $A$ of $\Delta R/R_J = A\Gamma$) in ferromagnetic systems.

**Figure 32.** MR jumps in the samples with the diameters (a) smaller and (b) larger than that of the Figure 31a sample. The critical magnetic field $B_c$ for MR jump shifts to the higher field with the larger $\Delta R$ ($B_c = 1.5$ T, $\Delta R/R_J = 7.9\%$) in the smaller diameter sample, compared with the Figure 1a sample ($B_c = 0.8$ T, $\Delta R/R_J = 2.3\%$). In contrast, the MR jump disappears in the large diameter sample. Reprinted with permission from [125], J. Haruyama et al., *Phys. Status Solidi A* 189, 609 (2002). © 2002, Wiley–VCH.

(1) Negative contribution: Since this makes MR decreases by DWs, MR is increased by the emission of DWs and abrupt MR jump.

(2) Positive contribution: In this case, MR is reduced by the MR jump. Since MR increases by the abrupt MR jump in our case, the contribution of presence of the DW should be negative.

The following two models are possible for such negative contributions to the best of our knowledge; (1) destruction of weak localization and (2) anisotropic MR (AMR). Here, since the decoherence for weak localization does not explain our results as mentioned later, AMR can be the origin. Because our structure is a nanowire with the high aspect ratio as high as 100, it provides a strong anisotropy and, hence, AMR is more sensitive to magnetic DW with random spin orientations. Increase of the spin coherence by the emission of the DW can drastically make the MR increase in our system. Hence, it can easily reflect the emission rate of the DWs and hence the MQT rate through the pinning barrier. If this negative contribution of the DW is quantitatively revealed, one will be able to find the value of $A$ and, then, estimate $\Gamma$ from $\Delta R/R_J = A\Gamma$. Since, however, we could not find detailed information of the DWs (e.g., the number of DWs in one Ni-wire, DW thickness, the number of spins, and those exact orientations in one DW) in this work, it is difficult here.

The wire diameter dependence of the MR jump also supports this argument. Figure 32 shows the results. $B_c$ shits to the higher magnetic field in the smaller wire-diameter sample as shown in (a), whereas MR jump disappears in the larger diameter sample in (b). In the larger diameter sample, the pinning of the DWs and AMR becomes weak, leading to the elimination of the MR jump. In contrast, they are enhanced in the smaller diameter sample, leading to the increase of $B_c$ and $\Delta R/R_J$.

Consequently, we conclude that the elimination of the hysteresis loop by the MR jump, the temperature dependence of $(\Delta R/R_J)^{-1}$ similar to that in Josephson junction, and the wire diameter dependence of MR jumps are the direct evidence for MQT of the magnetic DWs. The critical temperature, $T_c \sim 3$ K, between the thermal escape and MQT regimes in Figure 31c is actually the same as that in report by Hong and Giordano [101]. This conclusion is also consistent with the stochastic behavior of the MR jumps and the dispersion of $B_c$ in Figure 31a.

Finally, we discuss correlation between this MQT of DW and weak localization in the Ni-wire. Figure 33a shows the temperature dependence of magnetoconductance at each magnetic field. At $B = 0$ T, it can be well fitted by the formula for two-dimensional WL with magnetic impurities, as shown in the upper inset of Figure 33a. The best fitting gives $T_c$, a transition temperature between electron–phonon scattering and spin scattering regimes for dephasing, of 6 K. This $T_c$, relatively higher than those of nonmagnetic wires, is consistent with strong AMR in ferromagnetic nanowires. In addition, positive logarithmic dependence of MC was also found over a wide magnetic-field range in many other samples as shown in Figure 33b, despite the presence of MR jumps in the region. Figure 31a and b samples also exhibit qualitatively the same positive $G_0$

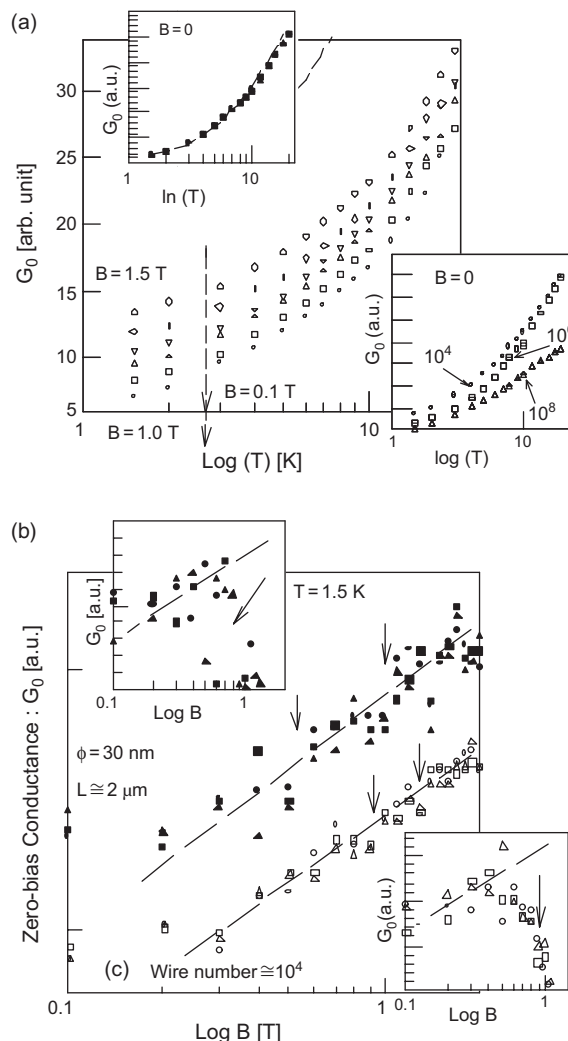

**Figure 33.** (a) Logarithmic temperature dependence of zero-bias magnetoconductance ($G_0$) around the critical magnetic field for MR jump ($B_c = 1.3$ T). Upper inset: Logarithmic temperature dependence of $G_0$ at zero magnetic field. Solid line is the calculation result by 2D weak localization formula. Lower inset: Dependence of the $G_0$ vs log($T$) relation on the number of the wires measured. $10^4$, $10^6$, and $10^8$ mean the number of the measured wires in each electrode area. All the electrodes were prepared on the same sample. (b) Typical logarithmic magnetic-field dependence of $G_0$ in two samples with mostly the same structure parameters. Arrows mean MR jumps. Dashed linear lines are only guides for the eye. Upper inset: That in the Figure 1a sample. Lower inset That of the upper curve in the Figure 1b sample. Reprinted with permission from [125], J. Haruyama et al., *Phys. Status Solidi A* 189, 609 (2002). © 2002, Wiley–VCH.

vs log[$B$] relations as shown in the insets of Figure 3b, although the range is smaller. These also qualitatively support 2D WL, although the relations saturate around $B = 0$ T. None successfully reported on such phase-interference effects in ferromagnetic nanostructures. One reason will be due to scattering by bad surface morphology due to surface anodization, because nanowires are directly placed on substrate surfaces in general measurement methods. In contrast, since our Ni-nanowires are imbedded into nanopores of alumina membrane, they can avoid such an influence leading to

this weak localization. However, electron phase coherence should easily destroyed by strong spin scattering in ferromagnetic structures, basically. Hence, more careful investigation will be indispensable to reconfirm our WL.

The problem is also "two-dimensional." The temperature dependence is mostly independent of the number of wires less than $10^6$, as shown in the lower inset of Figure 33a. It suggests that the dimension originates not from a large number of measured Ni-wires but from the individual Ni-nanowires, which should have only either 1D or 3D. Here, we have reported that the wire-array sample with smaller diameter (~10 nm) exhibited features following 1D electron–electron interaction reported by Davydov et al. [111]. Based on this, we propose a model in which current flows only along the wire surface in the wires with diameter larger than ~10 nm like that in carbon nanotubes (i.e., our nanowire consisted of a 2D Ni-sheet). Since our Ni-wire has an amorphous structure with strong disorder, current may flow only surface with low resistivity.

Here, it is of core importance to notice that the logarithmic temperature dependence in Figure 33a is independent of the abrupt MR jump caused around $B = 1.3$ T. The logarithmic magnetic-field dependence also still survives even with the MR jumps in Figure 33b. These imply that the MR jumps do not lead to dephasing in the WL regime. In this sense, our abrupt MR jump cannot be interpreted by the theory of Tatara and Fukuyama [105], if the WL is reconfirmed.

Caldeira and Leggett theoretically reported that MQT was easily suppressed by energy dissipation in its external environment [99, 104]. In contrast, in realistic magnetic systems, some candidates exist as the origin for such dissipation (e.g., magnons and phonons in ferromagnetic insulators, conducting electrons supporting magnetization moment in metallic weak ferromagnets with thin DW). Since our Ni-nanowire with WL does not correspond to any of such systems, further investigation will be required to clarify the energy dissipation mechanism.

This chapter still remains ambiguous at least as follows: (1) quantitative contribution of many wires to the MR jumps, (2) quantitative confirmation of MQT based on the temperature and wire-diameter dependence, (3) the reconfirmation of WL and, then, the reason for coexistence of 2D WL with ferromagnetism, (4) the reason for its "2D," and (5) the reason WL is independent of the MR jumps. To reveal these, more careful investigation will be expected theoretically and experimentally.

## 5.2. Coexistence of Phase Coherence and Ferromagnetism

Can Mesoscopic Phase Coherence of Electron Waves Coexist with Ferromagnetism in Ni-Nanowires Embedded into Alumina Membranes?

### 5.2.1. Introduction

We report possible coexistence of mesoscopic phase coherence of electron waves and ferromagnetism in Ni-nanowires, which are embedded into nano-pores of Alumina membranes. We successfully find the following phenomena: (1) positive and linear logarithmic dependence of zero-bias conductance on both temperature and magnetic field and (2)

periodic magnetoresistance oscillation, incredibly fittable by the revised formula of Altshuler–Aronov–Spivak oscillation, in the Ni-wires with larger diameters. These suggest the possible presence of two-dimensional weak localization in our Ni-nanowires. Our Ni-nanowires, which are electrochemically deposited and embedded into the pores of alumina membranes, provide high purity and good surface morphology. We argue that these reduce probabilities of parasitic spin scattering, leading to this coexistence.

Coexistence of mesoscopic and macroscopic phase coherence of quantum electron waves and ferromagnetism is recently of great interest. When sample sizes are reduced smaller than the phase coherent length of quantum electron waves, the phase of electron waves is conserved across the entire region of the sample. When the phase coherent length is on mesoscopic and macroscopic scales, this leads to mesoscopic and macroscopic phase coherence, respectively. A variety of phase interference effects emerge in such regimes, such as weak localization, Aharonov–Bohm effect, Altshuler–Aronov–Spivak oscillation, universal conductance fluctuation, metal–insulator transition, and superconductivity [113]. Mesoscopic coherence phenomena have been successfully studied in thin nonmagnetic metal films, semiconductor two-dimensional electron gas systems, and carbon nanotubes [114] in last the decade. Macroscopic coherence has been, of course, a manifestation of superconducting materials.

On the other hand, ferromagnetic materials have strong spin polarization, spin-flip scattering, and spin fluctuation. Hence, if the scattering lengths for such processes are smaller than phase coherent length, they will easily lead to decoherence and elimination of phase interference effects in ferromagnetic nanostructures. Tatara and Fukuyama also theoretically reported that abrupt motion of magnetic domain walls, including a large number of spins, yielded phase fluctuation and destroyed WL, a typical constructive phase interference phenomenon, in ferromagnetic nanowires [115]. In fact, none experimentally reported such coexistence. Therefore, coexistence of ferromagnetism and phase coherence seems to be theoretically and experimentally impossible in general respects.

In contrast, some recent works have surprisingly reported on the coexistence of macroscopic phase coherence and ferromagnetism in particular superconducting materials, (e.g., $d$-band metal $ZrZn_2$ [116] and $UGe_2$ [117]). With respect to mesoscopic phase coherence, our group also reported the possibility that abrupt motion of magnetic domain walls did not lead to dephasing for weak localization in nickel (Ni)-nanowires, which is a $d$-band metal embedded into porous alumina membranes [118–120]. Besides, very recently, Tatara and Barbara theoretically predicted that ferromagnetism did not affect the AB effect and AAS oscillation in 3$d$-band metals in an essential way. This is because AAS oscillation is suppressed for a minority spin channel in most 3$d$ metals due to strong $s$–$d$ scattering, whereas majority spin channel survives due to small density of sates in the $d$-band [121]. Therefore, coexistence of phase coherence and ferromagnetism is currently in the debating stage and none at least experimentally report on mesoscopic phase coherent phenomena in ferromagnetic nanostructures.

In this work, we for the first time report the possible coexistence of mesoscopic phase coherence and ferromagnetism

in Ni-nanowires, based on the following measurement results, e.g., (1) positive and linear logarithmic-temperature ($\log[T]$) dependence of zero-bias conductance ($G_0$) with the saturation region at low temperatures, which can be fitted by a formula of 2D WL, (2) positive and linear logarithmic magnetic-field ($\log[B]$) dependence of $G_0$ with the saturation region at low magnetic fields, and (3) periodic magnetoresistance oscillations, incredibly observed in the Ni-wires with larger diameters, like AAS oscillation. We point out that special structures of our Ni-nanowires, which are electrochemically deposited and embedded into the nanopores of alumina membranes, strongly contribute to coexistence of phase coherence and ferromagnetism.

### *5.2.2. Experiments and Discussion*

Figure 34 shows the schematic cross-section of our Ni nanowires, which were electrochemically deposited and embedded into nanopores of alumina membranes. We have

100 nm

**Figure 34.** Coss-sectional SEM image of a Ni-nanowire array, which was electrochemically deposited and embedded into nanopores of alumina membranes. We prepared arrays with three different mean pore diameters of about 30, 55, and 96 and with the same pore length of 2 mm for this work. This nanowire at least has the following three advantages. high purity, good surface morphology, and no surface oxidation. The first advantage arises from the electrochemical deposition and leads to reduction of scattering probabilities by impurities and defects. The second and third advantages arise from embedding the nanowires into the nanopores with good morphology of the inner walls and lead to reduction of probabilities of surface-spin scattering due to bad morphology and surface oxidation. Spin-flip scattering and spin fluctuation caused by such parasitic factors (i.e., impurities, defects, and poor surface morphology) lead to drastic reduction of phase coherence in ferromagnetic nanowires in an essential way. Hence, our special wire structure is relevant to realize coexistence of mesoscopic phase coherence and ferromagnetism. Magnetic field was applied along with the wire axis in all the measurements in this work.

actually reported a variety of quantum-mesoscopic phenomena using this membrane (e.g., [114, 118–120, 123, 124]). Since this membrane provides extremely high uniformity of structure parameters, observed characteristics in nanowire arrays, deposited into the nanopores, were the superposition of features of individual nanowires.

Figure 35a shows a typical $\log[T]$ dependence of $G_0$ at zero magnetic field. This implies the presence of a linear and positive $\log[T]$ dependence at high temperature and its saturation at low temperatures. There is a transition temperature, $T_c$, between these two regimes. The dotted line is the calculation result by the formula of 2D WL [122]

$$G(T) = G(0) + (e^2/2\pi^2\hbar)$$
$$\times (\pi d/L)\ln[1 + (T/T_c(B, \tau_s))^p] \qquad (35)$$

where $d$, $L$, $N_s$, and $p$ are the diameter and length of the wire, the relaxation time of spin-flip scattering, and the parameter for electron–electron interaction, respectively.

The measurement and calculation results are in excellent agreement. Based on the theory of 2D WL, the linear and positive $\log[T]$ regime at high temperatures means decoherence by electron–phonon scattering, whereas the saturation regime at low temperatures is the decoherence regime by

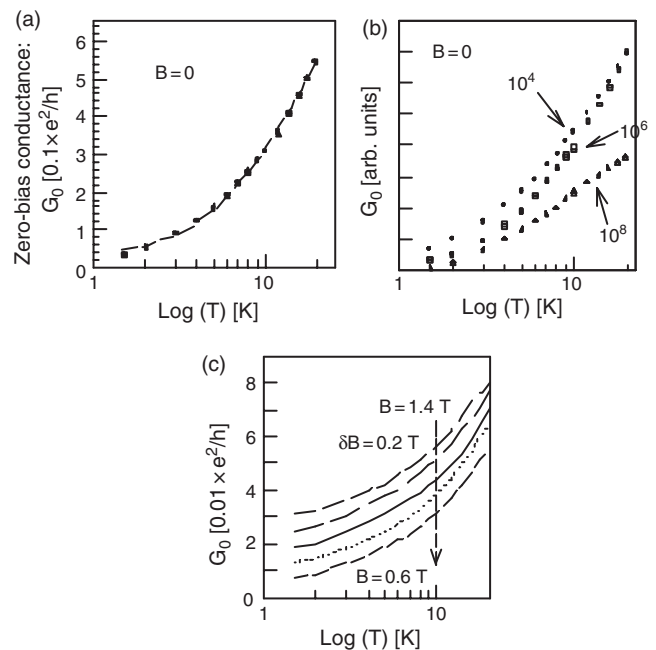

**Figure 35.** (a) Typical logarithmic temperature ($\log[T]$) dependence of zero-bias conductance $G_0$ in Ni-nanowires with mean radius of about 30 nm. Black symbols mean the measurement results and the dotted line is the calculation result by formula of two-dimensional weak localization [Eq. (35)]. They are in good agreement, implying strong spin-flip scattering. (b) Wire-number dependences of $10^4$, $10^5$, and $10^6$ are the number of the Ni-nanowires included in each array. This $G_0$ vs $\log[T]$ relation, however, did not mostly vary even in the array with the wire number up to $10^6$. This implies that this coexistence results not from collective phenomena of the wire array but from the individual Ni-nanowires. (c) Magnetic field dependence of the $G_0$ vs $\log[T]$ relation in Ni-nanowires similar to (a), exhibiting positive magnetoconductance, which is evidence for weak localization.

spin-flip scattering due to magnetic impurities. The best fitting gives $p = 1.9$ and $T_c = 6$ K in our case. This $T_c = 6$ K is much larger than that below 1 K in nonmagnetic nanomaterials with magnetic impurities in the WL regime and hence implies the presence of strong spin-flip scattering in our Ni-nanowires. This is qualitatively consistent with presence of strong spin-flip scattering in ferromagnetic materials. Therefore, this result suggests a possibility of coexistence of 2D WL and ferromagnetism in our Ni-nanowires.

Here, although we measured conductance of a Ni-nanowire array including the number of wires as large as about $10^4$, we conclude that this coexistence results not from collective phenomena of the wire array but from the individual Ni-nanowire, from the result of Figure 35b. Besides, we have already reconfirmed that electrical features of array samples are mostly consistent with those of individual wires, due to extremely high uniformity of the parameters of nanostructures in porous alumina membranes [114].

When a magnetic field is applied, this $G_0$ vs $\log[T]$ relation causes a parallel shift to higher conductance values, particularly in the saturation region at low temperatures (i.e., positive magnetoconductance behavior) (Fig. 35c). In contrast, the relation itself does not mostly change under applied magnetic field up to $B = 1.5$ T (Fig. 35c), although it is smeared by high magnetic field, particularly in the saturation region. This is also evidence of WL, because the electron phase is dephased by the magnetic field particularly in the spin-flip scattering regime, leading to an increase of conductance.

Associated with this respect, Figure 36 shows a typical $\log[B]$ dependence of $G_0$ in two samples with mostly the same structure parameters. First, we applied a high magnetic field of 7 T for initialization of magnetization and then we reduced magnetic field toward $B = 0$ T. Since magnetic length $[L_B = (h/eB)^{1/2}]$ is 88.9 nm which is shorter than phase coherence length $(L_\phi)$ of 490 nm (mentioned later) at $B = 0.1$ T, this field region above 0.1 T actually can contribute to decoherence by magnetic field. One can see a linear and positive $\log[B]$ dependence at high magnetic fields and its saturation at low magnetic fields in both the samples. These also qualitatively support the presence of 2D WL. The linear and positive $\log[B]$ dependence is attributed to decoherence by applied magnetic field, while its saturation is due to decoherence by spin fluctuation which becomes dominant around zero magnetic field with reversing magnetic field. This saturation regime without negative MC means the absence of spin–orbit interaction. This is also consistent with the fact that Ni has no spin–orbit interaction.

Consequently, positive $\log[T]$ and $\log[B]$ dependence of $G_0$ has revealed the possibility of coexistence of mesoscopic phase coherence and ferromagnetism in our Ni-nanowires. However, why two-dimensional WL exists is not answered. If the cross-section of nanowire has a circular shape, nanowire should not provide two dimensions in any cases, because smaller and larger diameter wires should have only one and three dimensions, respectively. In order to clarify this reason, we observed magnetoresistance of the Ni-wires with larger mean diameter, applying magnetic field along with the wire axis.

Figure 37a and b show the result. Surprisingly, one can find MR oscillations in both figures, although the behaviors are

**Figure 36.** Typical logarithmic magnetic-field ($\log[B]$) dependence of $G_0$. We basically measured magnetoconductance three times at each field, except for some field points with high repeatability of $G_0$, and plotted them on the figure with circles, triangles, and square. Dotted lines are only guides to the eyes. Inset: Magnetoresistance obtained from the upper feature of the main panel, exhibiting smeared oscillation with very small magnitude.

complicated in (b). Since the wire diameter is large and this is metal nanowire, any quantized levels cannot exist. Hence, as one of possibilities for this MR oscillation, we performed data fitting by the formula of AAS oscillation [114]

$$\delta G = -(e^2/\pi h)(2\pi r/L_s)[(1/2 + \beta)Z_\phi(L_\varphi(H)) - 3/2 Z_\phi(L'_\varphi(H))] + \alpha(H) \tag{36}$$

$$Z_\phi(L_\varphi(H)) = \ln(L_\varphi/\ell) + 2\sum_{n=1}^{\infty} k_0(n(2\pi r/L_\varphi))$$

$$\times \cos[2\pi n(\Phi/(hc/2e))] \tag{37}$$

$$1/L_\varphi^2 = 1/D\tau_\varphi \tag{38}$$

$$1/L'^2_\varphi = 1/L_\varphi^2 + 2/D\tau_{so} \tag{39}$$

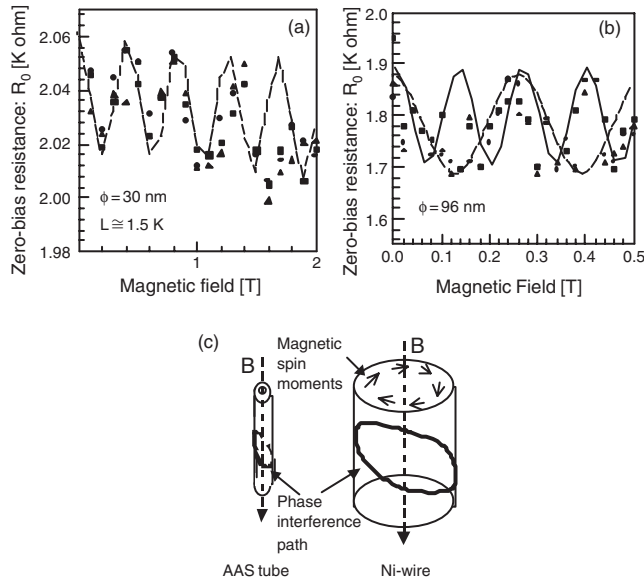
where $L_s$ $\beta$ $L_\varphi$, and $L'_\varphi$ in Eq. (36) are the tube length, the constant depending on electron–electron interaction, and the phase coherent length without and with SOI, respectively. $\ell$, $k_0$, and $\Phi$ in Eq. (37) are the mean free path, the Macdonald function, and the magnetic flux ($\pi r^2 H$), respectively. $D$, $\tau_\varphi$, and $\tau_{so}$ in Eqs. (38) and (39) are the diffusion constant, the relaxation time for inelastic scattering, and the relaxation time for SOI, respectively. Here, $\alpha(H)$ in Eq. (36) represents the increase or decrease of the mean value of conductance, depending on magnetic field $H$. We also neglected the contribution of magnetic field on $L_\varphi$ in Eq. (38). Hence, $L_\phi$ is basically only a fitting parameter.


**Figure 37.** (a) Magnetoresistance oscillation in the Ni-wires with mean diameter of 55 nm. Black symbols mean the measurement results (also three times) and the dotted line is the calculation result by a revised formula of Altshuler-Aronov-Spivak oscillation [Eqs. (36)–(38)]. (b) Magnetoresistance oscillation in the Ni-wires with mean diameter of 96 nm, which is larger than (a). Solid and dotted lines are the calculation results by the AAS oscillation formula mentioned previously. These indicate the presence of bimodal behavior. Namely, MR oscillation with periods of 0.25 T exists at magnetic field lower than about 0.25 T (dotted line), while MR oscillation with period of 0.12 T exists above about 0.25 T (solid line). One of the reasons for this behavior is the presence of a two-distribution peak of the wire diameters in this one array. When pore diameter is increased, such distribution is yielded in our anodization method. (c) Left: Schematic view of an AAS tube. In general AAS oscillation, the phase interference path of electron waves encircles the circumferential direction of this AAS tube. Since magnetic fluxes penetrating into the tube inner space modulate the vector potential there, the phase of electron waves encircling the tube circumference is modulated, and hence periodic MR oscillation emerges. Right: Schematic view of a cylindrical-ferromagnetic structure (i.e., large-diameter wire). The magnetic spin moments encircling the circumference form a single domain structure. Magnetic flux also penetrates into the center part of the wire.

The data and calculation result by AAS oscillation theory is in good agreement in each figure. MR oscillation with period ($\Delta B$) of 0.4 T and negative MR around 0 T is confirmed by this fitting at $B < 1$ T in (a), while bimodal behavior is identified with $\Delta B = 0.12$ and 0.25 T in (b). This $\Delta B$ of 0.12 T in (b) is good agreement with the relation of $\Delta B \propto r^{-2}$ for AAS oscillation theory ($r$ is the radius of tube), in comparison with $\Delta B = 0.4$ T in (a). These results imply a possibility that these periodic MR oscillations are AAS oscillations.

This observation of AAS oscillation emphasizes that the phase interference path for 2D WL and AAS oscillation exists along with the circumferential direction of the Ni-wire (Fig. 35c). This is the reason for the presence of two dimensions. Phase coherence length, $L_\phi$, obtained from the best fitting in Figure 37a, is as large as 490 nm, which is actually larger than the length of the wire circumference of 170 nm. Of course, this is larger than $LB$ at 0.1 T as mentioned.

This seems to be very strange, because (1) such a phase interference path should not exist due to dephasing by strong spin-flip scattering caused by ferromagnetism, and (2) Ni-wire has no tubelike structure (i.e, vector potential cannot survive in the inner part of the ferromagnetic wire). From the viewpoint of (1), however, some recent works revealed that magnetic spin moments exist along with circumference in ferromagnetic structures with cylindrical and disk shapes, leading to single domain structure with a circlelike shape (Fig. 37c) [123]. If our Ni-wire also has such a spin structure and electron waves flow along with these spin moments (Fig. 37c), dephasing by spin-flip scattering will be not caused and hence such a phase interference path can survive. From the viewpoint of (2) this wire system is quite different from the AAS tube. This is a very serious problem and we have no idea how to explain this at the current stage. However, the measurement and calculation results strongly suggest the presence of AAS oscillation and phase interference path along with the wire circumference in our Ni-nanowire.

Such MR oscillation, which was imposed on the positive $G_0$ vs log[B] relation, can be found even in Figure 36a measured in the smaller diameter wires, although they are very smeared and oscillation magnitudes are much smaller. In contrast, Figure 37a also exhibits negative MR, which exists around $B = 0$ T and also as a background feature of MR oscillation, like that in Figure 36a, although the slope value is smaller than that in Figure 36a. These mean that magnitude of AAS oscillation (i.e., phase modulation by magnetic field) becomes less distinct and smaller as the wire diameter decreases, while only dephasing becomes dominant leading to negative MR.

As the wire diameter decreases down to a range of 20 or 30 nm, the phase interference path with a circlelike shape is smeared leading to smaller $L_\varphi$, because clear magnetic spin moments along with the wire circumference become difficult to exist due to limited geometry space.

Only an unclear but quasi-2D interference path along with the wire circumference still survives. This leads not to distinct modulation of phase but only to dephasing, caused by magnetic field applied along with the wire axis, if $L_\varphi$ is still larger than the length of the wire circumference. This discussion well explains the wire-diameter dependence mentioned. Hence, $L_\phi$ should be larger than about 93 nm in the samples for Figures 35 and 36.

Besides, we also actually reported emergence of one-dimensional electron–electron interaction in the Ni-nanowires with further smaller diameter (less 10 nm) [124]. This supports our discussion, because the Ni-nanowires with such small diameter no longer have an interference path along with the wire circumference. In this case, only transversal dimension of the nanowire should be compared with phase coherent length or thermal diffusion length. When either of them is larger than the wire diameter, 1D electron–electron interaction emerges.

### 5.2.3. Conclusion

In conclusion, we reported on the possible coexistence of ferromagnetism and mesoscopic phase coherence in the Ni-nanowires, which was electrochemically deposited and embedded into the nanopores of alumina membranes. All

the results reported here qualitatively and quantitatively suggested the coexistence. None, however, experimentally reported on such phenomena in ferromagnetic nanostructures fabricated by other methods before. Our results imply a possibility that this may be due to not essential spin scatterings and fluctuation of bulk nanowires but parasitic spin scattering by impurities, defects, and bad surface morphologies. For instance, nanowires placed on substrate are easily anodized on the surface and the morphology is also much affected by the roughness of substrate surface, leading to strong surface scattering of spins. In addition, even a small amount of defects and impurities introduced during the fabrication processes will have a serious influence as the scattering origins for spins because of the nanosize of the wires. Our fabrication method using the nanopores of alumina membranes and electrochemical deposition can easily avoid these problems. Only such highly pure ferromagnetic nanowires with good surface morphology will lead to coexistence of phase coherence and ferromagnetism in an essential way, as Tatara and Barbara predicted [121].

## 6. CONCLUSIONS

Novel quantum-mesoscopic phenomena observed in the nanostructures and nanomaterials, which were realized by utilizing porous alumina membranes, have been reviewed. Multiwalled carbon nanotubes, Ni-nanowires, and tunnel junctions attached to them exhibited a variety of interesting properties. The top down method, such as nanolithography in semiconductor transistors and two-dimensional electron gas, is of course an established powerful tool for creation of nanostructures and study of nanoscience. However, the bottom up method as presented here, using nanoporous alumina membranes, will be more promising for study of nanoscience and its applications, because of its high uniformity, reproducibility, controllability, and simplicity. One can realize a variety of nanostructures by utilizing a porous alumina membrane as a nanotemplate.

Some of the works presented here still remain open questions. In particular, Ni-nanowire related phenomena reported in Section 5 are very anomalous with our strange interpretation. Measurement of one Ni-nanowire, hence, is required. For this, one can resolve alumina membrane, pick up one Ni-nanowire, place this on Si-substrate, and measures its physical properties. However, this leads to an increase of parasitic spin scattering due to surface defects and roughness, like a general measurement method. Hence, probing only one Ni-nanowire embedded in an alumina membrane will be relevant way by scanning probe microscopy.

In contrast, carbon nanotube related phenomena are quite original and fascinating. These also imply how carbon nanotube is an attractive nanomaterial. In particular, one can speculate strong quantum entanglement of singlet spins forming Cooper pairs. Hence, the study based on Section 4 must open up a new door to realization of quantum computation utilizing quantum entanglement. Recently, this has been actually reported and discussed both theoretically and experimentally. My target is also in this quantum computation. I believe that no materials can realize quantum computation with enough dephasing time, except for carbon nanotubes.

Carbon nanotubes with special structures will induce this process.

No one doubt that nanotechnology and nanoscience can be the mainstream in the 21st century. These will reveal to us fantastic and exciting phenomena hiding in the quantum and mesoscopic world. Some of those will be far beyond our imagination. Besides, application of such phenomena will drastically change our future life. I believe that the future will be brilliant. Effective combination of top-down and bottom-up methods will be a key for certain and quick realization of the future.

## GLOSSARY

**Carbon nanotube (CN)** Molecular tube consisting of rolled up graphene sheet, with diameter as small as 0.4 to a few 10 nm. A single-walled CN is rolled up graphene sheet exhibiting electron transport in the ballistic regime, whereas a multiwalled CN is coaxially rolled up multiple graphene sheets with that in the diffusive regime.

**Macroscopic quantum tunneling (MQT)** Tunneling is a typical phenomenon caused by electron waves in either microscopic or mesoscopic worlds. Of course, a "macroscopic particle," like a baseball, basically should not cause tunneling because it cannot wave. However, MQT surprisingly implies the presence of a single macroscopic degree of freedom governed by quantum mechanics in special cases. MQT has been actually reported in Josephson junction systems, (anti)ferromagnetic nanomaterials, and organic nanomaterials.

**Phase interference of quantum electron waves** When sample size is smaller than phase coherence length of thermal diffusion length of electrons, phase of quantum electron waves is maintained across the entire region of the sample. This leads to a variety of phase interference phenomena, such as (weak, anti, and strong) localization, universal conductance fluctuation, Aharonov–Bohm (Altshuler–Aronov–Spivak) effect, etc.

**Porous alumina membrane** Membrane including dense nanopores (5 to a few 10 nm in diameters) looking like a honeycomb on its top view. This is obtained from simply anodizing pure aluminium in solutions, through self-organization process.

**Proximity-induced superconductivity** When a superconductor (S) is connected to a normal conductor (N) with a highly transparent S/N interface, the Cooper pair wave function diffuses from S to N. This leads to "proximity-induced superconductivity" in a part of N, and hence conductance of the part increases. When diffusion of the Cooper pair is dominant at the end of this part, Thouless energy, $E_{Th}$, is defined from the uncertainty principle of $\Delta E_{Th} \cdot \Delta \tau \approx h/2\pi$. Below this $E_{Th}$, conductance decreases due to "reentrance effects."

**Single electron tunneling (SET)** Tunneling effect of electron dominated by charging energy ($E_c = e^2/2C$, where $C$ is the junction capacitance) of the tunnel junction. This $E_c$ realizes manipulation of electrons one by one (single electron). Typical phenomena are Coulomb blockade, Coulomb staircase, Coulomb oscillation, etc. Tunneling is a phenomenon representative of electron "waves," whereas $e$ is elementary charge of an electron representative electron particle. One

can actually "feel" duality of waves and particles in quantum mechanics by macroscopic measurement of SET.

# Metal Nanoclusters

## Yuan Wang, Yongge Wei

*Peking University, Beijing, China*

## CONTENTS

## 1. INTRODUCTION

Scientific interest in highly dispersed small metal particles could be traced back to the age of Faraday [1], who prepared Au colloids having beautiful color by chemical reduction in the presence of glutin. Currently small and highly dispersed nanoscopic metal or alloy particles with narrow size distributions are called metal or alloy nanoclusters in publications.

The difference between metal nanoclusters and metal colloids, dispersions of metal particles with average sizes ranging from 1 nm to submicrometer in a continuous media, is not rigorous in many cases. Herein we limit the discussions to metal or alloy particles having sizes in a range from 0.5 to 10 nm, which play an important role in so-called bottom-up architecture aiming to assemble functional structures or systems including catalyst, magnet, nanoelectronic, or optics devices, chemical or biochemical sensors, etc.

Subfields in this area have been well reviewed by Schmid and co-workers [2–9], the authors of three books [10–12], Toshima and co-workers [13–21], Templeton et al. [22], Rao et al. [23], Lewis [24], Schon and Simon [25, 26], Aiken and Finke [27], and Bonnemann [28]. A synopsis of the wet chemical preparation of mono- and bimetallic colloidal particles and survey of potential applications in catalysis and materials science have been contributed by Bonnemann and Richards [29] in 2001.

The properties of metal or alloy similar to other materials depend on the motion type of its electrons, which is confined by the space of the materials. Owing to the quantum mechanical rules, nanoscale particles, in which their electrons behave like "particles in a box," should have the so-called "quantum size effect" on their physical properties. Therefore there is a specific length scale, usually in the low edge region of nanodimension for metallic materials [30–32], below which the properties become sensitive to the physical size, which gives birth to a lot of novel and unique properties of the nanosized metal and alloy particles compared to their corresponding bulk materials.

It is well known that physical properties of a metal substance, such as optical, electrical, and magnetic properties, melting points, specific heats, and surface reactivity are size dependent. Metal nanoclusters exhibit size-dependent melting temperatures that are far below that of the bulk metal. Takagi in 1954 reported the earliest measurements on the reduced melting temperature of metal nanoclusters [33]. A brief summary of the research on the melting point of metal nanoclusters has been given recently by Martin and co-workers in their report for the research on the sintering temperatures of alkanethiol-capped Au and Pt nanoclusters with sizes of 6 and 4 nm, respectively. It is observed that the sintering temperature of the Au nanoclusters is close to 210 °C while that of the Pt nanoclusters is about 190 °C, much lower than the melting temperatures of 1064 and 1772 °C of bulk Au and Pt, respectively [34].

Some of new chemical, optical, and thermal properties of metallic nanocrystals and their dynamical processes have been investigated on the femto- to picosecond time scale [35].

One of the most important progresses in metal nanocluster catalysts during the last decade is that the impression of the inability of gold to catalyze has been scrapped due to the finding of excellent catalytic efficiency of supported gold nanocluster catalysts [36, 37]. The most attractive catalytic properties of supported gold nanoclusters are the high catalytic efficiency for the oxidation of CO in the presence of excess hydrogen and the notable selectivity in the oxidation of propylene to propylene oxide. This topic has been well reviewed by Choudhary and Goodman recently [38].

This chapter will deal with progress in some aspects of metal nanoclusters, including chemical preparation and

structure control, assembly or self-assembly of these attractive building blocks, and their current and potential applications in catalysts, biosensors, and magnetic materials. Applications of metal nanoclusters in micro- or nano-electronics have been well reviewed [2–7, 25, 26].

## 2. ART OF CHEMICAL PREPARATION

Interest in nanoscopic materials and their application to catalysts and nanodevices have greatly stimulated the research on developing new physical [23, 39] and chemical methods for the preparation and structure control of metal nanoclusters. The strategy usually adopted for chemically preparing metal nanoclusters is to lead metal atoms produced *in-situ* to aggregate and generate metal cores followed by depositing the further formed metal atoms on these cores. Because of the huge specific surface energy, colloidal nanoparticles are usually stabilized by protective agents including polymers, such as poly(*N*-vinyl-2-pyrrolidone) (PVP) and polyvinyl alcohol (PVA), coordination ligands such as PPh$_3$ and mercaptans, or surfactants to prevent them from aggregating during their preparation, application, and storage. On the other hand, the charge effect derived from adsorbed ions on the surface of small metal particles and the solvent effect, namely decreasing the surface energy of particles and activity of surface atoms by adsorbing various solvent molecules, have been known to be effective for stabilizing the tiny metals in colloidal solutions. Metal nanoclusters stabilized with only simple anions or infirmly adsorbed solvent molecules can be called "unprotected" or "naked" metal clusters. To study the influence of the protective agents on the properties of metal cores and to use small metal particles as building blocks effectively, a stable, "unprotected" metal colloid is desirable since the particles can be easily modified with various designed organic species or can be embedded in different materials with a wide range of loading.

Metal nanoclusters can be grouped under four heads according to the stabilizer in the products, namely polymer, surfactant or coordination ligands, solvent or anions, and solid support stabilized metal nanoclusters.

## 2.1. Polymer-Protected Metal Nanoclusters

### 2.1.1. Monometallic Nanoclusters

Polymer protected metal nanoclusters have a very long history of preparation. They are usually prepared by reducing metal ions with various reductants in the presence of suitable polymers usually having a nonpolar polymer chain and polar groups. Electrochemical or photochemical reductions are also effective for preparing polymer-protective metal nanoclusters; however, they are usually prepared by chemical reduction.

During the last two decades, lots of effort has been paid to prepare various polymer-protected metal nanoclusters and examine their catalytic properties. The most attractive polymer protective metal nanoclusters are PVP protected ones with metal particle sizes ranging from 1 to 3 nm, which were first prepared in the 1970s by refluxing a methanol or an ethanol (or alcohol/water) solution of noble metal chlorides containing PVP [40, 41]. Teranishi and Miyake examined in

detail the influence of preparation conditions such as the category and concentration of alcohols, ratio of PVP to Pd on the particle size, and distribution of PVP-protected Pd nanoclusters in 1998. It was observed in X-ray diffraction (XRD) measurements that the lattice constant of these Pd nanoclusters protected with PVP increased with a decrease in the metal particle size from 30 to 17 Å [42].

Recently, size-controllable synthesis of Ru nanoclusters has been done by Yan et al. [43]. In their work, series of PVP-stabilized ruthenium nanoparticles with various dimensions were prepared by heating or refluxing a polyol solution of ruthenium(III) salts; the average diameters of the resulting Ru nanoparticles can be controlled in the range of 1.4–7.4 nm with relative standard deviations of less than 0.3 by changing the polyols, the reduction temperature, and/or the amount of PVP. The factors affecting the size of PVP-stabilized Pd nanoparticles have also been investigated [44].

Besides PVP, functional polymers have also been chosen as protective agents to prevent metal nanoclusters from agglomeration. Narrowly dispersed gold nanoparticles of size less than 3 nm were synthesized by reducing metal ions with KBH$_4$ in the presence of linear polymers containing cyano or mercapto groups as protective agents [45].

An overview has been given by Mayer [46] on the generation of metal nanoparticles dispersed within amphiphilic polymeric systems, ranging from nonionic polymers and polyelectrolytes to amphiphilic diblock copolymers. Recently, $\pi$-conjugated polymer-protected gold nanoparticles of narrow size distribution, in a stable colloidal form, have been prepared, via reduction of HAuCl$_4$, in the presence of a $\pi$-conjugated poly(dithiafulvene) having electron donating properties [47].

Dendrimer-encapsulated Cu, Pd, Pt, Ag, and Au metal nanoclusters ranging in size from 1 to 3 nm have been prepared by reducing the corresponding metal ions in dendrites [48–62]. Hybrids of silver particles of 1 to 2 nm in size modified with highly branched amphiphilical polyethyleneimines could be adhered effectively to polar substrates providing environmentally friendly antimicrobial coatings [63] (see Fig. 1). Block copolymers of carbosilane dendrimers and polyisocyanopeptides may have the potential to be exploited as templates to direct the formation of nanowires of metal nanoclusters [64].

The self-assembly with ordered patterns of block copolymer micelles, which have dimensions of 10–100 nm and a good kinetic stability, is an interesting kind of template for generating two-dimensional (2D) arrays of inorganic nanoclusters [65–67]. Cohen and Boontongkong prepared a poly(styrene-*block*-acrylic acid) (PS-*b*-PAA) micellar thin film and loaded it with an aqueous AgAc solution treated with NaOH. Reduction of the sample in a hydrogen atmosphere (~2 atm at 85 °C for 30 h) resulted in a hexagonal array of silver clusters of ~4 nm in diameter within the thin film template. The uniform silver cluster size should be derived from the inherent size monodispersity of the individual micelles and their PAA cores [68] (see Fig. 2).

Stable Au, Pt, and Pd colloidal particles with average diameter of 4–6 nm have been prepared by reducing metal chlorides HAuCl$_4$, H$_2$PtCl$_6$, or Pd(NO$_3$)$_2$ with NaBH$_4$ during an acid catalytic hydrolysis process of *N*-[3-(trimethoxysilyl)propyl] ethylenediamine. These noble metal
**Figure 1.** Ag nanoclusters encapsulated by highly branched amphiphilical polyethyleneimine dendrimers. Reprinted with permission from [63], J. C. Tiller et al., *Chem. Commun.* 3018 (2002). © 2002, Royal Society of Chemistry.

colloidal particles containing sol could be gelled to give monoliths of various shapes by allowing them to gel in a container with desired shape [69, 70].

Inorganic polymers with special nanoporous structures have been used as templates for the preparation of metal nanoclusters. For example, in mesopore silica or mercapto group functionalized mesopore silica, narrowly dispersed Ag [71–74], Au [75, 76], Pt [76, 77], and Co–Ru alloy [78] nanoclusters have been prepared by *in-situ* electrochemical and chemical reduction or thermal decomposition.

Carbon nanotubes are also attractive supports for the synthesis of metal nanoclusters. Fe–Ni alloy nanoparticles inside carbon nanotubes via wet chemistry have been prepared [79]. The growth of Pd, Pt, Ag, and Au nanoparticles on the outer surface of carbon nanotubes has also been reported [80].

An ultraviolet (UV) photolysis (253.7 nm wavelength) method [81, 82] was used to prepare PVP-protected Pd and Ag nanoclusters in a mixture of 2-propanol and acetone. The size of obtained Pd nanoparticles (2–3 nm) is independent of palladium acetate concentration, whereas those of

**Figure 2.** Plan-view TEM of PS-*b*-PAA micellar thin film containing Ag nanoclusters. Reprinted with permission from [68], Y. Boontongkong and R. E. Cohen, *Macromolecules* 35, 3647 (2002). © 2002, American Chemical Society.

Ag colloids increase from 3 to 9 nm with increasing concentration of silver perchlorate [83].

The photochemical reductions of $AuCl_4^-$ for preparing Au nanoclusters protected by PVP have been conducted in formamide in the presence of PVP. It was found that the diameters of prepared Au nanoparticles depended on the concentration of $AuCl_4^-$. Narrowly distributed Au colloids with average sizes from 6 to 18 nm have successfully prepared by this process. The effective photoreduction of $AuCl_4^-$ in the nonaqueous system is attributed to the higher degree of dissociation of $AuCl_4^-$ in formamide. Silver, palladium, and platinum colloidal particles could also be produced with this modified photochemical process [84].

A microwave dielectric heating method was first adopted to prepare polymer-stabilized metal nanoclusters with small particle size by Liu and co-workers, which opened up a way to synthesize polymer protected metal nanoclusters in a fast and continuous manner. Platinum colloidal particles having nearly spherical shape and size of 2 to 4 nm were prepared by this method [85].

Polymer-supported metal nanoclusters have been prepared in supercritical carbon dioxide by reducing metal ions in polymer matrixes [86]. The chemical and physical properties of carbon dioxide in the supercritical state differ from those of conventional organic solvents. The preparation of nanomaterials, including metal nanoclusters, in such a special condition has just been reviewed by Cooper [87].

Stable polymer-protected metal nanoclusters are usually prepared in a higher ratio of polymer to metal; otherwise, unstable turbid dispersion with large particle size or precipitates will appear. This fact has been thought of as one of the main drawbacks of polymer protected metal nanoclusters because it limits the application relating to electron transportation. This defect can be overcome by the reaction of polymer protective agents such as PVP with preformed "unprotected" small metal nanoclusters. A very stable colloidal solution of PVP-protected Pt nanoclusters, Pt particle size of 1.5 nm, with a PVP-monomeric-unit/Pt molar ratio of 0.35 was prepared by this strategy recently by Wang et al. [88]. This success in the preparation of small metal nanoclusters with an extraordinarily high ratio of Pt to PVP revealed that to stabilize some small noble metal nanoclusters, a high PVP/Pt ratio as usually used is not necessary. It suggests that in the usual preparation process (i.e., reducing noble metal ions in the presence of PVP) the largely excess amount of PVP is needed for kinetic control of the reduction process rather than preventing the small metal particles from aggregating. For the latter purpose, a much lower PVP/Pt ratio than that usually expected is enough at common conditions (see Fig. 3).

### 2.1.2. Bimetallic Nanoclusters

At the end of the 1980s, the alcohol-refluxing method was extended to prepare bimetallic nanoclusters composed of two kinds of noble metals. PVP-protected Pt–Pd [89], Pt–Rh [90], and Au–Rh bimetallic nanoclusters with average particle size less than 3 nm were prepared and their catalytic properties for the hydrogenation of olefins were examined. The stability against aggregation of a Pt–Rh bimetallic nanocluster is much higher than that of a Pt nanocluster prepared

**Figure 3.** TEM image of a stable PVP-protected Pt nanocluster with a high Pt/PVP ratio (monomeric unit of PVP/Pt mole ratio: 0.35) prepared by dissolving a precipitate of "unprotected" Pt nanoclusters. The average diameter of the Pt nanoparticles is 1.5 nm. Reprinted with permission from [88], Y. Wang et al., *Chem. Mater.* 12, 1622 (2000). © 2000, American Chemical Society.

by the same method. From an XRD study on the Pt/Rh bimetallic nanocluster, we suggested that the products have a structure of alloy or random solid solution of the metal atoms. On the other hand, an extended X-ray absorption fine structure (EXAFS) analysis on the Pd–Pt (4/1) bimetallic nanocluster made by Toshima et al. suggested that a model of a Pt core completely covered with a Pd shell could express its structure [91]. An infrared carbon monoxide (IR-CO) probe characterization study on this Pd–Pt (4/1) bimetallic colloid [92] implied that the surface of the bimetallic nanocluster is enriched in Pd.

In 1996 Esumi and co-workers [83] reported the preparation of a Pd/Ag alloy nanoclusters of 1 to 4 nm protected with PVP using an UV-irradiation method. The optical absorption bands of the prepared Pd/Ag alloy nanoclusters become sharp and shift to longer wavelengths with increasing molar ratio of Ag. The observed spectra are in good agreement with the calculated spectra of alloy colloids.

Preparation of Au–Ag bimetallic nanoclusters, which usually have only one plasmon absorption band that redshifts with increasing Au content, has been intensively studied [93–104].

From the view point of electron interaction and position assembly effects, bimetallic nanoclusters composed of a noble metal and a light transition metal such as Cu, Ni, or Co are more plausible because they provide a high potential for tailoring the structures of atomic self-assemblies and electron characteristics. Therefore, changing not only the size and shape but also the metal compositions could modulate properties of these materials in a wide range, such as catalytic and magnetic behavior. In the beginning of the 1990s, a strategy for the synthesis of polymer-protective bimetallic colloids composed of a noble metal and a light transition metal such as Co, Ni, and Fe was proposed. A stable polymer-protective bimetallic colloid can be obtained which is composed of some metal element strongly

protected by a polymer agent and another metal element or its compound which by itself cannot form a stable polymer-protective metal sol due to the low protective effect of the same polymer on it, as long as the first kind of metal atom can be present in the surface of the colloidal particles under the preparation conditions [105, 106].

Preparation of PVP-protected Cu/Pd bimetallic colloids by co-reducing a mixture of the corresponding metal acetates in 2-ethoxyethanol at 70–130 °C was reported by Bradley and co-workers [107, 108]. This method provided bimetallic $Cu_{30}Pd_{70}$ nanoclusters with particle sizes of $4 \pm 0.4$ nm as confirmed by transmission electron microscopy (TEM), IR-CO probe, and X-ray absorption spectroscopy measurements. For this co-reduction process, a mechanism was suggested in which Cu(0) was deposited on the surface of the preformed Pd particles and migrated into the Pd particles after deposition but only to within a few atomic layers of the surface [108]. When the Cu/Pd ratio is higher than 1:1, a part of the Cu ions cannot be reduced to a metallic state by this method according to our experience, suggesting that Pd may have an acceleration effect on the Cu ion reduction [109].

Small Cu/Pd and Cu/Pt alloy nanoclusters with average particle size of 1 to 2 nm and narrow size distributions were successfully prepared in the whole range of metal composition by Toshima and Wang using a so-called "cold alloying process" that involves two steps [110, 111]. First, hydroxide colloids (the real structure is more complex) containing both of the corresponding metal elements were prepared in glycol by adding NaOH to solutions of Cu and noble metal salts in the presence of PVP. The obtained bimetallic hydroxide colloidal solutions, in the second step, were refluxed at 198 °C for several hours with a nitrogen flow passing through the reaction systems to take away water and by-products. This is the first example of preparing metal and bimetallic nanoclusters using a polyol reduction process. TEM, XRD, UV-visible absorption spectroscopy (UV-vis), X-ray photoelectron spectroscopy (XPS), and Auger spectra of the products proved the bimetallic nanoclusters with structures of alloy or random solid solution of Cu and Pt or Pd could be prepared at the whole Cu/Pt or Cu/Pd ratios (see Fig. 4).

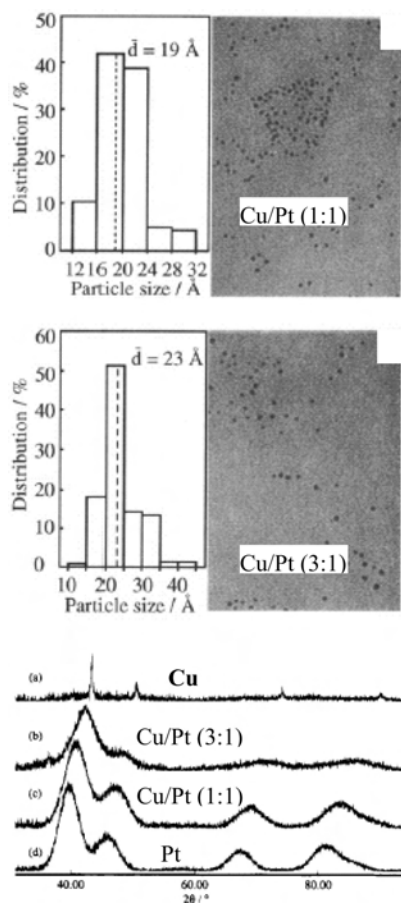
Unpublished data of energy dispersive X-ray (EDX) semi-quantitative analyses in high resolution TEM (HRTEM) revealed that each of the small particles prepared by this method contained both Cu and noble metal elements. Meanwhile it was also found that PVP-Pt nanoclusters prepared in glycol containing NaOH with a pH of 10 have a mean diameter of 1.1 nm with a narrow size distribution from 0.7 to 1.7 nm. Pt nanoparticles in this colloid are well separated from each other, which is quite different from those prepared with the alcohol refluxing method reported by Hirai and Toshima [40, 41]. The previous PVP-Pt colloid prepared by refluxing an alcohol solution of $H_2PtCl_6$ contains a lot of aggregators derived from gathering several or dozens of Pt particles with an average diameter of 1.6 nm and a size distribution from 1.2 to 2 nm. It is reasonable to believe that the unusual small particle size and perfect separation state of the PVP-protected Pt nanoparticles obtained in glycol containing NaOH are derived from the formation of Pt hydroxide precursors and the charging effect due to the adsorption of $OH^-$ groups on the Pt surface. The UV-vis


**Figure 4.** TEM micrographs and XRD diffraction patterns of PVP protected Cu/Pt bimetallic nanoclusters. Adapted with permission from [111], N. Toshima and Y. Wang, *Langmuir* 10, 4574 (1994). © 1994, American Chemical Society.

spectra of Pt/Cu alloy nanoclusters revealed that the plasmon band of Cu originally located at 562 nm shifts to the longer wavelength with increasing Pt content and decreases in intensity, depicting the changes in electronic structure in the alloy nanoclusters. A study on the EXAFS characterization of the structure of PVP-protected Cu/Pd alloy nanoclusters has been reported recently [112].

The cold alloying process was also adopted to prepare Cu/Rh, Co/Pt, and Ni/Pt bimetallic nanoclusters. PVP-protected Co/Pt and Ni/Pt alloy nanoclusters with diameters less than 3 nm and Co/Pt or Ni/Pt ratios up to 1:1 could be easily prepared by this method [109, 113].

Besides the formation of bimetallic alloy nanoclusters, small metal nanoclusters of a core–shell structure provide another practicable route to tailor the structure and property of bimetallic nanoclusters for the purpose of different potential applications. PVP-protected Pd–Pt bimetallic colloids in the size range from 1.5 to 5.5 nm with controllable core/shell structures have been successfully prepared by Wang and Toshima with a so-called "hydrogen-sacrificial protective strategy," in which hydrogen adsorbed on the preformed Pd cores is used to prevent the Pd cores from oxidizing by the added Pt (II) ions and to reduce Pt (II) ions under the catalytic function of the preformed small metal cores. A Pt or Pd shell of 1 or 2 atomic layers in thickness

covering the Pd or Pt cores having average diameters of 2.3 and 1.5 nm, respectively, was established as confirmed by TEM and IR-CO probe measurements [92] (see Fig. 5).

### 2.1.3. Shape Control

Shape control of colloidal metal nanoparticles protected by polymer has been conducted by several groups and is believed to be important for exploring the catalytic properties of nanoparticles with different shapes. During the process of reducing metal ions slowly, a shape selectivity may emerge if the catalytic reduction of the metal ions on a special crystal face of the preformed metal nanoparticles is much faster than those on the others. For example, if the reductive deposition rate of Pt atoms on the Pt{111} is much faster than those on Pt{100}, a high selectivity of cubic particles will form as the main product, whereas tetrahedral or octahedral Pt nanoparticles would be obtained when the ratio of the relative rates is reversed. Reaction conditions such as pH, temperature, adsorbent, reducing agent, and the metal precursors may have important influence on the final shape of the metal nanoparticles.

Ahmadi and co-workers reported the formation of tetrahedral, cubic, irregular-prismatic, icosahedral, and cubo-octahedral particles of Pt by reducing $K_2PtCl_4$ with $H_2$ in aqueous solutions of sodium polyacrylate. It was found that the ratio of polyacrylate to Pt ions is one of the key factors for controlling the shape of the products. Polyacrylate protected cubic and tetrahedral nanoparticles, 11 and 7 nm in size, respectively, were prepared with a shape selectivity of 80% and 60%, respectively [114, 115]. The shape distribution of platinum nanoparticles during the growth period and its dependence on the concentration of the capping polymer as well as the pH of the solution were studied with TEM [116]. The shape of platinum nanoparticles prepared by reduction of Pt(IV) ions in the presence of sodium polyacrylate (PAA) or PVP was also studied [117].

A poly(*N*-isopropylacrylamide) protected Pt colloid with a cubic shape selectivity of 68% was prepared using $H_2$ as a reductant by Miyazaki and Nakano at a temperature higher than the critical solution temperature [118].

**Figure 5.** Hydrogen-sacrificial protective strategy for the preparation of bimetallic colloids with a core/shell structure. Reprinted with permission from [92], Y. Wang and N. Toshima, *J. Phys. Chem. B* 101, 5301 (1997). © 1997, American Chemical Society.

Five types of crystal morphologies, including triangular, hexagonal, pentagonal, square, and rhombohedral, have been observed in PVP-protected Pd nanoparticles prepared by Choo et al. [119]. Using different solvents as the reaction medium, different morphologies of PVP-protected silver colloids with charming colors could be obtained through microwave irradiation on a solution of silver nitrate [120].

### 2.1.4. Immobilization

Polymer-protective metal nanoclusters are usually prepared as stable colloidal solutions which need to be immobilized for the demands of some specific application purposes. Several strategies for the immobilization of polymer protected metal nanoclusters have been proposed. Solidification of Pt and Rh metal nanoclusters protected with a co-polymer of $N$-vinyl-2-pyrrolidone and methyl acrylate was realized by Hirai and co-workers through the reaction between the residue groups of methyl ester in the protective agent with amino groups in a poly(acrylamide) resin [121, 122]. It could be expected that using this method the structure feature of the polymer protected metal nanoclusters is almost the same as that prepared after the solidification process. Specially designed polymer protective agents and supports have to be used in this strategy.

In the end of the 1980s, we proposed a procedure, namely a "coordination capture method" [90, 123], to immobilize PVP-protected metal nanoclusters onto ligand anchored supports in order to prepare a high performance catalyst which could be easily separated from the catalytic system (Fig. 6a, b). The surface of a silica support was modified with -$(CH_2)_3SH$ and -$(CH_2)_3SR$ groups, respectively, and the obtained products were simply stirred in a colloidal solution of PVP-protected metal nanoclusters of Pd, Pt, Au, or Pt/Rh alloy, resulting in a complete immobilization of the metal nanoclusters on the supports. This method characterized by taking advantage of the coordination action of the anchored ligands to metal atoms at the nanocluster's surface or the specific reaction between mercaptan and surface metal atoms provided a route of universal significance to combine the techniques of metal nanocluster preparation and the surface modification. XPS measurements on the products revealed that only a very limited amount of PVP still hung on the immobilized metal nanoclusters. Two factors should be controlled to achieve an ideal experimental result. First, the interaction between the coordination ligands and the metal atoms at the surface should be stronger than that between the polymer protective agents and metal nanoclusters. Second, the support surface should be amicable to the colloid solutions, which usually could be easily fulfilled by adding a suitable organic solvent to the reaction system. Today, it is well known that the coordination capture method is not restricted to polymer-protected metal nanoclusters or powder supports; for supports of plate shape and other metal nanoclusters as well as other anchored ligands, it also works well [124, 125].

The concept of "coordination capture" was greatly expanded by using double-ended dithiols which can be bonded on the surface of a metal plate with one tail and confine small metal nanoclusters with another tail of mercaptan group (Fig. 6c), providing a universal route to develop a

film of metal nanoparticles [126–136]. This technique has been used in the study of the intrinsic electronic properties of individual metal nanoparticles using scanning tunneling microscopy (STM) [135, 136] and the development of new electronic switches based on a redox process of the bridging ligand [137].

It has been well known that ionic or hydrogen bond complexes of polymers can form as precipitates when two kinds of soluble polymer having groups for forming ionic or hydrogen bonds are mixed together in suitable conditions such as pH and solvent. Therefore, if the polymer-protective

agent for metal nanoclusters is a polyelectrolyte or a macro-molecule containing polar groups, immobilization of the corresponding metal nanoclusters could be easily conducted by forming polymer ionic complex [138] or polymer hydrogen bond complex (Fig. 6d) [139]. The latter, proposed by Wang and Liu, is more convenient for real applications because many of the usually adopted polymer protective agents such as PVP, PVA, PAA, and DNA belong to this group. When an aqueous colloidal solution of PVP-protected metal nanoclusters was mixed with an aqueous solution of PAA, for example, a network of hydrogen bond complex of PVP–PAA with the encapsulated metal nanoclusters formed as a black precipitate, leaving a clear, colorless solution containing metal nanoparticles of an ignorable amount. If the immobilization is conducted in the presence of an inorganic support with a large specific surface area such as a silica, a supported metal catalyst with well-dispersed metal nanoclusters can be obtained. Out of question, this immobilization method can also be used to prepare film of layered structure using a layer-by-layer cross-adsorption procedure.

Metal nanoclusters including those protected by polymers could be embedded in inorganic metal oxide matrixes by an *in-situ* hydrolysis of organometallic compounds such as $CH_3Si(OCH_3)_3$ or $Si(OCH_3)_4$. This sol–gel process provides a convenient way to encapsulate small metal particles originally stabilized with different protective agents in nano- or microporous inorganic supports [140–142].

Electrophoretic deposition of Pt nanoclusters protected with PVP on TEM grids was reported by Teranishi et al. A monolayer of closely stacked Pt nanoclusters could be obtained this way [143].

## 2.2. Ligand and Surfactant-Protected Metal Nanocluster

Different from the polymer-protected metal nanoclusters, these colloidal metal nanoparticles are covered with a layer of organic molecules with their heads or tails contacting the surface metal atoms depending on the solvent used. Therefore the thickness of the organic shell on the metal core can be roughly estimated from the dimension and configuration of the molecules. Some surfactants have been known to be effective for stabilizing colloidal metal particles for a long time. Current interest in the preparation of surfactant stabilized metal nanoclusters is to control the particle size, shapes, and metal compositions in order to achieve new catalyst precursors or specific superlattice patterns that may be of importance for potential applications in recording media or nanostructured electronic devices.

### 2.2.1. Ligand Stabilized Metal Nanoclusters

The ligand (such as mercaptan or triphenylphosphine) stabilized metal nanoclusters are considered to be a new kind of building block material for fabricating future new electronic devices or nanoelectric digital circuits based on the so-called quantum size effect or single electron transition effect, which have been investigated theoretically and experimentally [3, 25, 26, 136, 144, 145]. Besides operating the nanoswitch of a single metal nanoparticle, the possibility of future application of nanoclusters in this field and some

other functional system strongly depends on the availability of ordered organized nanomaterials. Therefore, intensive effort has been paid to fabricate superlattice of metal nanoclusters in one, two, or three dimensions during the last decade. Compared with possible future applications in nanoeletronics, more realistic are the use of these building blocks for chemical or biochemical sensors, magnetic recording media, and catalysts.

The ligand or surfactant metal nanoclusters are usually prepared by chemical reduction of corresponding metal ions in the presence of the protective agents; they can also be obtained by reactions of the preformed metal cores with the protective agents. The latter provides a convenient way to transfer metal nanoclusters between different phases [88, 146, 147].

The well known $Au_{55}(PPh_3)_{12}Cl_6$ nanocluster and some of its derivatives characterized by definite or near definite numbers of metal atoms of Au, Pd, Pt, or Rh, for example, and protective coordination ligands were created by Schmid and co-workers [148–152], and their structures, properties, and possible applications have been well reviewed [2, 3, 10]. Additionally, alkylphosphine or alkylphosphine oxide passivated Cr and Ni nanoclusters have also been prepared [153]. Important progress in alkylphosphine stabilized metal nanoclusters is that a $Pd_{145}$ nanocluster with pseudo-$I_h$ symmetry, $Pd_{145}(CO)_x(PEt_3)_{30}$, has recently been confirmed by single-crystal X-ray diffraction studies [154]. It has been found that this $Pd_{145}$ nanocluster contains a spherical-like three-shell $Pd_{115}$ kernel encapsulated by a metal carbonyl cluster shell consisting of 30 Pd atoms, 30 perpendicularly ligating triethylphosphine molecules, and about 60 edge-bridging carbon monoxide ligands. Especially, within the center of the $Pd_{115}$ kernel, there is a perfect two-shell icosahedral Mackay hard-sphere nucleus, $Pd_{55}$, which is the first experimental verification of Mackay theory [155] by X-ray crystallography, and it also makes the $Pd_{145}$ nanocluster an interesting model for testing size-dependent physical properties of metal nanoclusters.

Mercaptan is very important ligand for stabilizing metal nanoclusters and has been used to fix many small metal nanoclusters on the surface of a support [123]. In 1994, Brust et al. reported the preparation of thiol-stabilized gold nanoparticles in a two-phase liquid–liquid system [156]. In this preparation, $[AuCl_4]^-$ ions were extracted into an organic solution containing alkylthiol with a long chain; then the Au(III) ions were reduced with $NaBH_4$ to lead to the formation of mercaptan stabilized Au nanoclusters that can be separated by adding a precipitating agent of methanol or acetone and re-dissolved like a common compound after being completely dried. In fact, reducing Au(III) ions with $NaBH_4$ or $LiB(C_2H_5)_3H$ in the presence of mercaptans in organic media such as methanol or THF could simply prepare stable colloidal solutions of mercaptan-stabilized gold nanoclusters [157–159]. In addition to Au nanoclusters, mercaptan stabilized Ag [160, 161], Pt [159, 162], Ir [159], and gold-containing alloy [163] Au/Ag, Au/Cu, Au/Ag/Cu, Au/Pd, Au/Pd, Au/Ag/Cu/Pd nanoclusters have been reported. Either aromatic [164, 165] or alkyl mercaptan with different chain lengths [166, 167] which may contain other functional groups [168–174] has been adopted

as the protective agent, especially when a ligand containing photofunctional groups is used, and a way to develop novel photofunctional materials opens [169, 170, 174]. It has been revealed that using a higher Au/S ratio, lower reaction temperature, and addition of NaBH$_4$ with a high speed favor forming small and narrowly distributed metal nanoclusters [168, 175].

Recently, novel pyrrolylalkanethiolate-stabilized gold and palladium nanoparticles have been prepared, and electrochemical polymerization of them gave remarkably stable poly(pyrrole metal nanoparticle) films on metal electrodes [176].

Alkyl amine [177–181], carboxylic acid [182], or alkyl isocyanide [162] stabilized metal nanoclusters were also synthesized, although their stabilities are not as high as mercaptan stabilized metal nanoclusters. As shown in Figure 7 as an example, good quality, monodispersed long-chain alkylamine capped copper metal nanoparticles have been successfully synthesized in a nonhydrolytic approach by the thermal decomposition of a Cu(II) precursor, copper (II) 1-$N,N$-dimethylamino-2-propanolate, [Cu(OCH(Me)CH$_2$NMe$_2$)$_2$], in a hot coordinating solvent [181].

The special high stabilizing effect of mercaptan on the metal nanoclusters is derived from the oxidation addition reaction of mercaptan group and the surface Mattel atoms which remove two hydrogen atoms from mercapto groups and form metal–sulfur bonds on the surface. It has been observed that heating treatment of the mercaptan-stabilized Au nanocluster in organic solvent may change its particle size or shape [183]. Compared to those prepared using conventional mono-alkylthiols, a designed four-chained disulfide stabilizer enabled Yonezawa and co-workers to prepare small gold nanoclusters and control the particle size with atomic precision when NaBH$_4$ was used as a reducing agent [184].

Macrocyclic thiol compounds such as thiolated alpha- or beta-cyclodextrins have been used to cap metal nanoclusters of Au, Ag, and Pd. This development in the coordination chemistry of metal nanoclusters should be very promising in some specially designed assembly of nanostructured functional materials [185–193].

Because of the strong interaction between mercapto group and metal atoms, adding a mercaptan with a long chain into usually prepared colloidal solutions of various

metal nanoclusters could easily produce the corresponding mercaptan-stabilized metal nanoclusters or modify the nanoparticles with functional groups via ligand-exchanging reactions.

Gold nanoparticles functionalized with thiol dendrons containing three redox active amidoferrocenyl units via ligand exchange have been reported; these dendronized gold nanoparticles could recognize H$_2$PO$^{4-}$ [59].

Metal nanoparticles with size dispersion less than 10% are usually called monodispersed metal nanoclusters. Although adjusting the preparation conditions could narrow the size distribution, the separation of different sized metal nanoparticles should be given more attention. The methods of precipitation by stages (i.e., adding precipitating agents step by step [194, 195], liquid gravity column chromatography [196], or capillary electrophoresis [197]) have proven to be helpful in narrowing the size dispersion of metal nanoclusters and studying the size-dependent properties.

A fundamental question has been proposed for a long time; that is, what and how strong is the ligand effect on the electronic properties of small metal nanoclusters? To answer this question we need small metal nanoclusters having the same metal core and various modifying shells of organic ligands because the core-level binding energies of small metal nanoclusters are also dependent on the metal particle size [198, 199]. In general, higher binding energies of core levels in metal nanoparticles relative to the values of bulk metal can be observed when the metal particles are small enough, and values increase with decreasing particle size. This phenomenon has been interpreted in terms of final state relaxation [200]. Based on the successful synthesis of Pt nanoclusters having the same metal core, 1.3 nm in average size, stabilized by alkylamine, alkylthiol, PPh$_3$, PVP, and PVA, respectively, we have revealed that the size-dependent effect on the Pt 4$f$ binding energy of the Pt cores (average Pt core size 1.3 nm, size distribution 0.8–2.8 nm) is +0.5 eV. The thiol-bonded effect on the Pt core causes a further 0.3 eV increase in the Pt 4$f$ binding energy. PPh$_3$ has a weak influence on the Pt 4$f$ binding energy of the Pt core, whereas PVP, PVA, and alkylamine do not cause obvious changes in the Pt 4$f$ signals [147].

An ultrafast electron dynamic study revealed that chemically prepared Au nanoclusters with a Au$_{28}$ nanocore surrounded by 16 glutathione molecules show an induced transient absorption in the visible region from 2.58 to 1.65 eV (480–750 nm) with a maximum around 2.07 (600 nm) after excitation with femtosecond laser pulses. The excited state relaxation shows a biexponential decay with a subpicosecond and a longer nanosecond decay time which is different from those observed for larger gold nanoparticles, suggesting that the examined gold nanocluster exhibits molecular properties [201]. A broad luminescence extending over the entire spectral range from the visible to the infrared (2.0–0.8 eV) was observed by Link and co-workers [202].

## 2.2.2. Surfactant Stabilized Metal Nanoclusters

Surfactant protected metal nanoclusters have been studied intensively and some new contributions will be mentioned here.

Goia and Matijevic studied the influence of difference in redox potentials of $M^{n+}/M$ and reductant/oxidation-product pairs on metal colloid formation in water and pointed out that the $\Delta E$ should be higher than 0.3–0.4 eV in usual cases. Suitable reductants and reaction conditions for the preparation of metal colloidal from various transition metal ions have been tabled [203].

Syntheses of cationic palladium nanoparticles stabilized by quaternary ammonium alkylisocyanides were reported. Reduction of $PdCl_4^{2-}$ by hydrazine in the presence of the surfactant gave rise to a stable aqueous dispersion of cationic palladium nanoparticles. The particle size depended on the alkyl chain lengths of the stabilizer molecules [204].

$NaBH_4$ is one of the widely used reducing agents in the preparation of metal colloids. However, when the reduction of light transition metal ions such as $Co^{2+}$ or $Ni^{2+}$ was conducted in water using $NaBH_4$, indefinite amounts of metal borides would be produced. A very smart strategy of universal significance for the preparation of various small metal nanoclusters (metal elements of 6–11 groups) in organic media stabilized with surfactant and ether or thioether was proposed by Bonnemann and co-workers [205]. The reaction is as follows: $MX_v + vNR_4(BEt_3H) + THF \rightarrow M_{colloid} + vBEt_3 + H_2$, where $NR_4^+$ works as the stabilizer.

A tetraoctylammonium-stabilized PtSn colloid, with nominal composition $Pt_3Sn$ as confirmed by point-resolved EDX analysis, was prepared by co-reduction of the metal salts and supported on silica. The supported bimetallic nanocluster, average size of 1.5 nm, has a highly disordered structure. By removing the stabilizer tetraoctylammonium by heating the samples in He to 200 °C, coalescence of neighboring particles produced a majority of cubic $Pt_{0.81}Sn_{0.19}$ particles, with average size of 3.1 nm and a minority phase of stoichiometric hexagonal PtSn of 4.4 nm in size [206].

A copper colloid stabilized by $N(octyl)_4^+$ with Cu particle size of 5 to 10 nm was prepared by the reduction of $[N(octyl)_4]_2[CuCl_2Br_2]$ in toluene using $Li[BEt_3H]$ as a reducing agent. An in-situ XANES (X-ray absorption near edge structure) investigation was performed for the first time during the colloid synthesis, which is helpful in giving direct insight into the mechanism of the colloid formation. An intermediate $Cu^+$ state prior to the nucleation of the particles was observed in this measurement [207].

Anionic surfactants such as alkylsulfate have also been used widely as the stabilizer of metal nanoclusters. Silver nanoparticles with well-defined size and shape distribution under sodium dodecylsulfate in solution were prepared by photochemical reduction of laser irradiation [208, 209]. Recently, a new method for the synthesis of surfactant-stabilized noble metal nanoparticles has been developed, whereby a sodium alkyl sulfate ($SC_nS$) surfactant bearing an alcohol-type functional group is used as the reductant, and there is no need for an external reducing agent. By changing the carbon chain length of the surfactant, the diameter of the nanoparticles could be controlled [210].

Polyfluorinated organic compounds are interesting in protecting metal nanoclusters due to their unique properties. Perfluorocarboxylate-stabilized silver nanoparticles have been prepared via the thermal decomposition of layered silver perfluorocarboxylates (Fig. 8) [211]. Palladium

**Figure 8.** Perfluorocarboxylate-stabilized silver nanoparticles from the thermal decomposition of layered silver perfluorocarboxylates. Reprinted with permission from [211], K. Kim et al., *Chem. Commun.* 442 (2002). © 2002, Royal Society of Chemistry.

nanoparticles can also be prepared by reduction of palladium(II) chloride in the presence of different compounds featuring long perfluorinated carbon chains [212].

It is important to select a suitable reductant besides the control of other reaction conditions in order to obtain a stable colloidal solution of small metal nanoclusters by the method of reducing metal ions. The reduction ability on an electrode, however, could be easily adjusted by changing the potentials. Therefore the electrochemical process should be a very promising strategy for synthesizing metal nanoclusters especially for those metal elements having a relatively low redox potential.

Recently a detailed study on the size-selective electrochemical preparation of $R_4N^+Br^-$ stabilized Pd colloids was conducted by Reetz and co-workers, in which a sacrificial anode of Pd is used, and the surfactant serves as the electrolyte and stabilizer. The results showed that parameters such as solvent polarity, current density, charge flow, distance between electrodes, and temperature could be used to control the size of the Pd nanoparticles in a range of 1.2 to 5 nm. $(n\text{-}C_6H_{13})_4N^+Br^-$-stabilized nickel and $(n\text{-}C_8H_{17})_4N^+Br^-$-stabilized Pt/Pd colloids were successfully prepared [213].

Using standard Schlenck techniques Sobal et al. [214] prepared a well controllable core–shell structured Ag/Co bimetallic nanocluster. The method consists of a thermal decomposition of dicobalt octacarbonyl in combination with a transmetalation reaction with water-free $AgClO_4$ using oleic acid and tridodecylamine as protective surfactants the following reaction

$$Co_2(CO)_8 + 2AgClO_4 \rightarrow 2Ag + Co + 8CO + Co(ClO_4)_2$$
As a result, bimetallic Ag/Co particles were formed. The core–shell structures of these bimetallic nanoclusters of non-alloying elements were clearly characterized by TEM, electron energy-loss spectroscopy (EELS), and EDX as shown in Figures 9 and 10.

Formation of stable gold nanoparticles of different size and shape has been reported via UV photoactivation of $HAuCl_4$ in variable concentrations of TX-100. It is observed that small gold nanoparticles preferentially coalesce together at higher temperature in micelles. Temperature induced changes in the shape of the micelle provide the required template conditions for linear growth of gold nanoparticles. The smaller gold particles preferentially dissolved by cyanide at a faster rate in air in comparison to that for the larger particles because of higher mobility and possibly because of lower redox potentials of the smaller
**Figure 9.** TEM image at low magnification of a monolayer of AgCo$_{0.81}$ particles deposited on a carbon coated copper grid. The core–shell structure is visible at higher magnification (inset). particles. These interesting experiments provide a meaningful variant way to create metal nanoclusters with different shapes and particle sizes [215].

Chemicals inducing the formation of a specific shape of metal particles are called shape-directing agents. The function of a shape-directing agent, tetra-*n*-octylammonium glycolate, which bears a hydroxyl group at the $\alpha$-position, on the shape selectivity of trigonal cross-section particles of Ni was studied. An *in-situ* Fourier transform infrared (IR) study of the formation of colloidal nickel from bis(cyclooctadiene) nickel in the presence of tetra-*n*-octylammonium glycolate revealed that the interaction of the alpha-hydroxy carboxylate with the surface of the colloidal metal particle is likely to be the morphology-determining factor in the shape-selective preparation of these metal particles [216].

### 2.2.3. Assembly and Self-Assembly

The fabrication of superlattice structures of nanobuilding blocks is thought to be a key factor relating to future optical and electronic devices [124, 217–231].

When the colloidal solutions of metal nanoclusters are led to slowly evaporate their solvent on a flat surface,

**Figure 10.** EELS element mapping of the Ag component (Ag $M_{4,5}$ edge) (a) and the Co component (Co $L_{2,3}$ edge) (b) in the bimetallic particles revealing an Ag$_{core}$Co$_{shell}$ structure. The element specific brightness of the same particle is marked by circles in both images. Reprinted with permission from [214], M. Hilgendorff et al., *Nano Lett.* 2, 621 (2002). © 2002, American Chemical Society.

nanoparticles with narrow size and shape distributions have a tendency to gather together and form two- or three-dimensional ordered superlattice patterns. This is one of the self-assembly processes. Perfect superlattice patterns of metal nanoclusters with the ordered scales up to submicrometer or even several micrometers have been constructed by simply evaporating solvent in a drop of colloidal solutions of metal nanoclusters stabilized by surfactant or coordinating ligands. For example, Au nanoclusters stabilized with alkylthiols [124, 232–236], 2,6-bis(1′-(8-thiooctyl)benzimidazol-2-yl)-pyridine [124], tetraalkylammonium salt [124, 237, 238], tetrapyridylporphine [239] or PPh$_3$ [240], Ag [241–247] and Pt nanoparticles [248] stabilized with alkylthiols, Pd nanoclusters stabilized with tetraalkylammonium salt [249], Co nanoparticles stabilized with carboxylic acid having a long chain [250], and Pt/Fe alloy stabilized with a mixture of oleic acid and oleic amine [251] have been successfully arranged into two- or three- dimensional superlattices, and the dynamic influence factors or driving forces in the self-assembly process have been discussed [244, 252–255]. Colloidal crystals of monodisperse Fe/Pt nanoparticles have also been grown by a three-layer technique of controlled oversaturation [256].

Highly ordered, hexagonally packed monolayer of gold nanoclusters protected with fluorinated alkane thiols has been reported by Yonezawa et al. These fluoro-alkylthiol-stabilized nanoparticles are soluble only in fluorocarbon media, and casting of these dispersions provided highly ordered, hexagonally packed monolayers on solid substrates [257]. Self-organized superstructures of fluorocarbon-stabilized Ag nanoparticles were also been studied [258].

Yonezawa and Kunitake synthesized a kind of gold nanoparticle stabilized with a water-soluble mercapto ligand (sodium 3-mercaptopropionate) by a modified citrate reduction of HAuCl$_4$. These gold nanoparticles were incorporated successfully into the interlayers of cast films of cationic bilayers by immersion of the film in gold nanoparticle dispersions [259]. Such amphiphilic gold nanoparticles were also obtained through ligand exchange reaction of alkanethiolate-protected gold nanoclusters with $\omega$-thiocarboxylic acids, and their assembly process was pH-controlled [260].

By use of the mercaptan stabilizer containing hydroxyl group, gold nanoparticles could be assembled with TiO$_2$ colloidal particle layer by layer resulting in a layered nanocomposite, which provided a convenient and universal process for assembling metal nanoclusters [261].

An organic/inorganic hybrid photoactive and electroactive functional film has also been made by this layer-by-layer deposition technique via alternate assemblies of aggregates of thionine dyes and Au nanoparticles on an amino functionalized support surface (Fig. 11) [262]. Hybrid nanocomposites of metal nanoclusters with silica such as highly ordered spherical mesoporous silica/gold [263] and silica/Ag [264] nanoparticles were also prepared through self-assembly recently. Pt nanoparticle-doped Nb$_2$O$_5$ composite films (~80 nm thickness) have been prepared by the liquid phase deposition method [265] (Fig. 12).

Gold nanoparticles and alkylthiols with various functional groups, including fullerene-C$_{60}$ [266], have also been used for fabricating novel photo- or electroactive nanostructures
**Figure 11.** Alternate assemblies of thionine and Au nanoparticles on an amino functionalized surface. Reprinted with permission from [262], S. Dong et al., *Chem. Commun.* 1706 (2002). © 2002, Royal Society of Chemistry.

**Figure 13.** An alternative Pd/Au bimetal nanoparticle thin film with redox activity via electrooxidative deposition of palladium and gold nanoclusters attached with the same biferrocene-terminated thiolates. [267–269] by self-assembly techniques. Recently, an alternative assembled nanoparticle thin film with redox activity has been formed by a combination of electrochemically oxidative deposition of palladium and gold nanoparticles attached with the same biferrocene-terminated thiolates (Fig. 13) [270].

It has been reported that IR light irradiation of a mixed toluene solution of ammonium salt-stabilized gold nanoparticles with a $3.8 \pm 0.8$ nm core and a porphyrin thioacetate derivative affords a thin photoactive film of the cluster–porphyrin network (Fig. 14) [271].

Three-dimensional Pt nanoparticle networks were prepared by cross-linking preformed aluminum-organic-stabilized Pt nanoparticles in solution with organic spacer molecules, through a protonolytic cross-linking reaction of reactive aluminum methyl groups at the particle surface. The hybrids were characterized by electron microscopy, IR spectroscopy, and anomalous small-angle X-ray scattering techniques [272].

One-dimensional organization of copper nanoparticles has been achieved by chemical reduction using lipid-copper hybrid nanofibers as a template; the reduction of copper ions resulted in the formation of copper nanoclusters at intervals of 2 to 5 nm along the nanofibers [273].

Spheric architectures of nanostructures containing Au or Ag could be obtained through the assembly of the corresponding smaller metal nanoclusters on spherelike templates [274, 275]. Direct self-assembly of thymine-functionalized Au nanoparticles with diaminopyridine-functionalized polyhedral oligomeric silsequioxanes (POSS) through tandem

hydrogen bonding and POSS recognition processes also forms well-defined spherical aggregates [276]. (Fig. 15).

Self-assembly of small metal nanoclusters, for example, of $Au_{55}$ into linear nanostructures, has been conducted with different strategies [277–280]. To arrange metal nanoclusters in a two-dimensional pattern of parallel rows of clusters with an adjustable periodicity down to a scale of several nm, however, is still a challenging task.

Dumpich and co-workers reported a method of fabricating metallic nanostructures by electron beam lithography on films of surfactant stabilized metal colloids. Destroying the organic stabilizers with high-energy electron beams may result in a patterned film of metal particles. This technique provides an interesting and powerful fabrication manner for metal nanostructures of various kinds of material and geometry [281].

The electron beam lithography technique has been demonstrated to be a very promising tool for making various designed patterns of assembled metal nanoclusters [282–285]. Figure 16 shows the nanowires of assembled Au nanoclusters derived from electron beam lithography on a Langmuir–Blodgett film of alkanethiol-capped 3 nm diameter gold nanoparticles reported by Werts and co-workers [286]. Nanowires with diameters less than 50 nm could be produced under controllability conditions; the patterns are formed by radiation-induced cross-linking of the alkyl chains and they can be contacted and studied electrically [286].

An electron beam can also be exploited in the growth of metal nanoparticles from small organometallic clusters or other metallic compounds on irradiation, and assemblies of Ru nanoparticle chains and wires [287] and 2D and 3D metal patterns [288] have been obtained directly.

Maoz and co-workers [289–292] developed a promising nanolithography technique in order to establish a

planed pattern of chemical information [i.e., using conductive atomic force microscopy (AFM) tip-induced nano-electrochemical oxidation of terminal $CH_3$ groups to carboxylic acid groups in a selected area of a methyl-terminated silane monolayer on silicon followed by a self-assembly process and chemical process to establish a chemical pattern of mercapto groups]. Nanostructured building blocks prepared *in-situ* could be fixed on the patterns of mercapto groups.

Using the "coordination capture" concept and manner, the organization of $[Au_{55}(Ph_2PC_6H_4SO_3Na)_{12}Cl_6]$ nanoclusters on various shaped patterns with top thiol groups created by the nanolithography technique has been well studied and perfectly assembled patterns with good stability of Au nanoclusters have been achieved by Liu and co-workers [293]. Figures 17 and 18 demonstrate the scheme of the nanolithography technique and the AFM image of the patterns of assembled organic template and parallel wires of gold nanoclusters.

Assembly of metal nanoclusters on proper templates could give rise to various promising structures. There is growing interest in attempts to combine biomaterials and nanoparticles in the fabrication of novel nanostructures as well as the investigation of their properties [294]. One of the research motivations for this combination is taking advantage of the well defined structures and special properties of biomolecules and their supermolecular structures to organize the nanoparticles into predefined, topologically intricate nanostructures or to synthesize miscellaneous materials for utilization in electronic, optical, and chemical devices. Several kinds of biomaterials have been used as templates for this purpose; for example, highly ordered protein assemblies, tobacco mosaic virus, and bacterial S-layers have been adopted for the generation of ordered arrays of metal and semiconductor nanoparticles [295–299].

DNA molecules have been used to mediate assembly of metal nanoparticles into linear, monolayer, and multilayer structures [300–306]. In addition, they have also been used to grow metal nanowires [307–310].

Very recently, we assembled Au or Pd nanoparticles respectively onto a self-assembled peptide nanofibril, used as a special 1D template, by mixing a preformed Au colloidal solution and the template directly or reducing Pd(II) ions with hydrogen in the presence of the template. It was found in surprise that double helical arrays of Au or Pd nanoparticles formed at a pH value near 6, whereas single-chain arrays of the metal nanoparticles formed at pH of 3.5. Pd nanowires in different shapes were also prepared. In addition, the assembled metal nanoparticles serving as labels were used to speculate the structure of the self-assembled peptide nanofibril [524].

Using the concepts of self-assembly of metal nanoclusters and the high specific selectivity of DNA segment combination, which were determined by the DNA configurations and the formation of hydrogen bonding, Elghanian and co-workers [311] reported a DNA sensing system in 1997, applicable to determine the sequence of a DNA or RNA molecules, which opened a new field to develop metal nanocluster-based biosensors having potential applications in medical and biological science. The development of biosensors is extremely significant in disease diagnosis and treatment, drug discovery, molecular biology and bioengineering, forensic identification, and environmental monitoring of biological agents and toxins [312, 313]. A biosensor, in principle, is based on the coupling of a ligand–receptor binding reaction [314] to a signal transducer, where the signal may have all sorts of physical characteristics including optical, radioactive, electrochemical, piezoelectric, magnetic, micromechanical, thermal, and mass spectrometric properties [315]. Since the metal nanocluster-based DNA sensor was published [311], there has been progressively increasing interest globally in studies on metal nanocluster-based biosensors. Due to their strong size-dependent natures and dimensional similarities to biomacromolecules, metal nanoclusters are most fascinating in making unique biosensors [316], for instance, DNA sensors [311, 316–340], glucose sensors [341–349], IgG protein sensors [350], and $H_2O_2$ sensors [351], when they are covalently hybridized with biological molecules such as peptides, proteins, enzymes, and nucleic acids. Recently, gold nanoparticles coated with haptenylated mercaptodextrans have been assembled, via binding specifically, to paramagnetic beads coated with a specific antibody, providing a way designed for biomolecule assay [352] (Fig. 19). Compared to traditional detecting techniques, metal nanocluster-based biosensors possess many desirable advantages; for example, it has low detection limits to picogram per ml, even to a single molecule, indestructive and highly selective detection, multiple modes of detection, and real-time detection, and it is label-free, environmentally friendly, cheap, and easy to miniaturize [353].

## 2.3. Anion and Solvent Stabilized Metal Nanoclusters

Stable colloidal solutions of "unprotected" small metal nanoclusters with a reasonable concentration of metal are of great importance in real applications such as fabrication of special electrode of fuel cells, catalysts, sensors and various composite materials. Successful examples for such preparations are still very limited. The unprotected metal nanoclusters are prepared in the absence of usual protective agents; however, they are not truly bare but stabilized by solvents or simple anions adsorbed on them, or by both. Cardenas-Trivino and co-workers prepared stable Pd colloids with average diameters of 6–8 nm in acetone or propanol using a solvated metal atom dispersion technique (SMAD). These Pd colloidal particles are "living" in the sense that they can be used to produce metal films [354]. Gold nanoparticles in acetone and films derived from their immobilization on functional group anchored surfaces have been studied [355]. A synthetic procedure for preparation of large quantities of monodisperse gold colloids based on the SMAD method was recently reported [356].

Recently, the authors succeeded in the effective preparation of small (1–3 nm) metal nanoclusters of Pt, Rh, Ru [88], and their alloys (unpublished data) in glycol containing NaOH without adding any other protective agent. These "unprotected" metal nanoclusters stabilized by organic solvent and $OH^-$ were prepared by reducing colloidal particles of the corresponding metal hydroxides or complexes. These metal nanoclusters are very tractable as building blocks for fabricating new function materials [357] in the sense that they can easily be separated from the solvent as precipitates by adding an aqueous solution of HCl and the precipitated metal nanoclusters are "resoluble" in many organic solvents.

**Figure 19.** Haptenylated mercaptodextran-coated gold nanoparticles for biomolecular assays. Reprinted with permission from [352], R. Wilson, *Chem. Commun.* 108 (2003). © 2003, Royal Society of Chemistry.

Stable cyclohexanone or cyclopentanone colloidal solutions of Pt nanoclusters, average size 1–2 nm, with a Pt concentration higher than 200 g/L can be easily obtained by dissolving the precipitated Pt nanoclusters in the solvents. Colloidal solutions of thin Pt nanowires having diameters of 1–3 nm and lengths up to 70 nm have been succeefuly prepared by reducing $K_2PtCl_4$ with $H_2$ in the presence of our "unprotected" Pt nanoseeds [525].

Tano and co-workers reported the preparation of stable palladium colloids with average Pd particle size of 8–10 nm from the thermal decomposition of Pd complexes in methyl isobutyl ketone [358].

As ionic liquids have high polarity, robust physical stability, low volatility, and tunable properties, they are full of potentials in making metal nanoclusters under these green solvents [359], and narrowly dispersed germanium nanoclusters have been electrodeposited from a dilute solution of $GeCl_4$ in the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate ([BMIm]$PF_6$) [360].

Colloidal early transition metals are of great interest in scientific research and applications. Organosols of zero valent Ti, Zr, V, Nb, and Mn with small particle size were prepared by Bonnemann and Brijoux by reducing the corresponding metal halides in tetra hydrofuran (THF) using K[$BEt_3H$] as a reductant [361]. Intensive studies on the Ti-THF nanocluster using HRTEM, EDX, XPS, XANES, and EXAFS analyses proved that this metal colloid consists of very small Ti particles in the zero valent state, stabilized by intact THF molecules [362].

Stable colloidal solutions of cubic Pt nanoparticles stabilized by oxalate with a particle size of 6.5 nm and shape selectivity larger than 90% were recently successfully prepared by the authors via the reduction of $K_2Pt(C_2O_4)_2$ in water with hydrogen at room temperature. It was observed that the shape selectivities of the Pt colloidal particles were strongly dependent on the precursors of metal salts used in the reactions, which should be related to the reaction speed and adsorption states on the formed metal nanoparticles. After the exposure to air and treatment with hydrogen, the oxalate stabilized Pt nanoparticles can self-assemble into Pt nanowires with diameters of those of the Pt nanoparticles and lengths of several hundreds of nm [363].

A stable colloidal solution of gold nanoparticles of 2 nm diameter was prepared in water containing $CS_2$ without adding any other stabilizers by reduction of $AuCl_4^-$ with $NaBH_4$. It was found that the surface plasmon band at around 520 nm was strongly damped due to small particle size and possibly chemisorption of a $CS_2$ derivative [364].

Polyoxometallates are important anionic stabilizers and supports for the preparation of metal nanoclusters due to their high surface charge plus significant steric bulk. Narrowly dispersed 2 or 3 nm Ir and Rh nanoclusters stabilized by $[P_2W_{15}Nb_3O_{62}]^{9-}$ were made by Finke et al. [365, 366] and their synthesis, characterization, and formation mechanisms were discussed in a recent review by Aiken and Finke [27]. Following Finke's precedent work using a Dawson polyoxmetallate as a nanocluster stabilizing agent, synthesis of Ag, Au, Pd, and Pt nanoparticles using Keggin polyoxometalates, such as $[SiW_{12}O_{40}]^{9-}$, as photocatalysts and stabilizers has also been conducted recently by Troupis et al. [367].

# 3. METAL NANOCLUSTER CATALYSTS

## 3.1. Quasi-Homogeneous Catalysts

PVP protected metal nanoclusters, which exhibit very high catalytic activities and stability in many organic reactions, and the well-known Nord colloid (PVA-protected Pd colloidal) [368] are representative examples of the quasi-homogeneous catalytic system.

In this catalytic system, the catalytic active species (i.e., metal nanoparticles) are similar to that of metal-supported catalysts but homogeneously dispersed as a colloid in the reaction media. Because of the very small particle size accompanied by a large specific surface area and high coordination unsaturating state of the surface metal atoms as well as the low resistance of mass transfer, the PVP-protected metal nanoclusters usually exhibit much higher catalytic activities than the corresponding traditional metal-supported catalysts. Recently, the hydrogen concentration–pressure isotherms of surfactant-stabilized palladium clusters and polymer-embedded palladium nanoclusters with diameters of 2, 3, and 5 nm were measured with the gas sorption method at room temperature. The results show that, compared to bulk palladium, the hydrogen solubility in the phase of the clusters is enhanced fivefold to tenfold [369].

Another important advantage of the metal nanocluster catalysts is that it provides many more possibilities than the traditional metal-supported catalyst to design and tailor the structures of the catalytic system such as the shape and size, metal element and composition in alloy nanoclusters, thickness and the core size in core–shell structured bimetallic colloidal particles, modifiers of small molecules adsorbed on the metal nanoparticles, structure and functional groups in the protective polymer. Stability of PVP-protective metal nanoclusters is quite good for many reactions in organic or water media; a reaction temperature higher than 150 °C is possible for some reactions if it is necessary. Polymer-protected metal nanocluster catalyst has an ascendency compared with nanoclusters stabilized with surfactants or coordination ligands in the stability and possibility of separation from the substrates and products. PVP-protected metal nanoclusters with a PVP molecular weight larger than 40,000 could be easily separated from solvent, without losing its catalytic activity, and washed with solvent in an ultrafilter equipped with a membrane having a cutoff molecular weight of 20,000 to 30,000, although this technique is not usually adopted in experiments. Addition of precipitate agents such as acetone to an alcohol colloidal solution of PVP-protective metal clusters could also separate the polymer-protective nanoclusters from the reaction system as a precipitate. For some special protective agents, changing pH or temperature will cause a separation of the catalyst as a precipitate.

Metal nanocluster catalysts have been successfully used in many reactions, such as the hydrogenation and selective hydrogenation of various unsaturated organic compounds, hydration of acrylonitrile to acrylamide, oxidation of organic compounds, Heck reaction, and visible light-induced hydrogen evolution, and various factors that may influence the catalytic properties have been investigated.

The Heck coupling reaction between aryl halides and olefins is usually conducted with a palladium complex

such as Pd acetate that decomposes during the reaction and forms Pd precipitate. Recently, series of well-defined homopolymer-stabilized Pd colloids with different metal particle sizes were used to catalyze the coupling reaction of *p*-bromobenzaldehyde with butyl acrylate. The PVP-protected Pd colloid catalyst exhibits very high stability and good activity. Extremely high total turnover numbers (TON, moles of substrate/moles of Pd; TON = 100,000) and turnover frequencies (TOF = TON/*h*; TOF > 80,000) were obtained [370].

Studies on the catalytic properties of colloidal bimetallic catalysts, a promising new kind of material, started about 10 years ago [90, 91, 371]. PVP-protected Pt/Rh and Pt/Pd bimetallic colloids with small metal particles exhibit much better activities than those of the corresponding monometallic colloids. The preparation, characterization, and application to catalysis of some polymer- or ligand-stabilized bimetallic nanoparticles have been reviewed by Toshima and Yonezawa [372].

The structure of the bimetallic nanoclusters has a significant influence on their catalytic properties. The catalytic properties of our Cu/Pd alloy nanocluster protected by PVP for the selective hydrogenation of 1,3-cyclooctadiene to corresponding monoene and selective hydration of acrylonitrile to acrylamide (see Scheme 1), an important industrial process, have been intensively studied. In the hydrogenation reaction, both the coexisting Cu in the alloy nanoclusters and PVP can improve the selectivity to the formation of monoene by several times; however, cooperation of both effects causes an extreme increase in the selectivity. An industrial process of producing acrylamide from acrylonitrile needs a very high selectivity, because a small amount of cyanohydrine in the product will cause a big problem in the following process of polymerization of acrylamide. Our Cu/Pd alloy nanoclusters not only exhibit a much higher activity than usual Cu-supported catalyst but also give rise to a selectivity near 100% to acrylamide and no cyanohydrine can be detected during the reaction. Both the catalytic selectivity and activity of the Cu/Pd alloy nanocluster catalysts for the aforementioned two reactions are sensitive to the Cu/Pd ratio in the alloy nanoclusters [111].

The selective hydrogenation of $\alpha,\beta$-unsaturated aldehydes to the corresponding unsaturated alcohols is an important step for the preparation of various fine chemicals (see Scheme 2). It is a challenging task to reduce the C=O group while leaving the C=C double bond since usual metal catalysts do in the reverse. The PVP-Pt/Co (3/1) alloy nanoclusters, narrowly distributed in a size range from 1 to 2.7 nm with an average diameter of 1.7 nm, prepared by the "cold alloying process" exhibit quite excellent catalytic properties for the selective hydrogenation of cinnamaldehyde to cinnamyl alcohol. The average activity of 114 mol CAL/mol

Selectivity: 99.8%
Conversion: 92.8%
**Scheme 2**

metal per hr and a selectivity of 99.8% at a conversion of 96.2% could be easily achieved [113, 373].

PVP-protected Ni/Pd bimetallic colloids with narrow particle size distribution prepared by a similar method show high catalytic activity in the hydrogenation of nitrobenzene. The highest activity can be achieved for a bimetallic nanocluster with a molar ratio of Ni:Pd = 2:3, which exhibits 3.5 times greater activity than that of a typical colloidal palladium catalyst [374].

Monometallic, bimetallic, trimetallic, and tetrametallic nanoclusters, average size ranging 1.6–2.1 nm, containing Cu, Pd, Pt, and Ru have been prepared by reduction of corresponding metal chlorides with tetraoctylammonium formate in dimethylformamide. Catalytic properties of these colloidal catalysts for the coupling reaction of phenylboronic acid and iodobenzene to give biphenyl (see Scheme 3) have been investigated. Pd and Pd/Cu nanoclusters are more active than the others, and the Pd/Cu nanoclusters exhibit better activity at higher conversions. Ru and, surprisingly, Cu nanoclusters were found to be both active and stable for this reaction [375].

Catalyst modification is a widely applied strategy in heterogeneous hydrogenation. The chiral modification of metal nanoparticles in metal-supported catalysts has been a well-known strategy providing a high enantioselectivity in the hydrogenation of some organic compounds having potential to generate chiral center during the reactions. Heterogeneous Ni catalyst modified with tartaric acid and Pt catalyst modified with cinchona alkaloids are the most successful catalytic systems in enantioselective heterogeneous catalysts, which have been intensively studied in the field of heterogeneous catalyst. It has been concluded that supported Pt catalysts with relatively low dispersion (particle diameter larger than 2 nm) are preferred for the hydrogenation of $\alpha$-ketoester derivatives [376–382].

A platinum colloid prepared using the alkaloid dihydrocinchonidine was found to catalyze the hydrogenation of $\alpha$-ketoester pyruvates with a good enantioselectivity and high catalytic activity [383, 384]. A very interesting result was reported by Zuo et al. that an enantiomeric excess in favor of R-(+)-methyl lactate up to 97.6% could be obtained in the hydrogenation of pyruvate over a PVP-stabilized platinum colloidal catalyst with an average Pt particle size of only 1.4 nm (see Scheme 4) [385]. Molecular mechanics calculations of the modifier–reactant interaction on the

(Selectiveity > 99.6%)

**Scheme 1**

**Yield: near 100%**
**Scheme 3**

**Scheme 4**

platform surface suggest that it is possible to obtain good enantioselectivity on the small clusters [386].

Metal cations can have significant modifying effects on the catalytic properties of metal nanoclusters. An acceleration effect of lanthanoid ions on the catalytic activity of Pd nanoparticles protected by lanthanoid polyacrylate (PAA-Pd-Ln) was observed in the hydrogenation of acrylic acid. However, $Ln^{3+}$ ions do not influence the catalytic activity of PVP-protected Pd colloid. On the other hand, the promotion effect of $Nd^{3+}$ ions on the PAA-Pd-catalyzed hydrogenation of methyl acrylate and allyl amine was observed, but not of 1-hexene. It was believed that the observed promotion effect stemmed from the following factors: $Ln^{3+}$ ions were concentrated around the Pd nanoparticles; the coordination of $Ln^{3+}$ ions to the substrates containing an oxygen or a nitrogen atom is an important factor for the promotion; and the dissociative hydrogen adsorption on the surface of Pd nanoparticles can be accelerated by the presence of $Ln^{3+}$ ions [387].

Selective hydrogenation of citronellal to citronellol was conducted over PVP-stabilized Pt and Ru colloids; metal cations were found to increase both the activity and the selectivity. The modification was assumed to be due to the adsorbed metal cations activating the C=O double bonds, resulting in accelerating the reaction rate and increasing the selectivity to unsaturated alcohols [388]. A similar positive influence of the metal cations was also observed in the hydrogenation of cinnamaldehyde to cinnamyl alcohol and of crotonaldehyde to crotyl alcohol over a polymer-protected Pt colloid catalyst [389].

The amazing promotion effect of metal cations appears again in the selective hydrogenation of *o*-chloronitrobenzene (*o*-CNB) to *o*-chloroaniline (*o*-CAN), in which eliminating chlorin is an obstacle to be overcome. The reaction was carried out in methanol at 303 K under 0.1 MPa of hydrogen over PVP-protected Ru–Pd and Ru–Pt bimetallic colloids [390] prepared by $NaBH_4$ reduction of the corresponding mixed-metal salts at room temperature. In the presence of cobalt ion, nearly 100% selectivity to (*o*-CAN) was achieved over PVP-Ru/Pt colloids at 100% conversion of *o*-CNB, with an activity two orders of magnitude higher than that of monometallic PVP-Ru colloid [391].

Besides simple metal cations, metal complexes were also found to enable an obvious improvement on the catalytic performance of metal nanoclusters dispersed in liquid [392], which revealed a new possibility to modify the surface of metal nanocluster catalysts with organometallic complexes of designed structures.

The size effect of Pd particles on the catalytic Suzuki reactions between phenylboronic acid and iodobenzene was investigated using catalysts of PVP-protected Pd colloids with varying particle size prepared by the stepwise growth reaction. The catalytic activity of the Pd nanoparticles was found to be in the order of Pd (3.9 nm) > Pd (3.0 nm) approximate to Pd (5.2 nm) > Pd (6.6 nm). The trend of increased catalytic activity with the decrease in particle size was believed to reflect the fact that the vertex and edge atoms of the particles are active sites for the Suzuki reaction. The lower catalytic activity for the smallest Pd nanoparticles might stem from a strong adsorption of the reaction intermediates on the particle surface [393]. The influence of protective agents, poly(amido-amine) dendrimers, block copolymer of polystyrene-*b*-poly(sodium acrylate), and PVP, on the catalytic properties of Pd nanoparticles in this reaction was also investigated [394].

Catalytic properties of colloidal Pt as electrocatalysts for the electrochemical oxidation of methanol were studied. Current efficiencies of $CO_2$ during methanol oxidation were determined by differential electrochemical mass spectrometry. It was observed that $CO_2$ formed via $CO_{ad}$ oxidation in a serial reaction, while formaldehyde and formic acid also formed in a parallel reaction. The further oxidation of these intermediates depends on the diffusion and convection conditions in connection with the surface structure of the Pt electrode. Ru promotes methanol oxidation to $CO_2$ via $CO_{ad}$, leading to a higher current efficiency of $CO_2$ [395].

Catalytic activities of palladium, platinum, rhodium, and Pd/Pt nanoclusters stabilized by various ligands with average sizes ranging from 1.3 to 3.2 nm and from 2.2 to 4.0 nm were evaluated by hydrogenation of 1,3-cyclooctadiene and methyl acrylate. The activities depend upon the particle size. The activities of heterogeneous catalysts prepared from supporting the metal nanoclusters on charcoal depend strongly on the covering strength of the stabilizer [396].

The catalytic properties of $Pd_{\sim561}phen_{\sim60}(OAC)_{\sim180}$ and $Pd_{\sim561}phen_{\sim60}O_{\sim60}(PF_6)_{\sim60}$ nanoclusters (where phen = phenanthroline) dispersed in water for several organic reactions have been studied by Vargaftik and co-workers [397–399].

Rh colloids stabilized with cationic surfactant have been demonstrated to be effective catalysts for the hydrogenation of arene derivatives such as anisole, toluene, and *p*-xylene in liquid–liquid biphasic systems in which the rhodium nanoparticles are suspended in an aqueous phase. A maximum TOF is obtained when the surfactant concentration is near the critical micellar concentration [400].

Microemulsion could be used as a microreactor for organic reaction catalyzed by metal nanoclusters. For example, in a water/AOT/*n*-heptane microemulsion, the reactions between $p$-$Me_2NC_6H_4NH_2$ and $Co(NH_3)_5Cl^{2+}$ forming *N,N*-dimethyl-*p*-semiquinonediimine, a process of relevance in color photography, over colloidal palladium catalysts with average diameter of 2.5 nm have been studied by Spiro and de Jesus. The palladium colloids were prepared by mixing microemulsions containing $K_2PdCl_4$ with ones containing 10 times this concentration of hydrazine, followed

by sonication. It was observed that the activation energies increased as the temperature fell [401].

The electrochemical mechanism in which electrons are transferred from reductant to oxidant through the nanoparticles of gold and other noble metals has been accepted to explain the catalytic functions of metal nanoclusters for many redox reactions occurring on the surface of metal nanoclusters, such as the reaction between $N,N$-dimethyl-$p$-phenylenediamine ($p$-Me$_2$NC$_6$H$_4$NH$_2$) and Co(NH$_3$)$_5$Cl$^{2+}$ forming $N,N$-dimethyl-$p$-semi-quinonediimine [401–404], the reduction of Fe(CN)$_6^{3-}$ to Fe(CN)$_6^{4-}$ by S$_2$O$_3^{2-}$ [405–407], or the reduction of water by reduced methyl viologen [408].

Usually when metal nanoclusters stabilized with surfactants or simple anions are used as catalysts, especially in the hydrogenation of organic compounds, a decrease in catalytic activity will soon be observed due to the easy aggregation of small metal nanoparticles under hydrogen, which should have relation to the adsorption of H$_2$ on the metal nanoparticles. Therefore, the lifetimes of these catalysts in a colloidal solution are usually not long enough for real applications, different from that of PVP-protected metal nanocluster catalysts. Aiken and Finke reported that the catalytic lifetime of a Rh nanocluster, particle size 2–4 nm, stabilized with polyoxoanion and tetrabutylammonium achieved a number $\geq 193{,}000$, which is near that of a heterogeneous catalyst, 5% Rh/Al$_2$O$_3$, and much higher than those of homogenous complex catalysts such as RhCl(PPh$_3$)$_3$ (Wilkinson's catalyst) or [(1,5-COD)Rh(CH$_3$CN)$_2$]BF$_4$. The Rh nanoclusters are prepared by the hydrogen reduction of [($n$-C$_4$H$_9$)$_4$N]$_5$Na$_3$[(1,5-COD)-Rh$_2$·W$_{15}$Nb$_3$O$_{62}$] [366, 409].

## 3.2. Immobilized Metal Nanocluster Catalysts

Research on adsorbing metal colloidal particles on a support could be traced back to before the 1970s. One example is the adsorption of Pd colloidal particles on Al$_2$O$_3$ contributed by Turkevich and Kim in 1970 [410]. Before 1990, the catalyst preparation procedure by immobilizing colloidal metal particles had not attracted reasonable attention, due to the lack of exciting results on the improvement of catalytic properties achieved in an unusual way, which seems a little complex compared with the traditional impregnation method in heterogeneous catalyst preparation. In 1989, Wang et al. prepared very active Rh and Pt nanocluster supported catalysts via coordination capturing Rh (3.5 nm) and Pt (1.6 nm) nanoclusters in PVP-protected metal colloids with mercapto group anchored on a silica support [123]. In the hydrogenation of hex-1-ene and cyclohexene, the catalytic activities of these mercaptan-fixed Rh and Pt nanoparticle catalysts are 100 to 300 times higher than those of commercial Rh/C and Pt/C catalysts at the same conditions. This is the first example of a mercapto-containing (which have been generally regarded as poisons for platinum metal catalysts) supported metallic catalyst with high activity for hydrogenation of alkenes. The as-prepared immobilized Pt and Rh nanoclusters are very stable during the reactions and can be reused many times. We have pointed out that the extremely high activities derived from the immobilization of metal nanoclusters via coordination capture can create favorable conditions for the substrates to easily access

the catalytic active sites in the catalyst and prevent the small colloidal particles from aggregating.

With thioether group anchored on silica such as -Si(CH$_2$)$_3$-S(CH$_2$)$_2$CH$_3$, Pd nanoclusters in PVP-protected Pd colloid can easily be immobilized. This catalyst shows a selectivity of 99% in the partial hydrogenation of cyclopentadiene (COD) to cyclopentene (COE) with an initial rate of 2.7 (mol H$_2$/s mol Pd) at room temperature and atmosphere pressure (unpublished data).

Immobilization of polymer (PVP)-stabilized metal colloids on different supports has also been realized by a modified coordination capture method in which the supports were pretreated with an ethanol solution of triphenylphosphine (TPP) and then were led to reaction with the PVP-protective metal colloidal solutions. TPP adsorbed on the surface of support captured the metal nanoparticles in colloidal solution. PVP and TPP in the solid products then were removed by washing with water and ethanol/toluene, resulting in a supported metal nanocluster catalyst having a similar size and size distribution of metal particles as their precursor. Platinum catalysts prepared in this way exhibited superior catalytic properties to their precursors in colloidal solution for the selective hydrogenations of $o$-chloronitrobenzene to $o$-chloroaniline and citronellal to citronellol. This revealed the great potential of nanoscale metal colloidal particles in catalysis [411].

Modification effects of metal cations on the catalytic properties of a Pt nanocluster supported catalyst, prepared by the modified coordination capture method, were investigated for the selective hydrogenation of $o$-chloronitrobenzene to $o$-chloroaniline, cinnamaldehyde to cinnamyl alcohol, and citronellal to citronellol. It was found that Ni$^{2+}$ and Co$^{2+}$ cations increased both the activity and the selectivity at the same time [412].

The immobilized polymer-protected metal colloid catalysts Wang et al. prepared in 1995 by the formation of polymer hydrogen bond complexes on inorganic support such as silica, like a skin of cross-linked polymer embedded with small metal nanoparticles, exhibit very high selectivity in the selective hydrogenation of COD to COE. The PVP-PAA-Pd catalyst supported on silica prepared by forming hydrogen bond complex between polyacrylic acid and PVP in a PVP-protected Pd colloid in the presence of a silica support can catalyze the reaction in a selectivity of 98% to COE at a COD conversion of 100% with a TOF of 2.25 mol H$_2$/mol Pd s. The catalytic selectivity of PVA-PAA-Pd catalysts prepared by the same is better than the PVP-PAA-Pd catalyst, although its catalytic activity is much lower than PVP-PAA-Pd catalyst, partly due to the large Pd particle size in the PAA-Pd colloid. PVP-Rh and PVP-Pt colloid catalysts can also be easily immobilized by this method and the obtained skin catalysts covered on silica support exhibit good activities in this hydrogenation reaction [139].

The selective partial hydrogenation of 3-hexyn-1-ol giving leaf alcohol, a valuable fragrance, and the selective oxidation of glucose giving sodium gluconate over supported nanosized metal colloidal particles originally stabilized with surfactant were examined by Bonnemann and co-workers. It has been described that independent of the support, the performance of these nanoparticle precursors may be optimized dependent on the size, composition, and structure of

the particles. Furthermore, the protective agents can shield the catalytic active surface of metal nanoclusters against poisons and addition of doping agents can enhance the catalytic properties [413, 414].

In 1999, Lange et al. reported a convenient method for preparing embedded polymer-protected metal nanocluster catalysts. The PVP-protected Pt nanoclusters with size of 1.4 nm embedded in amorphous microporous titania–silica mixed oxide by a sol–gel procedure exhibited a quite good selectivity to the formation of hexene in the hydrogenation of 2-hexyne. A 2-hexene selectivity of >94% was obtained at hexyne conversion up to 50%, and at complete conversion a selectivity to 2-hexenes of 88% (cis-2-hexene selectivity of 91%) was achieved. In colloidal dispersions of the PVP-stabilized catalyst in propanol, however, the initial hexene selectivity of 80% at a conversion less than 10% fell to ca. 45% at 100% conversion [140]. The obvious increases in the selectivity may be derived from the configuration confinement of PVP by the matrix of inorganic nanoparticles. This success showed an interesting variant procedure for developing new hybrid catalyst with some special catalytic properties.

SiO$_2$-embedded nanoscopic Pd/Au alloy colloids were prepared by embedding the alloy particles of 3 nm in size stabilized with tetraalkylammonium in a silica matrix using a sol–gel process with THF as the solvent. Removing the protecting agent could lead to a mesoporous texture with a comparatively narrow pore distribution and the SiO$_2$-embedded Pd/Au colloid preserves the size and the structural characteristics of the colloidal metal precursor. The new material exhibits good catalytic properties in selective hydrogenation of 3-hexyn-1-ol to the corresponding cis-hexanol derivatives [142].

Recently Niederer and co-workers reported the synthesis of metal nanoparticle containing [Me]($x$)-MCM-41 heterogeneous catalyst using surfactant stabilized palladium, iridium, and rhodium nanoparticles in the synthesis gel. Characterization results using XRD, inductively coupled plasma-atomic emission spectrometry (ICP-AES), thermogravimetric analysis (TA), TEM, and nitrogen sorption techniques on this catalyst revealed that the nanoparticles were present inside the pores of MCM-41. Catalytic properties for the hydrogenation of cyclohexene, cyclooctene, cyclododecene, and norbornene over these catalysts were examined [415].

Dendrimer-encapsulated Pd and Pt nanoparticles with narrow particle size distribution dispersed in supercritical CO$_2$ have been used as effective catalysts for the hydrogenation of styrene and Heck heterocoupling of iodobenzene and methacrylate [416].

Metal nanoclusters stabilized by surfactants can be easily adsorbed on supports to prepare metal supported heterogeneous catalysts. Mono- and bimetallic nanoparticles stabilized by lipophilic or hydrophilic surfactants of the cationic, anionic, or nonionic type have been used as precursors for preparing heterogeneous metal nanocluster catalysts, which are effective for the hydrogenation and oxidation of organic substrates. A comparison of catalytic results and CO chemisorption experiments revealed that the protecting surfactants still covered the nanoparticle surface after adsorption on supports, which markedly improved the lifetime of the catalysts [205].

A lanthanium oxide supported Ru colloid was used as the catalyst for the hydrogenation of benzene in an aqueous solution of sodium hydroxide. Selectivity to cyclohexene of higher than 50% at 50% conversion was achieved [417].

Frelink et al. reported in 1995 that the catalytic activities for oxidation of methanol of carbon-supported catalysts derived from colloidal techniques are 2–3 times higher than those prepared using either impregnation or ion-exchange methods [418].

Metal particle size would have an influence on the catalytic activity of a supported metal nanocluster electrocatalytic catalyst. Large particles are accompanied by a loss in specific area of the metal particles; however, if the small particles are entrapped in micropores of the support, an obvious decrease in the apparent catalytic activity may also be observed. It has been demonstrated that the optimal Pt particle size for reactions in a H$_2$/O$_2$ fuel cell is ~3 nm [419].

The microwave-assisted synthesis method has been used to prepare well-dispersed Pt nanoparticles, average size in 3.5–4 nm, supported on carbon for the application of fuel cells. This catalyst exhibits high electrocatalytic activity in the room-temperature oxidation of liquid methanol [420].

Highly active electrocatalytic electrodes of carbon–silica composites containing Pt nanoparticles of about 2 nm have been prepared by Anderson and co-workers [421] by embedding Vulcan carbon XC-72 carbon-supported Pt nanoparticles in a silica gel followed by a CO$_2$ supercritical drying process. The electrocatalytic activity for methanol oxidation over the colloidal-Pt-modified carbon–silica composite aerogels was reported to be 4 orders of magnitude higher than that over the native Pt-modified carbon powder. A further improvement in the activity was achieved by appropriately annealing the electrodes to increase the size of Pt nanoparticles to 3–4 nm.

Bimetallic colloidal nanoparticles containing Pt, especially the Pt/Ru nanoclusters with particle sizes of 1–2 nm stabilized by organoaluminum, were reported to be suitable for preparing fuel cell anode catalysts with an improved CO tolerance. The colloid precursors were supported and activated by thermal conditioning to remove the organic stabilizer [422–426]. It was also found that the size of organoaluminum-stabilized metal particles did not change during the thermal conditioning even at high metal loadings (20 wt% metal).

A Pt–Ru/graphitic carbon nanofibers nanocomposite containing Pt–Ru alloy nanoclusters having 6 nm average diameter and 1:1 bulk Pt/Ru ratio with a total metal content of 42 wt% has been prepared and used as an anode catalyst in a direct-methanol fuel cell. An average current density at 0.4 V of 0.21 A/cm$^2$ for the fuel cell was achieved [427].

Bimetallic Pt–Sn nanoclusters, PtSn (niggliite), and Pt$_3$Sn, with an average diameter of 5–8 nm, highly dispersed on a carbon powder support at a total metal loading of ca. 15 wt%, have been prepared and their electrocatalytic properties have also been investigated. It is observed that both the Pt–Sn/C nanocomposites as electrooxidation catalysts in a direct methanol fuel cell give fuel cell performances comparable to that expected for Pt–Sn catalysts prepared by more conventional methods [428].

Pt–Co bimetallic nanoclusters of 3–4 nm diameter prepared by Zhang and Chan using a water-in-oil reverse microemulsion of water-Triton X-100-propan-2-ol-cyclohexane were supported on a carbon electrode which has a high catalytic activity for methanol oxidation at room temperature [429].

Hydrogenation of butyronitrile and the adsorption of CO over Pt/Rh bimetallic nanoparticles supported on activated charcoal have been studied. The Pt/Rh ratio at the surface has an important influence on the catalytic activity and CO chemisorption ability. Maximum activity in this hydrogenation reaction and CO adsorption ability were observed at a Pt/Rh atomic ratio of 0.1. Detection of the different types of CO bonding at the surface by IR and the EXAFS characterization results revealed that Rh was enriched in the surface [430].

Catalytic properties for the selective hydrogenation of 3,4-dichloronitrobenzene to corresponding aniline under high pressure over a supported Pt catalyst prepared by immobilizing nanoparticles in surfactant-protected Pt hydrosols have been examined in batchwise and continuous manners [431].

$R_4N^+Br$-stabilized Pd colloids were embedded in inorganic matrix by an *in-situ* fluoride-catalyzed hydrolysis of $CH_3Si(OCH_3)_3$ and $Mg(OC_2H_5)_3$, resulting in micro/mesoporous hydrophobic sol–gel materials entrapped with individual Pd nanoclusters, which are active catalysts in the hydrogenation of 1,5-cyclooctadiene [141].

Multilayered polyelectrolyte films containing silver metal nanoparticles of 4–30 nm in average diameter were prepared by reducing silver ions in the films by heating or $NaBH_4$. These metal nanocluster embedded polyelectrolyte films exhibit obvious electrochemical catalytic properties and can be used as antimicrobial coatings [432].

Ag nanoparticles in a composite of organosulfur containing a conducting polymer (DMcT-PAn) component were found to have the capacity to improve the charge–discharge performance of the composite as a cathode material for lithium rechargeable batteries. Ag nanoparticles were bound to DMcT with a silver–sulfur bond in this composite system. The observed enhancement in the battery performance was attributed to the electrocatalytic activity of the metal nanoparticles and the increased conductivity of the composite films [433].

## 4. METAL NANOCLUSTER MAGNETIC MATERIALS AND DEVICES

Magnetism related to metal nanoclusters and cluster-assembled thin films has been reviewed recently [434]. In this section, we will give a brief description of metal nanoclusters and their assemblies as promising magnetic materials in order to make up for the lack of reviews in this aspect at present [435].

Nanoscale magnetic particles have attracted considerable growing interest [434–436], both theoretical and experimental, in recent years, because of their unique size-dependent magnetic properties and their potential in advanced magnetic functional materials. Both magnetic particles and their assemblies have attractive and extensive applications in various fields of materials science. Isolated magnetic particles can be used as magnetic fluid for magnetic separation

and magnetic sealing devices [437, 438]. Controlled assemblies of magnetic particles with other stuff will find their applications in smart AFM tips [439, 440], magnetic force-enhanced biomolecule recognition [441, 442], and magnetic field-assisted drug delivery [443–445]. Furthermore, self-assembly of magnetic nanoparticles as building blocks in chemically controllable manners can be used to build up novel magnetic nanostructures [446]. Due to collective physical phenomena of many elementary particulates magnetic properties of a nanostructured assembly are dominated by the interaction of its building blocks besides the nature of the blocks. This kind of nanoparticle-based self-assembly, which is governed by particle–particle and particle–substrate interactions, is extremely important in fabricating unique nanocomposite functional magnetic materials with potential in strong permanent magnets [447, 448], ultrahigh density data storage media [251, 449–451], and spintronic devices, including spin valves [452, 453] and spin-dependent tunneling junctions [454–456] based on the giant magnetoresistance (GMR) effect [457], for ultrasensitive magnetic heads [458, 459], and for nonvolatile magnetic random access memory (MRAM) [460–462].

In the design and preparation of nanostructured magnetic materials, controlled self-assembly of magnetic nanoparticles is an exciting and promising area and has stimulated great recent interest as it may offer a convenient tool for magnetic nanodevice fabrication [446]. Generally speaking, only the uniform nanoparticles as building blocks are, in principle, easy to self-assemble into well-defined 2D patterns and 3D architectures, which are considerably important in nanodevice fabrication. Recently developed solution-phase synthetic approaches (including the pyrolysis of organometallic compounds [463, 464], thermal [465, 466] or sonochemical decomposition of metal carbonyl compounds [467], and the reduction of metal salts by borohydride [468, 469], triethylborohydride [470, 471] or diols [251, 373], for preparing highly well-monodispersed elemental Fe [467, 472] and Co [465, 466, 468–471, 473–477], binary Fe–Pt [251, 478], Co–Pt [373, 464, 479–481], and Co–Ag [214], and ternary Fe–Co–Pt [482] and Fe–Pt–Ag [483] magnetic nanocrystals with narrow size distribution of standard deviation $\sigma$ within about 10%) have given scientists the chance to construct novel self-assembled magnetic nanostructures based on magnetic metal nanoclusters.

Chemical synthesis [484] and ordered assembly [485] of magnetic metal nanoparticles have just been reviewed. Electronic and magnetic properties of monodispersed FePt nanoparticles [486], arrays of ferromagnetic iron and cobalt nanoclusters wires along lines of magnetic flux of the applied field [487], control of the magnetic anisotropy of a Co/Pt nanomultilayer with embedded particles [488], and granular GMR sensors of Co/Cu and Co/Ag nanoparticles [489] have been reported recently. In the following examples of this section, we will focus on the potential applications of self-assembled nanostructures from magnetic metal nanoclusters.

### 4.1. Ultrahigh Density Data Storage Media

Magnetic data storage has been playing a key role in the development of audio, video facilities, and computers since its invention more than 100 years ago by Poulsen [490].

In 1956, the first hard disk drive was made by IBM and had a total storage capacity of 5 MB at a recording density of 2 kb/in$^2$. Since then the principle of magnetic data storage has been based on writing magnetic bits in plane on magnetic layers, which is the so-called longitudinal recording. In pursuit of lowering the cost and improving the performance, the areal density (i.e., the number of bits per unit area on a disk surface) has increased nearly 20 million-fold to more than 40 Gb/in$^2$ in modern disk drives and currently doubles every year. Recently, recording densities beyond 100 Gb/ in$^2$ have been reached in two laboratory demonstrations [491, 492]. This continued growth in areal density was achieved by scaling the critical physical dimensions of the constituted magnetic grains; however, there is a limit to this scaling that will be approached within the next few years [493]. One of these limits (i.e., thermal limits [494–496]) lies in the reduction in magnetic grain size, where due to enhanced thermal effects the onset of superparamagnetism at room temperature for small particles will define the size of the smallest possible particles to keep one from losing recording data. The size of a grain to block superparamagnetism is related to the thermal stability of the grain magnetization, which can be described by the stability ratio, $C = E/k_B T$, where $E$ stands for the magnetic anisotropy energy of the grain in question, $k_B$ is Boltzman's constant, and $T$ is the temperature. The magnetic anisotropy energy $E$ per grain is dependent on the grain volume $V_g$ and the anisotropy energy density $K_u$, and defined as $E = K_u V_g$. To store information reliably for 10 years, it requires $C = 60$ [494, 495]. If one assumes cylindrical particles with a height of the typical disk film thickness of 20 nm and $K_u$ of current media (about $3 \times 10^5$ J/m$^3$), this implies a minimum stable particle diameter of no less than about 7 nm for monodispersed particles.

To increase the storage density, however, the size of the grains needs to be reduced. This together with increasing magnetic isolation is the conventional way taken to scale media. Since ultimately the transition width is governed by the size of the grains, higher densities require smaller grains. Also, to maintain a satisfactory signal-to-noise ratio, it is imperative to keep the number of grains per bit constant, and thus the grain size is reduced as the density is increased. The anisotropy energy density $K_u$ can only be increased to some extent to uphold the thermal stability as the grain size is reduced, since the media switching field increases with $K_u$ and cannot go beyond the write field available from the head [493]. Various alternative routes to postpone perceived thermal limits [494–496] for acquiring higher recording densities have been proposed in recent years [493, 495–498]. One of the most promising ways is to use a nanoparticle medium, which is a magnetic film fabricated with metal nanoparticles. The present candidates for nanoparticle media are FePt [251] and CoPt [451] binary alloy with face-centered tetragonal structure, since they have high uniaxial magnetocrystalline anisotropy ($K_u \approx 7 \times 10^6$ and $5 \times 10^6$ J/m$^3$ for FePt and CoPt, respectively) and good chemical stability and show excellent hard magnetic properties [495, 499, 500]. Self-assembled FePt nanoparticulate film has been successfully used in preliminary longitudinal contact recording studies [251]. Earlier attempts to make FePt [501–503] and CoPt particle thin films [504, 505] have mainly relied upon sputter deposition or other vacuum techniques. But those methods

result in chemically disordered crystallites of face-centered cubic structure, which require high-temperature annealing to encourage the alloy films to adopt the magnetically advantageous face-centered tetragonal phase. A shortcoming of vacuum-deposition/annealing procedures is that they commonly lead to products characterized by a broad distribution of grain sizes, with a typical standard deviation of about $\sigma = 30$–35% [493], due to random nucleation in the initial stages of growth and subsequent agglomeration during annealing.

The broad distribution of grain sizes in a magnetic film is undesirable, because uniformity of grain size can help maintain a high signal-to-noise ratio in magnetic recording applications. In a recording medium with widely varying grain sizes, the smallest grains are most susceptible to demagnetization and losing their stored data, or they are superparamagnetic and not useful for magnetic storage, while the large grains contribute disproportionately to the noise. That is less of a problem when all grains are approximately the same size. In addition, today's magnetic reading heads detect signals from very small data bits most accurately when the bits are made up of grains with uniform size distribution. To produce high performance recording media with good thermal stability, large storage density, and low noise, one needs naturally to increase the number of grains of median size in a magnetic film with a simultaneous narrowing of their size distribution.

The keys to making nanoparticle media are controlling the size of magnetic grains and controlling their array from agglomeration in the films. In a recent report by Sun et al. [251], both problems have been solved primarily, using controllable solution-phase chemistry. The strategy adopted by Sun et al. is to make tiny bimetallic nanoparticles from iron and platinum compounds which as prepared are magnetically weak, allowing them to form self-assembled layers, followed by annealing at about 500 °C, and transforming them into stronger magnets at the end.

In this controllable procedure, monodisperse FePt nanoclusters, with a very narrow size distribution of standard deviation $\sigma < 5\%$, is first synthesized by reduction of platinum acetylacetonate with 1,2-hexadecanediol, and simultaneously thermal decomposition of iron pentacarbonyl in dioctylether, in the presence of oleic acid and oleyl amine stabilizers (see Fig. 20). The size and composition of these FePt nanoclusters can be readily controlled. Their composition is adjusted by controlling the molar ratio of iron carbonyl to the platinum salt. The size of FePt nanoclusters can be tuned from 3 to 10 nm by first growing 3-nm monodisperse seed nanoclusters *in-situ* and then adding more reagents to enlarge the existing seeds to the desired size. These nanoparticles are well isolated and purified easily by centrifugation after the addition of a precipitant such as ethanol and can be redispersed in a variety of nonpolar solvents.

To make a film, the resulting FePt nanoclusters are spread on a substrate. As the solvent is slowly evaporated, the weakly magnetic nanoparticles nestle down by self-assembly into a regular array. Within an array, the interparticle distance may be adjusted by replacing oleic acid and oleyl amine with shorter chain alkyl group via ligand exchange, and correspondingly the symmetry of the array can be controlled.
**Figure 20.** TEM micrograph of arrays of nanosized FePt particles (at right) that are smaller and more uniform in size than those obtained from a CoPtCrB material (left) that was used recently in a very high density data-storage demonstration. Next, the films are annealed at 560 °C, for about half an hour, to convert the internal particle structure from a chemically disordered face-centered cubic phase to the chemically ordered, ferromagnetic face-centered tetragonal phase. During the annealing, no agglomeration occurs and the organic stabilizers are fused into a hard coat surrounding each magnetic nanoparticle. The resulting magnetic films are chemically and mechanically robust. Sun et al. have shown that these materials can store data faithfully at a density equivalent to that of CoCr-based alloy hard disks on the market today (see Fig. 20 for the film structure). On the basis of conventional grain size scaling arguments, these materials may even allow one to boost that density 10-fold using current read and write heads.

This strategy, developed by Sun et al. as well as by workers at IBM, to fabricate nanoparticle media is an important milestone for ultrahigh density magnetic data storage, which also bring forth the fascination of magnetic nanoclusters in the process of self-assembly chemistry. Now, more effort is still needed for future practical applications. For instance, the biggest problem is that it is necessary to find a way to orient the particle easy magnetization axes all perpendicularly to the film, since the tiny FePt nanoclusters can freeze in place facing any direction and conventional recording heads work only if all the magnetic particles on a disk have their crystalline axes aligned with the disk's surface. Ultimately, if one would like to record one bit per nanoparticle for patterned media using magnetic metal nanoclusters, which would correspond to higher recording densities of about 10–20 Tb/in$^2$, it requires one to make a long-range regular array of the nanoclusters—this will be a formidable challenge to future self-assembly chemistry.

## 4.2. Exchange-Spring Strong Magnets

Permanent magnets are one of the most technologically important magnetic functional materials in science and technology and in our everyday life. The performance of permanent-magnet materials is evaluated by their maximum magnetic energy product—this figure of merit is a measure of the maximum magnetostatic energy that would be stored in free space between the pole pieces of a magnet made from the material in question [506]. The larger its magnetic energy product, the greater the performance of a permanent magnet, and hence it is called a strong magnet.

The maximum magnetic energy product is proportional to the area closed in the saturated hysteresis loop of a magnet, which arises from plotting the magnetization of the material as the applied magnetic field is cycled under its saturation field. This hysteresis loop is characterized by the saturation magnetization, that is, maximum magnetization and the coercivity of the material, which is the reverse applied field strength to reduce the magnetization to zero. The larger the coercivity of a magnet, the harder it is, whereas the smaller the coercivity of a magnet, the softer it is. To gain a strong magnet with a large magnetic energy product, it requires that there are both lager magnetization and lager coercivity in the material.

Progress in making strong permanent magnets has been limited by the difficulty of finding new compounds with these two necessary properties. For instance, $Fe_{65}Co_{35}$ alloy, a material with the largest room-temperature saturation magnetization of 24 kG, should have a theoretical maximum magnetic energy product of 144 MG Oe—the upper bound on the magnetic energy product for strong magnets. But in practice this material does not have such a large magnetic energy product because it is a soft magnet (i.e., its coercivity is actually fairly low and a small reverse field is sufficient to reduce the magnetization to zero).

About a decade ago, the idea of exchange coupling between a hard material and a soft material with a large magnetization occurred to physicists [507–509], which brought a new hope of producing magnets with their maximum magnetic energy product approaching the upper bound of 144 MG Oe. These kinds of exchange-spring magnets are nanocomposites that are composed of magnetically hard and soft nanophases that interact by magnetic exchange coupling. In a two-nanophase mixture of such materials, exchange forces between the phases mean that the resulting magnetization and coercivity of the material will be some average of the properties of the two constituent phases [508]. In order to realize the effective exchange coupling, the relative sizes of the grains of the two nanophases must be chosen carefully [507]: In general, the characteristic dimensions of the soft magnetic phase cannot exceed about twice the wall thickness of magnetic domains in the hard one. Typically, this limits the soft magnetic phase to be about 10 nm in diameter. Correspondingly, the hard one must have dimensions of this order too, or the volume fraction of the soft magnetic phase will be rather low, thus reducing the magnetization of the composite.

Following the concept of magnetic exchange coupling, a lot of techniques, including melt-spinning [510–512], mechanical milling [513–515], and sputtering [516–518], have been exploited to prepare exchange-spring magnets. However, all of these techniques have had only limited success in fabricating two-phase nanostructures with a high magnetic energy product, as they could not afford

to effectively control the so-required nanostructures for exchange coupling.

Recently, Zen and co-workers [448] reported on how to use self-assembly of magnetic nanoparticles as building blocks to fabricate novel exchange-spring magnets. Their method of chemical synthesis under controlled self-assembly is attractive potentially in making three-dimensional bulk magnets with high magnetic energy product. When monodispersed 4 nm $Fe_{58}Pt_{42}$ and 4 nm $Fe_3O_4$ nanoclusters are mixed in hexane under ultrasonic agitation and allowed to self-assemble three-dimensionally by either evaporation of the hexane or addition of ethanol, they form nanoscale structures which, when heated and chemically reduced by $H_2$ under Ar gas at 650 °C for one hour, form homogeneous mixtures, at 5-nm scale, of a hard tetragonal FePt phase and a high-magnetization soft $Fe_3Pt$ phase. The admixture of Pt in the $Fe_3Pt$ nanograins results from sintering at a temperature of 650 °C, which is used to induce the phase transition from disordered FePt to ordered tetragonal FePt. The magnetic energy product of this two-nanophase material is 20.1 MG Oe, which considerably exceeds the theoretical limit of 13 MG Oe for non-exchange-coupled isotropic FePt magnet by over 50%.

This self-assembly protocol opens the door to make strong magnets for practical applications [447], since the size and composition of the individual building blocks can be independently tuned, and the self-assembly results in homogeneous mixtures, at the nanosacle, to effective exchange coupling of the hard and soft magnetic nanophases. However, there are still many practical challenges to be faced when producing magnets with their magnetic energy products approaching the magic number of 144 MG Oe. For example, ways of compressing the two-nanophase material into a high-density compact must be explored, as well as improved alignment of the axes of the hard particles to exploit the full magnetic potential of the nanocomposite system [447]. Nevertheless, it could be expected that highly monodispersed magnetic metal nanoclusters, especially the uniform nanoparticles with zero distribution, will play an important role in making superstrong magnets in the future.

## 4.3. Metal Spintronic Devices

Since the discovery of the GMR effect [457] in 1988, spintronics [519–521], an innovative emerging electronics based on electron spin as well as charge, has made great progress in information science and technology for outstripping the performance of traditional electronics devices. Spintronic devices use magnetic moment to carry information and can combine the performance of standard microelectronics with spin-dependent effects that arise from the interaction between spin of the carrier and the magnetic properties of the material. Introduction of the electron spin degree of freedom to such devices gives them various advantages, including low electric power consumption, nonvolatile data retention, excellent radiation protection, superfast data processing speed, and high integration densities. At present, spintronic hard disk drive read-heads are well established commercially [458], MRAMs appear to be set to follow suit [519], and an all-metallic magnetic logic NOT gate [522] has just been achieved in a laboratory demonstration. In the

future, spintronics will lead to very rapid quantum computers [523].

One of the promising applications of ferromagnetic metals or alloys materials is to make spintronic devices that stand for information by the magnetization direction of the ferromagnetic metal components. Spin valves and spin-dependent tunneling junctions are fundamentally metallic spintronic devices developed currently in the world for hard disk drive read-heads and MRAM [521]. Both devices are based on the giant magnetoresistive effect of thin-film materials composed of alternate ferromagnetic and nonmagnetic layers. A spin valve has two ferromagnetic layers (alloys of nickel, iron, and cobalt) sandwiching a thin nonmagnetic metal (usually copper), with one of the two magnetic layers being "pinned" (i.e., the magnetization in that layer is relatively insensitive to moderate magnetic fields, and the other being "free"; i.e., its magnetization can be changed by a relatively small applied magnetic field). A spin-dependent tunnel junction (SDTJ) is a device in which a pinned layer and a free layer are separated by a very thin insulating layer, commonly aluminum oxide. As the magnetizations in the two layers change from parallel to antiparallel alignment, the magnetoresistance of them rises typically from 5 to 10% for spin valves and 20 to 40% for SDTJ, respectively. Pinning is usually accomplished by using an antiferromagnetic layer that is in intimate contact with the pinned magnetic layer. The two films form an interface that acts to resist changes to the pinned magnetic layer's magnetization.

To date, all the metallic films for these devices, including the recent magnetic logic gates under development [522], are fabricated with vacuum techniques of metal vapor deposition such as sputter. The fundamental developing work exploiting the self-assembly technique of metal nanoparticles has just begun at IBM. In a recent report [226], using monodisperse Co nanoclusters with $\sigma = 5\%$, Black and co-workers have self-assembled nanoscale ordered arrays of 10-nm ferromagnetic Co nanoclusters between lithographically patterned metal contacts spaced about 100 nm apart, for the study of SDTJ devices. After annealing under Ar with 5% $H_2$ at 400 °C for about one hour, to strip off the organic ligands protecting the clusters, the arrays convert into films displaying spin-dependent electron transport. At low temperatures, the current–voltage characteristics of the junction reflect single-electron tunneling through the array, and the observed magnetoresistance is on the order of 10% ratio, approaching the maximum predicted theoretically for ensembles of cobalt islands with randomly oriented easy magnetic axes. This work demonstrates that self-assembled Co-nanocrystal superlattices are excellent model experimental systems for studying magnetotransport in nanostructured materials. The observed spin-dependent tunneling in such nanoscale devices of highly uniform magnetic-nanocrystal arrays implies that magnetic metal nanoclusters have vast potential in making advanced spintronic devices. It is reasonable to believe that novel spin valves, spin-dependent tunneling junctions, and magnetic logic elements made from metal nanoclusters might become realized in the future, if the spin-dependent electron transport within an array of metal nanoclusters takes place at room temperature.

From these examples, we can see that, in various potential applications of magnetic metal nanoclusters for fabricating

advanced magnetical materials and devices, self-assembly has played a key role. This technique is an attractive tool in future nanofabrication because it provides the way to precisely engineer structures on the nanometer scale over large sample areas. However, there is still a long and hard road to the well-developed self-assembly chemistry. It requires more convenient routines to largely prepare size-, shape-, and composition-controllable, even uniform nanoclusters, and easily controlled processes to assemble the nanoclusters into regular arrays or patterns with different symmetry at will.

## 5. SUMMARY

Nanoclusters with small particle sizes and narrow size distributions of noble metals such as Au, Pt, Pd, Rh, Ru, and Ir, light transition metals such as Cu, Co, and Ni, early transition metals such as Zr and Ti, and some alloys of these elements are available from chemical preparations. The structure and composition of them are usually characterized using techniques of TEM, HRTEM, EDX, XPS and Auger Spectroscopy, EELS, XRD, EXAFS, IR-CO probe, STM, AFM, etc. Current interests in metal nanocluster preparation are control of the size, shape, composition, and core–shell structures, especially tailoring the physical and chemical properties by alloying different metals.

The so-called "unprotected" metal nanoclusters stabilized with organic solvent and simple anions are tractable building blocks in nanochemistry and nanomaterial science because they can be easily prepared in large scale, modified with various preferred ligands and embedded in a functional or matrix materials with high loading.

Self-assembly of narrowly distributed metal nanoclusters into an ordered superlattice pattern of large area has been intensively studied and some promising progress has been achieved based on narrowly distributed metal nanoclusters stabilized by ligands or surfactants during last decade. However, obstacles still need to be overcome before this technique can be put into real applications. It requires more convenient routines to largely prepare size- and shape-controllable, even uniform, nanoclusters, and easily controlled processes to assemble the nanoclusters into regular arrays and patterns with different symmetry at will.

Electron beam lithography and especially the conductive-AFM-tip-induced nanolithography technique have highlighted the generic, controllable, and realizable assembly methodologies to the nanoarchitectures.

More realistic possibilities for wide applications of metal nanocluster building blocks are catalysts, nanostructured magnets, and chemical or biochemical sensors.

Polymer-protective metal nanoclusters are suitable candidates for quasi-homogeneous catalysts due to their high stability in the conditions of many organic reactions and the weak interaction between the metal surface atoms and residue groups in usual adopted polymer protective agents. PVP is still the most preferred polymer protective agent for such a purpose.

Immobilization of preformed structure-controllable metal and alloy nanoclusters originally stabilized with various protective agents provides a promising new concept and practice to generate heterogeneous catalyst for various applications. The "coordination capture method," which fixes individual nanoparticles on the outer surface of a support via anchored ligands, not only contributes the most active catalysts for hydrogenation of organic compounds because of the easy access of the substrates to the small metal and alloy nanoclusters but also has been adopted in the meaningful exploration of the specific properties of small metal nanoclusters and their self-assemblies.

Embedding metal nanoclusters in porous inorganic oxide matrixes by stacking metal oxide nanoparticles around the various preformed metal nanoclusters or the adsorbing metal nanoclusters on supports could produce a new type of catalyst that should find real applications in many catalytic reactions and in the fuel cells operated at a relatively low temperature.

Modifying the catalytically active metal nanocluster surfaces with chiral ligands, metal cations, or metal complexes can greatly improve their catalytic selectivities in many reactions.

The combination of metal nanoclusters with biomolecules is a very challenging approach to assemble nanoclusters in a designed pattern that would find applications in developing new biomaterials or biosensors, nanoelectronics, and evaluating the superstructures and functions of boimolecules or organisms.

Syntheses and assemblies of bimetallic magnetic nanoclusters with narrowly distributed sizes and shapes would produce promising magnetic media of the highest recording density. Self-assembly of different magnetic metal and alloy nanoclusters using a wet chemical process, followed by suitable chemical and physical treatment, is a very promising and realistic approach to create new magnetic materials and devices with superior properties that are difficult to be realize through other routes so far.

## GLOSSARY
