In classical physical metallurgy there are several examples of materials developed over several decades and owing their properties to the existence of extremely fine grains. Two obvious cases are those of Al alloys hardened by pre-precipitates or metastable precipitates and high strength–low alloy steels where nitrides and carbonitrides act as grain refiners. Conventionally, these are not listed among nanomaterials and their science and technology are dealt with in well-established treatises. Other metallic materials have recently been discovered following the same leading idea of nanocrystal research (i.e., of producing very fine particles to improve properties). This chapter deals with a new class based on aluminum.

### 1.2. Techniques for the Production of Nanocrystalline Materials

Nanocrystalline metals and alloys can be obtained essentially by means of four different techniques:

- (a) introducing a high number of defects (i.e., dislocations and grain boundaries) in initially perfect crystals by severe plastic deformation which is achieved by ball milling, extensive rolling, extrusion, and equichannel angular pressing;
- (b) condensation of clusters or deposition of atoms on a substrate by chemical or physical vapor deposition;
- (c) crystallization of metastable systems such as glassy metals or undercooled liquids or precipitation from supersaturated solid solutions;
- (d) two-step production routes in which nanocrystalline powders are consolidated in order to obtain a bulk material.

In the following the essential features of each technique are described. Electro- and electroless deposition can be employed for some metals and alloys, but they will not be dealt with here since they are not appropriate for Al.

#### 1.2.1. Production of Powders and Compaction

Amorphous or nanocrystalline powders can be produced by ball milling. The technique has been considered as a tool for refining minerals for a long time. It gained more widespread application when it was realized that the mechanical action

can drive phase transformations (amorphization, disordering, etc.) and chemical reactions. The initial stage of ball milling invariably implies the introduction of disorder and defects in the material leading to the formation of crystals with size of the order of nanometers [2]. During the first stage of the process the deformation is localized in deformation bands of about 1  $\mu\text{m}$  thickness and grains of low dimension nucleate into these bands. For long treatment times grains of tens of nanometers are obtained in pure metals, without preferred orientation and with high-angle grain boundaries. The grain size approximately scales with the inverse of the melting point. In alloys and intermetallic compounds the grain refinement can be a precursor of phase transformations. Bulk materials can be obtained if the ball-milled powders are compacted by any powder metallurgy technique. Since these mostly imply hot pressing, the nanograins must resist growth enough to avoid coarsening to a large extent.

Pure Al has been obtained in nanocrystalline form with an average size of 25.5 nm by cryogenic milling using liquid nitrogen as cooling agent. The powders were found to resist grain growth up to temperatures close to 0.78  $T_m$  ( $T_m$  is the melting temperature) because of impurity pinning of grain boundaries [3].

Another technique for subjecting a sample to a very intense plastic deformation is equichannel angular pressing in which the material is forced to flow through an L-shaped die. A large amount of shear stress is experienced by the material with consequent grain refinement [4].

Inert gas condensation also results in Al particles of the order of 30 nm which were shown to remain fine sized up to the melting temperature if passivated with a small amount of oxygen [5].

### 1.2.2. Crystallization of Glassy Precursors

The metastable systems used for the production of nanocrystalline materials are amorphous metals prepared by rapid solidification by means of melt spinning in order to obtain ribbons about 30–40  $\mu\text{m}$  thick. Powders of the same size can be produced by atomization. A careful control of the heat treatment and, as a consequence, of the crystallization kinetics allows either the complete crystallization of the amorphous precursors into a nanocrystalline structure, or a partial crystallization with nanocrystals dispersed in the remaining amorphous matrix [6].

Nanocrystalline materials obtained by crystallization of amorphous precursors have the advantage with respect to the other production techniques that the preparation procedure is simple, can be easily controlled, and allows one to obtain materials constituted by grains of different size, from a few nanometers to tens of microns, simply varying the heat treatment conditions. A large part of this chapter will deal with such alloys.

## 2. NANOCRYSTALLINE ALUMINUM

This chapter is devoted to the description of constitution, structure, and properties of nanocrystalline Al alloys. Most of them have been obtained by rapid solidification as amorphous solids and then heat treated. The two processing steps

may appear to be ruled by very different alloy properties or even to be apparently contradictory. The requirements for amorphizing an alloy are: composition suited for high undercooling, high liquid viscosity, and relatively low tendency to crystal nucleation of both stable and metastable phases. For nanocrystallization the nucleation rate is expected to be high and atomic mobility low. All of these aspects will be treated in detail in the following with the aim of showing how each material parameter influences the processing steps and how the alloy composition can be chosen in order to reconcile possible discrepant tendencies.

### 2.1. The Reasons for Amorphization: Alloy Constitution and Size Effect

It is well known that the presence of deep eutectics in the alloy phase diagram is indicative of the tendency to amorphization for the compositions around the eutectic point. The liquid of eutectic composition is relatively stable with respect to crystal phases and often displays strong resistance to crystallization. It, therefore, can be undercooled to the glass transition where it transforms to a glassy solid. A parameter useful for the evaluation of the glass forming ability is the reduced glass transition temperature,  $T_{gr} = T_g/T_l$  ( $T_g$  = glass transition temperature;  $T_l$  = liquidus temperature). Values of  $T_{gr}$  exceeding 0.5 are typical for metallic alloys. Values in excess of 0.6 are associated with good glass forming compositions and with formation of bulk metallic glasses. Since  $T_g$  does not present large variations as a function of composition, the most relevant parameter for evaluating the tendency to amorphize is  $T_l$ .

The number of elements in the alloy is also relevant. In fact, in an alloy made of a high number of elements there is the possibility of crystallizing several phases. The short range order in the liquid may not correspond to that of any crystal phase implying that it is difficult for the system “to choose” a crystalline structure (the confusion principle). Therefore the tendency to give an amorphous structure will be increased.

The atomic size effect on glass forming tendency was studied by Egami et al. [7] for binary alloys. The mismatch between the atomic radii of the constituent elements of the alloy,  $\Delta r$ , shows an inverse proportionality to the minimum solute concentration ( $C_B^{\text{min}}$ ),

$$\left| \frac{\Delta r}{r_A} \right| = \frac{|\lambda_0|}{C_B^{\text{min}}} \quad (1)$$

$$\frac{\Delta r}{r_A} = \frac{r_B - r_A}{r_A} = \left( \frac{r_B}{r_A} \right)^3 - 1 \quad (2)$$

where  $A$  and  $B$  are the solvent element and the solute element respectively. The minimum value of the parameter  $\lambda_0$  necessary to obtain amorphous phases in binary alloys was empirically determined to be about 0.1.

### 2.2. Thermodynamic Aspects

Alloys that are able to form amorphous phases by rapid solidification show a substantial degree of chemical order in the liquid state. Macroscopic evidence for preferential

interaction between unlike elements is given by the strongly negative enthalpy of mixing which is a common characteristic of glass-forming liquid alloys [8].

Another peculiar feature of glass-forming metallic liquids is that their thermodynamic properties are temperature dependent: the degree of order increases with decreasing temperature. So the excess enthalpy and entropy of mixing become more negative as the temperature is lowered and the undercooling regime is entered. This gives rise to an excess heat capacity in the liquid state, the existence of which has been demonstrated for both metal–metal and metal–metalloid systems.

The existing data show that the excess heat capacity can be substantial for some alloys and has often a maximum at compositions corresponding to a compound in the solid state. It is nil for pure components, which have liquid heat capacities very close to those of the crystal phases at the melting point. As crystalline alloys usually obey the additive Neumann–Kopp rule, the excess liquid specific heat for alloys may be approximated by the specific heat difference  $\Delta C_p$  between liquid and crystal phases. This quantity is measured easily at the melting point and more rarely on undercooling near the glass transition temperature.  $\Delta C_p$  is substantial in the temperature range from the melting point to the glass transition with values of the order of the entropy of fusion of the alloy.  $\Delta C_p$  for pure elements has been determined in the undercooled regime for a limited number of cases; in all of them it is close to zero. Therefore, it is reasonable to attribute the largest part of the specific heat difference between liquid and crystal phases in glass-forming alloys to topological and chemical effects produced on alloying and to use  $\Delta C_p$  as an appropriate approximation for the actual excess specific heat.

A high value of the liquid specific heat with respect to the crystal lets the entropy of the liquid phase approach that of the solid quickly on decreasing the temperature according to

$$\Delta S = \Delta S_f - \int_T^{T_f} \Delta C_p d(\ln T) \quad (3)$$

where  $\Delta S_f$  is the entropy of fusion.

$\Delta C_p$  is approximated either by a fraction of the entropy of fusion (on average  $0.8 \Delta S_f$ ) or by its value at the melting point. With this position, all the thermodynamic quantities can be calculated in the undercooled regime (Fig. 1). In particular the difference between the free energy of the liquid and crystal phases may be evaluated with some confidence and used in calculations of the nucleation frequency and growth rate of the crystals from the melt.

For a liquid pure metal at the melting point the specific heat is close to that of the crystal, whereas it attains slightly higher values on undercooling. This means that pure metals lose little entropy on undercooling, so their reduced glass transition temperature will be low with respect to glass-forming alloys. The isoentropic temperature for Al (i.e., the temperature at which the entropy of the undercooled liquid would equal that of the crystal) has been computed by Fecht and Johnson with Eq. (3) as  $0.24 T_f$  and may be considered an ideal glass transition.

This analysis has been pursued further to obtain trends for  $T_g$  as a function of composition.

**Figure 1.** Schematic trend of the extensive thermodynamic functions for an undercooled metallic glass-forming liquid. Reduced coordinates are used. The reference state is the equilibrium crystal. The enthalpy and free energy are plotted from the melting point to the glass transition temperature. The entropy curve is extended (dashed line) to the hypothetical ideal glass transition,  $T_k$ . The enthalpy and entropy differences between liquid and crystals decrease on undercooling due to a positive  $\Delta C_p$ . Should  $\Delta C_p$  be zero, the free energy difference would follow the dashed line. The actual trend for a glass-former implies relative stabilization of the liquid, (i.e., a lower driving force for crystallization).

In a binary system an entropy balance can be established at every isoentropic temperature  $T_k$ .

Since the entropy of fusion at  $T_k$  is nil, an entropy cycle is written

$$\Delta S_{\text{for}} - x_A \Delta S_{f,A} - x_B \Delta S_{f,B} - \Delta S_{\text{mix}} = 0 \quad (4)$$

where  $\Delta S_{f,i}$  is the entropy of fusion of the constituents at  $T_k$ .  $\Delta S_{\text{mix}}$  is the entropy of mixing in the liquid state and  $\Delta S_{\text{for}}$  is the entropy of formation of the crystalline solid at the same temperature.  $\Delta S_{\text{for}}$  and  $\Delta S_{\text{mix}}$  may be inserted either as experimental data or by derivation from suitable models. If  $\Delta S_{f,A}$  and  $\Delta S_{f,B}$  are expressed through Eq. (3), using an effective value for  $\Delta C_p$  of pure elements, the temperature  $T_k$  which satisfies Eq. (4) may be calculated for every alloy composition. The result will be a trend of  $T_k$ , which can approximate that of  $T_g$  across the phase diagram. An example is shown in Figure 2 for a simple eutectic system displaying regular miscibility in the liquid state and assuming  $\Delta S_{\text{mix}} = 0$  in the solid state. Among glass-formers, the analysis was applied to the Al–Ce system [9] showing agreement with  $T_g$  values obtained both from experiments and extrapolation of data collected in ternary alloys.

### 2.3. Kinetic Aspects: Viscosity of Melts and Glass Transition

The glass transition is the phenomenon in which a viscous liquid passes continuously into the amorphous solid state during cooling [10]. In fact, when a liquid is cooled below its

**Figure 2.** Hypothetical glass transition trends for a simple eutectic system. The lines refer to different positions for the entropy of mixing in the liquid state to be used in Eq. (4) where the entropy of formation of the crystal phases is taken as nil: (a)  $\Delta S_{\text{mix}}$  ideal, (b)  $\Delta S_{\text{mix}} = 0$ , (c)  $\Delta S_{\text{mix}}$  negative. The actual trend for metallic glasses is reproduced by curve (c) which is computed with an amount of entropy implying that the liquid is ordered at short range. Reprinted with permission from [8], L. Battezzati, *Phil. Mag. B* 61, 511 (1990). © 1990, Taylor & Francis.

melting point, if nucleation and growth of crystalline phases are avoided, the viscosity increases until the liquid is frozen in a structurally still, glassy state. Therefore, liquid viscosity is a central parameter for glass formation.

At the melting point the viscosity ( $\eta$ ) is of the order of  $10^{-2}$ – $10^{-1}$  Pa s for glass-forming metals, whereas it is  $10^{-3}$  Pa s for normal liquids. In general, viscosities of metallic liquids at the equilibrium melting point fit the Andrade formula:

$$\eta_{T_m} = A_C \frac{\sqrt{mT_m}}{V^{2/3}} \quad (5)$$

where  $m$  is the molecular mass,  $T_m$  is the eutectic melting temperature, and  $V$  is the molar volume. The empirical quantity  $A_C$  takes different values for metallic elements, intermetallic compounds, and normal eutectics  $\{1.8 \times 10^{-7} (\text{JK}^{-1} \text{mol}^{1/3})^{1/2}\}$  with respect to glass-forming eutectics  $\{6.5 \times 10^{-7} (\text{JK}^{-1} \text{mol}^{1/3})^{1/2}\}$  [11].

Conventionally, the viscosity at the glass transition is taken as  $10^{12}$  Pa s for extremely slow cooling [12]. The viscosity behavior in the undercooling regime can differ markedly for various substances: for silica the viscosity during cooling increases continuously according to the Arrhenius equation, whereas for other substances (e.g., molecular, polymeric, ionic, and metallic materials) it shows deviations from the Arrhenius rate law. In all these cases the activation energy for viscosity is a temperature-dependent parameter.

Since viscosity increases several orders of magnitude from the melting point to the glass transition, the more gradual the increase (i.e., that described as an Arrhenius behavior), the better the glass-forming ability of the liquid. Typical examples are silicate glasses. Marginal glass-formers present a rapid rise in viscosity during cooling when approaching the glass transition. Most metallic melts, including those based on Al, belong to this category.

The temperature dependence of viscosity for glass-forming liquids is given by the empirical Vogel–Fulcher–Tammann relation,

$$\eta = \eta_0 \exp\left(\frac{D \cdot T_0}{T - T_0}\right) \quad (6)$$

where  $D$  is the fragility parameter,  $T_0$  is the Vogel–Fulcher–Tammann temperature, and  $\eta_0$  is the high temperature limit of viscosity, determined according to the relationship

$$\eta_0 = \frac{h}{V_A} \quad (7)$$

where  $h$  is Planck’s constant and  $V_a$  is the atomic volume of the liquid. The fragility parameter is useful to classify “strong” and “fragile” liquids according to Angell [10]. The former follow silica behavior while the latter show deviations from the Arrhenius equation. For silica, the fragility parameter is 100, to be compared with 2 for the most fragile liquids [13]. The fragility parameter is also a good indicator of the glass-forming ability: the larger the fragility parameter, the better the glass-forming ability of the liquid. In fact glasses with large fragility parameter have slow kinetics in the undercooled liquid regime, inhibiting crystallization of the liquid.

The change in viscosity implies the change of thermodynamic properties as well: heat capacity and the expansion coefficient may decrease more than a factor of two with respect to their normal liquid state values.

Thermodynamic and kinetic parameters are combined in the Adam–Gibbs theory, based on entropy. This theory uses the idea of a cooperatively rearranging region, that is, the smallest group of atoms that must move in concert to change configuration. The sizes of these cooperatively rearranging regions grow with decreasing temperature, decreasing the configurational entropy of the system. With this theory, the viscosity is expressed as

$$\eta = \eta_0 \exp\left(\frac{C}{T \cdot S_c(T)}\right) \quad (8)$$

where  $\eta_0$  is the high temperature limit of viscosity,  $C$  is a constant related to the enthalpy barrier for a cooperative rearrangement,  $T$  is temperature, and  $S_c$  is the configurational entropy of the liquid.

The Adam–Gibbs theory is in agreement with Angell’s fragility classification. In fact strong liquids, with a tendency to short range order, have configurational entropy that is not strongly dependent on temperature, instead of fragile liquids that show non-Arrhenius behavior.

Viscosity is usually linked to atomic diffusivity,  $D$ , through the Stokes–Einstein equation:

$$\eta = \frac{kT}{6\pi rD} \quad (9)$$

This relationship is useful in estimating the diffusion coefficient in the undercooled liquid state where any experimental measurement would be almost impossible. However, it has been recently verified for molecular liquids and confirmed for metallic melts and glasses that it breaks down at temperatures in the range  $1.2$ – $1.3 T_g$  [14–16]. Below

such temperatures it is suggested that the product  $\eta \cdot D^2$  is constant at each temperature. The diffusion coefficient in the temperature range relevant for the formation of nanocrystals should be computed accordingly especially for Al alloys where no data are available for both viscosity and diffusivity in the liquid and glassy state. Below  $T_g$  the diffusivity can usually be described by the Arrhenius equation. For metallic alloys the temperature range of  $T_g$  is most often close to that where crystallization occurs and the two processes may overlap.

### 3. DEVITRIFICATION OF AI GLASSES

#### 3.1. Thermodynamics of Phase Transformations

Rapidly solidified materials contain usually metastable phases and/or microstructures which transform via nucleation and growth. The driving force is the difference between the free energy of the metastable and stable equilibrium states. A schematic free energy diagram is drawn in Figure 3 for devitrification. It is shown that a gain in free energy may involve three main types of transformations: primary, polymorphic, and eutectic transformation.

A *polymorphic transformation* is defined as partitionless formation of a phase with different structure but the same composition as the matrix.

During a *eutectic transformation* two crystalline phases grow cooperatively with a discontinuous reaction. There is no difference in the overall concentration across the reaction front, but diffusion takes place parallel to the reaction front and the two components must separate into two phases.

A *primary crystallization* causes the formation of a phase with composition different from the original matrix which still remains as a major constituent of the material. During this reaction, a concentration gradient may be formed ahead of the particle interface with the matrix becoming enriched in a solute until a metastable equilibrium is reached.

The driving forces can be computed with some confidence by means of approximate formulae which are available for the different transformations [16].

**Figure 3.** Schematic Gibbs free energy curves for  $\alpha$ , the undercooled phase, and  $\beta$  and  $\gamma$  equilibrium phases. The arrows marks the extent of driving force for transformations: at  $x_1$  for polymorphic, at  $x_2$  for primary, and at  $x_3$  for eutectic.

Figure 4 represents a free energy versus composition scheme for primary crystallization. At the liquidus temperature a common tangent to the liquid and crystal free energy determines the composition of the nucleating phase. On undercooling, however, it is demonstrated that the maximum driving force for nucleation is determined by drawing a line parallel to the tangent originating from the crystal free energy curve. The free energy available for subsequent growth is determined by the line joining the free energy of the crystal of nucleating composition to that of the liquid of interfacial composition.

The first approximated formula proposed to compute  $\Delta G_v$  for the most stable nucleus is

$$\Delta G_v = (T_l - T)(\Delta S_{A,f} - R \log x_{A,l}) \quad (10)$$

where  $T_l$  is the equilibrium liquidus temperature,  $\Delta S_{A,f}$  is the entropy of fusion of the pure nucleating component, and  $x_{A,l}$  is the  $A$  concentration at the liquidus temperature. It was derived under the assumption of regular solution behavior of the liquid phase and no miscibility in the crystalline phase. The former position does not hold for glass-forming melts which are characterized by a dependence of the thermodynamic functions on temperature through a positive value of the liquid excess specific heat,  $\Delta C_p^{\text{ex}}$ . Could the excess free energy of the liquid phase be expressed by means of the subregular model? If the excess free energy of the liquid phase is expressed by means of the subregular model and there is no miscibility in the crystalline state,  $\Delta G_v$  would become

$$\Delta G_v = (T_l - T)[\Delta S_{A,f} - R \log x_{A,l} + x_{B,l}^2(4qx_{A,l} - p - q)] \quad (11)$$

where  $p$  and  $q$  are parameters expressing the temperature dependence of the excess free energy of the liquid phase.

A more general approach, however, is to describe the thermodynamics of metastable and stable phases by means

**Figure 4.** Schematic Gibbs free energy curves for liquid and crystal phases at a temperature where the liquid of composition  $x_m$  is in the undercooling regime. The line tangent to the liquid curve gives the chemical potential of the components. The arrows at  $x_s$  and  $x_n$  give the amount of variation in chemical potential of the components when a nucleus of these compositions is formed. The most probable nucleus has composition  $x_n$  since  $\Delta G(x_n) > \Delta G(x_s)$ .

of the optimization programs used to compute phase diagrams. This has been attempted in the case of the Al–Nd system for which the temperature- and composition-dependent driving forces for nucleation ( $\Delta G_v$ ) have been calculated after constructing free energy curves by means of the CALPHAD software [17].

In Figure 5 free energy curves are reported as a function of Nd content for the Al rich composition range at 700 K, a temperature in the undercooling regime. Note that the free energies of the metastable liquid and crystalline equilibrium phases are rather close due to the negative heat of mixing in the liquid being only slightly higher than the heat of formation of the stable intermetallic compound. After primary crystallization of Al the metastable equilibrium given by the dashed line will be established for compositions richer in Al than the tangent point to the liquid free energy. Since nucleation does not change significantly the composition of the matrix, the driving force for nucleation of primary Al, can be defined as the difference between the chemical potential of Al in the liquid and in the crystal phase, as shown by arrow a in Figure 5, for the  $\text{Al}_{97}\text{Nd}_3$  eutectic composition. Similarly, the driving force for primary nucleation of  $\text{Al}_{11}\text{Nd}_3$  is shown by arrow b. The driving force for the nucleation of Al is about twice as large as that for the nucleation of the  $\text{Al}_{11}\text{Nd}_3$  compound. Primary nucleation of face-centered-cubic (fcc)Al. Al will cause the rejection of Nd in the surroundings of primary precipitates reducing the driving forces for fcc-Al and enhancing that for  $\text{Al}_{11}\text{Nd}_3$ . So the intermetallic compound can nucleate beside fcc-Al leading to a eutectic crystallization. Once this has occurred growth is driven by the free energy difference indicated in Figure 5 by arrow c.

**Figure 5.** Gibbs energy versus composition for Al–Nd. The chemical driving force for crystallization are indicated: (a) primary Al, (b) primary  $\text{Al}_{11}\text{Nd}_3$ , (c) eutectic Al +  $\text{Al}_{11}\text{Nd}_3$ . Reference states are fcc-Al and hcp-Nd. Reprinted with permission from [17], M. Baricco et al., *Mater. Sci. Forum*, 269-272 553 (1998). © 1998, Trans Tech Publications.

## 3.2. Kinetics of Primary Crystallization

During primary crystallization, nanocrystals embedded in an amorphous matrix are formed. In rather wide temperature ranges their size increases quickly to a few nanometers and does not change significantly on further annealing. The usual requirements for obtaining this microstructure are high nucleation and growth rates in the very early stages of crystals formation and then both quantities must drop to negligible values. The two processes will now be described with reference to classical theories.

### 3.2.1. Nucleation

Nucleation can be homogeneous or heterogeneous. It is homogeneous if each point in the volume has the same probability of generating the new crystal. It is heterogeneous if it starts at sites either predictable or recognized *a posteriori*. They may be unevenly distributed in the matrix, but the process remains stochastic in each of them. In heterogeneous nucleation the term site not only has the meaning of place where the new phase originates, but it also conveys the idea of catalyzing the transformation.

In real systems there are interfaces, inclusions, or defects, so heterogeneous nucleation is extremely frequent. However, at times it is invoked also when the sites are unavoidable components (either known or unknown) of the matrix. If an impurity solute promotes the formation of a new phase, the nucleation may well be termed homogeneous since impurities are constituents of the material although being undesired. Analogously, point defects, such as vacancies, are intrinsic in solids and may occur in thermal equilibrium. Therefore, it would be preferable to consider them as components of the material instead of heterogeneities. A similar argument can apply to the free volume in liquids or glasses. On the other hand, excess vacancies, excess free volume, line defects, and interfaces introduce excess energy in the material and, as a consequence, are best considered as heterogeneities. Due to the excess energy associated with them, they can act as catalytic sites for transformations.

The steady-state nucleation rate in a condensed system,  $I_v^s$ , can be expressed as

$$I_v^s = \frac{24DN}{\lambda^2 n_c^{1/3}} \left( \frac{\Delta G^*}{3\pi k_B T} \right)^{1/2} \exp\left(-\frac{\Delta G^*}{k_B T}\right) \quad (12)$$

where  $D$  is a diffusion coefficient for atomic species crossing the interface between the matrix and the new embryo,  $N$  is the number of atoms per unit volume,  $\lambda$  is a diffusion distance,  $n_c$  is the number of elemental particles in the nucleus of critical size,  $\Delta G^*$  is the activation energy for the formation of a nucleus of critical size, and  $k_B$  is the Boltzmann constant. The above equation contains the product of two exponential terms (the one containing  $\Delta G^*$  is explicitly written; the other is  $D$ ). On increasing undercooling  $\Delta G^*$  decreases, favoring nucleation. If very low temperatures are reached, the nucleation rate decreases because the atomic mobility,  $D$ , is lower. The pre-exponential terms do not affect much the value of  $I_v$  when the temperature is changed.

Two thermodynamic parameters are relevant for  $\Delta G^*$ : the free energy difference between liquid (or glass) and crystals

and the interfacial free energy,  $\gamma$ , between the same phases. In fact,  $\Delta G^*$  for a spherical nucleus is defined as

$$\Delta G^* = \frac{16\pi}{3} \frac{\gamma^3}{(\Delta G_v)^2} \quad (13)$$

Expressions for the driving energy  $\Delta G$  have been discussed in the previous section. It is difficult to evaluate  $\gamma$ . It is taken to a first approximation as a fraction of the enthalpy of fusion or as an adjustable parameter. Recent theories are based on the concept of the interface not being a geometrical dividing surface but a diffuse layer. A discussion can be found in [16]. The practical outcome is an expression of  $\gamma$  as a function of temperature which apparently fits a number of experimental data on homogeneous nucleation rate. The formula is

$$\gamma(T)/\gamma(T_f) = \left[ 0.48 + 0.52 \cdot \frac{T}{T_f} \right] \quad (14)$$

where  $\gamma(T_f)$  is the interfacial free energy at the melting point.

In most transformations the time scale is such that the time necessary to reach the steady-state condition, the transient period,  $\tau$ , is negligible with respect to the overall transformation time. On the contrary, the time needed for quenching in rapid solidification experiments may become comparable to  $\tau$ . Actually it has been suggested that vitrification of some compositions occurs because the process is shorter than the transient time. The nucleation frequency during the transient period is given by the Kashchiev expression [18]

$$I(t) = I_{st} \left[ 1 + 2 \sum (-1)^n \exp\left(\frac{-n^2 t}{\tau}\right) \right] \quad (15)$$

During the quenching of a metallic alloy to a glass the transient period can be estimated using the expression [19]

$$\tau = \frac{r_c^2}{\pi^2 D} \quad (16)$$

where  $r_c$  is the radius of the nucleus of critical size.

Heterogeneous nucleation is so frequent because most substrates can act as catalysts by reducing the activation barrier due to interfacial energy provided that the new phase wets the substrate.

Information on the nucleation mechanism can be obtained by analyzing the distribution of dimensions of crystals in partially crystallized samples [20]. The model is based on the partition of the annealing time during an isothermal transformation in intervals,  $\Delta t$ . The number of crystals per unit volume ( $\Delta N_i$ ) formed in the time  $\Delta t$  depends on the nucleation mechanism. This approach provides a straightforward identification of the nucleation mechanism especially when applied to the initial stages of a polymorphic transformation and when the crystals are spherical and noninterfering. The expected distributions are described in the following.

**Quenched in Nuclei** Subcritical crystallike clusters are stochastically present in an undercooled melt. They are then frozen together with the matrix on rapid quenching [21]. Since the critical size decreases with decreasing temperature, a subcritical embryo may then become a nucleus and grow during an annealing treatment. Quenched-in nuclei are likely to have similar size, just above the critical one, and grow all at the same rate. Moreover there will be no other nucleus in the matrix since it will take time to induce further nucleation. Therefore it is expected that the crystal sizes are confined to a narrow range.

**Homogeneous Nucleation** If steady-state homogeneous nucleation is operative during a transformation the following equation will give  $\Delta N_i$ :

$$\Delta N_i = I(t)(1 - X_{i-1})\Delta t \quad i = 1, \dots, t/\Delta t \quad (17)$$

where  $X_{i-1}$  is the volume fraction transformed up to the  $(i-1)$ -th time interval and  $(1 - X_{i-1})$  accounts for the volume available for nucleation during the  $i$ th time interval. It is computed from

$$X_i = 4\pi/3u^3 \sum_{j=1}^i \Delta N_j [\Delta t(i+1-j)]^3 \quad (18)$$

where  $u_i$  is the crystal growth rate.

The resulting distribution has a decreasing number of crystals upon decreasing size because of the progressive reduction in the volume where nucleation is possible (Fig. 6a).

**Heterogeneous Nucleation** Heterogeneous nucleation is promoted by a limited number of active sites per unit volume,  $Z$ , so  $\Delta N_i$  can be calculated with the expression

$$\Delta N_i = I^*(t)(1 - X_{i-1}) \left( 1 - Z^{-1} \sum_{j=1}^{i-1} \Delta N_j \right) \Delta t \quad (19)$$

where  $(1 - Z^{-1} \sum \Delta N_j)$  gives the fraction of available sites at the  $i$ th time interval. Nuclei are formed when  $\sum \Delta N_j < Z$ ;  $\Delta N_j = 0$  when all sites are consumed. In Figure 6b the distribution of the crystals diameters is reported. There is a steady decrease in the number of crystals with decreasing size due to the reduction in both number of available sites and volume and a sudden drop to zero when no new nuclei can be formed.

**Homogeneous and Heterogeneous Nucleation with a Transient**

In the transient period an increasing number of nuclei form during each time interval before reaching the steady state. Then either a homogeneous process or a heterogeneous one sets in. As a consequence, the distribution has a similar shape as for either case (ii) (Fig. 6c) or (iii) (Fig. 6d) but decreases smoothly when reaching the higher values of the measured crystal sizes. These crystals are those formed in limited amounts during the early transient period and which had more time for growth.

For primary crystallization only a fraction of the alloy undergoes transformation so it is expected that a metastable equilibrium between crystals and amorphous matrix will be finally established and the amount of crystalline phase will

**Figure 6.** (a) The distribution of sizes of crystals grown after the occurrence of a homogeneous nucleation process. (b) The distribution of sizes of crystals grown after the occurrence of a heterogeneous nucleation process. (c) The distribution of sizes of crystals grown after the occurrence of a transient and a homogeneous nucleation process. (d) The distribution of sizes of crystals grown after the occurrence of a transient and a heterogeneous nucleation process. A similar distribution may be found in case of primary crystallization when only a fraction of the alloy transforms. In fact, the amount of crystals having small sizes would reduce quickly because of the reduction of volume available for transformation.

be determined by the lever rule. Therefore, the available volume for nucleation will be quickly reduced during the progress of transformation so there will be less crystals of small size. The size distribution of crystals could result in one similar to that expected for heterogeneous nucleation with a transient as shown in Figure 6d.

### 3.2.2. Growth

Considering a nucleus that starts to grow at the start of an isothermal anneal, different growth laws will be followed according to the transformation type (i.e., polymorphic, eutectic, or primary).

**Polymorphic Transformation** When crystals and matrix have the same composition, the growth process needs only the movement of atoms through the crystal–matrix interface. The growth rate ( $u_1$ ) is constant and has the temperature dependence

$$u_1 = u_0 \exp\left(\frac{-Q_s}{RT}\right) \cdot \left[1 - \exp\left(\frac{-\Delta G}{RT}\right)\right] \quad (20)$$

where  $Q_s$  is the growth activation energy and  $u_0$  is a pre-exponential factor. The term in square brackets contains the free energy difference between melt and crystal,  $\Delta G$ , and is nil at the melting point. It expresses the need for limiting the growth rate in proximity to the equilibrium transformation temperature when the rate of detachment of atoms from the crystal becomes sizeable. If the crystallization takes place in metallic glasses at temperatures well below the melting point

where  $\Delta G$  is substantial, then  $\exp(-\Delta G/RT)$  is negligible. Therefore at high undercoolings the growth rate follows an Arrhenius type equation:

$$u_1 = u_0 \exp\left(\frac{-Q_s}{RT}\right) \quad (21)$$

**Eutectic Transformation** When a eutectic transformation takes place the average composition of the transformed region equals the composition of the matrix before the occurrence of transformation. However, partition of species between the new phases is needed which takes place via long range diffusion. As a consequence, the growth rate depends on the interparticle spacing ( $\lambda$ ). In particular, if there is diffusion in the matrix ahead of the crystallization front, than  $u_e$  is proportional to  $\lambda^{-1}$ ; if there is diffusion at the interface between matrix and crystals then the growth rate is proportional to  $\lambda^{-2}$  [22]. Considering a high level of undercooling ( $\Delta G > RT$ ) the growth rate can be expressed as follows when diffusion occurs in the bulk volume:

$$u_e = \alpha_D \frac{4D}{\lambda} \quad (22)$$

where  $\alpha_D$  is the dimensionless supersaturation, a complex function of the elemental concentration in the matrix and the growing phase,  $D$  is a diffusion coefficient, and, when the diffusion occurs at the interface,

$$u_e = \alpha_D \frac{8 \cdot \delta \cdot D}{\lambda^2} \quad (23)$$

where  $\delta$  is the thickness of the crystallization front.

**Primary Crystallization** When a crystal poor in solute grows in a multicomponent matrix there is rejection of solute in the matrix. If the crystal grows richer in solute there is a depletion of solute in regions of the matrix near the particle. In both cases the growth of the new particle requires homogenization of the concentration gradient built up in the surrounding matrix, that is, a diffusion controlled process. So the growth rate is controlled by the diffusion rate.

If we assume that the diffusion coefficient is independent of concentration, the radius of a spherical particle during precipitation can be expressed as

$$r = \alpha \sqrt{Dt} \quad (24)$$

and the growth rate is

$$u_p = 1/2 \cdot \alpha \cdot D \cdot r^{-1} \quad (25)$$

where  $\alpha$  is a dimensionless parameter that depends on the composition of the material and on the composition of the crystal–amorphous interface.

### 3.3. Primary Nanocrystallization

#### 3.3.1. Nucleation and Growth During Nanocrystallization

At the very early stages of primary nanocrystallization high nucleation frequency and high growth rate occur on isothermal annealing at suitable temperatures. Soon after, both nucleation and growth slow down and in practical terms cease. During the formation of the Al nanocrystals a concentration gradient builds up in the amorphous phase at the crystal–matrix interface due to the rejection of solute from the crystal. The rare earth (RE) elements are slow diffusers in the alloy so their high content ahead of the interface reduces the rate of homogenization of the matrix and contributes to slowing of the growth rate of the Al crystals. In fact, when a high enough density of crystals is reached, impingement among their diffusional fields can become effective and change the growth law as described in the following section [23]. The ensemble of phenomena now described produce typical differential scanning calorimetry (DSC) results on continuous heating where the precipitation peak is rather sharp and then is followed by a long tail characteristic of the homogenization stage of the transformation.

#### 3.3.2. Soft Impingement

During the early stages of primary crystallization from an amorphous matrix, the growing crystals can be considered isolated because their diffusion fields do not interfere with each other. In this case the growth follows the parabolic behavior reported in Section 2.3. On the contrary, when the number of crystals becomes large (a good estimate is  $10^{14} \text{ m}^{-3}$ ) the growth rate slows down due to soft impingement. The situation of two growing grains is represented in Figure 7 at two different times,  $t_1$  and  $t_2$ . At  $t_1$  every particle is considered isolated and the concentration of the solute far from the particle is the initial solute concentration in the metastable phase ( $c^m$ ). At a later time  $t_2$  the two grains are in competition for the solute (i.e., their diffusion fields overlap and the solute concentration far from the particles changes from the initial  $c^m$ ). This implies that the quantity of solute available for growth is decreasing and the process is slowing down.

As early as 1950, Wert and Zener [24] first modelled soft impingement, considering spherical particles of a  $\beta$  phase

**Figure 7.** The solute concentration profiles in the  $\alpha$  matrix between two growing grains of  $\beta$  phase at two annealing times.

that grows with a parabolic law in an  $\alpha$  matrix and assuming that all the crystals are already nucleated when the transformation starts.

The volume fraction ( $X_i$ ) was defined as

$$X_i = \left( \frac{r^I}{r^f} \right)^3 \quad (26)$$

where  $r^I$  is the radius that identifies the position of the interface,  $r^f$  is the final radius of the transformed region, and

$$1 - X_i = \frac{c(t) - c^\alpha}{c^m - c^\alpha} \quad (27)$$

where  $c(t)$  is the time-dependent concentration of solute far from the growing crystal, and  $c^\alpha$  is the concentration of solute in the  $\alpha$  phase.

Zener and Wert derived the following equation for the increase in the transformed volume fraction:

$$\frac{dX_i}{dt} = \frac{3}{2} k^{2/3} D X_i^{1/3} (1 - X_i) \quad (28)$$

where  $k$  is

$$k^{2/3} = \frac{2(c^m - c^\alpha)}{(c^\beta - c^\alpha)(r^f)^2} \quad (29)$$

and  $c^\beta$  is the concentration of solute in the  $\beta$  phase. Equation (33) was solved numerically to obtain an expression for  $c(t)$  versus time and, as a consequence, of growth rate.

Another model was proposed by Ham in 1958 [25]. He considered spherical particles distributed on a regular cubic lattice, obtaining an equation identical to that presented by Zener and Wert for which he provided an analytical solution. The model was shown to explain rather nicely the rate of heat evolution in DSC when applied to the devitrification of  $\text{Al}_{88}\text{Y}_7\text{Fe}_5$  [26].

## 4. Al–TM–RE ALLOYS: DESCRIPTION AND PROPERTIES

This section reviews specific features of Al–TM–RE alloys with TM = transition metal and RE = rare earth element or Y which behaves similarly to RE in these materials. In the systems described below samples are all produced by melt spinning, using different wheel speeds that will be specified when possible. DSC, X-ray diffraction (XRD), and transmission electron microscopy (TEM) are the typical investigations adopted to study microstructural evolution during heat treatments.

### 4.1. Structural Aspects: Amorphous Structure

X-ray diffraction patterns of glass-forming Al–TM–RE alloys present a broad signal, called a prepeak, at angles much lower than the halos typical of the amorphous phase. Further, an unusual shoulder of the main halo of the diffraction pattern is found. The intensity of both signals depends on composition. These particular features of the XRD pattern are shown in Figure 8 in the case of  $\text{Al}_{87}\text{Ni}_7\text{Nd}_6$  amorphous ribbons [27].

**Figure 8.** XRD pattern of the  $\text{Al}_{87}\text{Ni}_7\text{Nd}_6$  as-quenched alloy. It presents a prepeak at  $2\theta \sim 20^\circ$  and a composite halo. The maximum of the main halo is close also to the angular position of the (111) reflection of Al pattern and has a shoulder at high angles. There are no evident scattering contributions close to the angular position of the other reflections of Al. The explanation for the main composite halo is controversial. It was attributed to a contribution to the total diffracted intensity from very short Al-TM distance [28], at variance to the possibility of amorphous phase separation [56], or to the presence of quenched-in Al nuclei [29]. The appearance of a glass transition in the DSC trace of this alloy shows that it is mostly constituted by a homogeneous amorphous phase ruling out phase separation in the liquid. Therefore, the halo in the pattern should be attributed to the local environment of the elements in the amorphous alloy and to the contribution of small Al crystals present in the matrix. Reprinted with permission from [27], L. Battezzati et al., *Mater. Trans.*, 43, 2593 (2002). © 2002, The Japan Institute of Metals.

Amorphous ribbons of  $\text{Al}_{85}\text{Y}_x\text{Ni}_{15-x}$ , with  $2 < x < 12$ , show two different patterns: Y-rich glasses ( $x \geq 8$ ) have a single main halo; Y-poor glasses have a shoulder on the high-angle side of the main halo close to the (200) Bragg reflection of Al [28]. It was suggested that the shoulder is due to scattering from fine quenched-in Al nuclei. The main halo should mask the broad (111) Bragg peak. Since the intensity of the shoulder increases with decreasing Y content, it was concluded that the number of Al nuclei of critical size depends on RE content in the alloy.

The prepeak found at lower angles might suggest short range order due to Y–Y pairs. In fact, its intensity increases with Y content. This implies that the Y–Y distance is relevant for the prepeak and so most Y atoms must assume a definite configuration (Fig. 9), being all surrounded by Al atoms, so the Y–Y coordination number is zero. The prepeak shifts to higher angles as the Ni content is increased so this is attributed to the replacement of some of the Al atoms by the smaller Ni atoms.

In the case of  $\text{Al}_{90}\text{Fe}_x\text{Ce}_{10-x}$  ( $x = 5, 7$ ) [29] pulsed neutron diffraction indicates that the Al–Fe distances are anomalously short, while some Al–Al distances are anomalously long. The prepeak is present both in pulsed neutron and X-ray diffraction patterns. These results suggest a strong interaction between Al and Fe, leading to short range order. In neutron scattering experiments, the position of the prepeak shifts to higher  $Q$  on increasing Fe concentration. Analyzing the radial distribution functions, Ce atoms are basically randomly distributed in the glass. Fe atoms are

**Figure 9.** The most probable configuration of Al and Y atoms in an amorphous Al–Y–Ni alloy.

surrounded by about 10 Al atoms, with 6 of them in close contact with Fe, and the distance between Al–Fe in close contact is less than the sum of atomic radii, suggesting a strong interaction between Al and Fe more than Al and Ce with this alloy composition. This short range order, similar to the local order in quasicrystals, might explain the origin of the prepeak.

The atomic structure of  $\text{Al}_{87}\text{Y}_8\text{Ni}_5$  alloy was investigated by both ordinary and environmental radial distribution functions around Y and by anomalous X-ray scattering around the Ni  $K$ -edge [30]. From the distances between pairs of atoms and coordination numbers collected in these measurements it resulted that the number of Y–Y pairs is insignificant; about 16% of the atoms surrounding a Y atom are Ni and, therefore, the rest of the coordination shell is mostly occupied by Al. A strong interaction also between Y and Ni is inferred from the number of Ni–Y pairs, higher than that expected from the alloy composition. A locally ordered structure of the three elements is present in the amorphous phase, thus favoring glass formation in this alloy. These results seem apparently to be in contrast with those derived above with considerations of XRD patterns. It should, however, be noted that the composition is changed by a few atomic percent. This suggests that these materials are very sensitive to alloy formulation as both structure and transformation behavior are concerned. In the following detailed analysis of various binary and ternary systems this feature will clearly appear. Whenever possible the properties of the materials (mechanical, chemical) will be reported stressing the effect of refined microstructures.

#### 4.2. $\text{Al}_{100-x}\text{Sm}_x$ ( $8 < x < 12$ )

A varied transformation mechanism was found in this series of binary alloys which serve as model materials. In the case of  $\text{Al}_{92}\text{Sm}_8$ , primary crystallization occurs with the formation of Al nanocrystals with a grain size of about 15 nm. A polymorphic crystallization is found in  $\text{Al}_{90}\text{Sm}_{10}$ , with the formation of a metastable intermetallic phase. For  $\text{Al}_{88}\text{Sm}_{12}$  and  $\text{Al}_{86}\text{Sm}_{14}$  a eutectic crystallization gives a mixture of stable (Al and  $\text{Al}_{11}\text{Sm}_3$ ) and metastable phases.

### 4.2.1. $Al_{92}Sm_8$

Both partially and completely amorphous ribbons can be produced by melt spinning. In partially crystalline ribbons, Al and  $Al_{11}Sm_3$  crystallize during rapid solidification [31,32]. Even in the case of apparently amorphous ribbons, tiny fractions of  $\alpha$ -Al were detected by XRD and TEM on the air side. The stability of the amorphous phase was checked with DSC (Fig. 10) [33]. Continuous heating experiments evidenced the presence of two transformations, the first of which starts at 180 °C and the second at 266 °C (heating rate of 40 K min<sup>-1</sup>). XRD patterns of samples heated up to the end of the two transformations show the formation of Al nanograins of about 10 nm in size during the first transformation (Fig. 11) and, successively, the formation of Al and  $Al_{11}Sm_3$ . The kinetic of formation of the nanocrystals [34] was studied in isothermal conditions performing DSC measurements at various temperatures and annealing times. The evolution of the crystalline fraction of  $\alpha$ -Al (Fig. 12) versus time was determined for samples heated at 171 °C by comparing the amount of heat released after the isothermal treatments to the amount of heat evolved from a totally amorphous sample. A sigmoidal shape is expected for a single stage process; however, the crystalline fraction displays a more complex behavior as a function of time, suggesting a sum of different processes. The variation of the density of Al nanocrystals and their size versus time of annealing are reported in Figure 13 as obtained from TEM observations (Fig. 14). The transformation can be described with nucleation and growth of a high density of Al nanocrystals. The clustering of Al atoms to form crystalline grains implies rejection of Sm into the matrix and the establishment of a concentration gradient at the crystal–matrix interface. This concentration gradient is hardly recovered during isothermal annealing, because of the low diffusivity of Sm. An example of such nanocrystals is shown in the TEM image of Figure 15.

The size distribution of Al nanocrystals (a typical example is reported in Fig. 16) can be interpreted according to the classification described in Section 3.2.1. The frequency of crystal diameters has a tail at “high” values (>10 nm) indicating a transient effect. On decreasing size the number of crystals decreases with a shape which appears intermediate between Figure 6d and e. It may be due to homogeneous nucleation possibly occurring during quenching from

**Figure 10.** A DSC trace showing the exothermal signals due to crystallization of an amorphous  $Al_{92}Sm_8$ .

**Figure 11.** XRD pattern obtained with a  $Al_{92}Sm_8$  alloy after the first crystallization event shown in Figure 10.

the melt and causing the formation of a distribution in the size of quenched-in nuclei which have grown during the anneal or to heterogeneous nucleation.

### 4.2.2. $Al_{90}Sm_{10}$ , $Al_{88}Sm_{12}$

For  $Al_{90}Sm_{10}$  different phases were observed as a product of rapid solidification and, then, different transformation paths were found during heating [31,35]. If a full amorphization is obtained, it transforms polymorphically to a metastable cubic phase having large unit cell which then decomposes in two steps to the equilibrium phase mixture, as represented by

When crystalline phases are found in the as quenched ribbons then the transformation sequences are

(increase in crystalline fraction)

The structure of all metastable phases (MS1, M1, M2) has been determined [36]. M2 forms only during undercooling and does not nucleate from the glass. It simply grows if already present. Different phases are obtained on annealing the single phase glass. This reveals the existence of a hierarchy in stability of phases occurring in different temperature ranges.

**Figure 12.** The evolution of the crystalline fraction of Al versus time for a  $Al_{92}Sm_8$  sample annealed at 171 °C.

**Figure 13.** The number density of Al nanocrystals as a function of annealing time for the temperatures indicated in the insert for a  $\text{Al}_{0.2}\text{Sm}_8$  alloy.

Only partially crystallized samples were obtained for  $\text{Al}_{88}\text{Sm}_{12}$  alloy during rapid solidification. Al,  $\text{Al}_{11}\text{Sm}_3$ , and M1 compete with the formation of the amorphous phase and were found in the as quenched ribbons beside a little fraction of glassy phase.

#### 4.2.3. Al-RE (RE = Y, La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er, or Yb) [37, 38]

In these binary alloys the glass-forming ability is probably due to a strong attractive interaction of the constituent elements. This should result in the diffusion of the constituent atoms becoming difficult and the viscosity high in the strongly supercooled liquid.

The composition range for the formation of the amorphous phase is 9–13% Y, 7–11% La or Ce, 10% Pr, 8–12% Nd or Gd, 8–16% Sm, 9–14% Tb, and 9–12% of Dy, Ho, Er, or Yb. Except for the Al-Nd system these ranges are situated between a shallow eutectic point and  $\text{Al}_{11}\text{R}_3$  (R=La,

**Figure 14.** Bright field TEM image of nanosized Al crystals embedded in an amorphous matrix in  $\text{Al}_{0.2}\text{Sm}_8$  alloy annealed at 171 °C for 60 s. The corresponding diffraction pattern is also shown: there are crystalline reflections on top of amorphous halos.

**Figure 15.** High resolution TEM image of isolated Al nanocrystals in an  $\text{Al}_{0.2}\text{Sm}_8$  rapidly quenched alloy annealed at 150 °C for 180 s. Lattice fringes correspond to the (111) lattice spacing of Al.

Ce, Pr, Nd, or Sm) or  $\text{Al}_3\text{R}$  (R=Y, Gd, Tb, Dy, Ho, Er, or Yb) compounds.

The onset temperature of the first DSC peak ( $T_x$ ) increases from 434 to 534 K with increasing RE content from 7 to 12 at%, but no further increase is seen in the concentration range 12–15 at%. Such a dependence is probably associated with different mechanisms of crystallization.

Actually, DSC curves for  $\text{Al}_{91}\text{Tb}_9$ ,  $\text{Al}_{90}\text{Tb}_{10}$ , and  $\text{Al}_{91}\text{Dy}_9$  show a first broad exothermic peak due to the precipitation of fine-grained fcc-Al and a second one due to a eutectic-like reaction involving Al, an unknown compound, and  $\text{Al}_3\text{Tb}$  or  $\text{Al}_3\text{Dy}$ . When the primary Al phase does not precipitate,  $T_x$  increases as seen in various Al-RE amorphous alloys with RE=Y, La, Ce, Nd, or Sm. So it is concluded that the strong compositional dependence of  $T_x$  is due to a change in crystallization process from  $\text{Am} \rightarrow \text{Am} + \text{Al} \rightarrow \text{Al} + \text{Al}_3\text{R}$  to  $\text{Am} \rightarrow \text{Al} + \text{X} + \text{Al}_3\text{R} \rightarrow \text{Al} + \text{Al}_3\text{R}$  or  $\text{Am} \rightarrow \text{Al} + \text{Al}_3\text{R}$ .

#### 4.3. Al-Ni-Ce

Ternary and multinary alloys will be discussed in the following. For some systems there has not been a systematic work as a function of composition so each alloy will be reviewed separately.

**Figure 16.** The distribution of the crystal sizes of Al in a  $\text{Al}_{0.2}\text{Sm}_8$  sample annealed at 171 °C for 4 minutes. The shape of the histogram is intermediate between those shown in Figure 6c and d (see text).

### 4.3.1. $Al_{88}Ni_{10}Ce_2$ [39]

Rapidly solidified ribbons were found to be completely amorphous in XRD and TEM analysis. Two DSC exothermic signals were detected in the temperature ranges from 405 to 540 K and from 595 to 630 K (heating rate of 0.67 K s) and were assigned respectively to the precipitation of fcc-Al from the amorphous phase and to the transformation of the remaining amorphous matrix to  $Al_3Ni$  and  $Al_{11}Ce_3$ .

The temperature dependences of nominal yield strength ( $\sigma_y$ ), nominal ultimate tensile strength ( $\sigma_b$ ), and elongation ( $\varepsilon_f$ ) of the amorphous alloy were investigated, pointing out that  $\varepsilon_f$  increases from 1.8 to 45% at 465 K and then decreases rapidly. This behavior was attributed to the effect of elongation induced crystallization; in fact TEM observations of the sample subjected to tensile tests at 465 K showed fcc-Al nanoparticles (10–15 nm) dispersed homogeneously in the amorphous matrix. This phenomenon was attributed to the following processes: (a) preferential precipitation along the shear planes due to an increase in temperature resulting from deformation, (b) increase in the flow stress at the precipitation sites, and (c) propagation of the deformation to other regions along the tensile direction. This large elongation is very important for the processing of gas atomized amorphous powders to be consolidated in a bulk form, because it occurs in a temperature range well below the precipitation temperature of the compounds.

### 4.3.2. $Al_{84}Ni_{10}Ce_6$ [40]

This alloy shows an high glass-forming ability and fully amorphous powders are produced by high pressure gas atomization that can be compacted by a high pressure die casting process obtaining sheet and cylinder samples with thicknesses of 0.5 and 5 mm respectively. For sheet samples an amorphous surface layer of about 0.03–0.05 mm was obtained; for cylinder samples the layer was 0.18–0.20 mm thick. The hardness of the amorphous layer of the sheet samples was 370  $H_v$  and the crystallization temperature was determined as 556 K. The corrosion resistance against NaOH solution for the amorphous layer was found to be better than the highest corrosion resistance in conventional alloys.

### 4.3.3. $Al_{87}Ni_{10}Ce_3$ , $Al_{85}Ni_{10}Ce_5$ , $Al_{80}Ni_{10}Ce_{10}$ , $Al_{87}Ni_7Cu_3Ce_6$ [41–44]

In these systems Ce plays an important role for the increase in glass-forming ability. The critical content in Ce for the formation of an amorphous phase was evaluated to be 3 at% since both partially and completely amorphous ribbons were produced with the  $Al_{87}Ni_{10}Ce_3$  alloy.

The XRD diffraction patterns revealed a single symmetric halo for  $Al_{80}Ni_{10}Ce_{10}$ , whereas  $Al_{85}Ni_{10}Ce_5$  shows a halo with a shoulder as discussed in Section 4.1. Also the DSC trace for  $Al_{80}Ni_{10}Ce_{10}$  is different from the others; in fact it has only one exothermic peak. In the cases of  $Al_{87}Ni_{10}Ce_3$  and  $Al_{85}Ni_{10}Ce_5$  there are two exothermic peaks. The XRD patterns of samples annealed up to the first crystallization step show the reflections due to fcc-Al nanocrystals and an amorphous matrix in the case of  $Al_{87}Ni_{10}Ce_3$  and fcc-Al plus two compounds in  $Al_{85}Ni_{10}Ce_5$ .

For  $Al_{87}Ni_{10}Ce_3$  amorphous ribbons, an atom probe analysis carried out to obtain a concentration depth profile (Fig. 17) provided the composition of the two phases of the alloy after heating up to the first crystallization peak. The  $\alpha$ -Al phase contains more than 95 at% Al and the remaining amorphous matrix has 25% Ni and 3% Ce. The  $\alpha$ -Al nanocrystals are evaluated to be about 15 nm in size by TEM. An enrichment in Ce content is found at the crystal–amorphous interfaces which is more evident when plotting the number of detected solute atoms versus the total number of detected atoms (Fig. 18a). The slope of the plot represents the local concentration of the alloy. Ni and Ce atoms are rejected from the growing Al crystals and an enrichment in Ce concentration is evident at the interface at a distance of about 3 nm. On the contrary, a similar enrichment is not observed for Ni atoms that display homogeneous concentration in the matrix. The concentration profile derived is schematically described in Figure 18b. It is concluded that faster homogenization is achieved for Ni than for Ce.

This family of Al-based alloys shows good mechanical properties; for example yield strength up to 800 MPa can be reached in the amorphous state, which can increase up to 1500 MPa after partial crystallization (i.e., when nanocrystals are embedded in the amorphous matrix).

Replacing Ni with Cu ( $Al_{87}Ni_7Cu_3Ce_6$ ) results in the increase in density of nanocrystalline particles formed during primary crystallization with the grain size becoming smaller (about 8 nm). Moreover Cu enriched clusters are present in the remaining amorphous phase, similar to Guinier–Preston zones in conventional crystalline alloys for precipitation hardening. These clusters may form in the early stage of annealing or even during cooling from the melt. They introduce a higher degree of heterogeneity in the local alloy composition and increase the density of nuclei during crystallization. The decrease in particle size of the Al phase causes an increase in tensile fracture strength with respect

**Figure 17.** Chemical analysis of a  $Al_{87}Ni_{10}Ce_3$  amorphous alloy heated up to the first crystallization DSC peak obtained with spatial resolution by means of the atom probe-field ion emission technique. to the ternary alloy (from 1050 to 1250 MPa) and in hardness. Such an effect on mechanical properties was attributed by the authors to higher hardness of Al nanocrystals with respect to the amorphous phase. This statement was later questioned by others (see Section 4.4.2 below).

#### 4.3.4. $\text{Al}_{87}\text{Ni}_{10}\text{Ce}_3$ [45, 46]

This composition was confirmed to be a marginal glass-former by rapid solidification since partially amorphous ribbons were obtained. It is interesting to remark that they contained nanosized Al crystals dispersed in an amorphous matrix so a two-phase microstructure was produced directly by quenching. It was also found that the devitrification behavior is very sensitive to changes in composition. In fact one of two samples, apparently identical in XRD analyzes, was found to contain less than 1% Si as a contaminant. The silicon contamination produces a change in devitrification behavior evidenced by DSC (Fig. 19a) in which three transformation steps are present instead of the two observed in the uncontaminated  $\text{Al}_{87}\text{Ni}_{10}\text{Ce}_3$  sample (Fig. 19b).

### 4.4. Al–Ni–Y

#### 4.4.1. $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$ , $\text{Al}_{88}\text{Ni}_8\text{Y}_4$ [47]

Ribbons of these alloys were produced by melt spinning, using different wheel speeds (20, 30, 40, 55, and 63  $\text{ms}^{-1}$ ). A two-phase microstructure, composed by Al nanocrystals homogeneously dispersed in the amorphous matrix, was obtained using wheel speeds greater than 30  $\text{ms}^{-1}$  for  $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$  and 20  $\text{ms}^{-1}$  for  $\text{Al}_{88}\text{Ni}_8\text{Y}_4$ . The crystallite size and volume fraction of fcc-Al increases with decreasing wheel speed.  $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$  shows a higher tendency to form a nanocrystalline structure, confirmed by X-ray diffraction analysis. Moreover, increasing Y content in place of Ni, the crystallite size decreases and the volume fraction of fcc-Al increases.

**Figure 19.** DSC traces for two ribbons of nominal composition  $\text{Al}_{87}\text{Ni}_{10}\text{Ce}_3$ . The ribbon which provided curve (b) was later found contaminated with 1% Si. There is a clear effect of the contaminant on temperatures and mechanism of transformations. Reprinted with permission from [46], L. Battezzati, et al., in *Proceedings of the 22nd Risø International Symposium on Material Science: Science of Metastable and Nanocrystalline Alloys, Structure, Properties and Modeling, 2001*, (A. R. Dinesen, M. Eldrup, D. Juul Jensen, S. Linderroth, T. B. Petersen, N. H. Pryds, A. Schröder Pedersen, and J. A. Wert, Eds.) Risø National Laboratory, Roskilde, Denmark, p. 211, 2001. © 2001, Risø National Laboratory.

TEM observations show that in  $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$  ribbons, produced with a wheel speed less than 30  $\text{ms}^{-1}$ , some intermetallic compounds (i.e.,  $\text{Al}_3\text{Y}$ ) are present beside fcc-Al. The ribbons structure is fully crystalline when using a wheel speed of 20  $\text{ms}^{-1}$ . On the contrary,  $\text{Al}_{88}\text{Ni}_8\text{Y}_4$  ribbons maintain a microstructure consisting of amorphous matrix and fcc-Al even at a wheel speed of 20  $\text{ms}^{-1}$ . For both alloys the diameter of fcc-Al crystallites ranges from 10 to 90 nm, when wheel speed is decreased.

DSC curves for  $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$  ribbons present three exothermic peaks in the temperature ranges from 437 to 446 K, from 600 to 603 K, and from 698 to 715 K, respectively (heating rate of 40  $\text{K min}^{-1}$ ). They are associated with (a) the precipitation of fcc-Al, (b) the transformation of the remaining amorphous matrix to fcc-Al plus an intermetallic compound ( $\text{Al}_3\text{Y}$ ), and (c) the transformation of phases induced by crystallization. The area of the first peak decreases with decreasing wheel speed, but that of the second peak remains unchanged. This means that the volume fraction of the fcc-Al phase increases on decreasing cooling rate and so it is possible to control the amount of the fcc-Al phase by changing the wheel speed. On the contrary, with increasing wheel speed, the crystallization temperature tends to increase indicating a higher stability of the remaining amorphous phase.

The microhardness of these alloys does not change linearly with wheel speed; its highest value is reached for a particle size of 10 nm and for volume fraction,  $V_f$ , of about 10%.

#### 4.4.2. $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$ , $\text{Al}_{86}\text{Ni}_{11.67}\text{Y}_{2.33}$ , $\text{Al}_{84}\text{Ni}_{13.33}\text{Y}_{2.67}$ , $\text{Al}_{82}\text{Ni}_{15}\text{Y}_3$ [48]

Different wheel speeds were used to produce ribbons by melt spinning. Samples with different compositions produced at 60  $\text{ms}^{-1}$  are compared to obtain information on their respective glass forming ability. A fully amorphous

material was obtained for  $\text{Al}_{86}\text{Ni}_{11.67}\text{Y}_{2.33}$  and  $\text{Al}_{84}\text{Ni}_{13.33}\text{Y}_{2.67}$  alloys, while only partially crystalline ribbons are produced in the case of  $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$  and  $\text{Al}_{82}\text{Ni}_{15}\text{Y}_3$  systems.

Analyzing XRD diffraction patterns of ribbons melt spun at different wheel speeds, it is concluded that for  $\text{Al}_{88}\text{Ni}_{10}\text{Y}_2$  there is a wide range of solidification rates in which a microstructure constituted by fcc-Al dispersed in the amorphous matrix is obtained. Using a wheel speed of  $20 \text{ ms}^{-1}$  a fully crystalline microstructure is evident. The same microstructural transitions were detected for  $\text{Al}_{86}\text{Ni}_{11.67}\text{Y}_{2.33}$ , but they occur at lower wheel speeds. In fact, a fully amorphous structure was obtained using a wheel speed of  $60 \text{ ms}^{-1}$ . In the case of  $\text{Al}_{84}\text{Ni}_{13.33}\text{Y}_{2.67}$  alloy, a limited range of wheel speeds can be used to obtain a nanocrystalline structure in which the presence of intermetallic compounds is evident. The results are similar for the  $\text{Al}_{82}\text{Ni}_{15}\text{Y}_3$  alloy, even if the glass-forming ability is lower than the previous case; in fact, fully amorphous ribbons are not obtained even using the highest wheel speed. When Al nanocrystals were obtained their dimensions, determined by Scherrer analysis, were about 10 nm; the result was confirmed by TEM observations.

The as-quenched ribbons were also studied by DSC, using the area of the first devitrification peak to determine the volume fraction crystallized to fcc-Al. These measurements indicate that glass formation is easiest at around 15 at% total solute content, corresponding to the composition for which nanoscale fcc-Al particles are obtained at the lowest quenching rate. Furthermore, at this solute content and below, there is a wide range of quenching conditions for the direct synthesis of a two-phase microstructure (fcc-Al plus amorphous matrix). At higher solute content, the glass-forming ability decreases and the two-phase structure is not obtained.

Microhardness measurements have been made for the ribbons of all compositions and a linear increase in microhardness with solute content was detected. The trend in mechanical properties of Al-Ni-Y alloys indicates that the main cause of increase in hardness is the solute content in the amorphous matrix and not the amount of nanocrystalline Al.

#### 4.4.3. $\text{Al}_y(\text{Ni}_{7/15}\text{Y}_{8/15})_{(100-y)}$ [28, 49]

These alloys can be divided into two distinct groups, based on their crystallization behavior.

Compositions with  $y < 85$  exhibit an endothermic glass transition just before the first exothermic peak.  $T_g$  ranges from 548 K ( $y = 84$ ) to 660 K ( $y = 75$ ). Similarly, the enthalpy of the first crystallization event increases from 44.8 to  $73.2 \text{ J g}^{-1}$ . On the contrary, for the alloys with  $y > 85$  no glass transition is visible; the first exothermic peak has an enthalpy of about  $24 \text{ J g}^{-1}$ . The activation energy,  $E_a$ , for the first peak, computed by means of the Kissinger method, increases from  $1.6 \pm 0.1 \text{ eV}$  ( $y = 81$ ) to  $2.1 \pm 0.3 \text{ eV}$  ( $y = 86$ ).

As for the mechanical properties, the Young modulus decreases from about 82 ( $y = 75$ ) to about 52 GPa ( $y = 88$ ).

#### 4.4.4. $\text{Al}_{85}\text{Ni}_{15-x}\text{Y}_x$ ( $3 < x < 12$ ) [49]

$\text{Al}_{85}\text{Ni}_{15-x}\text{Y}_x$  ( $3 < x < 12$ ) alloys can also be divided in two groups. For  $Y \geq 8$ , DSC curves show a well-defined glass transition and XRD patterns show a single main halo. But if

Y content is less than 8 at%, DSC curves do not show a glass transition and in the XRD pattern the halo has a shoulder.  $T_g$  increases from 526 K for  $x = 8$  to 538 K for  $x = 11$  and the enthalpy for the first peak increases from 43.1 to  $68.7 \text{ J g}^{-1}$  respectively. The first crystallization temperature,  $T_x$ , is about 560 K for alloys with Y content less or equal to 8 at% and is about 520 K for Y-poor ( $x < 8$ ) alloys, for which the enthalpy of the first crystallization increases from 22.4 to  $26.6 \text{ J g}^{-1}$ .

The activation energy for the first peak increases from  $2.8 \pm 0.2 \text{ eV}$  ( $x = 5$ ) to  $3.8 \pm 0.5 \text{ eV}$  ( $x = 10$ ). For these alloys, the Young modulus decreases from 58 GPa ( $x = 3$ ) to 48 GPa ( $x = 10$ ). The highest tensile strength found is 930 MPa and corresponds to  $x = 4$ .

## 4.5. Al-Ni-Sm

### 4.5.1. $\text{Al}_{85}\text{Ni}_{12-x}\text{Sm}_x$ ( $2 < x < 10$ ) [50]

Only fully crystallized ribbons were obtained in the case of  $\text{Al}_{88}\text{Ni}_{10}\text{Sm}_2$ . On the contrary,  $\text{Al}_{88}\text{Ni}_4\text{Sm}_8$  ribbons were obtained fully amorphous and their DSC curves show four exothermic peaks: the first transformation starts at  $250 \text{ }^\circ\text{C}$  and is due to the precipitation of  $\alpha$ -Al from the amorphous matrix. The other transformations are due to the formation of several intermetallic compounds. Isothermal treatments were performed at  $225 \text{ }^\circ\text{C}$  for different times and the crystalline fraction of  $\alpha$ -Al nanocrystals was determined: it reaches about 70% after 120 minutes of annealing. Microhardness also changes as a function of annealing time and, as a consequence, of the fraction of Al nanocrystals: it increases rapidly from  $280 H_v$  for as-quenched alloy to  $370 H_v$  after 120 minutes of annealing, when it reaches a plateau. Wear measurements show a relevant increase in resistance for alloys annealed from 30 to 120 minutes.

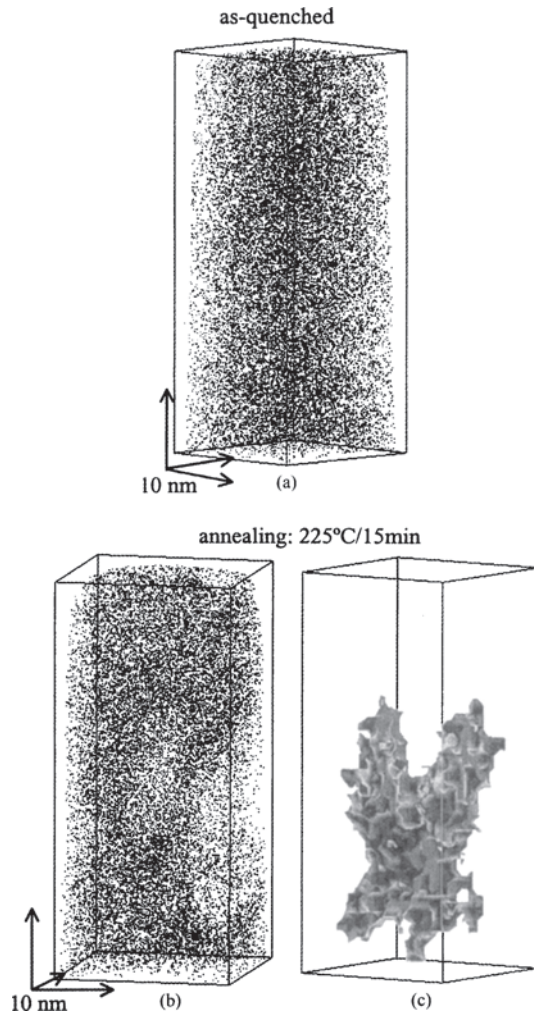

### 4.5.2. $\text{Al}_{88}\text{Ni}_4\text{Sm}_8$ [51]

The structural evolution of this alloy during devitrification was studied using TEM and atom probe field-ion microscopy.

TEM dark-field micrographs, together with the corresponding selected-area electron diffraction, of  $\text{Al}_{88}\text{Ni}_4\text{Sm}_8$  annealed at  $200 \text{ }^\circ\text{C}$  for 30 min show fine  $\alpha$ -Al nanoparticles embedded in an amorphous matrix. The average particle size is 20–25 nm and increases up to 30–35 nm in samples annealed at  $225 \text{ }^\circ\text{C}$  for 120 min. An increase in density of nanocrystals is also found for the latter heat treatment. High resolution TEM (HRTEM) observations show  $\alpha$ -Al nanoparticles composed of interconnected arms; such a shape suggests dendritic growth. The presence of an intermetallic compound in the partially crystallized alloy is evidenced by field-ion microscopy and TEM.

Three-dimensional elemental maps are represented in Figure 20. The distribution of Sm atoms in the as-quenched alloy is random (Fig. 20a), confirming its fully amorphous state. Then, after an annealing treatment at  $225 \text{ }^\circ\text{C}$  for 15 min (Fig. 20b), some regions appear to contain a lower density of Sm atoms. Figure 20c shows an isoconcentration surface of 100 at% Al, which corresponds to  $\alpha$ -Al nanoparticles in dendritic shape. This is a further confirmation of

**Figure 20.** Three-dimensional map of the element concentrations in  $\text{Al}_{88}\text{Ni}_4\text{Sm}_8$  obtained by elaboration of atom probe data: (a) Sm in the amorphous alloy, (b) Sm in the partially crystalline ribbon, (c) Al in the partially crystalline ribbon. Reprinted with permission from [51], T. Gloriant et al., *Mater. Sci. Eng. A* 304–306, 315 (2001). © 2001, Elsevier Science.

the total rejection of the solutes from the crystallites during the nanocrystallization process.

Analyzing an integrated concentration depth profile of Sm and Ni obtained from an Al-amorphous interface it is deduced that there is no enrichment in solute at the interface. It is interesting to note the difference with respect to  $\text{Al}_{87}\text{Ni}_{10}\text{Ce}_3$  alloy described above; in fact the diffusion-field impingement occurs later during the reaction and does not limit crystal growth so that the nanoparticles can grow in dendritic shape.

The volume fraction of Al nanoparticles increases up to 35 ( $\pm 5$ )% in the material annealed for 225 °C for 30 min and, as a consequence, the Al content in the amorphous matrix passes from 88% in the as-quenched ribbon to 83.5%, the Ni content reduces to 3.5%, and the Sm content rises up to 13%.

## 4.6. Al–Ni–Nd

### 4.6.1. $\text{Al}_{96-x}\text{Ni}_x\text{Nd}_4$ ( $x = 2, 4, 6, 12$ ) [52]

The XRD results for these alloys indicate a change from crystalline to fully amorphous ribbons on increasing the Ni content. DSC curves show that in the case of compositions with  $x = 2$  and  $x = 4$  two exothermic peaks are present, corresponding to the precipitation of Al and intermetallic compounds. When the Ni content is higher than 6 at%, the first broad peak disappears and a sharp exothermic reaction takes place, due to the eutectic formation of Al and intermetallic compounds.

A change in mechanical properties is detected on increasing the Ni content. In fact  $\sigma_f$  rises from 400 MPa ( $x = 0$ ) to 1000 MPa ( $x = 2, 4$ ), when there is a coexistence of amorphous phase and nanocrystalline Al. It decreases to 850 MPa ( $x = 8$ ) because of the presence of only amorphous phase and then rises again up to about 1000 MPa when the Ni content is raised further.

### 4.6.2. $\text{Al}_{88}\text{Ni}_{10}\text{Nd}_2$ [53]

Two crystallization stages are again detected by DSC. The volume fraction of Al nanocrystals,  $V_f$ , increases from 0% for the as-quenched ribbons to 32% for ribbons heated up to 525 K.

Samples heated after the first crystallization peak show extraordinary values of tensile fracture strength ( $\sigma_f$ ), up to 1980 MPa, for alloys heated up to 430 K; this value is attributed to the microstructure constituted by Al nanoparticles dispersed in the amorphous matrix. In fact, in this annealing state  $V_f$  reaches 18% and correspondingly the maximum value of fracture elongation,  $\sigma_f$ , of about 3% is obtained.

The microhardness increases linearly from 220 to 400  $H_v$ , when samples are annealed at 525 K.

The size of Al particles in the two-phase state is about 8–10 nm.

## 4.7. Al–Ni–Gd

### 4.7.1. $\text{Al}_{100-x}\text{Ni}_x\text{Gd}_y$ ( $5 < x < 11$ $12 < x + y < 18$ ) [54]

In this study  $\text{Al}_{100-x}\text{Ni}_x\text{Gd}_y$  alloys with a fixed concentration of 7 at% of Ni or Gd were studied and a composition area near  $\text{Al}_{87}\text{Ni}_7\text{Gd}_6$  was identified for the best glass-forming tendency. Here good intermediates for developing a two-phase microstructure via thermal treatment should be found.

DSC patterns show always three exothermic peaks. On increasing the Ni content, the first crystallization peak becomes sharper and shifts to higher temperature, from 488 K for  $\text{Al}_{88}\text{Ni}_5\text{Gd}_7$  to 577 K for  $\text{Al}_{82}\text{Ni}_{11}\text{Gd}_7$ . Similarly, on increasing the Gd content, the first crystallization peak shifts from 451 K for  $\text{Al}_{88}\text{Ni}_7\text{Gd}_5$  to 601 K for  $\text{Al}_{82}\text{Ni}_7\text{Gd}_{11}$ . The activation energy (calculated by means of the Kissinger method) increases monotonically when the content of either Ni or Gd is increased with the Gd being more effective. A higher activation energy for crystallization (or a higher crystallization temperature) means higher thermal stability; so for this ternary system it is concluded that Gd is more effective than Ni in increasing the glass-forming ability. This

was attributed to sluggish mobility of Gd with respect to Ni atoms.

## 4.8. Al–Fe–Nd

### 4.8.1. $Al_{86}Fe_5Nd_9$ , $Al_{86}Fe_9Nd_5$ , $Al_{88}Fe_9Nd_3$ [55]

$Al_{86}Fe_5Nd_9$  melt spun ribbons were found to be fully crystalline by XRD and TEM analysis.

Their DSC curve has a principal exothermic peak and then two exothermic small signals. The first peak is due to the crystallization of fcc-Al and a metastable phase that transforms to the stable crystalline phases at higher temperatures. The equilibrium phases are Al,  $Al_3Fe$ , and a phase indicated as  $\Phi$ , which may be defined as  $Al_{10}Fe_2Nd$ .

The  $Al_{86}Fe_9Nd_5$  alloy has a fraction of fcc-Al nanocrystals besides the amorphous phase after melt quenching. Its DSC trace has three exothermic peaks; the first one corresponds to the transformation of the amorphous matrix to fcc-Al and the same metastable phase as  $Al_{86}Fe_5Nd_9$ . The equilibrium phases are again reproduced as in  $Al_{86}Fe_5Nd_9$ .

### 4.8.2. $Al_{88}Fe_9Nd_3$ [46]

This composition is a good example to show the quenching sensitivity of this class of alloys. In fact various microstructures were observed after rapid solidification, depending on the solidification rates (Fig. 21): predominance of amorphous phase + Al, predominance of Al + amorphous phase, fully crystalline state made of Al +  $Al_3Fe$  +  $\beta-Al_{11}Nd_3$ .

Different transformation paths were found on heating these ribbons (Fig. 22) but the same crystalline products

**Figure 21.** XRD patterns obtained with  $Al_{88}Fe_9Nd_3$  ribbons of increasing thickness from (a) to (d) (i.e., quenched at decreasing rate). In (a) the material is almost fully constituted by Al and amorphous phase. In (b) and (c) the metastable crystalline compounds  $(Al, Fe)_2Nd$  and  $(Al, Fe)_{17}Nd_2$  also appear. In (d) the pattern of the equilibrium phases was obtained. Reprinted with permission from [46], L. Battezzati, et al., in *Proceedings of the 22nd Risø International Symposium on Material Science: Science of Metastable and Nanocrystalline Alloys, Structure, Properties and Modeling*, 2001, (A. R. Dinesen, M. Eldrup, D. Juul Jensen, S. Linderroth, T. B. Petersen, N. H. Pryds, A. Schrøder Pedersen, and J. A. Wert, Eds.) Risø National Laboratory, Roskilde, Denmark, p. 211, 2001. © 2001, Risø National Laboratory.

**Figure 22.** DSC traces obtained with the  $Al_{88}Fe_9Nd_3$  ribbons, the structure of which is shown in Figure 20. The differences in the exothermic signals show that various transformation paths are followed. Reprinted with permission from [46], L. Battezzati, E. Ambrosio, P. Rizzi, A. Garcia Escorial and K. R. Cardoso, in *Proceedings of the 22nd Risø International Symposium on Material Science: Science of Metastable and Nanocrystalline Alloys, Structure, Properties and Modeling*, 2001, (A. R. Dinesen, M. Eldrup, D. Juul Jensen, S. Linderroth, T. B. Petersen, N. H. Pryds, A. Schrøder Pedersen, and J. A. Wert, Eds.) Risø National Laboratory, Roskilde, Denmark, p. 211, 2001. © 2001, Risø National Laboratory.

were always recovered at 600 °C. The transformation paths of the partially crystalline materials are

amorphous phase + Al  $\rightarrow$  Al + amorphous phase

$\rightarrow$  Al +  $(Al, Fe)_{17}Nd_2$  +  $(Al, Fe)_2Nd$

$\rightarrow$  Al +  $Al_3Fe$  +  $\Phi$

Al + amorphous phase

$\rightarrow$  Al + unidentified metastable ternary phase

$\rightarrow$  Al +  $Al_3Fe$  +  $\Phi$

It is apparent that several intermetallic phases can form in a limited range of compositions. The local metastable equilibria and concentration profiles dictate the phase selection on annealing.

## 4.9. Al–Fe–Y

### 4.9.1. $Al_{90}Fe_5Y_5$ , $Al_{85}Fe_{7.5}Y_{7.5}$ , $Al_{80}Fe_{10}Y_{10}$ [56]

The XRD diffraction pattern of these ternary alloys shows a broad peak that indicates an amorphous material (result confirmed by TEM) and a prepeak due to local ordering of the Y–Y pair. The glass transition is evident in DSC curves followed by three exothermic peaks in all three alloys.

There is no primary crystallization of  $\alpha$ -Al phase. In fact, on annealing the samples after the first DSC peak, partial crystallization of an intermetallic compound,  $Al_9(Fe, Y)_2$ , takes place that then transforms into  $\alpha$ -Al and  $Al_{70}Fe_{16}Y_{14}$ .

### 4.9.2. $Al_{88}Fe_5Y_7$ [26]

TEM analysis of the  $Al_{88}Fe_5Y_7$  melt spun ribbons reveals an amorphous structure with a random distribution of micrometer size intermetallic crystals.

The DSC thermogram shows three peaks. The first one corresponds to Al nanocrystal precipitation, with dimension of about 20–30 nm; the second one and the last one are partially overlapped and are due to the precipitation of intermetallic compounds.

#### 4.9.3. $Al_{85}Y_{10}(Fe,Co,Ni,Cu)_5$ [57]

Completely amorphous ribbons were produced by melt spinning as confirmed by XRD and TEM analysis.

A change in transition metal produces a corresponding change in the devitrification behavior of the material, evidenced by DSC studies: the alloy with Cu shows two exothermic peaks, the alloys with Fe and Co show three peaks, and the alloy with Ni presents five signals. Furthermore, the transition metals have different effects on the stability of the amorphous phase. Specifically, a decrease in crystallization temperature is observed in the following order: Fe > Co > Ni > Cu. The same scaling is found for the melting temperature,  $T_m$ , of the Al rich compounds. Ni addition is the most effective in improving the glass-formation ability.

After heating samples through the first peak of crystallization, XRD patterns show a mixture of crystalline phases, consisting of a fcc solid solution possibly of Y and Ni, Cu, Fe, Co in Al. The other phases have not been identified. After heating through the second DSC peak fcc solid solutions and  $Al_3Y$  orthorhombic appear in all the ternary alloys.  $Al_3Co_2$  and  $Al_3Ni$  were identified in the respective alloys.

#### 4.9.4. $Al_{90}Fe_7Nb_3$ , $Al_{87}Fe_{10}Nb_3$ [58]

The rapidly solidified ribbons were found to be fully amorphous. DSC traces show two transformations; the first one corresponds to the precipitation of  $\alpha$ -Al nanocrystals with a size of 25–40 nm for  $Al_{87}Fe_{10}Nb_3$  and a size of about 200 nm for  $Al_{90}Fe_7Nb_3$ . The second peak is due to the precipitation of the equilibrium phases,  $Al_3Fe$  and  $Al_3Nb$ .

An increase in Fe content implies higher temperatures of transformation and smaller size of  $\alpha$ -Al nanocrystals.

### 4.10. Al–Ni–Fe–Nd

#### 4.10.1. $Al_{88}Ni_7Fe_3Nd_2$ , $Al_{88}Ni_5Fe_5Nd_2$ , $Al_{88}Ni_{10}Nd_2$ [59]

The melt-spun ribbons analyzed by TEM and XRD show only a single amorphous phase. Their DSC curves present two exothermic peaks. The first one is broad and corresponds to the precipitation of  $\alpha$ -Al nanocrystals. The second one is due to the precipitation of intermetallic compounds. The quaternary alloys present a shift to higher temperature of the transformations, due to a higher stability of the amorphous phase. The temperature increase is dependent on the Fe content.

A complex behavior as a function of testing temperature was found for tensile strength ( $\sigma_b$ ), yield strength ( $\sigma_y$ ), and fracture elongation ( $\epsilon_f$ ). All three alloys have  $\sigma_b$  higher than 800 MPa in the temperature range from room temperature to 580 K. This value is about 3 to 4 times higher than conventional heat resistant Al alloys. This is probably due to the Al nanoparticle dispersion and to the increase in thermal stability with solute enrichment of the amorphous matrix.

The elongation of  $Al_{88}Ni_{10}Nd_2$ ,  $Al_{88}Ni_7Fe_3Nd_2$ , and  $Al_{88}Ni_5Fe_5Nd_2$  at room temperature is 2–3% and reaches values of 42, 29, and 22% respectively at the first peak and 54, 48, and 39% at the second one.

### 4.11. Al–Ni–Fe–Gd [60, 61]

Twenty-four compositions were studied, containing 83, 85, and 87 at% Al.

The best glass-forming ability was found for 85 at% Al, followed by 87 at% Al. In the latter series the compositions with the best glass-forming ability are  $Al_{87}Ni_6Fe_1Gd_6$  and  $Al_{87}Ni_5Fe_1Gd_7$ .

Measurements gave the surprising result that the density of  $Al_{85}Ni_5Fe_2Gd_8$  exceeds the weighted average of its elemental densities by more than 5%, instead of less than 1% for  $Al_{85}Ni_6Fe_3Gd_6$  or  $Al_{87}Ni_6Fe_1Gd_6$ . This was attributed to a more closely packed atomic structure in the amorphous state and to stronger interactions between transition metal and rare-earth elements affecting glass-forming ability.

DSC traces of  $Al_{85}Ni_5Fe_2Gd_8$  show a  $T_g$  signal and then four exothermic peaks; a glass transition is not observed for  $Al_{85}Ni_6Fe_3Gd_6$  that shows five transformations steps from the amorphous phase to stable crystalline phases.

As for mechanical properties, tensile strength reaches values of 1280 and 1210 MPa for amorphous  $Al_{85}Ni_6Fe_3Gd_6$  and  $Al_{85}Ni_5Fe_2Gd_8$ , respectively, and Young's modulus values are 72.7 and 75.3 GPa.

### 4.12. Al–Ni–Zr, Al–Ni–Hf [62]

Melt-spun ribbons were completely amorphous as confirmed by TEM and XRD.

In Al–Ni–Zr alloys with Zr > 5 at%, DSC curves show two exothermic peaks; the first one is due to the precipitation of a fcc-Al phase. The precipitation temperature increases with increasing Zr content. The second peak corresponds to the crystallization of the remaining amorphous matrix. The same behavior was observed in Al–Ni–Hf alloys. Probably the atomic radius of the solute elements plays an important role in determining the formation of the amorphous phase and the mechanism of crystallization. In fact, comparing the minimum solute concentration in the  $Al_{90-x}Ni_{10}M_x$  systems for the single precipitation of fcc-Al particles, a critical concentration value was found of 5 at% for M = Ce and 7 at% for M = Zr.

The minimum solute concentration necessary to form amorphous phases is 2 at% for Ce, 3 at% for Zr, and 4 at% for Ti. For these elements, the atomic radius is quite different: 1.83 Å for Ce, 1.62 Å for Zr, and 1.47 Å for Ti. This values are also relevant to determine the grain size of the Al nanoparticles. TEM analysis reveals a larger crystal size when using Zr: 20 nm for the partially crystallized  $Al_{87}Ni_{10}Zr_3$  and 15 nm for the same composition with Ce.

### 4.13. $Al_{90}Fe_5Gd_5$ [63]

The as-quenched ribbons are fully amorphous to XRD and HRTEM. After an isothermal anneal up to 445 K (i.e., just below the crystallization temperature), the material becomes partially crystallized. Alloys with a slightly higher aluminium

content,  $\text{Al}_{90.5}\text{Fe}_{4.75}\text{Gd}_{4.75}$ , are obtained partially crystallized directly after quenching. For both of them the volume fraction of fcc-Al is about 28%. The size of crystalline particles is about 8 nm.

Tensile strength is shown to present a maximum for the annealed samples (1010 MPa), whereas Young's modulus is higher for the fully amorphous material.

The deformed materials were analyzed with scanning electron microscopy (SEM), which shown fracture surfaces typical of metallic glass materials, with vein patterns. Moreover the observations revealed that the distribution of macroscopic plastic deformation is extremely inhomogeneous.

#### 4.14. Al–V–M (M=Fe, Co, or Ni) [64]

The melt-spun ribbons present a nonequilibrium structure consisting of nanoscale amorphous particles surrounded by fcc-Al as revealed by XRD patterns and TEM images. The compositions which promote this structure are  $\text{Al}_{94}\text{V}_4\text{Fe}_2$ ,  $\text{Al}_{94}\text{V}_4\text{Co}_2$ , and  $\text{Al}_{93}\text{V}_5\text{Ni}_2$ . The sizes of the coexistent amorphous and Al phases are about 10 to 25 nm and 7 to 20 nm, respectively. The as-quenched structure is composed of the Al and amorphous phases for the alloys containing Fe and Co and by the Al and icosahedral phases for the alloy containing Ni.

Phase transitions take place through two stages, shown as exothermic signals in DSC traces. For  $\text{Al}_{94}\text{V}_4\text{Fe}_2$  the crystallization process may be described as

The mechanical properties are good. Measurements of tensile fracture stress,  $\sigma_f$ , and microhardness,  $H_v$ , yielded high values in the series  $\text{Al}_{98-x}\text{V}_x\text{M}_2$  at 4% V. In fact, for the as-quenched structure values of 1350 MPa and 470  $H_v$ , respectively, are obtained for the alloy with Fe, 1230 MPa and 460  $H_v$  for that with Co, and 1090 MPa and 430  $H_v$  for that with Ni. These values decrease after the first transition to icosahedral phase.

#### 4.15. Concluding Remarks

Although a large amount of information on Al–TM–RE alloys has been collected, there is some scatter in the data and there is still a lack of systematic representation of the results. For the ease of consultation the most relevant data discussed above are summarized in Table 1. For each alloy two temperatures are listed, as reported by the various authors, at the given heating rates: the onset of primary crystallization and that of the subsequent full devitrification of the matrix. Care should be taken in comparing the values since the microstructure of the rapidly solidified materials may differ from sample to sample. This information is provided in the Notes column detailing also the technique(s) used to study the sample structure, together with the value of the glass transition temperature when existing. The central column summarizes the most relevant mechanical properties of the ribbons either in the as-quenched state and/or after annealing.

In Figures 23 and 24 data extracted from Table 1 are plotted to display the most prominent chemical effects on

the first transformation temperature. Figure 23 is about  $\text{Al}_{88}\text{TM}_{12-x}\text{RE}_x$  alloys. When TM = Ni a clear increase in temperatures is found. The two alloys containing 88 at% Al and TM = Fe have much higher transformation temperatures. They are, however, less easily quenched to a glassy state. In Figure 24 the onset temperature is reported as a function of rare-earth element in alloys of  $\text{Al}_{88}\text{Ni}_7\text{RE}_6$  composition [27, 65]. It is apparent that the temperature decreases on increasing atomic number of rare-earth elements.

## 5. BALL MILLING OF ALLOYS

In the following systems the effect of the ball milling on the amorphization tendency and on devitrification behavior was studied.

### 5.1. Al–Ni–Co–Ti/Zr [66]

Mechanical grinding of Al-based alloys with Al > 80 at% containing late transition metals such as Ni (6–9 at%) and Co (3–5 at%) with an atomic ratio Ni/Co equal to 2 leads to the formation of nanostructured materials made of fcc-Al solid solution and  $\text{Al}_9(\text{Co,Ni})_2$  compound. Upon adding a few atomic percent of Zr or Ti there appear differences in the amorphization reactions. In fact, with  $(\text{Al}_{0.88}\text{Ni}_{0.08}\text{Co}_{0.04})_{100-x}(\text{Zr/Ti})_x$  for  $x = 1$  to 5%, partial to complete amorphization occurs via the following sequence: fcc-Al +  $\text{Al}_9(\text{Co,Ni})_2$  +  $\text{Al}_3\text{Zr}$  / or  $\text{Al}_3\text{Ti}$  → fcc-Al + amorphous I → amorphous II.

The experimental procedure consists of preparing by arc melting a mixture of pure elements under purified argon atmosphere, and then crashing them into fine powders. XRD patterns show complete amorphization after 100–120 h of milling.

### 5.2. $\text{Al}_{95}\text{Cu}_5\text{Zr}_5$ [67]

Atomized powder of 100–200  $\mu\text{m}$  diameter were milled up to 140 h. The microhardness of the as-milled material is higher than that of the as-cast powders indicating that a degree of metastability has been introduced in the material during ball milling. It approaches that of the as-spun ribbons of the same composition.

XRD patterns show only the presence of  $\alpha$ -Al, but SEM examinations also reveal other precipitates. After annealing at 500 °C, XRD patterns indicate the presence of  $\text{Al}_3\text{Zr}$  +  $\text{Al}_2\text{Cu}$  and the milled material still retains a considerable hardness. It is suggested that extrusion of ball-milled powders may be performed to obtain bulk materials.

### 5.3. $\text{Al}_{80}\text{Ni}_8\text{Fe}_4\text{Gd}_8$ [68]

Amorphous powders of this alloy were produced using the ball-milling technique after a treatment for 80 hours. The composition range for easy amorphization is different for rapid quenching and mechanical alloying. It was necessary to reduce the Al content for mechanical alloying with respect to that presenting good glass-forming ability in the melt-spinning process.

**Table 1.** A list of Al–TM–RE alloys produced by rapid solidification in the structural state given in the Notes column. The temperatures significant for phase transformations are provided at the given heating rate (glass transition temperature,  $T_g$ , onset of primary Al crystallization,  $T_1$ , onset of the second crystallization event,  $T_2$ ). The most relevant mechanical properties are collected (tensile strength,  $\sigma_b$ , Vickers hardness,  $H_v$ ).

Alloy	$T_1$ (K)	$T_2$ (K)	Rate (K min) <sup>-1</sup>	Mechanical Properties	Notes	Ref.
Al <sub>88</sub> Ni <sub>10</sub> Nd <sub>2</sub>	403	586	20	$\sigma_b = 1220$ MPa	Amorphous to XRD and TEM	[53]

**Figure 23.** The onset temperature of primary Al crystallization as a function of rare-earth content in  $Al_{88}TM_{12-x}RE_x$  amorphous alloys. The rare symbol is accompanied by (Fe) when  $TM = Fe$ ; otherwise  $TM = Ni$ .

The DSC trace shows a sharp exothermic signal at a temperature 60 K higher than for 85 at% Al melt-spun ribbons.

Microhardness tests (performed with a load of 200 g) on powder consolidated into buttons present values of 625–650  $H_v$ . Measuring the length of cracks produced by indentation, fracture toughness is calculated to be 1–5  $MPa m^{1/2}$ . This value can be improved at the expense of hardness for example after a milling treatment of 20 h.

## 6. NANOQUASICRYSTALLINE ALLOYS

Quasicrystals have been one of the major discoveries in solid state research during the 1980s. Their structure is quasi-periodic and can be approximated by stacking of McKay polyhedral clusters. They were discovered as metastable phases in rapidly solidified Al–Mn alloys [69], but properties have been determined in single quasicrystals which are equilibrium phases in some ternary systems such as Al–Cu–Fe [70]. From the point of view of applications, quasicrystals contain dislocations which can hardly move in the quasiperiodic structure without destroying it. Although brit-

**Figure 24.** The onset temperature of primary Al crystallization as a function of rare-earth content in  $Al_{87}Ni_7RE_6$  amorphous alloys.

tle, it is expected that a dispersion of icosahedral particles can harden a ductile matrix [6].

The binary Al–Mn icosahedral phase occurs as a primary phase on solidification forming large dendritic quasicrystals. It was earlier shown that, due to the similarity of the structure of the liquid and the I-phase, the corresponding interfacial energy is much lower than that between liquid and crystalline intermetallic compounds. This explains their ease of nucleation at temperatures where the growth rate is high enough to cause the formation of particles of micrometer size in the time duration of the quench in a melt-spinning apparatus (of the order of milliseconds) [71].

Inoue adopted the strategy of alloying Al–Mn and Al–Cr with lanthanide elements with the aim of producing materials consisting of quasicrystals in an Al matrix. The addition of lanthanides which are usually amorphizing elements in Al would help in decreasing the nucleation and growth rates of the primary phase. The optimum microstructure was formed in ribbons of  $Al_{94.5}Cr_3Ce_1Co_{1.5}$  composition (Fig. 25) which were used to determine the relevant properties of the material. The tensile stress is 1340 MPa and hardness is of the order of 330  $H_v$ . There is a decrease in tensile strength from the value of as-prepared to those of cold rolled ribbons which is attributed to work softening caused by increase of the volume fraction of interfaces between Al and I-phase with increasing amount of deformation. The interfaces may act as sinks for dislocations produced in the ductile Al.

An analogous microstructure to that observed in ribbons was produced in atomized powders. The powders were extruded to obtain bulk specimens exhibiting tensile strength

**Figure 25.** High resolution TEM micrograph and selected area diffraction pattern of a rapidly solidified  $Al_{94.5}Cr_3Ce_1Co_{1.5}$  alloy. The area imaged has a disordered structure at short range since there are no lattice fringes visible, but an icosahedral configuration at long range is testified by the fivefold symmetry of the diffraction pattern superimposed to halo rings. above 500 MPa with elongation around 20% at room temperature and of 200 MPa at 573 K. Comparison with conventional Al alloys shows that these properties are by far superior [72].

In the development of the research, the same group discovered nanoquasicrystalline microstructures in the  $\text{Al}_{98-x}\text{V}_x\text{Fe}_2$  system with  $x = 3$  or 5 at% [64]. The striking finding is, however, that a nanogranular amorphous-crystalline microstructure occurred at the  $\text{Al}_{94}\text{V}_4\text{Fe}_2$  composition. The alloy apparently consists of a primary nanostructured amorphous phase surrounded by Al crystals. The cause for achieving such a microstructure was attributed to the high cooling rate which inhibited the formation of the I-phase but it is not fully clear yet. If the amorphous phase supplants the I-phase for kinetic reasons it has to be admitted that a liquid-liquid phase separation should occur prior to solidification. Although phase separation in glass-forming melts has been found in Zr based alloys, it has not been demonstrated in Al liquid alloys to date. There has been a report of phase separation at low temperature in a quaternary  $\text{Al}_{88}\text{Gd}_6\text{La}_2\text{Ni}_4$  [73] alloy which has not been confirmed yet. The other remarkable points are that well prepared ribbons show tensile strength close to 1400 MPa and hardness above 450  $H_v$ , and that the tensile strength is as high as 620 MPa at 680 K.

Further research on this type of alloy led to quaternary compositions such as  $\text{Al}_{93}\text{Fe}_3\text{Cr}_2\text{Ti}_2$  and  $\text{Al}_{92}\text{Fe}_3\text{Cr}_3\text{Ti}_2$  consisting again of a mixed Al-quasicrystal structure. They were produced as bulk cylinders by extruding atomized powders. The extrudates displayed ultimate tensile strength of 660 and 580 MPa with 5.8% and 3.5% elongation, respectively, and kept good strength at high temperature. In the above formulation Mn can substitute for Fe and Cu for Ti with still rather good properties. The amount of open information on these material is limited to date and it is expected that advancement will occur in producing high strength Al alloys [6, 74].

## 7. NANOCRYSTALLIZATION INDUCED BY DEFORMATION

Plastic deformation in metallic glasses is inhomogeneous in that it takes place in highly localized shear bands. They propagate in the material with negligible deformation hardening usually at 45° with respect to the tensile or compressive axis. Therefore, metallic glasses represent a class of perfectly elastic-plastic solids. Shear bands are observed in all deformation processes such as bending and rolling.

It was demonstrated by careful analysis of the microstructure of bent ribbons of amorphous  $\text{Al}_{90}\text{Fe}_5\text{Gd}_5$ ,  $\text{Al}_{90}\text{Fe}_5\text{Ce}_5$ , and  $\text{Al}_{87}\text{Fe}_{8.7}\text{Y}_{4.3}$  that Al nanocrystals formed within the shear bands and not in other portions of the alloys [75]. More recently, the phenomenon has been observed in other alloys either submitted to bending or tensile testing, having Al content of at least 87 at%. Usually alloys with Al content below this value do not present nanocrystal formation in shear bands [76].

The reason for partial crystallization is still not fully understood. It has been suggested that adiabatic heating within the shear bands may cause growth of crystal nuclei

quenched in the alloy during rapid solidification and that the local large plastic strain could promote short range rearrangement of atoms. It should be noted, however, that neither XRD patterns nor DSC traces are changed when employing heavily deformed samples with respect to as-quenched ones as shown by the analysis of heavily rolled  $\text{Al}_{87}\text{Ni}_7\text{Nd}_6$  ribbons [77]. More work should be done to elucidate the cause and the extent of precipitation induced by deformation. It is worth mentioning that amorphous Al-Sm phases could be produced by co-rolling foils of the two elements [78]. The process has some common features to that of ball milling mixtures of powders. However, the finding that deformation induces amorphization may appear in contrast to the effect of cold work for partial crystallization and shows that the whole topic is not yet fully understood.

## 8. CONCLUSIONS

In this chapter Al-TM-RE systems were described, focusing attention on the effects caused by atomic composition, rare-earth and transition metal type, and the addition of a fourth element on glass formation, their stability, and the transformation due to devitrification.

Nanocrystalline Al alloys can be obtained also by direct quenching from the liquid state for marginal glass-forming compositions. However, the two-stage process, quench plus annealing, provides means for a better control of microstructure.

The alloy compositions do not correspond to regions near deep eutectics as for most glass formers but to zones of the phase diagrams where intermetallic compounds exist having a high melting point. Nevertheless, there are zones of the multinary systems where glass formation is relatively easy because of the sluggish tendency of these compounds to nucleation in the highly undercooled melt. It is actually more likely that fcc-Al and/or metastable compounds form during the quench. The metastable phases are more frequently encountered in ternary Al-TM-RE alloys where TM = Fe which also possess a higher melting point. Therefore, quenching will be more effective when TM = Ni. Some alloys display a manifest glass transition before crystallization: the temperature interval in between the two transitions should be suited for processing the materials (e.g., compaction of rapidly solidified powders, flakes, or ribbons). However this interval is limited to a few tens of degrees even in the most favorable cases because of the inherent fragility of the melt where mobility soon becomes high above  $T_g$ .

The nucleation of Al is very frequent upon annealing on either pre-existing or new embryos. Growth and coalescence of crystals is hampered by the matrix surrounding the fine particles, the reason being that a compositional gradient for RE elements is established which are slow diffusers in these materials. This is shown also by the fact that the rare earths are more effective than the transition metals in raising the thermal stability.

The nanocrystalline Al alloys have promising mechanical properties. Their hardness and tensile or compressive strength are in the range of those of steels. Some of them also display good wear resistance. These properties deserve further research to optimize the alloy compositions and improve their thermal stability in view of selected applications.

## GLOSSARY

**CALPHAD** A computer technique for calculating phase diagram.

**Equichannel angular pressing** Technique for heavy deformation of materials in which the material is forced to flow along a L-shaped die.

**Eutectic transformation** A transformation of a phase which demixes into two phases of different structure and composition.

**Isoentropic temperature** The temperature at which the entropy of an undercooled melt would equal that of the corresponding crystal.

**Liquid fragility** Liquids are defined as fragile when their viscosity decreases rapidly above the glass transition temperature. Their viscosity is well represented by the Vogel-Fulcher-Tammann equation.

**Polymorphic transformation** A transformation of a phase into another phase having different structure.

**Primary transformation** The formation of a phase from a matrix having different structure and composition.

**Quasicrystals** Crystals with a quasi-periodic structure that can be approximated by stacking of McKay polyhedral clusters.

**Soft impingement** The impingement of the diffusion fields around growing crystals, acting during the primary crystallization, and causing growth rate to slow down.

## ACKNOWLEDGMENTS

The work on the topic of nanocrystalline Al alloys is performed within the Research Training Network of the European Commission “Nano Al” HPRN-CT-2000-00038. Studies on thermophysical properties of alloys are supported by ESA-ESTEC Contract 14306/01/NL/SH-MAP, Project AO-99-022 “Thermolab,” and ASI Contract. I/R/073/01.

## 1. INTRODUCTION

The development of soft magnetic wire-shaped materials with amorphous, nanocrystalline, and granular character has been demonstrated to improve the characteristics of different electromagnetic and electronic devices. Such magnetic wires with diameter ranging from 1 to 125  $\mu\text{m}$  can be obtained by different methods such as the in-rotating-water technique or the drawing glass-metallic quenching (Taylor-Ulitovsky) technique. The magnetic and transport properties of ferromagnetic amorphous wires obtained by in-rotating-water quenching technique with a typical diameter of around 120  $\mu\text{m}$  have become an interesting subject for applied and basic research studies owing to their outstanding magnetic properties. Peculiar magnetic phenomena associated with

the magnetization reversal process and the appearance of a large Barkhausen jump (denominated as magnetic bistability) and the giant magnetoimpedance (GMI) effect have been observed and intensively studied along the last decade [1, 2].

Recently the Taylor-Ulitovsky method, which has been known since the 1950s [3], has been employed to produce a long and thin ferromagnetic microwire with a tiny metallic nucleus (1–20  $\mu\text{m}$  in diameter) coated by an insulating sheath (1–10  $\mu\text{m}$  in thickness) [4]. Figure 1 shows a micrograph of a typical microwire where its composite character can be clearly seen. As will be presented in the next section, their amorphous or metastable crystalline (nanocrystalline or granular) character is achieved due to the high-quenching rate by the introduction of the molten alloy into a water jet during the drawing of the microwire. A number of outstanding magnetic properties, such as magnetic bistability, enhanced magnetic softness, and GMI effect (up to 600%), have been found recently in such microwires [4–8]. These properties are correlated with the shape and magnetoelastic anisotropies depending on the dimensions, microstructure, composition and strong internal stresses originating from the difference of the thermal expansion coefficients of the metal and the glass. Consequently, the magnetic properties could be modified by either heat treatment or chemical etching of the glass coating or by the selection of adequate chemical composition of the metallic nucleus.

Figure 1. Micrograph of a glass-coated microwire.

It is well known that the two-phase system consisting of nanocrystallites randomly distributed in a soft magnetic amorphous phase is an important group of soft magnetic materials. Yoshizawa and co-workers [9, 10] revealed that the presence of small additions of Cu and Nb to some FeSiB-based alloys can allow the creation of a two-phase material by partial devitrification of the conventional amorphous alloy. These materials are obtained by annealing the amorphous precursor in the range of 500–600 °C, 1 hour (i.e., at temperatures between partial and full crystallization processes). In this way, materials with different microstructures and magnetic properties can be obtained depending on the annealing parameters as well as on the chemical composition. It must be mentioned that most results have been reported mainly on ribbon shaped materials. After partial devitrification, the sample consists of small (around 10 nm grain size) nanocrystals embedded in the residual amorphous matrix. In addition, the devitrification process of these amorphous alloys (most typical composition  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{13.5}\text{B}_9$  with trademark *finemet*) leads to the possibility of obtaining rather different microstructures depending on the annealing parameters as well as on the chemical composition. Its outstanding magnetic softness has been explained by Herzer [10, 11] and is related to the ratio of the exchange correlation length or domain-wall thickness,  $L$ , to the orientation fluctuation length of randomly distributed local easy axes, which can be approximated as the average crystalline size  $D$ . For  $L \gg D$ , the macroscopic magnetic anisotropy averages out and the domain wall can move without being pinned. For some particular compositions, and for a critical crystallized volume fraction when the average magnetostriction vanishes, the magnetoelastic contribution to the macroscopic anisotropy also becomes negligible.

Few attempts have been done to fabricate glass-coated amorphous microwires of *finemet*-type [4–6, 13–15]. Particularly a decrease of coercivity,  $H_c$ , has been generally observed at annealing temperature,  $T_{\text{ann}}$ , below 600 °C. Such decrease of  $H_c$  has been ascribed to the structural relaxation of the material within its amorphous charac-

ter in a similar way as for metallic glass alloys in the shape of a ribbon [10–12]. A considerable hardening is then observed in  $\text{Fe}_{73.4}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_x\text{B}_{22.5-x}$  ( $x = 11.5, 13.5,$  and  $16.5$ ) microwires after treating at  $T_{\text{ann}}$  above 650 °C [13, 14]. This magnetic hardening irrespective of the amorphous nature of the alloy can be very useful for different technological applications such as information storage. Unfortunately, such magnetic hardening observed in conventional *finemet* compositions during the second recrystallization process is accompanied by a strong deterioration of mechanical properties [10–14]. But recently similar magnetic hardening has been observed at lower annealing temperature during the first recrystallization process [7, 15] allowing one in this way to avoid such brittleness.

On the other hand, granular systems based on immiscible (Co,Fe,Ni)–(Cu,Pt,Au,Ag) elements have been intensively studied in the last few years due to their potential technological applications. Such immiscible alloys exhibit peculiar magnetic transport properties as the giant magnetoresistance (GMR) effect and relative magnetic hardening which can be useful for various applications in magnetic recording and sensors [16–19]. These systems have been recently obtained by different routes such as sputtering, mechanical alloying, rapid solidification, etc. The samples obtained by these techniques have different shapes and geometry: thin films, powders, multilayers, and ribbons. The GMR effect and enhanced magnetic hardness have been observed for these materials consisting of ferromagnetic nanoparticles, usually of Co or Fe, embedded in a nonmagnetic metallic matrix (typically Cu, Au, or Ag). The high quenching rate characteristic of the melt spinning method has been used for fabrication of metastable crystalline materials where the crystalline phases, stable at high temperatures, can be quenched-in at room temperature. In this case, the GMR effect and enhanced coercivity were obtained after recrystallization of the metastable phases [20, 21]. At zero field, when magnetic moments of the particles are not aligned (e.g., oriented randomly), the resistivity of the material is high. When an external magnetic field aligns these moments, the resistivity decreases, as in the previously discovered multilayered GMR materials [18]. This effect is large and almost independent on the magnetic field direction [17, 19, 22]. (The maximum GMR amplitude of around 60% at ambient conditions was obtained in sputtered polycrystalline Co/Cu multilayers with (1, 1, 1) texture [23].)

It is noticeable that in the last few years the quenching and drawing technique has been developed to produce ferromagnetic microwire alloys of immiscible elements with magnetic and granular nature. Attempts have been done to fabricate and characterize the structure and the magnetic properties of glass-coated microwires produced from immiscible elements such as [(Co–Fe–Ni)–(Cu,Ag,Au,Pt)], which can be obtained from the decomposition of metastable and unstable phases of the so-called granular solids. The high quenching rate of the Taylor–Ulitsvski technique is useful for fabrication of metastable crystalline materials when the crystalline phases, stable at high temperature, can be quenched-in at room temperature [21, 24, 25].

The aim of this chapter is to present, first, the most relevant aspects concerning the fabrication process following by a section devoted to present significant results

on the remagnetization process, compositional dependence, and processing of glass-coated microwires with amorphous, nanocrystalline, and granular character in order to design their magnetic properties. The other section is devoted to the mechanical properties of glass-coated microwires.

## 2. CASTING METHOD

Microwires are manufactured by means of a modified Taylor–Ulitovsky process [3, 26–34] based on direct casting from the melt, as schematically depicted in Figure 2. In the laboratory process, a few grams of the master alloy with the desired composition is put into a glass (Pyrex, Nonex, etc.) tube and placed within a high frequency inductor heater. The alloy is heated up to its melting point, forming a droplet. While the metal melts, the portion of the glass tube adjacent to the melting metal softens, enveloping the metal droplet. A glass capillary is then drawn from the softened glass portion and wound on a rotating coil. At suitable drawing conditions, the molten metal fills the glass capillary and a microwire is thus formed where the metal core is completely coated by a glass shell. The amount of glass used in the process is balanced by the continuous feeding of the glass tube through the inductor zone, whereas the formation of the metallic core is restricted by the initial quantity of the master alloy droplet. The microstructure of a microwire (and hence its properties) depends mainly on the cooling rate, which can be controlled by a cooling mechanism when the metal-filled capillary enters into a stream of cooling liquid (water or oil) on its way to the receiving coil.

The main advantages of this method of microwire fabrication are:

- (i) repeatability of microwire properties in mass production;
- (ii) wide range of geometrical parameters and physical properties;
- (iii) fabrication of continuous, long pieces of microwire up to around 10,000 m;

**Figure 2.** Schematic drawing of microwire fabrication process by the Taylor–Ulitovsky method. Reprinted with permission from [34], V. S. Larin et al., *J. Magn. Magn. Mater.* 249 39 (2002). © 2002, Elsevier Science.

- (iv) control and adjustment of geometrical parameters (inner metallic nucleus diameter and glass thickness) during the fabrication process

The casting process is carried out at a temperature that melts the alloy and softens the glass tube.

### 2.1. Fabrication Process and its Limitations

#### 2.1.1. Casting Rate

There are several factors affecting the casting rate. This rate is limited, first, by the ability of metal to follow the moving glass. Its actual limit can be calculated by assuming that it is necessary to accelerate the initially still molten metal and glass up to the operating rates [31, 32]. A force,  $F$ , must then be imposed to the metal to fill the capillary. Assuming a conical shape at the end of the glass capillary, the casting rate,  $V_c$  (which corresponds to the average speed of the accelerated metal  $\langle dz/dt \rangle$ ), is found from the balance between the work done by this force and the kinetic energy of metal filling the capillary,

$$(v\rho)V_c^2/2 = Fz \quad (1)$$

where  $v = \pi z(R^2 + r^2 + Rr)/3$  is the volume of the conical portion in Figure 3 (geometrical parameters are given there), and  $d_m$  is the density of metal. The value of  $r$  is determined by the final size of the metal core. The limit of the casting rate,  $V_c^*$ , can be obtained from (1), where  $F$  coincides with the adhesion force  $F_a$  for metal/glass interface:

$$V_c^* = \sqrt{\frac{6F_a}{\pi d_m (R^2 + r^2 + Rr)}} \quad (2)$$

Thus, the limiting rate of casting grows with an increase in the adhesion for a given metal/glass pair and drops with an increase in the core radius.

**Figure 3.** Maximum value of the diameters of the metallic nucleus to obtain microwire (FeSi system) with amorphous microstructure for a range of glass-coating thickness. Reprinted with permission from [34], V. S. Larin et al., *J. Magn. Magn. Mater.* 249, 39 (2002) © 2002, Elsevier Science.

The limiting casting rate associated with the dynamical viscosity of the glass (which is a function of temperature) and the acceleration of moving glass can be represented as

$$F = F_\eta(T) + F_a \quad (3)$$

$$F_\eta(T) = k(T)\eta(T)V_c S_{gl}/h \quad (4)$$

where  $F_\eta(T)$  is the tensile force acting on the microwire, which is related to the dynamical adhesion of glass at casting temperature,  $F$  is the total force,  $k(T)$  is the coefficient of resistance to fluidity,  $\eta(T)$  is the dynamical viscosity,  $S_{gl}$  is the cross-section of the glass coating,  $h$  is the length of the stretching path, and  $F_a$  is the force related to the acceleration of the glass portion. Thus, taking into account Eqs. (3) and (4), the limiting rate  $V_c^*$  is

$$V_c^* = 1/(k(T)\eta(T)S_{gl} + F_a)^{1/2} \quad (5)$$

### 2.1.2. Diameter of a Microwire

Typical limits for the metallic core diameter are between 0.8 and 30  $\mu\text{m}$ , while the thickness of the coating ranges between 2 and 15  $\mu\text{m}$ . It should be noted that even during the stationary casting process, there is some variation (although not large) in diameter of the metallic nucleus and in the glass coating thickness along the wire length. The experimental evaluation of this variation in terms of the diameter of metallic nucleus and the total diameter as a function of the sample length is shown in Figure 4 for the case of Fe–Si–B/Pyrex microwire.

The geometrical characteristics of the microwire depend on the physical properties of the glass and metal, the diameter of the initial glass tube, and the parameters of the heating inductor. It has been proved that the strongest effect on the geometry of a microwire comes from the glass properties. Therefore, the radius of the metal core is estimated to be [31–34]

$$r_m = 0,9 \left( \frac{\eta^5}{\sigma^2 v_\lambda} \right)^{\frac{1}{3}} \frac{1}{d} \frac{\eta^5}{\sigma^2 v_\lambda} f(v, \eta, \sigma, d_l) \quad (6)$$

with  $\eta$  as

$$\eta = 6\sqrt{6\rho} \left( \frac{\omega^2}{N_0} \right)^{\frac{1}{3}} M^{-5/6} d^{4/3} T^{1/2} \left( \cosh \frac{2\lambda_i^0}{\gamma R T} - 1 \right) \quad (7)$$

**Figure 4.** Variation of the diameter of the metallic nucleus (marked as Metal) and of the total diameter (marked as Glass) with the sample length in the case of Fe–Si–B–Pyrex microwire. Reprinted with permission from [34], V. S. Larin et al., *J. Magn. Magn. Mater.* 249, 39 (2002). © 2002, Elsevier Science.

where  $R$  is the universal gas constant,  $\omega$  is the internal volume of molecules in liquid per gram-molecule,  $N_0$  is the Avogadro constant,  $\lambda_i^0$  is the internal hidden evaporation heat per gram-molecule,  $\gamma$  is the coordination number,  $M$  is the molecular weight,  $\sigma$  is the surface tension,  $\rho$  is the curvature radius of the surface in the transition area between the liquid drop and microwire,  $d_l$  is the density of liquid,  $f(v, \eta, \sigma, d)$  is a factor which can be experimentally evaluated (it depends weakly on the casting rate), and

$$v_\lambda = \frac{2\nu r_w^2}{\sqrt{3}\rho^3} \pm \sqrt{\left( \frac{2\nu r_w^2}{\sqrt{3}\rho^3} \right)^2 - \frac{2\sigma}{r_w d_l}} \quad (8)$$

where  $\nu = \eta/d_l$  is the kinematical density and  $r_w$  is the total microwire radius. Taking Eqs. (1) to (8), it can be concluded that there exists a limiting casting rate for fabricating a microwire with the smallest possible diameter.

The limit for the upper diameter limit can be obtained at low casting rates, since the contribution of  $v_\lambda^2/2$  is neglected, yielding

$$r_{m,\max} = \left( \frac{\sqrt{3}\sigma}{2\nu d_l} \right)^{1/3} \frac{\rho}{v_\lambda^{1/3}} \quad (9)$$

Thus, the diameter of a microwire produced by the Taylor–Ulitovsky method has both upper and lower limits depending on the rate of casting.

### 2.1.3. Composition of the Metal Core

The present method allows preparation of pure metals such as Ag, Au, Cu, Ni, Sn, Pb, and Pt. Semiconductors such as Ge, Si, or Bi can also be cast. The alloys of these metals can be also processed, but not over the whole range of compositions. For example, the content of Cr in Ni and Co based alloys can be up to 20%; the content of Mo, W, V in Ni, Co, and Fe based alloys can be up to 8–10 at%. Some limitations relate to the melting temperature, which must not be too high. On the other hand, rare earth metals and metals which react with the glass and atmosphere (Ti, Cr, Mo, W, Nb, Al, Na, La, Nd) are not suitable for this technology.

Of principal interest is the fabrication of magnetic microwires with soft magnetic characteristics for which Fe, Ni, and Co are the main elements of the alloy. In the case of amorphous microwire, elements such as Si, B, C, and Al are added to enable the amorphicity of the alloys.

Metastable supersaturated solid solutions can be obtained for immiscible metal systems in a solid and even liquid state, such as Cu–Co, Cu–Co–Ni, Ag–Fe, Ag–Co. As-cast microwire can exhibit a structure of a supersaturated solid solution of transition metals in Cu or Ag. After suitable thermal treatments small single domain particles of Co or Fe can precipitate.

An overview of the metallic alloy compositions is presented in Table 1.

## 2.2. Microstructure of Cast Microwires

The properties of microwires are related to a great extent to the microstructure, geometry, and chemical composition of the metallic nucleus. The analyzed method of casting

**Table 1.** Glass coated microwires.

Material	Diameter of core ( $\mu\text{m}$ )	Total diameter ( $\mu\text{m}$ )	Characteristics
Silver (Ag)	2–30	12–36	$\rho = 0.020 \text{ Ohm/mm}^2\text{m}$ TRC = 3000 1/grad $10^6$
Gold (Au)	2–25	12–32	$\rho = 0.035 \text{ Ohm/mm}^2\text{m}$ TRC = 3200 1/grad $10^6$
Copper (Cu)	1–30	10–36	$\rho = 0.022 \text{ Ohm/mm}^2\text{m}$ TRC = 3000 1/grad $10^6$

offers the possibility of rapid cooling and solidification of liquid metal in a nonequilibrium process, allowing the formation and existence of metastable metallic phases. The microstructure of rapidly cooled metal depends on its chemical composition, the melting temperature of metal, and the cooling rate. Depending on the critical cooling rates, different metastable phases can be formed (i.e., supersaturated solid solution, microcrystalline, nanocrystalline, granular and amorphous phases). In certain cases, a mixed microstructure consisting of nano- or microcrystals embedded in the amorphous matrix can be formed as well.

### 2.2.1. Cooling Rate of the Metallic Nucleus

The cooling rate  $V_t$  depends both on the geometry of the microwire (i.e., diameter  $d$  of the metallic nucleus and thickness  $t$  of the glass coating) and on the parameters of the technological process related to thermal conductivity [31],

$$V_t = \alpha(T_2 - T_k)(d + t)/[(\rho_m d^2 C_m + \rho_g C_g)(dt + t^2)] \quad (10)$$

where  $\rho_m$ ,  $\rho_g$ ,  $C_m$ ,  $C_g$  are the density and specific heat of metal and glass, respectively,  $T_k$  is the temperature of the cooling liquid,  $\alpha$  is thermoconductivity parameter at the boundary microwire/cooling medium, and  $T_2$  is the temperature of the metal when entering the cooling zone. The value of  $T_2$  can be deduced from

$$T_2 = \alpha^* T_1 \exp[1/Vl(T_1 - T_a)]/h \quad (11)$$

where  $T_1$  is the temperature at the base of the droplet,  $T_a$  is the air temperature,  $V$  is the casting rate, and  $\alpha^*$  is a

heat transmission parameter at the movement of a cylinder in the gaseous medium. The characteristic cooling rates of the metallic nucleus in the gaseous medium ranges from  $10^2$  to  $10^4 \text{ K}^{-1}$ , whereas in a stream of liquid it ranges between  $10^5$  and  $10^7 \text{ K}^{-1}$ .

### 2.2.2. Metastable Phases in Cast Microwire

Various types of metallic alloys of metastable systems can be prepared by increasing the cooling rate (the so-called quenching rate). In principle, phase diagram of metal–metaloid, metal–metal eutectic type, and alloys with a limited solidification range in a solid state have a significant role.

The "critical quenching rate,"  $V_{cr}$ , is

$$V_{cr}^* = (T_l - T_g)/t \quad (12)$$

where  $T_l$  and  $T_g$  are the liquids and devitrification temperatures respectively, and  $t$  is the maximum time at which any part of the material quenches from  $T_l$  to  $T_g$ . A "critical quenching rate" can be defined as the minimum quenching rate necessary to obtain any metastable structure at a given thermal exchange coefficient. The critical quenching rate can be characterized by the maximum metallic nucleus diameter (at a given glass-coating thickness and thermal exchange coefficient,  $\alpha$ ) at which any of the metastable phases can be obtained.

As an example, Figure 4 illustrates the maximum diameters of the metallic nucleus necessary to obtain a microwire in order for the FeB system to exhibit an amorphous

microstructure. Microwires with diameters below the corresponding curves are obtained in an amorphous state.

### 3. MAGNETIC BEHAVIOR

#### 3.1. Amorphous Glass-Coated Microwires

In fact studies of magnetic properties of amorphous glass coated microwires started even in the 1970s [35], but recently these tiny glass-coated ferromagnetic wires have been rediscovered mainly due to a number of unusual magnetic properties and their potential applications [4–7].

Hysteresis loops of three main families of amorphous microwires—Fe-rich (positive magnetostriction constant,  $\lambda_s$ ), Co-rich (negative  $\lambda_s$ ), and Co–Mn (nearly zero  $\lambda_s$ )—are shown in Figure 5 a–c, respectively. As can be observed, the shape of the hysteresis loops as well as the magnetic properties (coercivity,  $H_c$ , magnetic anisotropy field, magnetic permeability) depend drastically on the composition of the sample.

Mainly attention has been paid to the studies of samples with positive magnetostriction constant (Fe-rich compositions) exhibiting perfectly rectangular hysteresis loops (so-called magnetic bistability) and to nearly-zero magnetostriction compositions with good magnetic softness (Co-rich compositions). It must be noted that such magnetic behavior is drastically determined by the strong and complex internal stresses acting on the metallic nucleus due to the glass coating. In fact, investigations on the progressive elimination of the glass insulating coating by chemical etching on magnetic properties [36, 37] showed considerable change of the soft magnetic behavior as the thickness of glass coating has been diminished.

**Figure 5.** Hysteresis loops of  $\text{Fe}_{70}\text{B}_{15}\text{Si}_{10}\text{C}_5$  ( $\lambda_s > 0$ ),  $\text{Co}_{75}\text{Si}_{10}\text{B}_{15}$  ( $\lambda_s < 0$ ), and  $\text{Co}_{68}\text{Mn}_7\text{Si}_{10}\text{B}_{15}$  ( $\lambda_s \approx 0$ ) microwires. #### 3.1.1. Magnetic Bistability

As can be observed in Figure 6, the switching field,  $H_s$ , that is, the magnetic field required to reverse magnetization (so observing a rectangular hysteresis loop), increases and the remanent magnetization decreases for the same metallic nucleus composition ( $\text{Fe}_{65}\text{B}_{15}\text{Si}_{15}\text{C}_5$ ) with decreasing of the geometric ratio  $\rho (=r/R)$  (where  $r$  is metallic core radius and  $R$  is total radius). Such an increase of the switching field has been attributed to the increasing strength of internal stresses as well as increasing glass coating thickness. The switching field,  $H_s$ , should be proportional to the energy required to form the domain wall  $\gamma$  involved in the bistable process. The wall energy is related to the magnetoelastic anisotropy and, therefore, to the applied tensile stress as given by [38]

$$H_s \approx \gamma \propto [3A\lambda_s(\sigma_a + \sigma_r)]^{1/2} / \cos \alpha \quad (13)$$

where  $\alpha$  is the angle between magnetization and axial direction,  $A$  is the exchange energy constant,  $\lambda_s$  is the saturation magnetostriction constant, and  $\sigma_r$  is the residual tensile stress. Consequently,  $H_s$  must be proportional to  $(\sigma_a + \sigma_r)^{1/2}$  for  $\cos \alpha \approx 1$ . On the other hand, it was shown [39, 40] that the strength of the internal stresses increases as decreasing the ratio  $\rho$ .

From the rectangular shape of the hysteresis loop it should be suggested that the remagnetization process of such microwires is controlled by the nucleation or depinning and consequent fast domain wall propagation inside the single domain inner core of the metallic nucleus.

Temperature and field dependencies of the domain wall propagation velocity,  $v$ , have been measured in  $\text{Fe}_{65}\text{B}_{15}\text{Si}_{15}\text{C}_5$  amorphous microwire exhibiting rectangular hysteresis loops ( $H_s = 110 \text{ A/m}$ ) with diameter of the metallic nucleus around  $14 \mu\text{m}$  and length  $120 \text{ mm}$  (see Fig. 7) [41]. The measured values of  $v$  were found to be between 35 and 65 m/s. A slight increase of the domain wall velocity is observed as the measuring temperature increases from 5 to 300 K. Observed domain wall velocity was found to be much higher than in Ni single crystals ( $0.0001 \leq v \leq 10 \text{ m/s}$ )

**Figure 6.** Effect of ratio  $\rho$  on hysteresis loop of  $\text{Fe}_{70}\text{B}_{15}\text{Si}_{10}\text{C}_5$  ( $\lambda_s > 0$ ) microwire. (a)  $\rho = 0.63$ ; (b)  $\rho = 0.62$ ; (c)  $\rho = 0.48$ ; (d)  $\rho = 0.26$ ; (e)  $\rho = 0.16$ . Reprinted with permission from [4] M. Vázquez and A. Zhukov, *J. Magn. Magn. Mater.* 160, 223 (1996). © 1996, Elsevier Science.

**Figure 7.** Effect of temperature and magnetic field on velocity of domain wall propagation of  $\text{Fe}_{65}\text{B}_{15}\text{Si}_{15}\text{C}_5$  microwire. Reprinted with permission from [40], A. Zhukov, *Appl. Phys. Lett.* 78, 3106 (2001). © 2001, American Institute of Physics.

[42] but lower than in FeSiB amorphous wires prepared by quenching into water ( $150 \leq v \leq 500$  m/s) [43]. Like in the case of Ni single crystals, significant deviations from the linear field dependencies  $v(H)$  have been observed.

The values of the magnetic field given on the horizontal axis in the Figure 7 are lower than the switching field. This means that after overcoming this first highest energy barrier corresponding to the domain wall nucleation, the domain wall propagates even in a field lower than the switching field (i.e., that the nucleation field is higher than the propagation field). The critical magnetic field,  $H_{cr}$ , actually can be obtained by the extrapolation of the curves that will be presented in Figure 9 at  $v = 0$ . This extrapolation gives values of  $H_{cr}$  around 5–10 A/m, which are one order of magnitude lower than the switching field.  $H_{cr}$  can be interpreted as the intrinsic coercivity of the material and characterizes the efficiency of the obstacles for the domain wall propagation. On the other hand, it was shown that the reversed domains already exist at the wire ends [44] due to the effect of the demagnetizing fields [45]. Therefore, one can assume that the appearance of the large Barkhausen jump should be related to the depinning of domain walls of such closure domains (i.e., to the critical size achieved by one of the reversed domains under the effect of the applied magnetic field).

### 3.1.2. Effect of Thermal Treatments (Tailoring of the Magnetic Properties)

In the vicinity of the zero magnetostriction alloy composition the hysteretic magnetic properties depend strongly on the metallic alloy composition, such as shown in Figure 8. The shape of the hysteresis loop of the sample with  $x = 0.08$  (Fig. 8a) suggests the presence of a transverse magnetic anisotropy. The initial magnetic permeability,  $\mu_{15}$ , estimated from the hysteresis loop is around 60 and the coercivity  $H_c \approx 5$  A/m. The sample with  $x = 0.09$  (Fig. 8b) exhibits a rather good combination of relatively low values of coercivity ( $H_c \approx 5$  A/m) and relatively high initial magnetic permeability ( $\mu_{15} \approx 2000$ ). The sample with  $x = 0.10$  (Fig. 8c) has a rectangular hysteresis loop (labeled as magnetic bistable behavior). This sample has  $H_c \approx 25$  A/m and relatively low magnetic permeability at magnetic field below coercivity ( $\mu_{15} \approx 1-10$ ).

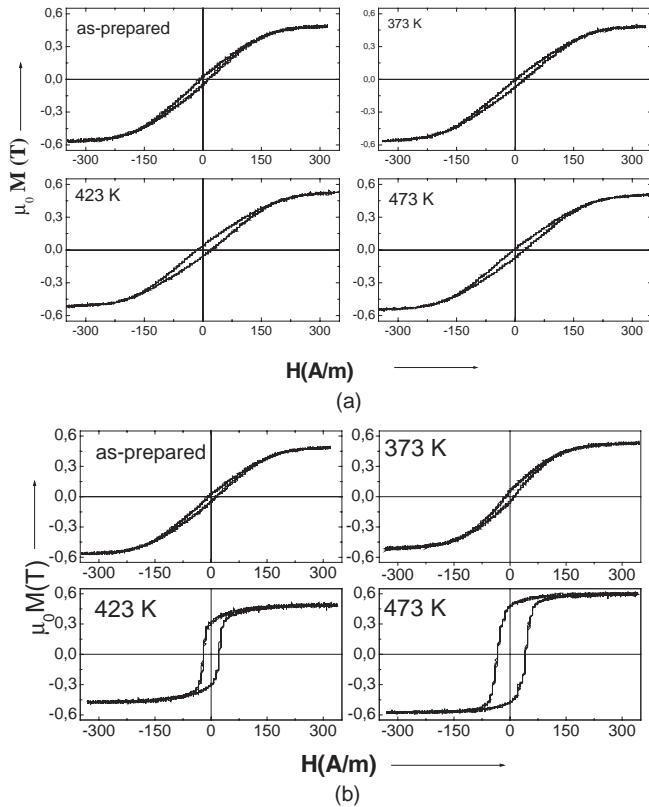

**Figure 8.** Effect of composition on hysteresis loop of  $(\text{Co}_{1-x}\text{Mn}_x)_{75}\text{Si}_{10}\text{B}_{15}$  ( $x = 0.08-0.11$ ) microwires. Reprinted with permission from [7], A. Zhukov, *J. Magn. Magn. Mater.* 242–245, 216 (2002). © 2002, Elsevier Science.

It is worth mentioning that as in the case of amorphous ribbons heat treatment especially in the presence of the external magnetic field and/or applied stress significantly affects the magnetic behavior of amorphous magnetic materials [46, 47]. Therefore similar studies have been performed in glass coated microwires.

Series of different treatments up to 473 K, such as conventional annealing (CA) and magnetic field annealing (FA), have been performed in the samples with  $x = 0.08$  [37]. Figure 9a shows as an example the hysteresis loops obtained for the sample  $x = 0.08$  after heat treatments at 373, 423, and 473 K. The conventional low-temperature thermal treatments (CA) (in the range of 373–473 K, 1 hour) produce small changes in the coercive field, which can be ascribed to the relaxation of internal stresses within the amorphous state. Nevertheless, when the thermal treatment was carried out under the presence of an axial magnetic field (FA), significant changes of the hysteresis loop were detected (see Fig. 9b). This change produces an increase of the initial permeability,  $\mu_i$ , coercivity,  $H_c$ , and remanent magnetization,  $\mu_0 M_r$ , and a decrease of the anisotropy field,  $H_K$  (see Fig. 10a). The changes of the shape of the hysteresis loop with FA should be connected to the induction of magnetic anisotropy with easy axis along the longitudinal direction of the microwire. This anisotropy is developed by the combined effect of the high internal stress and the magnetic field applied during the treatment [37, 46, 47].

Similarly to conventional furnace annealing, current annealing could be used for the tailoring of the magnetic properties of amorphous microwires [48, 49]. Dependencies of coercivity on the annealing time,  $t_{ann}$ , for CA and FA with current density 227 A/mm<sup>2</sup> for three microwires are shown in Figure 11. In the case of the  $\text{Fe}_{70}\text{B}_{15}\text{Si}_{10}\text{C}_5$  microwire, both treatments (CA, FA) at 30 mA ( $j = 227$  A/mm<sup>2</sup>) caused a decrease of  $H_c$  with  $t_{ann}$ . In the case of FA, such a decrease of coercivity is more significant. In contrast, in the case of  $\text{Co}_{56.5}\text{Fe}_{6.5}\text{Ni}_{10}\text{B}_{16}\text{Si}_{11}$  samples, both treatments result in

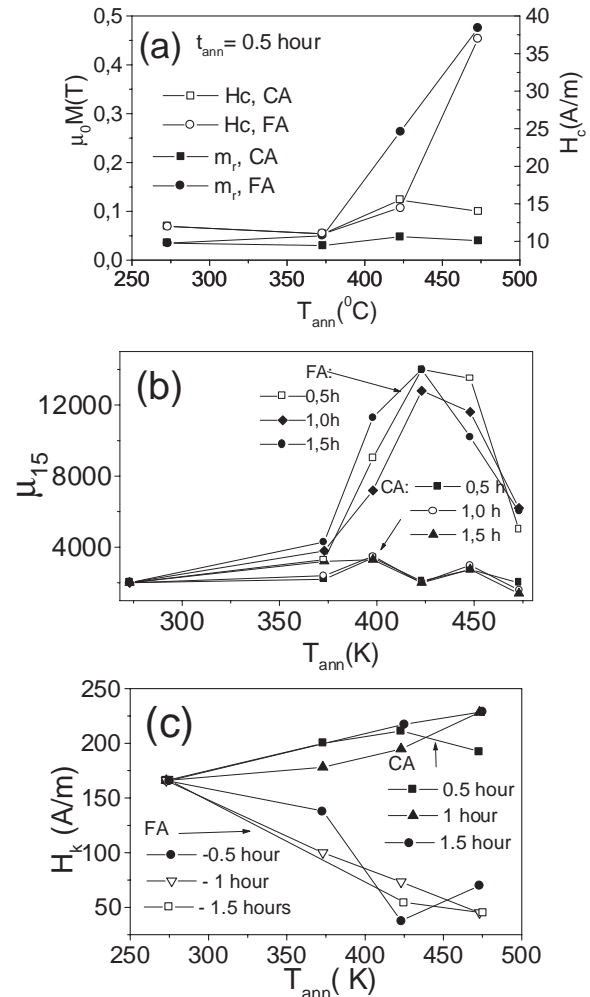

**Figure 9.** Effect of conventional (a) and magnetic field annealing (b) on hysteresis loops of  $(\text{Co}_{0.92}\text{Mn}_{0.8})_{75}\text{Si}_{10}\text{B}_{15}$  microwire at different annealing temperatures. Reprinted with permission from [36], A. Zhukov et al., *J. Appl Phys.* 87, 1402 (2000). © 2000, American Institute of Physics.

opposite effects [48]. CA treatment gives rise to a roughly monotonic decrease of the coercivity, while FA results in an increase of  $H_c$ , with a broad maximum at  $t_{\text{ann}} \approx 10$  min. Similarly to  $\text{Fe}_{70}\text{B}_{15}\text{Si}_{10}\text{C}_5$  samples, a monotonic decrease of  $H_c$  has been observed for the  $\text{Co}_{68}\text{Mn}_7\text{Si}_{10}\text{B}_{15}$  sample after both CA and FA treatments. Besides, as in the case of the  $\text{Co}_{56.5}\text{Fe}_{6.5}\text{Ni}_{10}\text{B}_{16}\text{Si}_{11}$  sample, the FA current annealing treatment results in higher  $H_c$ , as compared to the CA treatment.

The observed difference between the CA and FA should be attributed to the effect of the stress+longitudinal field induced magnetic anisotropy in the last case, where the strong internal stresses contribute as the reinforcing factor. This feature implies that the application of the longitudinal magnetic field during annealing favors the formation of the internal axially magnetized core with longitudinal magnetic anisotropy. In the mean time, the CA results only in internal stress relaxation.

### 3.1.3. Soft Magnetic Behavior and GMI Effect

Transformation of a rectangular hysteresis loop into a flat and almost unhysteretic loop is observed in nearly zero magnetostrictive compositions (Fig. 8) in the series of  $(\text{Co}_{1-x}\text{Mn}_x)_{75}\text{Si}_{10}\text{B}_{15}$  ( $x = 0.08, 0.09$ , and  $0.10$ ) microwire compositions (Fig. 8 a–c) with  $x$  increasing from 0.08 to 0.10. Careful selection of the metallic alloy composition permits

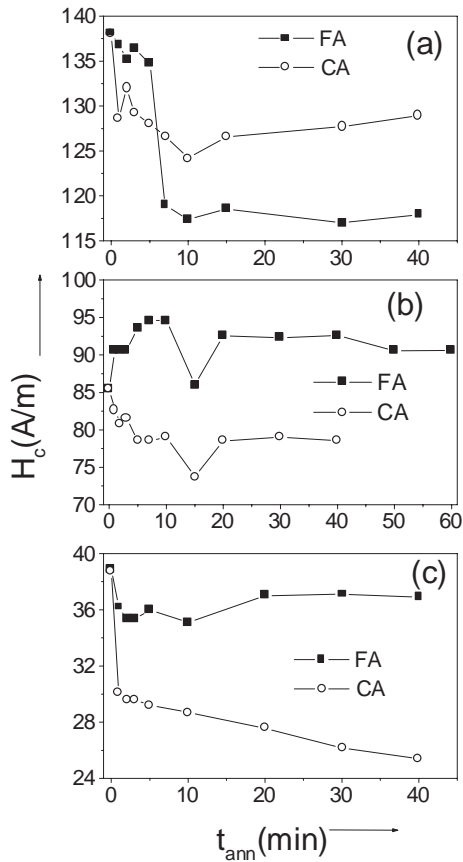

**Figure 10.** Effect of magnetic field annealing on some magnetic properties of  $\text{Co}_{69}\text{Mn}_6\text{Si}_{10}\text{B}_{15}$  microwires: initial magnetic permeability,  $\mu_{15}$  (a), anisotropy field,  $H_k$  (b), and coercivity and remanent magnetization (c). Reprinted with permission from [36], A. Zhukov et al., *J. Appl Phys.* 87, 1402 (2000). © 2000, American Institute of Physics.

one to obtain the sample with enhanced magnetic softness and small magnetic anisotropy (the sample with  $x = 0.09$  is an example).

The very soft magnetic behavior of CoMnSiB microwires makes them very interesting to investigate the magnetoimpedance effect. A high GMI has been observed in  $\text{Co}_{68.5}\text{Mn}_{6.5}\text{Si}_{10}\text{B}_{15}$  microwire annealed at  $100^\circ\text{C}$  for 1 hour (see Fig. 12a). A maximum GMI ratio,  $(\Delta Z/Z)_m$ , as well as a field of maximum,  $H_m$ , increases with the frequency of the driving current,  $f$  (see Fig. 12a) [50]. This GMI effect is extremely sensitive to the application of external tensile stresses: magnetic field,  $H_m$ , corresponding to the maximum of  $(\Delta Z/Z)$  shows a roughly linear increase with  $\sigma$  (Fig. 12b). The origin of this dependence should be related to the change of the domain structure inside the outer shell with circular orientation. As is well known, applied stress introduces a magnetoelastic anisotropy contribution which plays a very important role in the magnetization process of the metallic nucleus, even in this microwire

**Figure 11.** Comparative evolution of  $H_c$  with annealing time for CA and FA of  $Fe_{70}B_{15}Si_{10}C_5$  (a),  $Co_{56.5}Fe_{6.5}Ni_{10}B_{16}Si_{11}$  (b), and  $Co_{68}Mn_7Si_{10}B_{15}$  (c) microwires annealed at  $j \approx 227$  A/mm<sup>2</sup> with the annealing time,  $t_{ann}$ , as a parameter. Reprinted with permission from [47], V. Zhukova et al., *J. Non-Cryst. Solids* 287, 31 (2001). © 2001, Elsevier Science.

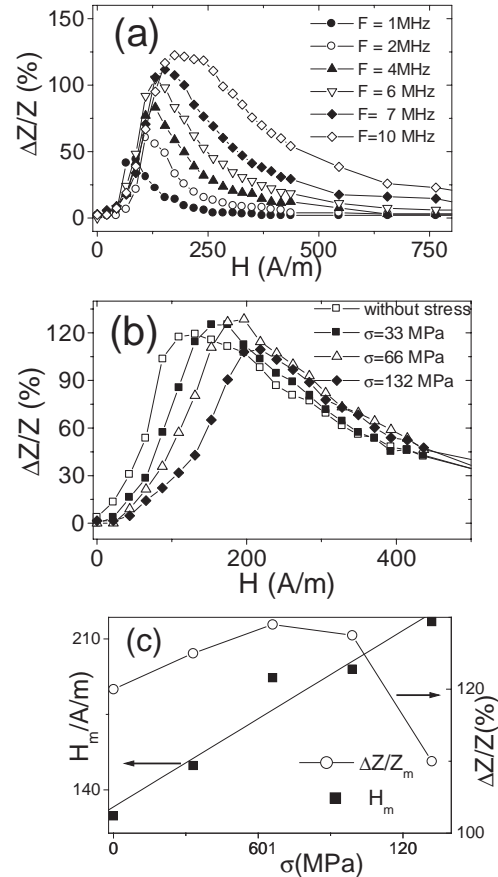

exhibiting an extremely low magnetostriction constant (of around  $-3 \times 10^{-7}$ ) [51–53].

It is remarkable to mention that according to [54, 55], the value of the dc axial field that corresponds to the maximum GMI ratio,  $H_m$ , should be attributed to the static circular anisotropy field,  $H_k$ . This argument allows us to estimate the magnetostriction constant using the dependence  $H_m(\sigma)$  presented in Figure 12c and the well-known expression for the stress dependence of anisotropy field [56]:

$$\lambda_s = (\mu_0 M_s/3)(dH_k/d\sigma) \quad (14)$$

The  $H_m(\sigma)$  dependence (see Fig. 12c) is roughly linear with a slope of around 0.7 A/(m×MPa), which allows an estimation of the unstressed value of the saturation magnetostriction constant,  $\lambda_{s,0}$ . We have found that  $\lambda_{s,0} \approx -2 \times 10^{-7}$ , which is rather reasonable in comparison with the recently reported values measured from the stress dependence of initial magnetic susceptibility ( $\lambda_{s,0} \approx -3 \times 10^{-7}$  for such composition) [51, 53].

Both hysteresis loop and GMI effect also depend on the internal stresses induced by the glass coating. The strength of such internal stresses depends on the glass-coating thickness, increasing with an increase of the relative volume of

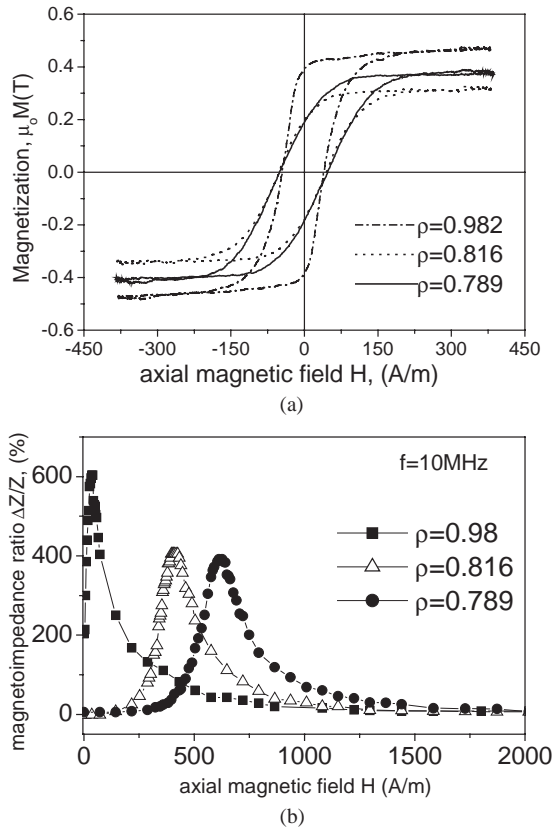

**Figure 12.** Effect of the frequency  $f$  (a) and applied stresses (b) on  $\Delta Z/Z$  ratio of  $Co_{68.5}Mn_{6.5}Si_{10}B_{15}$  amorphous microwire and dependence of  $H_m$  and  $\Delta Z/Z$  on applied stresses (c). Reprinted with permission from [7], A. Zhukov, *J. Magn. Magn. Mater.* 242–245, 216 (2002). © 2002, Elsevier Science.

the glass. Bulk hysteresis loops of three magnetically soft glass-coated  $Co_{67}Fe_{3.85}Ni_{1.45}B_{11.5}Si_{14.5}Mo_{1.7}$  microwires with different geometric ratios  $0.78 \leq \rho \leq 0.98$  are shown in Figure 13a. As can be observed in this figure, the magnetic anisotropy field,  $H_k$ , increases with decreasing ratio  $\rho$  (i.e., with the increase of the glass-coating thickness).

The  $(\Delta Z/Z)(H)$  dependencies measured at  $f = 10$  MHz and  $I = 0.75$  mA for the samples with ratios  $\rho = 0.98, 0.816,$  and  $0.789$  are presented in Figure 13b. A maximum relative change in the GMI ratio,  $\Delta Z/Z$ , up to around 615% is observed at  $f = 10$  MHz and  $I = 0.75$  mA in the sample with  $\rho \approx 0.98$  (see Fig. 13b) [7, 57].

As may be seen from Figure 13, the field corresponding to the maximum of the GMI ratio,  $H_m$ , increases and  $(\Delta Z/Z)_m$  decreases with  $\rho$ . Such  $H_m(\rho)$  dependence should be attributed to the effect of the above-mentioned internal stresses,  $\sigma$ , on the magnetic anisotropy field. Indeed, the value of the dc axial field corresponding to the maximum of the GMI ratio,  $H_m$ , should be attributed to the static circular anisotropy field,  $H_k$  [56]. The estimated values of the internal stresses in these amorphous microwires are of the order of 1000 MPa, depending strongly on the thickness of glass coating and metallic nucleus radius [5, 40]. Such elevated internal stresses give rise to a drastic change of the magnetoelastic energy,  $K_{me} \approx 3/2\lambda_s\sigma_i$ , even for

**Figure 13.** Effect of the geometrical parameter  $\rho$  on hysteresis loop (a) and  $\Delta Z/Z(H)$  dependencies (b) of  $\text{Co}_{67,05}\text{Fe}_{3,85}\text{Ni}_{1,4}\text{B}_{11,55}\text{Si}_{14,5}\text{Mo}_{1,65}$  microwires. small changes of the glass-coating thickness at fixed metallic nucleus diameter. Consequently, such change of the ratio  $\rho$  should be related to the change of the magnetostriction constant according to Eq. (14).

**3.1.4. Magnetoelastic Properties**

The behavior of coercivity and remanence with applied tensile stress depends strongly on the microwire composition and geometrical characteristics exhibiting a quite different character for Fe- and Co-rich compositions (Fig. 14). Generally, a proportionality of the switching field,  $H_s$ , to the square root of the applied stresses has been observed in Fe-rich compositions, as predicted by Eq. (20) (Fig. 14a).  $H_s(\sigma)$  dependence in Co-rich  $(\text{Co}_{1-x}\text{Mn}_x)_{75}\text{Si}_{10}\text{B}_{15}$  ( $x = 0.08-0.11$ ) microwires with small positive magnetostriction constant is quite different from Fe-rich microwires [7]. Besides, the evolution of  $H_s(\sigma)$  depends also on the composition.

In fact, some increase of the coercivity  $H_c$  with  $\sigma$  after initial roughly independent behavior has been observed for  $x = 0.11$  (Fig. 14b). The sample  $(\text{Co}_{0,9}\text{Mn}_{0,1})_{75}\text{Si}_{10}\text{B}_{15}$  with an initially rectangular hysteresis loop shows a decrease of the coercivity and the remanent magnetization with  $\sigma$  and, finally, loses the magnetic bistability after application of certain  $\sigma$  (Fig. 14c).

The estimations of the magnetostriction constant were based on the variation of the initial magnetic permeability

**Figure 14.** Effect of microwire composition on stress dependence of coercivity:  $\text{Fe}_{65}\text{B}_{15}\text{Si}_{15}\text{C}_5$  (a);  $(\text{Co}_{1-x}\text{Mn}_x)_{75}\text{Si}_{10}\text{B}_{15}$  with  $x = 0.11$  (b);  $x = 0.09$  (c); and stress dependence of the magnetostriction constant for  $x = 0.09$  (d). Reprinted with permission from [7], A. Zhukov, *J. Magn. Mater.* 242–245, 216 (2002). © 2002, Elsevier Science.

with tension in such microwires [56]. According to this method, the magnetostriction constant,  $\lambda_s$ , can be evaluated from the relation

$$\lambda_s = -(\mu_0 M_s^2/3)d(\chi_i^{-1})/d\sigma \quad (15)$$

where  $M_s$  is the saturation magnetization,  $\chi_i$  is the initial magnetic susceptibility, and  $\sigma$  is the applied tensile stress.

The dependence of  $\lambda_s(\sigma)$  for the samples with 0.09 is shown in Figure 14d. It should be noted that the observed evolutions have mostly an illustrative character, since the level of the magnetic response from a single microwire is quite small. The sample with  $x = 0.09$  exhibiting a positive magnetostriction constant shows also a decrease of the  $\lambda_s$  with  $\sigma$  and even changes its sign at certain  $\sigma$  (around 200 MPa).

The stress dependence of the magnetostriction constant,  $\lambda_s$  (Fig. 14d), allows one to ascribe positive values of the

order of  $10^{-7}$  for the magnetostriction constant in the sample with  $x \geq 0.09$ . Such as was found in other amorphous materials, the application of tensile stresses results in a decrease of the  $\lambda_s$  in the case of positive magnetostriction constant which even can change the sign of  $\lambda_s$  in the sample with  $x = 0.09$  when  $\sigma$  reaches some certain value (see Fig. 14d). In fact it was experimentally found in nearly zero magnetostrictive amorphous ribbons [58] that

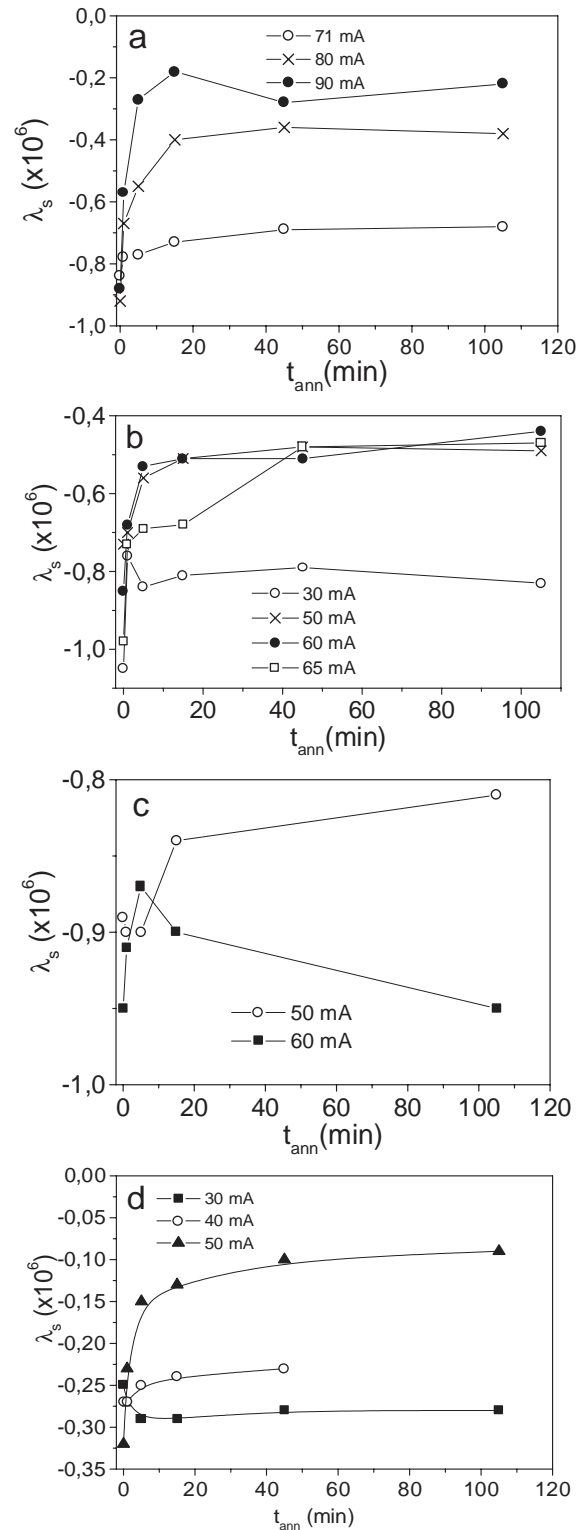

$$\lambda(\sigma) = \lambda(0) - B\sigma \quad (16)$$

where  $\lambda(0)$  is the saturation magnetostriction constant without applied stresses and  $B$  is a positive coefficient of the order of  $10^{-10}$  (MPa) $^{-1}$ . For magnetostriction  $\lambda(0)$  of about  $1 \times 10^{-7}$  a stress of around  $10^3$  MPa needs to be applied to reach compensation of magnetostriction [56, 58, 59]. In fact, internal stresses induced during the preparation can reach values which indicate that high quenched-in internal stresses seem to be able to change effectively the value of the magnetostriction constant [60].

The small angle magnetization rotation method [61] also has been successfully applied to estimate the magnetostriction constant of Co-rich amorphous microwires exhibiting inclined hysteresis loops (i.e., with the magnetization rotation mechanism of the magnetization reversal) [60].

The microwires were submitted to current annealing at different annealing times,  $t_{\text{ann}}$ . The evolution of  $\lambda_s$  with the annealing time (the current,  $i$ , as parameter) for selected glass-coated amorphous microwires is presented in Figure 15a–d. As can be observed, all samples exhibit negative  $\lambda_s$  ranging between  $-0.9 \times 10^{-6}$  and  $-0.3 \times 10^{-6}$ . Under the effect of Joule heating, increasing both  $t_{\text{ann}}$  or  $i$ ,  $\lambda_s$  tends to increase approaching zero (see Fig. 15a–d). The general tendency of increasing of  $\lambda_s$  with  $t_{\text{ann}}$  and  $i$  should be attributed to the relaxation of the internal stresses during the annealing and consequently [see Eq. (22)] with the stress dependence of the  $\lambda_s$ . As has been mentioned, strong internal stresses have been predicted in glass-coated microwires due to a significant difference between the thermal expansion coefficients of the metallic nucleus and the glass coating [7]. Therefore one can expect an increase of the magnetostriction constant after annealing.

Similarly to the magnetostrictive behavior widely reported [58, 59] for amorphous ribbons and conventional wires of similar compositions, rather low magnetostriction values exhibited by annealed microwire samples could be explained assuming the existence of two kind of short ordering, namely: an ordered highly anisotropic phase centered at Fe atoms with uniaxial shape and magnetic anisotropy and with positive magnetostriction, mainly due to anisotropic exchange mechanism, and a disordered phase at Co-rich atoms with negative magnetostriction. If we also assume that the positive magnetostriction phase (Fe atoms) undergoes a first order transformation from the uniaxial structural units (low temperature phase) toward a more symmetric and less anisotropic structural unit (high temperature phase), this allows us to explain the general behavior of macroscopic average magnetostriction,  $\lambda_s^{\text{av}}$ , of such Co-rich alloys. In fact, for pure Co the magnetostriction at room temperature is  $-4 \times 10^{-6}$  and evolves with the temperature as expected from the single ion model. Therefore, the changes

**Figure 15.**  $\lambda_s(t_{\text{ann}})$  dependences for glass-coated amorphous  $\text{Co}_{57}\text{Fe}_{6.1}\text{-Ni}_{10}\text{B}_{15.9}\text{Si}_{11}$  (a),  $\text{Co}_{67.5}\text{Fe}_4\text{Ni}_{1.5}\text{B}_{14}\text{Si}_{12}\text{Mo}_1$  (b),  $\text{Co}_{69.1}\text{Fe}_{3.2}\text{Ni}_{14.8}\text{Si}_{9.9}$  (c), and  $\text{Co}_{69.5}\text{Fe}_{3.9}\text{Ni}_{12.8}\text{Si}_{10.8}\text{Mo}_2$  (d) microwires. Reprinted with permission from [60], V. Zhukova et al., *J. Phys.* 34, L113 (2002). © 2002.

of  $\lambda_s^{av}$  with the current annealing treatment repeated in this work on glass-coated amorphous microwires are assumed to be a consequence of the atomic rearrangements of topological character associated with both structural and stress relaxation processes. These processes would produce relative changes of the two mentioned volume fractions, so affecting the  $\lambda_s^{av}$ . In this way some peculiarities observed in Figure 15b–d can be roughly understood. It is worth mentioning that the high value of the internal stresses of these glass-coated microwires allows the thermal treatments to be considered as a stress annealing and, consequently, they could develop an uniaxial magnetic anisotropy [37, 53], which should play an important role on the magnetostrictive behavior. Particularly, the induction of a strong magnetic anisotropy at low annealing temperature has been observed in CoMnSiB microwires under the effect of applied axial magnetic field. Such peculiar behavior was interpreted as a reinforcing effect of the mentioned high internal stresses during field annealing of Co-rich microwires [37].

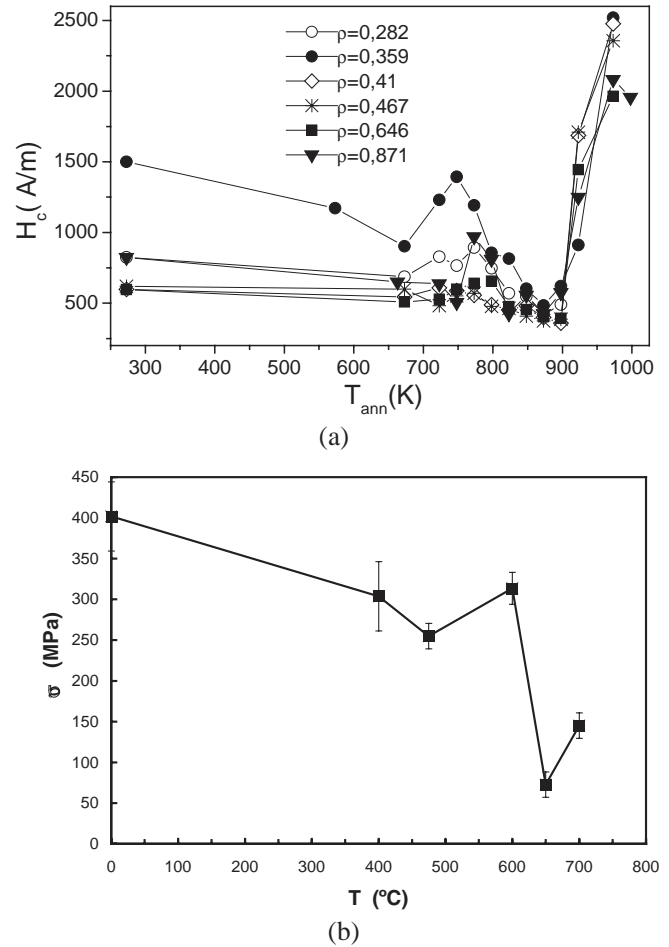

As reported previously, the magnetostriction constant can be also estimated from the stress dependence of GMI (see Fig. 12 and its description in Section 3.1.3).

## 3.2. Nanocrystalline Microwires

### 3.2.1. Soft Nanocrystalline Microwires

Properties of as-prepared microwires of “finemet”-type compositions  $\text{Fe}_{73.4}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_x\text{B}_{22.5-x}$  ( $x = 11.5, 13.5, \text{ and } 16.5$ ) significantly depend on their geometry [13, 62]. Hysteresis loops, of typically rectangular shape, have been observed in the as-prepared state. The coercivity of the sample  $\text{Fe}_{72.3}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{14.5}\text{B}_{9.1}$  strongly increases as the ratio  $\rho$  decreases. These results of  $H_c$  versus  $(d/D)$  could be understood taking into account that the strength of internal stresses acting in the metallic nucleus increases with  $\rho$  [39, 40, 63].

The typical dependence of the coercive field,  $H_c$ , of  $\text{Fe}_{71.8}\text{Cu}_{1.0}\text{Nb}_{3.1}\text{Si}_{15.0}\text{B}_{9.1}$  alloy on annealing temperature with the ratio  $\rho$  as parameter is presented in Figure 16 [13]. Generally, a decrease of  $H_c$  has been observed at  $T_{\text{ann}}$  below 400 °C. A weak local minimum of  $H_c$  has been observed at about 400–450 °C with the temperature of that minimum depending on both alloy composition and geometry. Such a decrease of  $H_c$  could be ascribed to the structural relaxation of the material remaining the amorphous character such as has been widely reported in metallic glass alloys. A small relative hardening (increase of coercivity) can be observed after annealing around 450–500 °C, which could be ascribed to the very beginning of the first stage of devitrification [9–13]. It is interesting to note that the sample’s geometry affects the value and the position of the local extremes on the  $H_c(T_{\text{ann}})$  dependence (see Fig. 16). A deeper softening (optimum softness) with a rather low value of  $H_c$  is obtained in samples treated at  $T_{\text{ann}} = 500\text{--}600$  °C. Such magnetic softening is related to the nanocrystallization, related to precipitation of fine grains (10–15 nm) of  $\alpha\text{-Fe}(\text{Si})$  phase within the amorphous matrix. Such interpretation has been confirmed by the X-ray diffraction studies of as-prepared and annealed at different temperatures samples [13, 14].

**Figure 16.** (a) Dependence of coercivity on the annealing temperature,  $T_{\text{ann}}$ , for  $\text{Fe}_{71.8}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{15}\text{B}_{9.1}$  with the ratio  $d/D$  ranging from 0.282 to 0.646. Reprinted with permission from [7], A. Zhukov *J. Magn. Magn. Mater.* 242–245, 216 (2002). © 2002, Elsevier Science. (b) Dependence of tensile yield on the annealing temperature in  $\text{Fe}_{71.8}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{15}\text{B}_{9.1}$  microwire. Reprinted with permission from [81], V. Zhukova et al., *J. Magn. Magn. Mater.* 249, 79 (2002). © 2002, Elsevier Science.

Excellent magnetic softness (coercivity of about 15 A/m) has been realized in  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_x\text{B}_{22.5-x}$  microwires with  $x = 13.5$  [13, 14] at appropriate annealing conditions.

### 3.2.2. Semihard Magnetic Nanocrystalline Microwires

An abrupt increase of  $H_c$  is shown by the samples treated at  $T_{\text{ann}}$  above 600 °C, indicating the beginning of the precipitation of second crystalline phase—iron borides (with grain size larger than 50 nm). Such beginning of the increase of  $H_c$  varies depending mainly on sample composition as well as geometry. It must be noted that for the thickest glass coating the increase of  $H_c$  appears at lower temperature, which could be related to the fact that the internal stresses induce some ordering to hinder the crystallization. It is important that the hysteresis loop in certain microwire compositions remains roughly rectangular in the whole range of annealing temperatures for certain compositions (Fig. 17) [14]. Such

**Figure 17.** Hysteresis loop of  $\text{Fe}_{71.8}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{15}\text{B}_{9.1}$  in as-prepared and annealed at different temperature microwires (b). Reprinted with permission from [7], A. Zhukov, *J. Magn. Magn. Mater.* 242–245, 216 (2002). © 2002, Elsevier Science.

temperature dependence of the hysteresis loops permits one to tailor the coercivity of microwires with rectangular hysteresis loops in a wide range of coercivities. This fact is very important for some particular applications of glass-coated microwires (see Section 5).

The effect of annealing temperature on the coercivity,  $H_c$ , of the alloy  $\text{Fe}_{72.3}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{14.5}\text{B}_{9.1}$  with ratio  $\rho$  as parameter is shown in Figure 18. A sharp magnetic hardening (increase of coercivity) can be observed after annealing around 500–550 °C. It should be indicated that such maximum takes place at the same range of the annealing temperature as the first small increase of  $H_c$  in  $\text{Fe}_{73.4}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_x\text{B}_{22.5-x}$  ( $x = 11.5$  and  $13.5$ ) related to the first recrystallization process (compare with Fig. 16a) [3, 11, 12, 62, 64].

This strong magnetic hardening is followed by new magnetic softening with an increase of  $T_{\text{ann}}$  above 550 °C and consequent new magnetic hardening at  $T_{\text{ann}} > 650$  °C which is accompanied by deterioration of mechanical properties.

**Figure 18.** Coercivity dependence with the annealing temperature of  $\text{Fe}_{72.3}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{14.5}\text{B}_{9.1}$  microwire. Reprinted with permission from [62], J. González et al., *IEEE Trans. Magn.* 36, 3015 (2000). © 2000, IEEE.

In the case of  $\text{Fe}_{73.4}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{13.4}\text{B}_{9.1}$  samples such strong magnetic hardening is not observed (see Fig. 16).

X-ray analysis of  $\text{Fe}_{72.3}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{14.5}\text{B}_{9.1}$  does not detect a presence of crystalline phases in as-prepared state as well as after annealing at 550 °C. On the other hand, transmission electron microscopy (TEM) diagrams of the sample annealed at 550 °C permit one to detect a small amount of fine grains of  $\alpha$ -Fe,  $\gamma$ -Fe, and  $\alpha$ -Fe(Si) [62]. The TEM image presented in Figure 19 shows that the average grain size of such crystallites is around 20–70 nm in annealed sample at 550 °C.

Observed structural features permit one to correlate observed magnetic hardening with precipitation of fine crystallites. Such a difference in magnetic behavior with conventional *finemet*-type microwires can be attributed to different alloy compositions as well as to high internal stresses. It is well known that the best magnetic softness is achieved when the nanocrystalline structure consisting of small  $\alpha$ -Fe(Si) grains and amorphous matrix has a vanishing magnetostriction constant. It is possible that even a small change of the alloy composition does not permit one to achieve such a vanishing magnetostriction constant.

On the other hand, strong internal stresses due to glass coating can result in a change of structure of the precipitating fine grains. Thus, strong internal stresses (about  $10^3$  MPa or even more) are mainly induced by the difference in the thermal expansion coefficients of the glass and the metallic nucleus. It is well known that internal strains of different nature can be the origin of martensite-type transformation in alloys of Fe. Probably, the strong internal stresses induce a precipitation of the  $\gamma$ -Fe fine grains instead or apart from  $\alpha$ -Fe(Si) grains during the first stage of the crystallization process. Particularly, the presence of crystalline  $\gamma$ -Fe could be the reason for the observed magnetic hardening [62]. As a consequence, the origin of such strong magnetic hardening at low annealing temperatures without deterioration of mechanical properties could be ascribed to some peculiarities of the first recrystallization process under the effect of strong internal stresses induced by glass coating and differences in the alloy composition.

### 3.3. Granular Glass-Coated Microwires

#### 3.3.1. Structure and Phase Composition

Granular systems formed by immiscible elements (Co, Fe, Ni)–(Cu, Pt, Au, Ag) have been recently introduced [21, 65–67]. Such immiscible alloys exhibit unusual magnetic properties such as the GMR effect related to mixed ferromagnetic–paramagnetic microstructure and scattering of the electrons on grain boundaries between these two phases. A rapid quenching technique such as melt spinning has been employed recently for fabrication of Co–Cu ribbons [68]. The high quenching rate characteristic of the melt spinning method has been used for fabrication of metastable crystalline materials when the crystalline phases, stable at high temperature, can be quenched-in at room temperature. In this case the GMR and enhanced coercivity were obtained generally after recrystallization of such metastable phases.

Recently, the Taylor–Ulitsky technique has also been employed to obtain granular glass-coated microwires (km long) [21, 69] from immiscible elements. Such granular structure has been achieved mainly by decomposition of metastable crystalline phases. A high quenching rate is also useful for fabrication of metastable crystalline materials when the crystalline phases, stable at high temperature, can be quenched-in at room temperature.

Figure 20 shows the X-ray diffraction (XRD) analyses for the as-prepared  $\text{Co}_x\text{Cu}_{100-x}$  microwires, which confirms the presence of a single phase for  $x = 10$  with a lattice parameter  $a = 0.36$  nm, while in the other compositions, with  $x > 10\%$ , two phases were detected. It should be mentioned that  $\text{Co}_x\text{Cu}_{100-x}$  alloy ribbons obtained by rapid solidification were characterized by X-ray diffraction by various authors [67, 70, 71]. It was found by the XRD method that, in the as-quenched  $\text{Co}_x\text{Cu}_{100-x}$  ribbons, single phase face-centered cubic (fcc) peaks appear for  $x < 20\%$  [67] (sometimes only for  $< 10\%$  [72]) and  $x > 35\%$ . Since the lattice parameter was larger than for pure Co ( $a = 0.35447$  nm) and smaller than that of pure Cu ( $a = 0.3615$  nm), the same dissolution of Co atoms in the Cu matrix has been proposed. In any case, fcc Co particles were also reported in [72].

**Figure 20.** X-ray diffraction pattern of  $\text{Co}_x\text{Cu}_{100-x}$  microwires with  $x = 10, 15,$  and  $50\%$ . Reprinted with permission from [21], A. Zhukov et al., *J. Appl Phys.* 85, 4482 (1999). © 1999, American Institute of Physics.

The experimental data on X-ray diffraction of microwires from immiscible elements are generally in agreement with those previously reported for ribbons with small Co concentrations, when single phase peaks have been observed at  $x < 10\%$ . Indeed, the presence of two phases can be deduced from careful analysis of the maxima for  $x > 10\%$ , with interatomic spacings of 0.209 nm (Cu) and 0.206 nm (Co). Nevertheless, it is important to mention that the coexistence of two phases is found even for  $x > 35\%$ .

Like in  $\text{Co}_x\text{Cu}_{100-x}$  microwires with  $x > 10\%$ , the XRD analyses for the as-prepared Cu–Fe microwires showed two maxima in the diffraction peak with the lowest diffraction angle corresponding to the Cu and the body-centered cubic  $\alpha$ -Fe phases.

In some cases this granular structure is metastable at room temperature and the consequent heat treatment results in the recrystallization of this structure with the formation of stable phases. At certain conditions of such heat treatment this new granular structure can exhibit interesting magnetic and transport properties.

As an example, Figure 21a–c shows the X-ray diffraction patterns for the  $\text{Co}_{29}\text{Ni}_{25}\text{Cu}_{45}\text{Mn}_1$  sample, in its as-prepared state and after thermal treatment at two different temperatures  $T_{\text{ann}}$ . In the as-prepared microwire, quenched from a high temperature, only a single phase, with a lattice parameter  $a = 0.3573$  nm, was found (Fig. 21a). When the sample was heated at high temperatures, this metastable phase started to decompose. This can be seen in the sample treated at 973 K, where the segregation mechanism is

**Figure 21.** X-ray scan of as-prepared and annealed  $\text{Co}_{29}\text{Ni}_{25}\text{Cu}_{45}\text{Mn}_1$  microwires. Reprinted with permission from [21], A. Zhukov et al., *J. Appl Phys.* 85, 4482 (1999). © 1999, American Institute of Physics.

not yet complete (Fig. 21b). After annealing at 1073 K the sample shows the equilibrium phases, consisting of a copper-rich matrix ( $a = 0.3591$  nm) with Co-rich particles ( $a = 0.3545$  nm) (Fig. 21c) [68, 69]. Annealing at higher temperature results in a very marked embrittlement of the glass coating. For alloys in the Co–Ni–Cu system containing more than 20% Ni a continuous series of (fcc) solid solutions is found to be stable at high temperatures [73]. When the alloy is quenched from the melt during the production of the microwire, a metastable cubic phase is found at room temperature. On heat treating this material, the segregation takes place and the metastable phase starts to decompose into a paramagnetic Cu-rich phase with a larger lattice parameter than the precursor phase, and a fine grained Co-rich phase with a smaller lattice parameter.

It is well known that the presence of the glass coating introduces strong internal stresses inside the metallic nucleus due to the difference in the thermal expansion coefficients of metallic nucleus and glass coating [5, 38, 39]. The strength of such internal stresses depends on the metallic nucleus diameter as well as on the glass-coating thickness [38, 39]. Therefore, it is expected that the geometry affects the structural and magnetic features of glass-coated microwires.

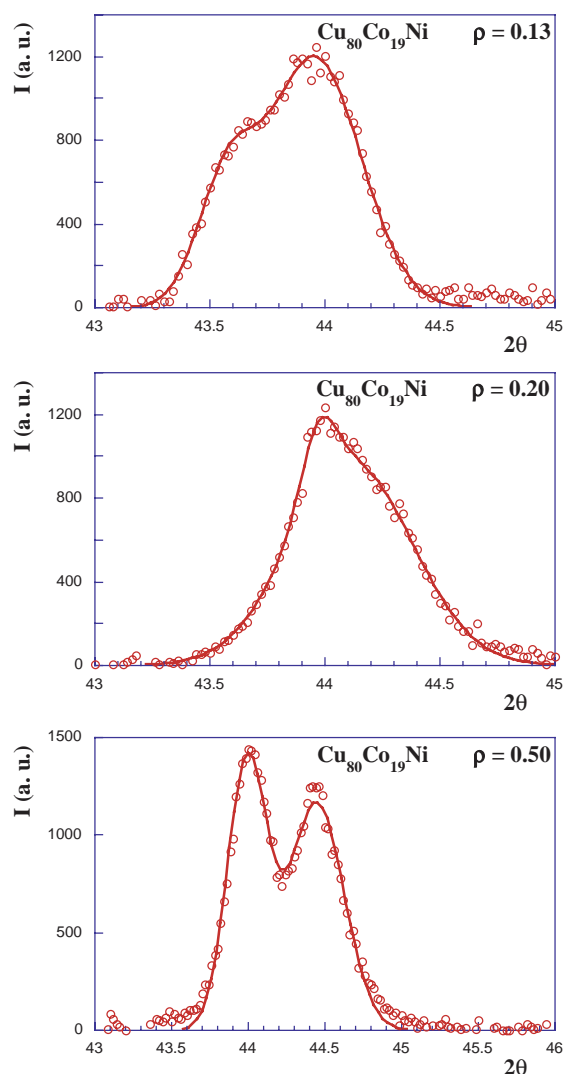

X-ray diffraction patterns for the as-prepared  $\text{Co}_{20}\text{Cu}_{80}$  microwires with different values of the  $\rho$  show peaks corresponding to two crystalline phases. Figure 22 shows these XRD patterns for the three microwires in this system with different values of  $\rho$ . The diffraction peak with the lowest diffraction angle corresponds to the Cu matrix with an interatomic spacing,  $d$ , of 0.209 nm. A detailed examination of

**Figure 22.** X-ray scan of  $\text{Co}_{20}\text{Cu}_{80}$  microwires with different ratios  $\rho$ . Reprinted with permission from [72], J. González et al. *J. Magn. Magn. Mater.* 221, 196 (2000). © 2000, Elsevier Science.

this peak allows the detection of a second small and broad maximum near this first peak which could be attributed to Co crystallites embedded in the Cu matrix. It can be observed that the higher the value of  $\rho$ , the more intense this second peak. The observed second crystallization peak corresponds to fcc metastable Co, as has been previously observed in ribbons [67, 70, 71].

Similar behavior in the XRD patterns was observed for microwires of composition  $\text{Co}_{19}\text{Cu}_{80}\text{Ni}_1$  with different  $\rho$  values (see Fig. 23). Inside the diffraction peak with the lowest diffraction angle two maxima were detected: the first one can be attributed to an overlapping of two peaks corresponding to interatomic spacings of 0.209 nm (Cu) and 0.208 nm ( $\text{Cu}_{3.8}\text{Ni}$ ) (the technique can hardly resolve these differences) and the second one corresponding to an interatomic spacing of 0.205 nm (Co) [74]. Figure 23 shows this first peak for the three values of the  $\rho$  parameter, which indicates its sensitivity to the geometry. This peak,

**Figure 23.** First crystalline peak and the corresponding fittings to a sum of two Gaussian functions for  $\text{Co}_{19}\text{Ni}_1\text{Cu}_{80}$  microwires with different ratios  $\rho$ . Reprinted with permission from [72], J. González et al. *J. Magn. Magn. Mater.* 221, 196 (2000). © 2000, Elsevier Science.

corresponding to the  $\text{Cu}_{3.8}\text{Ni}$  new phase in these samples, is accompanied by the presence of new peaks juxtaposed to the 0.181 and 0.128 nm (it is very clear in this last case) Cu spacings appearing in Figure 22 for the  $\text{Co}_{20}\text{Cu}_{80}$  system.

The proportions of each phase were calculated, for each sample, from the relative area under all the peaks measured over all the  $2\theta$  region of measurement. When relative peaks overlapped (which occurred in most cases), the experimental signal was fitted to the addition of two Gaussian functions in order to obtain the characterizing values of the position of the maximum and the width of the peak. Thus, the Co or Fe phase content in each sample was calculated as

$$\%_{\text{Co, Fe}} = \frac{\int_{40}^{80} I_{\text{corr Co, Fe}} d(2\theta)}{\int_{40}^{80} I_{\text{corr}} d(2\theta)} \quad (17)$$

where  $I_{\text{corr}}$  denotes the total measured diffracted intensity corrected for background and  $I_{\text{corr Co, Fe}}$  is the diffracted intensity corrected for background, corresponding to the peaks associated with Co or Fe phases.

The dependence of the Co particle content (in percentage) on the  $\rho$  parameter for  $\text{Co}_{19}\text{Cu}_{80}\text{Ni}_1$  and  $\text{Co}_{20}\text{Cu}_{80}$  microwires is shown in Figure 24. An increase of the Co-phase content with  $\rho$  can be observed in the  $\text{Co}_{20}\text{Cu}_{80}$  microwires, particularly at high values of  $\rho$ . This effect should be related to the strength and complexity of the internal stresses in the metallic core, arising from the insulating glass coating. It is reasonable to assume that these internal stresses increase as the  $\rho$  parameter decreases [38, 39] and, consequently, they could hinder the segregation of the magnetic Co phase. Surprisingly the  $\text{Co}_{19}\text{Cu}_{80}\text{Ni}_1$  alloy does not show such continuous behavior and the Co content is much higher than in CuCo microwires: this is evident in the raw diffraction patterns where the peak corresponding to the Co phase is much more intense.

Figure 25 shows the variations in the mean diameter  $\Delta$  of Cu and Co particles or grains as a function of the parameter  $\rho$  for  $\text{Co}_{20}\text{Cu}_{80}$  and  $\text{Co}_{19}\text{Cu}_{80}\text{Ni}_1$  alloys. From these results the dependence of the grain size seems to be quite insensitive to  $\rho$  in both alloys, although the presence of Ni increases significantly the size of such Co and Cu particles. The last two cases show that the presence of small amounts

**Figure 24.** Effect of geometry on Co-phase content and coercivity in  $\text{Co}_{20}\text{Cu}_{80}$  and  $\text{Co}_{19}\text{Ni}_1\text{Cu}_{80}$  microwires. Reprinted with permission from [72], J. González et al., *J. Magn. Magn. Mater.* 221, 196 (2000). © 2000, Elsevier Science.

**Figure 25.** Effect of geometry on average grain size of  $\text{Co}_{20}\text{Cu}_{80}$  and  $\text{Co}_{19}\text{Ni}_1\text{Cu}_{80}$  microwires. Reprinted with permission from [72], J. González et al., *J. Magn. Magn. Mater.* 221, 196 (2000). © 2000, Elsevier Science.

of Ni atoms drastically changes the structural characteristics of these alloys.

The overview of Figures 20–25 indicates the sensitivity of the structure either to the composition (substitution of one atom of Co by Ni) or to the geometry (parameter  $\rho$ ) or both.

It must be pointed out here that the results for the  $\rho$  dependence of the Cu and Fe grain sizes and for the amount of Fe phase for the two different CuFe compositions is consistent with the fact that the different compositions show the same variations.

### 3.3.2. Effect of Composition and Geometry on Magnetic Behavior

The hysteresis loops, at room temperature, for three different compositions in the series  $\text{Co}_x\text{Cu}_{100-x}$  are presented in Figure 26. As can be observed, in as-prepared samples the saturation magnetization decreases and both the magnetic anisotropy field and the coercive field increase, as the Co content increases. As can be expected, the high saturation magnetic field of the samples with small Co content could be explained considering that Co precipitates behave as small superparamagnetic particles or as isolated spherical ferromagnetic particles. In the second case the magnetic

**Figure 26.** Hysteresis loops of  $\text{Co}_x\text{Cu}_{100-x}$  microwires. Reprinted with permission from [21], A. Zhukov et al., *J. Appl. Phys.* 85, 4482 (1999). © 1999, American Institute of Physics.

anisotropy field can be related to the demagnetizing factor of such particles, being in good accordance with experimental data for  $\text{Co}_{20}\text{Cu}_{80}$  particles ( $H_k = \mu_o M_s/3$ ). It should be also noted that the magnetization behavior of ribbons of similar composition is still a topic of discussion and sometimes it is interpreted as being superparamagnetic [67] and sometimes not [65].

It may be argued that the sample with  $x = 50$  is not entirely superparamagnetic since its coercivity as well as the remanence shows nonzero values being, however, relatively small. The variations of the magnetization with the Co content can be explained on the basis of two contributions, namely: one coming from the superparamagnetic particles and other from the ferromagnetic contribution which originates from large Co grains or agglomerates of smaller Co particles [65–69]. The first contribution is negligible for a large Co content (that is, the  $x = 70$  sample). Besides the large ferromagnetic grains, a source of the coercivity can also be, in the case of  $x = 10$ , the interactions between superparamagnetic particles.

The shape of the hysteresis loop seems to be rather insensitive to the  $\rho$  parameter: the magnetic anisotropy field remains almost unmodified by changes of the  $\rho$  parameter. In contrast, considerable changes in the coercive field have been detected when the  $\rho$  parameter changes. These changes are shown in Figure 24, together with changes of average grain size with  $\rho$ . Certain correlations, such as decrease of coercivity with increase of Co phase (Fig. 24) content and grain size (see Fig. 25), can be outlined.

The hysteresis loops of as-prepared  $\text{Fe}_{30}\text{Cu}_{70}$  samples for two different  $\rho$  values can be seen in Figure 27. The reduction of the  $\rho$  parameter leads to important changes in the hysteresis behavior. In fact, for the lower value of  $\rho = 0.3$  the hysteresis loop may indicate the presence of two magnetic phases with two different values of anisotropy field, one high and one low (see Fig. 27). On the other, hand, a single magnetic phase with enhanced anisotropy field can be deduced from the magnetization curve of the sample with the larger value of  $\rho = 0.6$  [72]. The coercive field is smaller in the sample with the lower  $\rho$ . As in Co–Cu microwires, an effect of internal stresses on the crystallization process can be deduced.

**Figure 27.** Hysteresis loop of  $\text{Fe}_{30}\text{Cu}_{70}$  microwires with different ratios. Reprinted with permission from [72], J. González et al., *J. Magn. Magn. Mater.* 221, 196 (2000). © 2000, Elsevier Science.

Comparison with structural analysis indicates that for  $\text{Fe}_{30}\text{Cu}_{70}$  microwires,  $\rho = 0.3$ , where the coexistence of two magnetic phases is suggested, corresponds to a maximum in the observed content of the Fe phase [74].

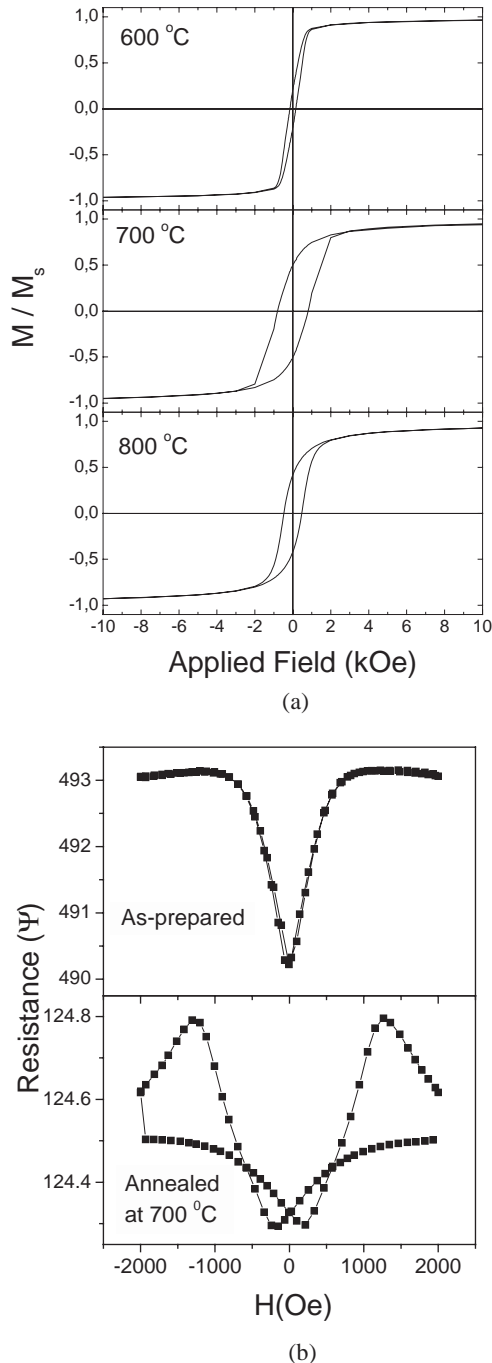

### 3.3.3. Effect of the Thermal Treatment on Magnetic Properties

In order to achieve higher coercivity, the different families of microwires were submitted to thermal treatments (up to 800 °C, for 1 hour). After the treatments, the magnetic properties of some samples underwent significant changes. Comparative results on the effects of annealing temperature,  $T_{\text{ann}}$ , on coercivity of all studied microwires are shown in Figure 28. The annealing temperature dependence of the coercivity can be explained qualitatively, by taking into account the structure of the as-prepared samples. It is evident that for the samples having a two-phase structure in the as-prepared state, no significant changes of the magnetic properties were observed. But for single phase as-cast microwires ( $\text{Co}_{10}\text{Cu}_{90}$  and  $\text{Co}_{29}\text{Ni}_{25}\text{Cu}_{45}\text{Mn}_1$ ) a substantial increase of the coercivity is observed after annealing above 500 °C [21]. Therefore, a precipitation of Co or Ni crystallites from the metastable Cu-rich solid solution can be responsible for the enhancement of the coercivity upon annealing [67]. The solubility of Co and Ni in Cu decreases as the temperature decreases and, at room temperature, it is quite small (less than 0.1% for Co). Consequently, these elements are almost immiscible at room temperature. Therefore, a single phase solid solution is unstable at room temperature and the annealing results in its decomposition.

A magnetic hardening (up to 200 Oe) is observed for the  $\text{Cu}_{90}\text{Co}_{10}$  microwires after annealing temperatures of around 500 °C. Most significant magnetic hardening was observed for the  $\text{Co}_{29}\text{Ni}_{25}\text{Cu}_{45}\text{Mn}_1$  microwire. The room temperature hysteresis loop of Co–Ni–Cu–Mn microwires is presented, as an example, in Figure 29a, after annealing for one hour at various temperatures. The variation of the coercivity with the annealing temperature for the different microwires was obtained from such curves. The as-prepared  $\text{Co}_{29}\text{Ni}_{25}\text{Cu}_{45}\text{Mn}_1$  sample shows a relatively low coercivity (50–100 Oe). When raising the annealing temperature to 700 °C, a strong increase in  $H_c$  is obtained, reaching

**Figure 29.** Hysteresis loops of  $\text{Co}_{29}\text{Ni}_{25}\text{Mn}_1\text{Cu}_{45}$  microwires measured at different annealing temperatures (a) and magnetoresistance (b) measured at 100 K in as-prepared and annealed at 700 °C microwires. Reprinted with permission from [72], J. González, et al., *J. Magn. Magn. Mater.* 221, 196 (2000). © 2000, Elsevier Science.

the maximum value of 700 Oe for the  $\text{Co}_{29}\text{Ni}_{25}\text{Cu}_{45}\text{Mn}_1$  microwire. A further increase of the annealing temperature results in a decrease of the coercivity. The largest reduced remanence ratio  $M_r/M_s = 0.5$  is also found after annealing at 700 °C and the estimated saturation magnetization for this sample is about 3.6 kG. As has been mentioned previously, the structure of these annealed samples consists

of a paramagnetic Cu-rich phase and a fine grained ferromagnetic Co phase; in this stage the coercivity increases quickly. Increasing the annealing temperature further, the equilibrium of phases is reached more rapidly, the grains start to grow, and the coercivity decreases. These results are in agreement with the magnetic hardening in bulk Co–Ni–Cu permanent magnet alloys, and the maximum value of the coercivity obtained after the annealing at 700 °C for one hour agrees with that previously reported [73].

Magnetoresistance (MR), up to about 8% has been recently found in granular Fe, Ni, Co-rich microwires [75, 76]. This MR correlates quite well with the structure and the magnetization curves. Thus, the micro-X-ray absorption near edge structure (micro-XANES) spectroscopy reflects that the MR is related to fcc small grains of Fe–Ni ( $\gamma_1$  phase) embedded in fcc Cu ( $\gamma_2$  phase). By the micro-XANES method it was shown that Fe atoms remain in the fcc  $\gamma_1$  phase even after the annealing. These data are consistent with the phase diagram of Fe–Ni–Cu alloys and with the similar results on the fcc small grain Co in Co–Cu and/or Co–Ni–Cu microwires.

In the case of Co–Ni–Cu–Mn microwires field dependence of MR is quite different for the as-prepared and heat treated samples, reflecting also the difference of their structure and magnetization curves (see Figs. 21, 29a). Only small hysteresis correlated with low coercivity has been observed in as-prepared sample, while significant hysteresis with the MR maximum at around  $\pm 1200$  Oe is observed in the sample annealed at 700 °C. The relative change of the resistance under magnetic field in Co–Ni–Cu–Mn microwires is around 4% (Fig. 29b).

#### 4. MECHANICAL PROPERTIES

Most early reports on glass-coated microwires were devoted to their mechanical properties [77–80]. Thus, the effect of annealing and crystallization on tensile strength and Young modulus was studied in amorphous Fe-rich and stainless steel microwires produced by the Taylor–Ulitsky technique [78, 79]. High tensile strength (around 250 kg/mm<sup>2</sup>) was observed in amorphous  $\text{Fe}_{80}\text{P}_{16}\text{C}_3\text{B}_1$  microwires as compared with the crystalline microwires (around 130 kg/mm<sup>2</sup>). Such tensile strength is found to decrease, increasing the metallic nucleus diameter. This tendency has been attributed to the higher cooling rate with decreasing metallic nucleus diameter. On the other hand, the Young modulus of amorphous samples (8000 kg/mm<sup>2</sup>) is found to be much lower than that of crystalline (13,000 kg/mm<sup>2</sup>) samples of the same composition. Fracture surfaces of the amorphous microwires consist of a smooth region produced by shearing and a vein pattern [79]. It was observed later that additions of Si, Co, or Cr result in increasing averaged tensile strength [80].

Recently interest in studies of mechanical properties has been renewed mostly due to the promising technological applications of glass-coated microwires. In this way, tensile strength and fracture character have been recently studied in CoMnSiB microwires [53]. A wide number of samples of the CoMnSiB series have been studied and the average load for fracture has been found to range between  $20 \pm 3$  g, with a maximum of 30 g and a minimum of 15 g. The tensile strength is then  $624 \pm 94$  MPa, with maximum and minimum

values of 936 and 468 MPa, respectively. The tensile strength in the amorphous state seems to be due to the metallic nucleus of the microwire. The glass coating does not seem to contribute significantly in resistance to fracture. The glass around the point of fracture breaks, probably because of the sound wave produced by the rupture or the metallic nucleus, which is then visible.

Moreover, samples with higher tensile strength seem to break in a slightly different mode than the ones breaking under lower stress. Thus sometimes the fracture plane is basically perpendicular to the axis of the microwire. On the other hand, another group of samples broken under stresses over the average show a more complex situation. These samples show some structure in the surface of the metallic nucleus of the microwire that could have improved the adhesion of the metallic nucleus to the coating and increased strength slightly.

An interesting correlation of mechanical and magnetic properties has been observed in *finemet*-type microwires during the devitrification [81]. As mentioned previously, annealing of initially amorphous  $\text{Fe}_{73.4}\text{Cu}_1\text{Nb}_{3.1}\text{Si}_{13.4}\text{B}_{9.1}$  microwires results in the two-step crystallization process. First fine  $\alpha$ -Fe(Si) nanocrystals of grain size around 10 nm have been precipitated at temperatures around 550–600 °C. At temperatures above 600 °C, the beginning of the precipitation of iron borides (with grain size larger than 50 nm) has been found [81].

Such as described in Section 3.2 typically a decrease of coercivity has been observed at annealing temperatures below 650 °C with two minimums of coercivity,  $H_c$ , at about 400–450 and at 550–650 °C. Such soft magnetic behavior has been ascribed to the first crystallization process leading to the precipitation of fine nanocrystals  $\alpha$ -Fe(Si) of grain size around 10 nm with 70–80% of relative volume, as has been widely reported for *finemet* ribbons (see for example [9–12, 14]). An abrupt increase of the coercivity is shown by the samples treated at temperature above 600 °C. The beginning of such an increase should be connected to the precipitation of iron borides (with grain size larger than 50 nm) which implies a magnetic hardening character.

Tensile yield,  $\sigma_y$ , has been measured for samples annealed at different temperatures. These results are presented in Figure 16b. Maximum  $\sigma_y$  was found for the as-fabricated sample (402 MPa). Then, a certain correlation can be outlined with respect to the dependence of coercivity on annealing temperature. Like in the case of coercivity, tensile yield,  $\sigma_y$ , decreases with  $T_{\text{ann}}$  with a small local minimum around  $T_{\text{ann}} = 450$  °C. Some increase of  $\sigma_y$  has been observed at  $T_{\text{ann}} = 575$  °C. Finally strong deterioration of the tensile yield has been observed at  $T_{\text{ann}} > 650$  °C and a small increase at  $T_{\text{ann}} = 700$  °C. The samples annealed at the two highest temperatures were extremely brittle. The  $\sigma_y$  results in Figure 16b for these types of microwires correspond only to the maximum measurable value. In most opportunities, samples would fracture even under very careful handling.

The character of the sample fracture has also been studied for the samples annealed at a few annealing temperatures by means of scanning electron microscopy. The annealing does not deteriorate significantly the glass coating as well as the metallic nucleus. The fracture character is complex.

The metallic nucleus seems to be responsible for the tensile yield, with the possible contribution of plasticity. It is possible that the thermal treatment deteriorates the glass-coating interface due to the difference in thermal expansion coefficients, having a slight effect on the tensile yield.

For the annealing temperatures higher than 600 °C, the character of the fracture is different. If the metal core is now brittle, the glass coating can be responsible for the sample fracture and the sample breaks immediately after the coating itself.

The correlation of the mechanical properties with magnetic behavior is to be related to structural changes introduced by the annealing. The precipitation of the second crystalline phase leads to a completely crystalline structure, introducing strong internal stresses and change in the character of the chemical bonding. This crystallization process makes the sample brittle [9–12].

## 5. APPLICATIONS

The latest advances in magnetic materials are based on the miniaturization of modern magnetic materials. In this sense tiny metallic wires (of the order of 3 to 30  $\mu\text{m}$  in diameter) covered by an insulating glass coating are quite suitable for the sensor applications. Such wires possess a number of excellent magnetic properties such as magnetic bistability with the extended range of the switching fields, enhanced magnetic permeability, GMI effect, and high stress sensitivity of the magnetic parameters (switching field, GMI effect, magnetic permeability, etc.), which can be tailored by varying the metallic alloy composition, sample geometry (metallic nucleus diameter and glass coating thickness), and conditions of heat treatment. Several examples of applications of tiny glass-coated microwires will be reviewed.

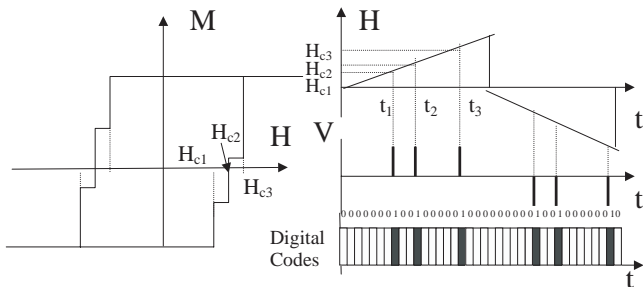

A magnetoelastic sensor of the level of liquid can be designed using the very sensible stress dependence of the hysteresis loop and particularly of the coercivity in nearly zero magnetostriction  $\text{CoMnSiB}$  microwires (see Fig. 14c). Such a sensor essentially consists of a piece of  $(\text{Co}_{0.9}\text{Mn}_{0.1})_{75}\text{Si}_{10}\text{B}_{15}$  microwire surrounded by primary and secondary coils [7, 82]. The sample is loaded with approximately 10 g and therefore exhibits a flat hysteresis loop. The weight is attached to the bottom of the sample. When a liquid arrives to cover the weight, the actual stress, affecting the sample, decreases giving rise to the appearance of the rectangular hysteresis loop. The principle of the work is based on the change of the voltage of the secondary coil, which increases drastically when the hysteresis loop of the sample C became rectangular after essential decrease of the stress. A simple circuit including the amplification of the signal and alarm set was used to detect changes of voltage in the secondary coil under the change of the tensile stresses due the floating effect of the weight on the liquid.

The other example is based on the wide range of coercivity which can be obtained in microwires due to its strong dependence on the geometric dimensions and heat treatment. It was realized in the method of magnetic codification using magnetic tags [7, 83]. The tag contains several microwires with well-defined coercivities, all of them characterized by a rectangular hysteresis loop. Once the magnetic tag is submitted to the ac magnetic field, each particular

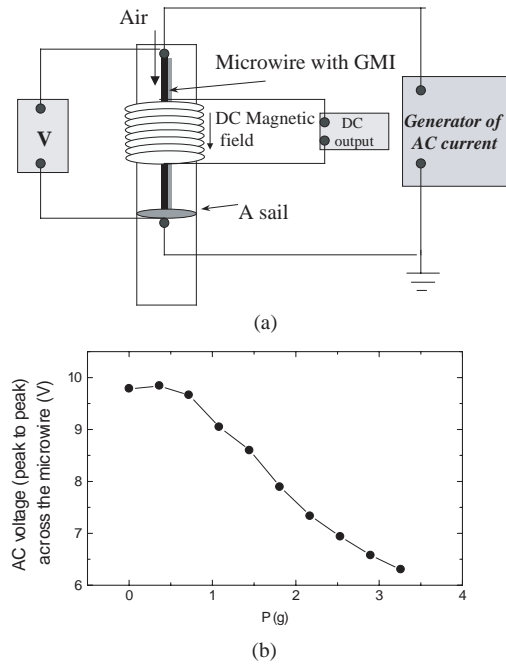

microwire remagnetizes at a different magnetic field giving rise to an electrical signal on a detecting system (see Fig. 30). The extended range of switching fields obtained in Fe-rich microwires gives the possibility to use a large number of combinations for magnetic codification.

The high sensitivity of the GMI ratio to quite small values of mechanical load makes this stress sensitive GMI effect very interesting for practical purposes. Figure 30 shows a magnetoelastic sensor of air flux based on GMI exhibited by nearly zero magnetostrictive  $\text{Co}_{68.5}\text{Mn}_{6.5}\text{Si}_{10}\text{B}_{15}$  microwire. The principle of work of this sensor device is briefly described [7, 84]. The microwire has a rather high dc electrical resistance per length owing to its tiny dimensions. Therefore, large changes (about 130%) of the magnetoimpedance could induce rather large changes of the ac voltage under mechanical loading. Indeed, under the effect of tensile stresses, the GMI ratio at fixed applied field,  $H$ , decreases giving rise to a significant change of the ac voltage between the sample's ends. A dc magnetic field corresponding to the maximum ratio  $(\Delta Z/Z)_m$  without stresses has been applied by means of a small solenoid 7 cm in length and 1 cm in diameter. In the case of a driving current with frequency 10 MHz and amplitude 1.5 mA supplied by an ac current generator, the change of ac voltage (peak to peak) between the ends of the sample is around 3.5 V for small mechanical loads attached at the bottom of the microwire (see calibration curve in Fig. 31b). This huge change presented at the output permits one to use this kind of sensor in different technological applications related to the detection of small mechanical stress.

The observed magnetic response on the external variable stresses can be used in many applications to detect different temporal changes of stresses, vibrations, etc. As an example we introduce a "magnetoelastic pen" which can be used for identification of signatures [7, 85]. It is well known that the signature of each person can be represented by typical series of the stresses. The sequence and strength of those stresses are characteristic features of any personal signature. So temporal changes of the stresses while signing can be used for the identification of signature itself. We have used this behavior and designed a setup consisting of a ferromagnetic bistable amorphous wire with positive magnetostriction, a miniaturized secondary coil, and a simple mechanical system inside the pen containing a spring, which transfers the applied stresses to the ferromagnetic wire (see Fig. 32).

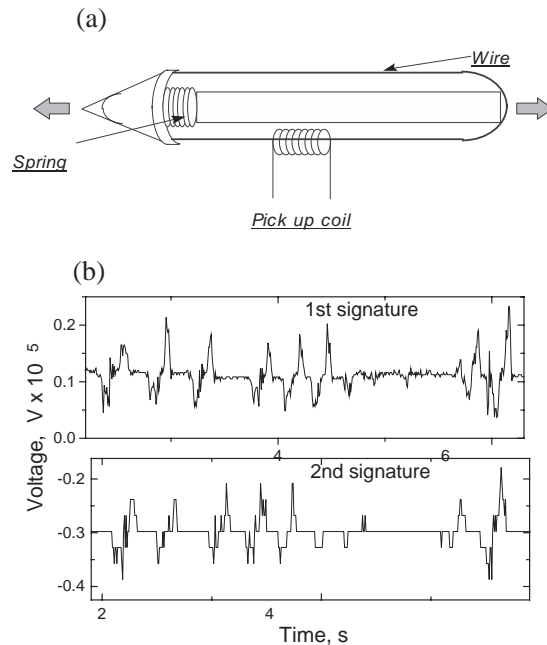

**Figure 30.** Schematic representation of the encoding system based on magnetic bistability of the microwires. Reprinted with permission from [6], A. Zhukov et al., *J. Mater. Res.* 15, 2107 (2000). © 2000, Materials Research Society.

**Figure 31.** Schematic representation of the magnetoelastic sensor based on stress dependence of GMI effect (a) and its calibration curve (b). Reprinted with permission from [7], A. Zhukov et al., *J. Magn. Magn. Mater.* 242–245, 216 (2002). © 2002, Elsevier Science.

The resulting temporal dependence of the stresses, corresponding to a signature, is reproducible for each individual person. The main characteristics of this dependence are time of signature, sign, and sequence of the detected peaks.

**Figure 32.** Schematic representation of the magnetoelastic pen (a) and two magnetoelastic signatures (b). Reprinted with permission from [7], A. Zhukov et al., *J. Magn. Magn. Mater.* 242–245, 216 (2002). © 2002, Elsevier Science.

Examples of two magnetoelastic signatures corresponding to the same person are shown in Figure 32b.

## 6. CONCLUSIONS

The following conclusions can be summarized:

The Taylor–Ulitsky technique can be fruitfully employed to fabricate technologically attractive ferromagnetic tiny amorphous, nanocrystalline, and granular system metallic wires covered by an insulating glass coating.

A single and large Barkhausen jump is observed for soft magnetic microwires with positive magnetostriction. Negative magnetostriction microwires exhibit almost unhysteretic behavior. The origin of such magnetic bistability is explained in terms and nucleation and domain wall propagation mechanism. In this way the appearance of a single and large Barkhausen jump is related to the fact that the nucleation magnetic field is higher than the propagation field.

The domain wall velocity measured at temperatures 5–300 K in the range of applied magnetic field of 65–100 A/m in amorphous Fe-rich microwire is found to be much higher than in Ni single crystals but slightly lower than in conventional amorphous wires due to the strong internal stresses. An increase of the domain wall velocity has been found with increasing temperature and magnetic field.

The internal stresses frozen-in during the fabrication process are much stronger than for “in-rotating-water quenching.” As a result, the coercivity decreases with the ratio  $\rho = d/D$ . Significant changes of the soft magnetic properties have been observed in Fe- and Co-rich microwires after different treatments (conventional and current annealing with or without axial magnetic field). Upon heat treatment, FeSiBCuNb initially amorphous microwires devitrificate into nanocrystalline structure. Such devitrification permits one to obtain enhanced magnetic softness in microwires of certain compositions. On the other hand at certain conditions the magnetic bistability has been observed even after the second crystallization process, allowing one to increase the switching field by more than two orders of magnitude up to 5.5 kA/m.

The experimental results on the soft magnetic properties obtained in Fe- and Co-rich microwires (submitted to conventional and current annealing with or without field) can be explained as a consequence of the induced magnetic anisotropy. This anisotropy is arising from the counterbalance between internal quenched-in stresses owing to the difference in thermal expansion coefficients of the metal and the glass. This induced anisotropy should be understood as originating from the simultaneous action of the large internal stresses and the axial applied magnetic field. A stress dependent GMI effect has been found under adequate treatment. Enhanced magnetic softness (initial permeability,  $\mu_1$ , up to 14,000) and GMI effect (up to 600%) were observed in amorphous Co-based microwires with nearly zero magnetostriction after adequate annealing. Large sensitivity of GMI and magnetic characteristics on the external tensile stresses have been observed.

The correlations between their structures and magnetic properties and the geometry (ratio  $\rho$ ) and compositions of Co–Cu, Fe–Cu, and Co–Ni–Cu microwires have been studied. The microstructural properties (interatomic distance,

lattice parameters, grain size, segregation, and relative percentage of phases) are strongly dependent on the geometrical parameters, that is, the relation rate of the diameter of the metallic core relative to the total diameter of the microwire. This effect should be attributed to the internal stresses within the metallic core arising from the different thermal expansion coefficients of the glass coating and the core.

On the other hand high quenching rate permits one to obtain microwires from immiscible elements in a metastable state. These microwires can exhibit hard magnetic behavior and magnetoresistance. The coercivity depends both on the composition of the metallic nucleus and on the thermal treatment. It is worthy to note that elevated coercivity (up to 800 Oe) and GMR have been obtained by annealing  $\text{Co}_{29}\text{Ni}_{25}\text{Cu}_{45}\text{Mn}_1$  samples with a metastable single phase structure in the as-prepared state after the decomposition of this metastable phase.

## GLOSSARY

**Coercivity** The value of reverse driving field required to drive the magnetization to zero after being saturated.

**Giant magneto-impedance effect** Large change of the electric impedance of a magnetic conductor when is subjected to an external dc magnetic field.

**Magnetic bistability** Magnetic flux reversal a single and large Barkhausen jump between two stable remanent states. This results in a macroscopic squared hysteresis loop.

**Magnetoresistance** Change of the electric resistance of a magnetic sample when is subjected to an external dc magnetic field.

**Saturation magnetostriction constant** The fractional change in length as the magnetization increases from zero to its saturation value.

## 1. INTRODUCTION

A ferroelectric is a system that exhibits a spontaneous polarization below the Curie temperature,  $T_c$ , which can be reversed by the application of an electric field. Conventionally, a ferroelectric is called displacive when the elementary dipoles strictly vanish in the paraelectric phase, and order-disorder when they are nonvanishing but thermally average out to 0 in the paraelectric phase. More rigorously, one may distinguish the two types on the basis of the dynamics of their phase transition and the nature of the soft mode involved, whether the frequency shifts to 0 or the linewidth becomes broad [1, 2]. To date, barium titanate (BaTiO<sub>3</sub>) is well accepted as a displacive and order-disorder mixed type of ferroelectric [3–5].

Since the discovery of ferroelectricity in BaTiO<sub>3</sub> in the 1940s, it has been recognized as one of the most important functional materials and has been used in many practical applications in the form of single crystals and ceramics. At high temperature above  $T_c = 393$  K, BaTiO<sub>3</sub> is stabilized in a paraelectric cubic phase (space group  $O_h^1$ ). With decreasing temperature, it undergoes a sequence of structural phase transitions from the cubic to the ferroelectric tetragonal ( $C_{4v}^1$ ) at 393 K, orthorhombic ( $C_{2v}^{14}$ ) at 278 K, and rhombohedral ( $C_{3v}^5$ ) at 183 K, in which the spontaneous polarization,

$P_s$ , is along the prototype cube  $\langle 001 \rangle$ ,  $\langle 110 \rangle$ , and  $\langle 111 \rangle$  directions, respectively. Based on the temperature dependence of  $P_s$ , these three transitions are first-order transitions, the cubic-to-tetragonal phase transition being a first-order transition close to a second-order phase transition [1, 4–6]. In the three low-temperature ferroelectric phases, the existence of spontaneous polarization results in remarkable ferroelectric, dielectric, piezoelectric, pyroelectric, electrooptic, and nonlinear optical properties. As a result, the tetragonal and cubic phases are especially important for commercial technological applications. In ferroelectric BaTiO<sub>3</sub>, the spontaneous polarization, the ferroelectric distortion (tetragonality  $c/a$  ratio), and the tetragonal-cubic transition temperature can be altered by external field changes in the temperature, applied field, stress, or chemical composition. The temperature dependence of  $P_s$  is referred to as a pyroelectric property, the electric field dependence of  $P_s$  as a dielectric property, and the stress dependence of  $P_s$  as a piezoelectric property. They all possess anomalous peaks near the phase transition, particularly the ferroelectric tetragonal-paraelectric cubic phase transition. By varying the chemical composition of BaTiO<sub>3</sub> such as by the addition of strontium or calcium, the tetragonal-cubic phase transition temperature can be shifted downward so that the anomalous dielectric, piezoelectric, and pyroelectric properties can be used to build high-performance devices at ambient temperatures [1, 7].

For BaTiO<sub>3</sub> bulk materials, the room-temperature structural and physical properties are summarized in Table 1. In the ferroelectric tetragonal phase,  $P_s = 26 \mu\text{C}/\text{cm}^2$  with coercive field  $E_c = 1.5 \text{ kV}/\text{cm}$  at room temperature;  $P_s = 18 \mu\text{C}/\text{cm}^2$  at  $T_c$  and jumps to 0 above  $T_c$ . The dielectric constant is strongly anisotropic with  $\epsilon_c = 400$  along the  $c$  axis and  $\epsilon_a = 4000$  perpendicular to the  $c$  axis at room temperature. The piezoelectric coefficient is proportional to  $P_s$ , but the piezoelectric effect is 0 in the paraelectric phase above  $T$  [1, 2]. For conventional ceramics with a grain size of 20–50  $\mu\text{m}$ , the room-temperature dielectric constant is around 2000 at 1 kHz. Previous investigations revealed that the spontaneous polarization, tetragonality, Curie temperature, and various properties related to the spontaneous polarization of the final BaTiO<sub>3</sub> devices strongly depend on the

particle size. For example, the maximum room-temperature dielectric constant  $\epsilon \sim 5000$  was observed in fine ceramics with a grain size of about 1  $\mu\text{m}$  [8–10]. To elucidate the physical mechanism of the ferroelectric properties in reduced dimensions and to determine the ultimate level to which a microelectronic device based on such systems can be miniaturized, the grain size effects in ferroelectrics are most striking [21, 28–33]. These works pointed to prior studies on BaTiO<sub>3</sub> nanostructured materials and also facilitated the application of ferroelectric nanoparticles in advanced technologies.

In condensed-matter physics, many fundamental properties of materials are characterized by their feature length. For example, one of the feature lengths in a semiconductor is the exciton Bohr radius. Heath even stated that, if a crystal is fabricated such that at least one of its dimensions is comparable with the feature length of some property, the property is confined and becomes dependent on the size and shape of what is now called a *quantum crystal* [34]. In semiconductor nanosystems, the quantum size confinement effect, which establishes the physical fundamentals necessary to generate properties different from their bulk counterparts, has led to dipole-forbidden interband transitions,

exciton level discretization, bandgap enhancement, and so on [34–36].

In perovskite-type ABO<sub>3</sub> ferroelectric oxides (BaTiO<sub>3</sub> and PbTiO<sub>3</sub>), the characterizations showed a fascinating dependence of the structural and dynamical behaviors on both details of the chemical composition and the delicate balance between the long-range Coulombic interaction and the short-range electric repulsive and covalent interactions [5, 37–40]. The long-range Coulombic interaction was found to play an important role in forming ferroelectric phases, of which the correlation length between polar units was estimated to be 10–50 nm parallel to the polar direction and 1–2 nm perpendicular to the polar direction [6, 21]. If the dimensionality of the ferroelectric nanomaterials were comparable to this correlation length, the long-range cooperative interaction would be reduced, leading to a phase transformation. Preliminary experimental investigations have revealed some major impact on the lattice vibration, phase transitions, and dielectric, ferroelectric, and optical properties. Some results are presented in Table 1. With decreasing ferroelectric nanocrystallite size below the submicrometer scale, there was a monotonic reduction in the tetragonal–cubic phase transition temperature, a decrease in tetragonality, and a grain size-induced

tetragonal to high-symmetry paraelectric phase transition at/below room temperature. The concept of a ferroelectric critical size, which is necessary to support the long-range cooperative ordering processes necessary for ferroelectricity, has been applied in ferroelectric BaTiO<sub>3</sub> and PbTiO<sub>3</sub> nanocrystals [21, 22, 32, 33, 41].

In this review, we summarize the wet chemical solution methods for producing crystalline BaTiO<sub>3</sub> nanoparticles (nc-BaTiO<sub>3</sub>) with narrow size distributions and size tunability, the vapor deposition methods in particular for growing single crystal ultrathin films, and fabrications of nanoceramics and nanocomposites in Section 2. BaTiO<sub>3</sub> nanoparticle and single-crystal thin films are also treated as building blocks to create nanostructured materials, one-dimensional (1D) and 3D superlattices. The spectroscopic characterizations of structural changes and defects are presented in Section 3. In this section, the surface, defect, and microscopic interaction models for understanding the mechanism of grain size-induced phase transformations are also discussed. The dielectric, ferroelectric, and optical properties of nanocrystalline BaTiO<sub>3</sub> are summarized in Section 4. The lattice dynamic theory in ferroelectric nanocrystals is summarized and the present results on ABO<sub>3</sub> ferroelectric nanoparticles are discussed in Section 5. In addition to BaTiO<sub>3</sub> nanostructured materials, barium strontium titanate (Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub>) nanostructured materials, including synthesis, dielectric, and nonlinear optical properties, are presented in Section 6. Some applications of BaTiO<sub>3</sub> nanostructured materials in the fields of optical modulators, transducers and actuators, and thermal and chemical sensors are given in Section 7. Finally, a short summary is presented.

## 2. SYNTHESSES OF NANOCRYSTALLINE BaTiO<sub>3</sub>

Synthesizing crystalline BaTiO<sub>3</sub> nanostructured materials (nanocrystalline particles, rods, films, and their superlattices) of high purity, stoichiometry, grain size with tunability, and narrow distribution is one of the basic requirements for BaTiO<sub>3</sub> nanoscience and nanotechnology. Various wet chemical solution methods and vapor phase deposition methods have been developed to prepare BaTiO<sub>3</sub> and related nanostructured materials. Using these nanocrystals as building blocks, attempts to fabricate complex superlattices, nanoceramics, and nanocomposites were also performed. In Section 2.1, wet chemical solution methods to prepare nanoparticles and fine microstructure thin films are reviewed, by which the grain size and grain shape have been separately controlled during growth. In Section 2.2, vapor phase deposition methods to grow epitaxial single-crystal thin films and superlattices are discussed. In addition to nanoparticles of 0D nanocrystals and nanorods of 1D nanocrystals, single-crystal thin films with thickness on the nanometer scale form 2D nanocrystals. In Section 2.3, BaTiO<sub>3</sub> nanoceramics fabricated with BaTiO<sub>3</sub> nanopowders as starting materials are discussed. In Section 2.4, BaTiO<sub>3</sub> nanoparticle dispersoids composites are discussed.

### 2.1. Chemical Solution Methods

To date, various wet chemical methods have been developed to synthesize BaTiO<sub>3</sub> nanostructured materials, including coprecipitation such as barium titanate oxalate tetrahydrate (BTOT) and barium titanate oxalate [42–44], freeze-dried nitrate method [45], alkoxide hydrolysis [46], stearic acid gel (SAG) [47, 48], sol-gel [21], hydrothermal methods [31, 49, 50], and solution phase decomposition [51]. The most important advantages of the wet chemical solution methods are easily controlling the chemical stoichiometry and producing particles of grain size on the nanometer scale with a relatively narrow distribution, coupled with low crystallization temperature owing to constituent mixing on the quasi-atomic level in solution state [42]. Using these wet chemical solution methods, various BaTiO<sub>3</sub> nanostructured materials have been successfully fabricated. For example, an ensemble of monodispersed BaTiO<sub>3</sub> nanoparticles with grain size as small as 8 nm and a self-organization of BaTiO<sub>3</sub> nanoparticles are illustrated in Figure 1. Owing to the wet chemical solution process, a dopant such as paramagnetic ions or rare-earth ions could be easily introduced during preparation of the precursor solution [52–54].

In the wet chemical solution processes for synthesizing nc-BaTiO<sub>3</sub>, difficulties arise from the different behaviors of titanium and barium ions versus hydrolysis. To avoid the development of a highly cross-linked Ti–O network in the final structure, various methods were proposed to control the formation of Ti–O–Ti bonds. One method was to use titanium precursors with bidentate ligands (chelates, oxalate, citrate) attached to Ti<sup>4+</sup> ions before reaction with Ba<sup>2+</sup> ions [42, 46]. A second method was to employ organic solvent without water as the dispersing agent to realize the

**Figure 1.** Transmission electron microscopy images of (a) a high-resolution lattice image of an individual 8-nm-diameter nanoparticle and (b) an ensemble of discrete BaTiO<sub>3</sub> 8-nm nanoparticles. Inset: Selected area electron diffraction pattern of (c) self-organization of BaTiO<sub>3</sub> nanoparticles and (d) superlattice of 8-nm-diameter BaTiO<sub>3</sub> nanoparticles. uniform distribution of barium and titanium metalorganics in the gels [47, 48, 55]. These methods involved several reaction steps to deposit the precursor and required calcination at higher temperature to generate crystalline BaTiO<sub>3</sub> nanopowders. Controlling the calcining temperature and time, BaTiO<sub>3</sub> nanopowders with various grain sizes were obtained. For instance, using the SAG technique, Wang et al. and Qiu et al. reported that the average grain size of BaTiO<sub>3</sub> nanopowders prepared at 600–950 °C ranged from 25 to 60 nm [47, 48]. In these methods, a key point was to obtain a homogeneous precursor with uniform distribution of the different components. If not, a number of defects could occur in the nanocrystals [56].

In contrast to those coprecipitation processes, by which the nanopowders obtained were usually aggregate, sol-gel methods with metal alkoxides allowed for fabrication of monodispersed nanoparticles of barium titanate with improved homogeneity and purity. The low-temperature hydrothermal methods (LTHMs) not only allowed fabrication of monodispersed nanoparticles but also reduced the crystallization temperature of BaTiO<sub>3</sub> to less than 100 °C. In the following, these two methods are discussed in detail for fabricating BaTiO<sub>3</sub> nanocrystals. Nanofabrication using mesoporous sieves and microemulsions are also reviewed. At the end of this section, the fabrication of nanocrystalline thin films using wet chemical solution methods is discussed.

### 2.1.1. Sol-Gel Method

The sol-gel method was widely used to produce nanocrystalline BaTiO<sub>3</sub> powders and films. This process involved dissolving the metal-containing compounds in the solvent, hydrolyzing to polymeric condensation, drying the resulting solution into various gels, and, finally, annealing the gels at high temperature to form BaTiO<sub>3</sub> nanocrystals [21, 25, 54, 57, 58]. In this process, the choice of starting materials, concentration, pH value, and heat treatment schedule had a strong influence on the properties of the BaTiO<sub>3</sub> nanoparticles. Barium acetate and titanium isopropoxide were often used as starting materials to generate BaTiO<sub>3</sub> nanopowders. However, the different rates in the hydrolysis and condensation of Ba and Ti precursors often led to chemical component segregation in the obtained gels. To avoid this problem, acetic acid or acetylaceton was used to modify the hydrolysis rate of the Ti precursor, because these complexing agents act as chelating agents to coordinate with Ti species [23, 25, 54].

Compared with the case of mixed Ba and Ti alkoxides, Gablenz et al. and Yang et al. demonstrated that using barium titanium double alkoxides as the raw materials allowed one to produce BaTiO<sub>3</sub> nanoparticles with a higher degree of homogeneity, a relatively narrow grain size distribution, and an exact [Ba/Ti] stoichiometry [59, 60]. In the case of double alkoxides, the absence of free barium alkoxide and titanium alkoxide led to relatively low hydrolysis and condensation rates, but the gelation time was remarkably increased, owing to the evolution of oligomeric structures. During the refluxing period, the oligomeric structures were found as a transition between noncrystalline and crystalline states. The shortest gelation time was observed near the crystalline state [60].

Furthermore, it was found that the pH value of the solvent had a great influence on colloid formation, gel structure, grain size distribution, and degree of aggregation [61, 62]. When the pH value was below 7, no gel formed and the obtained powder had a strong degree of aggregation. However, increasing the pH value above 8, the nanoparticles obtained at 600 °C were homogeneous with an average grain size of 13 nm and a high specific surface area of 33.27 m<sup>2</sup>/g. Luan and Gao analyzed the dependence of the zeta potential on the pH value and found that the hydrolysis was completed more rapidly than the polymerization as the hydrolysis speed was faster than that of polymerization under alkaline conditions. The hydroxide ions reacted with tetrabutyl titanate and water molecules to form the complexion [Ti(OH)<sub>6</sub>]<sup>2-</sup>, which neutralized with the Ba<sup>2+</sup> ion and then polymerized to Ba<sup>2+</sup>[Ti(OH)<sub>6</sub>]<sup>2-</sup>. At the same time, the high-repel potential energies among colloidal particles had reduced the degree of agglomeration, since the pH value was far away from the isoelectronic point (pH = 1.8). Therefore, the nanopowders obtained at high pH were homogeneous and ultrafine. In contrast, when the pH value was below 7, because the polymerization speed was much faster than the hydrolysis speed, polymerization had already started before the completion of hydrolysis. The product was hydrate TiO<sub>2</sub> instead of the Ti complexion. Because the pH value was near the isoelectronic point, the gel particles were much more highly agglomerated.

For the obtained gels, a high-temperature heat treatment above 600 °C was required to remove unreacted organics and to crystallize the films. The following steps represented the transformation from the precursor to the crystalline BaTiO<sub>3</sub>: transformation of the precursor to the amorphous barium titanate, three-dimensional nucleation of the crystalline barium titanate in the amorphous matrix, and crystal growth of BaTiO<sub>3</sub> by a solid-state reaction [63]. The choice of heat treatment schedule, including postannealing temperature and time, and the increased rate of temperature during heating affected the nucleation and crystal growth processes of BaTiO<sub>3</sub> and hence determined the nanocrystallite size and its distribution [62, 63]. The final annealing temperature played a dominant role in determining the grain size and its distribution in the obtained nanomaterials. Conventionally, the higher the annealing temperature or the longer the time, the larger the grain size obtained. In synthesizing ferroelectric Pb(Zr, Ti)O<sub>3</sub> nanoparticles [62], the slow heating rate was found to inhibit the interparticle sintering—nanoparticle aggregation. Moreover, the annealing atmosphere also affected the quality of the nanoparticles; the inert atmosphere reduced the interparticle sintering in comparison with air or oxygen atmosphere. However, these heat treatment techniques were not reported for synthesizing BaTiO<sub>3</sub> nanocrystalline particles and thin films. Because BaTiO<sub>3</sub> is similar to Pb(Zr, Ti)O<sub>3</sub> in its chemical qualities, these heat treatment techniques should be beneficial for synthesizing monodispersed freestanding BaTiO<sub>3</sub> nanocrystalline particles and thin films.

With these techniques, monodispersed BaTiO<sub>3</sub> nanoparticles and related nanostructured materials have been successfully fabricated. The grain size was adjusted from a few nanometers up to micrometer size by combining solid-state polymerization and heat treatment [21, 53, 59–61, 63].

### 2.1.2. Low-Temperature Hydrothermal Method

In contrast to sol-gel processing, the low-temperature (below 100 °C) hydrothermal method with inorganic precursors offers a promising cost-effective approach to producing crystalline BaTiO<sub>3</sub> nanoparticles and relevant nanomaterials. Thermodynamic calculations of the Ti-Ba-CO<sub>2</sub>-H<sub>2</sub>O system indicated that BaTiO<sub>3</sub> is the thermodynamically favored phase at pH greater than 12 and high concentrations (2 M) of Ba<sup>2+</sup> [64, 65]. Based on this prediction, BaTiO<sub>3</sub> nanocrystals were produced by rapid hydrolysis of compounds such as TiCl<sub>4</sub>, Ti alkoxides, or BaTi double alkoxides in an aqueous medium under strong alkaline conditions, and the grain size was tuned by controlling the reaction conditions such as concentration, pH, and temperature [31, 49, 52, 64–67].

Conventionally, the low-temperature hydrothermal synthesis of BaTiO<sub>3</sub> nanoparticles was carried out in a batch-type reactor below 100 °C under atmospheric pressure. There were two effective routes using synthesized titania gel or titania nanoparticles to produce BaTiO<sub>3</sub> nanoparticles.

For the case of titania gels, the raw materials were either inorganic such as barium chloride, titanium chloride, and sodium hydroxide base or organic salts such as barium acetate, titanium isopropoxide, and the organic base, tetramethylammonium hydroxide. A typical chemical reaction from inorganic salts can be written as

where the ionic species react in an aqueous solution with a temperature of 80–95 °C to form monodispersed crystalline nanoparticles with a grain size of 30–220 nm [31, 33, 52]. In a typical case, 164 mL NaOH solution of concentration 3.0 mol/L was preheated to 85 °C in a beaker, and 96 mL BaCl<sub>2</sub>-TiCl<sub>4</sub> solution of 1 mol/L was then added under stirring. The entire system was kept at 85 °C for 10 min. The nanoparticles obtained were determined to have an average grain size of approximately 80 nm and a specific surface area of 25 m<sup>2</sup>/g. In this route, the stoichiometry in nc-BaTiO<sub>3</sub> was achieved when the Ba/Ti molar ratio was 1.07 in the starting solution, and the aging time for full crystallization was as short as 4 min [31, 68]. Furthermore, Her et al. developed a controlled double-jet precipitation technique and realized continuous precipitation of monodispersed colloidal barium titanate nanopowders, for example, in a moderate-sized experimental reactor with about 50 pounds per day [31, 69]. The nanoparticle agglomeration could be avoided by controlling the flow rate and the volume of reactants. As known, one important source of contamination of nc-BaTiO<sub>3</sub> is the formation of BaCO<sub>3</sub>, through the reaction of Ba<sup>2+</sup> with CO<sub>3</sub><sup>2-</sup> ions coming from air or dissolved in alkaline solutions. To reduce the final amount of this secondary phase, special care was taken in avoiding contact of NaOH solution with the atmosphere.

Moreover, the crystalline BaTiO<sub>3</sub> nanoparticles were directly formed by hydrolyzing the barium titanium double alkoxides at 60 °C under a pH of 13 without any further calcination [60]. With barium titanium double alkoxides as the raw materials, a semicontinuous hydrothermal process was also designed to produce BaTiO<sub>3</sub> nanopowders [70]. The grain size of the nanoparticles obtained by

hydrolyzing double alkoxides was around 10 nm. MacLaren and Ponton investigated the formation mechanisms of low-temperature hydrothermal conversion of BaTiO<sub>3</sub> nanoparticles from an amorphous hydrous TiO<sub>2</sub> gel, which was derived from hydrolysis of titanium isopropoxide, in a solution of barium acetate and strong tetramethylammonium hydroxide base. On the basis of the fast reaction rate for the formation of nc-BaTiO<sub>3</sub>, it was proposed that the BaTiO<sub>3</sub> nanoparticles were formed by an *in-situ* transformation of amorphous TiO<sub>2</sub> gel [67].

The second route was low-temperature hydrothermal conversion of titania nanoparticles in barium hydroxide solutions [65, 71, 72]. This route coupled two low-temperature hydrothermal steps: synthesis of monodispersed titania nanoparticles and hydrothermal conversion of the prepared titania nanoparticles to nanocrystalline BaTiO<sub>3</sub>. At first, the morphology observations seemed to support a *dissolution-precipitation* mechanism—involving dissolution of TiO<sub>2</sub> into Ti(OH)<sub>x</sub><sup>4-x</sup> species, precipitative BaTiO<sub>3</sub> nucleation by reaction with barium ions/complexes in solution, and recrystallization/growth—for the hydrothermal conversion of titania nanoparticles into nc-BaTiO<sub>3</sub> [65, 71]. However, recent measurements indicated that the particle size and morphology of the BaTiO<sub>3</sub> nanoparticles remained the same as the precursor titania nanoparticles. A shrinking-core *in-situ* transformation diffusion-reaction mechanism was proposed for this TiO<sub>2</sub>-to-BaTiO<sub>3</sub> conversion process [72]. In principle, the grain size of the BaTiO<sub>3</sub> nanoparticles can be tuned by varying the size of the titania nanoparticles. In the development of nanocrystalline titania, TiO<sub>2</sub> nanoparticles with a grain size as small as approximately 3 nm were successfully prepared [73]. Thus, monodispersed BaTiO<sub>3</sub> nanoparticles with a grain size less than 10 nm can be prepared from titania nanoparticles by this low-temperature hydrothermal process.

As discussed above, the low-temperature hydrothermal process provides an alternative to postannealing to control the phase structure of ferroelectric nanocrystals. Combining these two crystallization methods, two-phase coexisting barium titanate nanoparticles were synthesized with TiCl<sub>4</sub> and BaCl<sub>2</sub> as the raw materials, of which the second-phase clusters of the BaTiO<sub>3</sub> hexagonal phase or BaTi<sub>2</sub>O<sub>5</sub> were embedded within the BaTiO<sub>3</sub> nanoparticles [49, 74, 75].

To date, the low-temperature hydrothermal method has enjoyed considerable success for the production of monodispersed barium titanate spheric nanoparticles with a grain size ranging from 5 nm to the submicrometer, with a narrow distribution, and with a high purity. It has promise not only as a suitable laboratorial process but also as a suitable industrial process to produce barium titanate nanoparticles, starting from cheaper inorganic precursors (titanium oxide or chloride; barium hydroxide or chloride) [69, 70].

### 2.1.3. Nanofabrication

Among the important characteristics of nanoparticle systems are facile manipulation and reversible assembly that allow for the possibility of incorporating nanoparticles into nanoscale electric, electronic, optical, and mechanical devices. Such bottom-up or self-assembly approaches have also been attempted in BaTiO<sub>3</sub> nanofabrications.

The mesoporous silicate molecular sieve has uniform columnar periodic hexagonal mesopores ranging from 15 to 100 Å and separated by 8- to 9-Å walls, and is an important nanoreactor. BaTiO<sub>3</sub> nanoparticles were embedded in the uniform mesopores by soaking a mesoporous silicate molecular sieve into a BaTiO<sub>3</sub> precursor solution and with calcination at 700 °C to crystallize BaTiO<sub>3</sub> nanoparticles [76, 77]. Using sol-gel-type hydrolysis [46, 60], the crystalline BaTiO<sub>3</sub> nanoparticles embedded in mesoporous sieves can also be directly fabricated without any calcination.

Water-in-oil microemulsions are another important kind of nanoreactor, which are also used to synthesize BaTiO<sub>3</sub> nanoparticles. The water droplet size in microemulsions can be tuned between 8 and 55 nm by varying the length of the hydrophilic part of the surfactant molecules, and, consequently, the size of the resulting BaTiO<sub>3</sub> nanoparticles can be determined [78]. In these microemulsions, the crystalline BaTiO<sub>3</sub> and SrTiO<sub>3</sub> nanoparticles were directly prepared by a sol-gel-type hydrolysis reaction without calcination [78, 79].

In the synthesis of nanostructured materials, a general approach based on solution phase decomposition in a structured inverse micelle medium has been developed to separately control the shape and size of colloidal inorganic nanocrystals. The anisotropic growth is controlled by using a mixture of surfactants, where the different surfactants are used to selectively control the growth rates of different faces [80]. Of interest, this technique was successfully extended to synthesize BaTiO<sub>3</sub> nanoparticles and nanorods. First, O'Brien et al. synthesized monodispersed perfect cubic BaTiO<sub>3</sub> nanoparticles with diameters ranging from 6 to 12 nm. At the same time, the propensity of these BaTiO<sub>3</sub> nanoparticles to self-assemble into superstructures was also demonstrated, as illustrated in Figure 1 [51]. In their typical synthesis, 1 mmol barium titanium ethyl hexanoisopropoxide was injected into a mixture of 50 mL diphenyl ether and 3 mmol stabilizing agent oleic acid at 140 °C under argon or nitrogen. Excess 2-propanol was removed under vacuum. The mixture was cooled to 100 °C and 30 wt% hydrogen peroxide solution (0.9 mL) was injected through the septum. The solution was maintained in a closed system and stirred at 100 °C (under a mild reflux with the remaining water content) over 48 h to promote further hydrolysis and crystallization of the product in an inverse micelle condition.

Recently, Urban et al. synthesized perfect single-crystalline cubic BaTiO<sub>3</sub> and SrTiO<sub>3</sub> nanorods with diameters ranging from 5 to 60 nm and lengths in excess of 10 μm [81, 82]. In their typical reaction, a 10-fold molar excess of 30% H<sub>2</sub>O<sub>2</sub> was added at 100 °C to 10 mL heptadecane solution containing 10 mmol barium titanium isopropoxide alkoxide precursor and 1 mmol oleic acid. The reaction mixture was subsequently heated to 280 °C for 6 h, and a white precipitate composed of nanorod aggregates was obtained. Anisotropic nanorod growth was due to precursor decomposition and crystallization in a structured inverse micelle medium formed by the precursor and oleic acid under these reaction conditions.

This developing nanotechnology will provide more complex nanostructured systems for fundamental investigations on nanoscale ferroelectricity, piezoelectricity, and paraelectricity.

### 2.1.4. Nanocrystalline Film Deposition

The microstructures of nanocrystalline BaTiO<sub>3</sub> thin films are mainly composed of ultrafine grains (random or highly oriented) and epitaxial single crystals. The epitaxial single-crystal thin films with thickness on the nanometer scale will be discussed in the next section. For ultrafine microstructured films, the sol-gel method is a good candidate for coating substrates with a large area or complex shape. Using the same precursors as in the preparation of nanoparticles, thin films were prepared by spin-coating, dip-coating, or spray-coating techniques [24]. For instance, BaTiO<sub>3</sub> nanocrystalline films of thickness 200 nm–3 μm were successfully produced on a Si single crystal or on platinum-coated Si single-crystal substrates, in which the average grain size was about 25 nm annealed at 750 °C [25, 54, 83]. Studies of the film deposition mechanism revealed that the nanocrystalline granular microstructure was formed due to homogeneous nucleation in a layer-by-layer film process. When one limits the trend of homogeneous nucleation but enhances the heterogeneous nucleation at the substrate via some tricks such as lowering the thickness of each coating layer, a nanocrystalline columnar microstructure was obtained [24, 84, 85].

The conventional sol-gel process required heat treatment at temperatures above 600 °C in order to crystallize the BaTiO<sub>3</sub> films. This limited the practical application of ferroelectric thin films in integrated semiconductor circuits owing to severe interface diffusion at high crystallization temperature. To reduce the processing temperature, an alternative was to combine the merits of the sol-gel and low-temperature hydrothermal methods. In this so-called sol-gel-hydrothermal process, the as-dried BaTiO<sub>3</sub> gel films were used as the precursor films for post hydrothermal treatment. Using this process, BaTiO<sub>3</sub> nanocrystalline thin films have been obtained at temperatures below 100 °C [86–88].

Alternatively, BaTiO<sub>3</sub> nanocrystalline thin films were also fabricated *in-situ* by low-temperature hydrothermal-electrochemical methods [64, 89–91]. One method was to use titanium metal electrode contributing the Ti source within BaTiO<sub>3</sub> thin films by anodic oxidation of Ti reacting with Ba<sup>2+</sup> and OH<sup>-</sup> ions [64, 90]. Another method was to electrophoretically deposit BaTiO<sub>3</sub> nuclei within solution on the substrates [89, 91]. With the latter technique, Tamaki et al. successfully obtained epitaxial nc-BaTiO<sub>3</sub> thin films with a grain size less than 10 nm on La<sub>0.7</sub>Sr<sub>0.3</sub>MnO<sub>3</sub>-coated SrTiO<sub>3</sub> single-crystal substrate [91]. It should be noted that these films were usually characterized by partial substrate coverage or high surface roughness.

## 2.2. Vapor Phase Methods

Besides wet chemical solution methods, BaTiO<sub>3</sub> nanostructured materials were also prepared by vapor deposition methods, in which vapor and/or plasma were generated by electrical, optical, or chemical methods [18, 92–97]. Among those various physical vapor deposition processes such as thermal evaporation, magnetron sputtering, and laser ablation, the main difference is the interaction process used to generate a vapor and/or plasma by the removal of the target material. The type, density, energy, and excitation of atoms, molecules, clusters, and micro- and macroparticles

within the generated vapor (plasma) resulted in different microstructures of nanocrystalline particles and thin films. Compared with the wet chemical solution methods, the unique advantage of the vapor deposition methods was to grow epitaxial single-crystal thin films. At present, BaTiO<sub>3</sub> epitaxial thin films have been achieved in an atomic scale layer-by-layer growth mode using metalorganic chemical vapor deposition (MOCVD) and laser molecular beam epitaxy (laser MBE) techniques [94–97]. In this section, the laser MBE technique for growing BaTiO<sub>3</sub> epitaxial single-crystal thin films and related superlattices is discussed in detail.

### 2.2.1. Epitaxial Thin Film

Pulsed laser deposition performed in an ultrahigh vacuum, that is, laser MBE, has been verified as a suitable method for growing single-crystal thin films and artificial superlattices in an atomic scale two-dimensional layer-by-layer growth mode. It combines the merits of pulsed laser deposition and conventional MBE for growing epitaxial thin films, especially suitable for high-melting-point perovskite oxide ceramics such as BaTiO<sub>3</sub> and multicomponent solids such as (Ba, Sr)TiO<sub>3</sub> controlled in atomic scale [96–99]. The details of the laser MBE apparatus and processes are described in the literature [97, 98].

Using the laser MBE technique, Lu et al. and Yoneda et al. fabricated *c*-axis-oriented BaTiO<sub>3</sub> ultrathin films of 1- to 50-unit-cell layers on SrTiO<sub>3</sub> (001) and MgO (001) substrates [96, 97]. The epitaxial relationship of BaTiO<sub>3</sub> films on both SrTiO<sub>3</sub> and MgO substrates was determined to be [100] film||[100] substrate (in the growth plane) and (001) film||(001) substrate (along the growth direction). For the BaTiO<sub>3</sub> single crystal, the thermal expansion coefficient is  $\alpha = 15.7 \times 10^{-6}/^{\circ}\text{C}$  along the *a* axis at room temperature [17]. In contrast, for the SrTiO<sub>3</sub> substrate, the cubic lattice parameter is  $a = 3.905 \text{ \AA}$  and  $\alpha = 11.7 \times 10^{-6}/^{\circ}\text{C}$  at 300 K, and for the cubic MgO substrate,  $a = 4.213 \text{ \AA}$  and  $\alpha = 14.8 \times 10^{-6}/^{\circ}\text{C}$  at 300 K [100]. From the viewpoint of lattice mismatch, the magnitude of mismatch between the MgO substrate and the bulk BaTiO<sub>3</sub> *c* axis is smaller than that between the MgO substrate and the bulk BaTiO<sub>3</sub> *a* axis. If the epitaxial relationship depends only on the lattice-matched condition, the *a* axis of the BaTiO<sub>3</sub> films on the MgO substrates should be oriented in the growth direction and the *c* axis in the growth plane. However, the BaTiO<sub>3</sub> films obtained on MgO substrates were *c*-oriented. Therefore, the lattice mismatch strain is not the only factor that determines the orientation of the BaTiO<sub>3</sub> films. Studying BaTiO<sub>3</sub> epitaxial films on various substrates, it was found that, owing to lattice and thermal expansion coefficients between the thin film and the substrate, the net elastic strain in the film growth dictated the orientation of the epitaxial BaTiO<sub>3</sub> thin films [100–102]. On the other hand, the magnitude of mismatch between the bulk BaTiO<sub>3</sub> *a* axis and the SrTiO<sub>3</sub> (+2.3%) was smaller than that between BaTiO<sub>3</sub> and MgO (−5.2%). Owing to this different epitaxial strain, the BaTiO<sub>3</sub> thin films had different crystal quality and tetragonality, for example,  $c/a = 1.003$  and  $1.018$  for the 200-nm-thick epitaxial film, respectively, on the SrTiO<sub>3</sub> and MgO substrates [96]. For BaTiO<sub>3</sub> epitaxial thin films on a MgO

substrate, the lattice parameter perpendicular to the surface was found to be nearly independent of the film thickness and close to the *c*-axis bulk value, while the in-plane lattice parameter was intermediate between the bulk *a*- and *c*-axis values and approached the bulk *a*-axis value with increasing film thickness to 2000 nm [102, 103]. In summary, the lattice strain in BaTiO<sub>3</sub> epitaxial thin films could be tuned by choosing the substrate and controlling the film thickness. To eliminate the substrate clamping effect, preparing freestanding BaTiO<sub>3</sub> single-crystal thin films is the next object.

On the SrTiO<sub>3</sub> substrates with various orientations, the surface morphology of BaTiO<sub>3</sub> epitaxial films exhibited different roughness. For the typical perovskite oxides with formula ABO<sub>3</sub>, there are two possible terminating atomic layers, AO (A-site plane) and BO<sub>2</sub> (B-site plane), on the (100) surface. In the 10-nm-thick BaTiO<sub>3</sub> (001) epitaxial thin film on a SrTiO<sub>3</sub> (001) substrate, the *in-situ* reflection high-energy electron diffraction intensity oscillation indicated the BaTiO<sub>3</sub> thin film to be in a unit-cell layer-by-layer growth. Angle-resolved X-ray photoelectron spectroscopy analysis revealed that the topmost surface atomic plane for this BaTiO<sub>3</sub> ultrathin film was the TiO<sub>2</sub> layer. Thus, the BaTiO<sub>3</sub> film growth sequence was determined as TiO<sub>2</sub> (substrate)/BaO/TiO<sub>2</sub>/.../BaO/TiO<sub>2</sub>. The root mean square surface roughness was 0.2 nm observed by atomic force microscopy [104]. In contrast, the topmost surface of BaTiO<sub>3</sub> (001) epitaxial films with a thickness greater than 80 nm was determined as the BaO plane, even though the SrTiO<sub>3</sub> (001) substrate had the dominant topmost surface of TiO<sub>2</sub> [96, 99]. These facts also suggested that the film growth did not simply depend on the lattice-matched condition between the BaTiO<sub>3</sub> films and the substrates [96, 105]. It should be noted that the substrate surface treatment was very important for the growth of high-quality epitaxial films in the layer-by-layer mode, especially for the ultrathin films of unit-cell layers [97, 99].

To date, epitaxial BaTiO<sub>3</sub> single-crystal thin films have been successfully deposited on various single-crystal substrates such as SrTiO<sub>3</sub>, LaAlO<sub>3</sub>, SrRuO<sub>3</sub>, MgO, MgAl<sub>2</sub>O<sub>4</sub>, and sapphire [94, 97–99, 103]. These epitaxial films may provide a wide range of applications in microelectronics, integrated optics, and microsystem technology, such as sensors, microactuators, memories, and optical waveguide devices. Of interest, BaTiO<sub>3</sub> is also a good candidate for the insulating layer in high-*T<sub>c</sub>* oxide devices due to its similar perovskite structure and small lattice mismatch with the high-*T<sub>c</sub>* oxide superconductors. The heteroepitaxial growth of BaTiO<sub>3</sub> ultrathin films using the laser MBE technique creates a new way to fabricate superconductor–insulator–superconductor tunnel junction devices [97, 99].

In semiconductor nanotechnology, the MBE technique was widely used to fabricate ordered nanostructures through the self-organized growth mode. For Ce:BaTiO<sub>3</sub> oxide, the strain-driven self-organized growth of nanoscale islands was also exploited using the laser MBE technique on MgO (100) substrates. The distributed coherent Ce:BaTiO<sub>3</sub> square base pyramidal nanoislands were fabricated on top of a thicker wetting layer [106].

### 2.2.2. Strained Superlattice

Synthetic superlattices are an essential approach to artificially controlling the crystal structures and ferroelectric properties. By changing the constituent layer thickness and stacking periodicity of the superlattice, the lattice strain stored in epitaxial thin films can be tuned [107]. With this approach, the dielectric constant, remanent polarization, Curie temperature, and/or lattice dynamics properties of BaTiO<sub>3</sub> have been remarkably tuned [99, 108–110].

In addition to BaTiO<sub>3</sub>, heteroepitaxial thin films of SrTiO<sub>3</sub>, CaTiO<sub>3</sub>, and BaZrO<sub>3</sub> perovskite oxides were also achieved in the layer-by-layer growth mode using laser MBE. Thus, atoms of Ba and Ti in BaTiO<sub>3</sub> can be replaced site selectively with atomic accuracy and lattice strain introduced by a combination of different layers. For instance, BaTiO<sub>3</sub>/SrTiO<sub>3</sub> artificial superlattices with periodicity of the BaTiO<sub>3</sub>/SrTiO<sub>3</sub> layers varying from 1 unit cell to 125 unit cells were obtained [98, 109]. In the BaTiO<sub>3</sub>/SrTiO<sub>3</sub> (BaTiO<sub>3</sub>/CaTiO<sub>3</sub>) superlattices, there is a relatively large mismatch of 2.5% (5.5%) between the in-plane lattice parameters. When the film thickness reaches a critical thickness, misfit dislocations will form, which relax lattice mismatch strain and deteriorate the surface roughness [111]. The critical thickness for the strained superlattice has been experimentally determined as 220 Å for the BaTiO<sub>3</sub>/SrTiO<sub>3</sub> superlattice and 55 Å for the BaTiO<sub>3</sub>/CaTiO<sub>3</sub> superlattice [107, 112].

### 2.3. Nanoceramics

For BaTiO<sub>3</sub> ceramics, not only their dielectric properties but also their mechanical properties were found to depend strongly on the microstructures, such as grain size, grain geometry, and relative density. Using BaTiO<sub>3</sub> nanoparticles as starting powders significantly lowers the sintering temperatures and enhances the mechanical and electrical properties of the final ceramics, due to improved homogeneity, purity, controlled grain size, and its distribution, and thus creates opportunity to develop better performing nanoceramic devices [79, 113–115].

With monodispersed BaTiO<sub>3</sub> nanoparticles as the starting material, Her et al. obtained BaTiO<sub>3</sub> fine ceramics using conventional ceramic processing. In a typical case, the polyvinyl alcohol was first added to BaTiO<sub>3</sub> nanopowders approximately 100 nm in size as a binder to prepare green pellets. Second, the polyvinyl alcohol-containing BaTiO<sub>3</sub> nanopowders were cold-pressed to form a pellet under 340 MPa. Then the pellet was sintered in air at a high temperature at a heating rate of 2°/min from room temperature to 600 °C and then at a heating rate of 8°/min from 600 °C to sintering temperature. Fine ceramics with a high density of 5.90 g/cm<sup>3</sup> (98.2% of the theoretical density of 6.01 g/cm<sup>3</sup>) and 6.00 g/cm<sup>3</sup> (99.8% of the theoretical density) were produced by sintering at temperature as low as 1200 °C and 1250 °C, respectively, in which the average grain size was over 1–2 μm. The dielectric constant for the ceramics sintered at 1200 °C was 9700 at 120 °C and 5000 (with a dissipation factor of 2.0%) at room temperature [31]. Intensive investigations indicated that the maximum room-temperature dielectric constant of BaTiO<sub>3</sub>

ceramics was obtained with density near the theoretical density and optimal grain size near 1 μm [10, 31, 113, 116, 117]. Moreover, using BaTiO<sub>3</sub> nanoparticles allows thinner layers of ceramic in multilayer capacitors without loss of dielectric properties.

BaTiO<sub>3</sub> nanoceramics were also fabricated by using BaTiO<sub>3</sub> nanoparticles with even smaller grain size and/or controlling the sintering schedule. Using nanopowders with a grain size of about 10 nm as the starting materials, Luan et al. fabricated BaTiO<sub>3</sub> nanoceramics under hot pressing at uniaxial pressures in vacuum. It was found that both the density and the grain size increase quickly with increasing sintering temperature. The average grain size and relative density changed from 280 to 1800 nm and from 93.2 to 98.8%, respectively, when the sintering temperature increased from 1050 to 1150 °C [118]. At 1250 °C under atmospheric pressure, Bocquet et al. obtained BaTiO<sub>3</sub> nanoceramics with a grain size of 200–800 nm and a relative density of 98%. The dielectric constant was measured as  $\epsilon_{RT} = 2780$  at room temperature and  $\epsilon_{max} = 10,520$  at  $T_c = 115$  °C [70].

Ragulya developed a rate-controlled sintering process, which controlled the densification rate instead of controlling the linear heating rate during sintering. Using this technique, he obtained BaTiO<sub>3</sub> nanoceramics with a relative density up to 99.9% and the average grain size ranged from 100 to 300 nm for BaTiO<sub>3</sub> nanopowders with a grain size of 20–25 nm. Two optimal rate-controlled temperature–time paths for preparing BaTiO<sub>3</sub> nanoceramics were also reported [119]. In comparison with conventional temperature-controlled sintering, the rate-controlled sintering allowed one to obtain nanoceramics of smaller grain size and narrower distribution.

Spark plasma sintering is a process that makes use of a microscopic electrical discharge between particles under mild pressure (30–50 MPa). This process enables a compact powder to be sintered to high density at relatively lower temperatures and in much shorter sintering times, typically a few minutes, compared with the conventional sintering process of cold isostatic pressing. Using the spark plasma sintering method, starting from BaTiO<sub>3</sub> nanopowders with a grain size of 60 nm, Takeuchi et al. produced dense BaTiO<sub>3</sub> nanoceramics with a relative density greater than 95% and an average grain size less than 500 nm under 1100 °C for 5 min. The temperature increased from room temperature to sintering temperature at a heating rate of approximately 160 °C/min, which was controlled by the applied current. It was found that the grain size of the initial nanopowders significantly affected the grain size of the resulting ceramics. For BaTiO<sub>3</sub> nanoceramics with an average grain size of 300 nm, the room-temperature dielectric constant, spontaneous polarization, and remanent polarization were measured as 3000 at 100 kHz, 15 μC/cm<sup>2</sup>, and 2 μC/cm<sup>2</sup>, respectively [10].

In addition to suppressing exaggerated grain growth, the lower sintering temperature and/or shorter sintering time allow use of less expensive electrode materials in fabricating ceramic multilayer capacitors [10, 45, 120].

## 2.4. Nanocomposites

### 2.4.1. Ceramic Matrix Composites

Since ceramic nanocomposites, materials reinforced by secondary dispersoids of a few tens to a few hundreds of nanometers in size (nanoparticles), were proposed in the field of engineering ceramics, significant improvements have been reported in their mechanical properties, such as fracture strength, hardness, and fracture toughness. From the viewpoint of mechanical properties, ferroelectricity or piezoelectricity shows an interesting property. By utilizing the electromotive force of the ferroelectric material, one is able to detect crack propagation. When the ferroelectric materials are subjected to an electric field, additional internal stresses are induced; since the internal stresses are anisotropic, they can increase or decrease fracture toughness, depending on the poling direction [121]. In this regard, ferroelectric nanoparticle-dispersed ceramic nanocomposites are expected to exhibit such intelligent functions as predicting fracture, controlling crack propagation, and so on.

As one of the most important ceramic nanocomposites, BaTiO<sub>3</sub> ferroelectric nanoparticle-dispersed MgO ceramic composites were developed through hot pressing or pulse electric current sintering (PECS) [122, 123]. Using nc-BaTiO<sub>3</sub> with an average grain size of 100 nm as the starting material, Hwang et al. obtained highly densified nc-BaTiO<sub>3</sub>/MgO ceramic nanocomposites and showed that these nc-BaTiO<sub>3</sub>/MgO ceramic nanocomposites introduced ferroelectricity/piezoelectricity into the nanocomposites and still retained their mechanical properties. They also demonstrated that the PECS technique took advantage of shorter time and lower temperature to sinter ceramic nanocomposites in comparison with the hot-pressing technique, which increased the tetragonality of the BaTiO<sub>3</sub> dispersoids because Mg<sup>2+</sup> was not substituted for Ti<sup>4+</sup> in the hot-pressed samples [123]. Compared with these two sintering methods, the PECS is a reasonably better sintering technique for fabricating various ceramic nanocomposites containing BaTiO<sub>3</sub> nanoparticles with even smaller grain size.

### 2.4.2. Polymer Matrix Composites

For ferroelectric nanoparticle dispersive nanocomposites, polymer is another kind of important matrix. The ferroelectricity impacted on polymeric nanocomposites could provide various applications in pyrosensors and piezosensors. In the 1990s, the considerable progress in nanotechnology rendered possible the fabrication of ferroelectric nanoparticle/polymeric nanocomposites. The basic process for fabricating polymer-based nanocomposites is to mix monodispersed ferroelectric nanoparticles into the polymer with the aid of suitable solvents [124–126].

The pyroelectric vinylidene fluoride/trifluoroethylene [P(VDF-TrFE)] copolymer is a useful matrix to form nanocomposites. P(VDF-TrFE) 70/30 mol% copolymer has a Curie temperature of 102 °C upon heating and a melting temperature of 150 °C. To prepare BaTiO<sub>3</sub> nanoparticles/copolymer nanocomposites, the copolymer was first dissolved in methyl-ethyl-ketone solvent and ferroelectric BaTiO<sub>3</sub> nanopowder was then blended into the solution to form a mixture. The powder in the mixture was dispersed

in an ultrasonic bath to produce a homogeneous suspension. The experiments revealed that the qualities of the BaTiO<sub>3</sub> nanoparticles such as agglomeration and grain size limited the volume fraction of nanoparticles in the composite. Using small uniform monodispersed BaTiO<sub>3</sub> nanoparticles can increase the volume fraction of nanoparticles in the composites. Thin films of ferroelectric nanoparticles/copolymer nanocomposites were also fabricated using the spin-coating technique. Finally, heat treatment at 120 °C was performed to remove the solvent. Experimental measurements indicated that all three figures of merit (current, voltage, and detectivity) increased with increasing volume fractions of nanoparticles in the composite [124, 125].

Using this mixing technique, Yamamoto et al. prepared 40 vol% nc-BaTiO<sub>3</sub>/chloroprene polymer composites and investigated the grain size effect on the piezoelectric properties of BaTiO<sub>3</sub>/polymer nanocomposites. It was revealed that the piezoelectric constant was closely related to the crystallographic phase of nc-BaTiO<sub>3</sub>. With BaTiO<sub>3</sub> nanoparticles in the cubic phase, the piezoelectric coefficient  $d_{33}$  of BaTiO<sub>3</sub>/polymer nanocomposites was very small (about 2 pC/N), but when the grain size was increased above the critical size, the  $d_{33}$  tetragonal nc-BaTiO<sub>3</sub> dispersoids increased rapidly to 23 pC/N [126].

At the conventional crystallization temperature of BaTiO<sub>3</sub> nanoparticles (>600 °C), the polymer matrix was severely destroyed. As discussed in Section 2.1, low-temperature hydrothermal processing can reduce the crystallization temperature of BaTiO<sub>3</sub> nanoparticles below 100 °C. Taking advantage of this property, Collins and Slamovich extended it to directly prepare nc-BaTiO<sub>3</sub>/polymer nanocomposite thin films. Thin-film composites of BaTiO<sub>3</sub> nanoparticles in polymeric matrix were processed by hydrothermally treating a film of titanium alkoxide mixed within polybutadiene-polystyrene triblock copolymer in an aqueous solution of 1.0 M Ba(OH)<sub>2</sub> at a temperature ranging from 60 to 90 °C. The subsurface growth of BaTiO<sub>3</sub> proceeded through the percolating network of hydrolyzed titanium alkoxide, which enabled the reaction solution to permeate throughout the thin films. In their BaTiO<sub>3</sub>/polymer nanocomposite thin films, the grain size of the subsurface BaTiO<sub>3</sub> nanoparticles was approximately 5–10 nm, independent of the processing temperature, but the grain size of the surface nanoparticles was over 60–180 nm, depending on the processing temperature. The room-temperature dielectric constant of the 90 wt% BaTiO<sub>3</sub>/polymer nanocomposite films was 10–15 at a frequency of 10 kHz. These ferroelectric nanoparticle/polymeric nanocomposite thin films could be used for applications ranging from nonlinear optics to abrasion-resistant coatings [127].

## 3. SPECTROSCOPIC CHARACTERIZATION

### 3.1. Structural Changes

In the BaTiO<sub>3</sub> nanocrystals, the structural and physical properties were strongly dependent on the grain size. With decreasing grain size of the nanoparticles, the anomalous lattice expansion, tetragonality decrease, and tetragonal-cubic phase transition were experimentally observed at room temperature [21, 22, 33, 44, 49, 128]. Figure 2 presents one

**Figure 2.** Lattice parameters determined from the (200) XRD data and representing the room-temperature cubic-to-tetragonal structural transition with increasing processing temperature. example of lattice constant variation in the sol-gel-derived BaTiO<sub>3</sub> nanocrystalline particles as a function of heat treatment temperature, that is, nanoparticle grain size. It was clearly demonstrated that, with decreasing grain size, the lattice constant, *a*, of BaTiO<sub>3</sub> nanoparticles increased anomalously in both the tetragonal and the cubic phases, while the lattice constant, *c*, decreased, which resulted in a decrease in tetragonality and tetragonal-to-cubic phase transition [21]. In the monodispersed BaTiO<sub>3</sub> nanoparticles derived by the alkoxide method, the elongation of the lattice constant of *a* was measured to be greater than 2.5% in a 15-nm nanocrystallite using the electron diffraction technique [129]. In Figure 3, the room-temperature tetragonality as a function of grain size, which was determined using specific surface area data, is presented for hydrothermally derived BaTiO<sub>3</sub> nanoparticles. Below 300 nm, the tetragonality decreased exponentially, and the tetragonality of nc-BaTiO<sub>3</sub> became 1 at a critical size of approximately 120 nm, while a size-induced ferroelectric tetragonal-paraelectric cubic phase transition took place [22]. It should be noted that the reported critical size for the grain size-induced BaTiO<sub>3</sub> tetragonal-cubic phase was closely correlated with the particular processing and the grain size determination methods. Some experimentally obtained critical sizes are listed in Table 2. It can be seen that they are on the order of 50 nm as

**Figure 3.** Change in tetragonality *c/a* with particle size at room temperature. Reprinted with permission from [22], K. Uchino et al., *J. Am. Ceram. Soc.* 72, 1555 (1989). © 1989, American Ceramic Society.

**Table 2.** Critical size of the tetragonal-cubic phase transition at room temperature for BaTiO<sub>3</sub> nanoparticles.

Synthesis method	Critical size	Measurement method	Ref.
sol-gel	50 nm	XRD SEM	[21, 58]
Hydrothermal	90 nm	XRD	[22]

determined by the X-ray diffraction (XRD) technique [21, 22, 25, 44, 49, 58, 128, 130].

Thermal measurements on BaTiO<sub>3</sub> polycrystals with a grain size ranging from 10 μm to 35 nm were performed using differential scanning calorimetry (DSC) [21, 128]. The DSC data are presented in Figure 4. As illustrated in Figure 4, endothermic features near 125 and 5 °C for larger grain specimens featured the first-order cubic-tetragonal and tetragonal-orthorhombic phase transformations, respectively. With decreasing grain size, the cubic-tetragonal and tetragonal-orthorhombic transformations shifted to lower and higher temperatures, respectively. For 35-nm nanocrystals, there was only a single very broad and weak endothermic peak, which featured BaTiO<sub>3</sub> nanocrystals in a locally acentric distorted cubic phase. In contrast to the 211 J/mol of cubic-tetragonal transformation enthalpy for a single crystal, the transformation enthalpy was reduced to 183 J/mol for the 10-μm grains and 78 J/mol for the 100-nm grains [21]. The thermal features observed in BaTiO<sub>3</sub> with finite grain size revealed the suppressed phase transformation characteristics.

Dielectric measurements of BaTiO<sub>3</sub> fine ceramics and nanocrystalline thin films showed also that the phase transitions were strongly dependent on the grain size [8–10, 23, 25]. Some experimental results are shown in Figure 5. It is obvious that, with decreasing grain size, the maximum value of the cubic-tetragonal phase transition decreased, and the dielectric peak became broader while the dielectric constant as a function of temperature deviated from the Curie-Weiss behavior above the ferroelectric phase transition and that the ferroelectric phase transformation at last disappeared over temperatures between -85 °C and 200 °C, as illustrated

in BaTiO<sub>3</sub> nanocrystalline thin films with an average grain size of 25 nm. In most of the literature, the ferroelectric phase transition temperature  $T_c$  was observed to decrease with decreasing grain size [10, 22, 130]. It should be noted that, in Figure 5a, the cubic–tetragonal phase transition temperature for a 0.7- $\mu\text{m}$  ceramic was slightly higher than that for a 6.8  $\mu\text{m}$  ceramic, which was attributed to the strong elastic constraint being correlated with the grain size effect in this sample [9].

In BaTiO<sub>3</sub> fine ceramics and nanocrystalline thin films, the broadening of the ferroelectric–paraelectric phase transition as a function of grain size was even explained by an intrinsic grain size–induced diffuse phase transition model [131–133]. For the diffuse phase transition in ferroelectric perovskite solutions, the experimental data of dielectric constants above the phase transition were described by the empirical relationship:

$$\frac{1}{\epsilon} - \frac{1}{\epsilon_{\max}} = \frac{1}{\Lambda}(T - T_c)^\gamma \quad (3.1)$$

where  $\epsilon_{\max}$  is the maximum dielectric constant at the apparent transition temperature  $T_c$ ,  $\Lambda$  is a constant, and  $1 \leq \gamma \leq 2$ .  $\gamma = 1$  is the a normal phase transition and  $\gamma = 2$  is the a pure diffuse phase transition [134, 135]. For BaTiO<sub>3</sub> nanoceramics with various grain sizes, the experimental dielectric data

above the ferroelectric–paraelectric phase transition were successfully fitted with this relationship; the diffusivity, which was described by the critical exponent  $\gamma$ , was observed to increase with decreasing grain size [131, 132].

On the other hand, the room-temperature dielectric constant was strongly dependent on the grain size, which exhibited a maximum value for ceramics with a grain size around 1  $\mu\text{m}$ , but decreased dramatically with further decreasing grain size. The room-temperature dielectric constant was 230 for the sample with a grain size of 25 nm, which was one order of magnitude smaller than the maximum value of 5000 for fine ceramics with a grain size of 1  $\mu\text{m}$  [23, 25].

Of interest is to compare BaTiO<sub>3</sub> with another important ferroelectric PbTiO<sub>3</sub> system. A PbTiO<sub>3</sub> single crystal has a tetragonal structure ( $a = 3.899 \text{ \AA}$ ,  $c = 4.153 \text{ \AA}$ ,  $c/a = 1.065$ ) at room temperature and is transformed to a cubic paraelectric phase ( $a = 3.96 \text{ \AA}$ ) above  $T_c = 763 \text{ K}$ . At present, the experimental results on PbTiO<sub>3</sub> nanoparticles indicated that the lattice constant, tetragonality, Curie temperature, and phase transition latent heat changed similarly to nc-BaTiO<sub>3</sub> with varying nanocrystallite size. When the grain size was below approximately 150 nm, the lattice parameter  $a$  increased and  $c$  decreased with decreasing grain size. The resulting tetragonal distortion decreases exponentially below 60 nm and becomes 1 at a grain size extrapolated to be between 7 and 12.6. The Curie temperature of the tetragonal–cubic phase transition in nc-PbTiO<sub>3</sub> was also observed to decrease with decreasing grain size [32, 41, 136–139].

In the cases of BaTiO<sub>3</sub> and PbTiO<sub>3</sub> nanoparticles, the dielectric, thermal, and structural data indicated that the ferroelectric tetragonal–paraelectric cubic transition temperature,  $T_c$ , decreases monotonically and the transition peak becomes broad with decreasing grain size. The relationship between  $T_c$  and the nanocrystallite size,  $R$ , can be written as

$$T_c = T_c(\infty) - D/(R - R_c) \quad (3.2)$$

where  $T_c(\infty)$  denotes the value of the bulk crystals,  $R_c$  is the critical size, and  $D$  is a constant [22, 138, 139]. For BaTiO<sub>3</sub>,  $T_c(\infty) = 128 \text{ }^\circ\text{C}$ ,  $D = 700$ , and  $R_c = 110 \text{ nm}$  [22]. The broad tetragonal–cubic phase transition due to a reduction of grain size in nc-PbTiO<sub>3</sub> was also explained in terms of a diffuse phase transition model [32, 134].

### 3.2. Hydroxyl Defects

There were usually a lot of residual hydroxyl OH<sup>−</sup> defects within the BaTiO<sub>3</sub> nanoparticles derived from wet chemical solution methods. In the BaTiO<sub>3</sub> nanopowders prepared by the hydrothermal method, an absorption band near 3500  $\text{cm}^{-1}$  was observed. In contrast, the band was measured near 3510  $\text{cm}^{-1}$  in the sol–gel-derived nanopowders [21, 128]. This difference was attributed to different hydroxyl defect occupations within the nanoparticle matrix, since the hydrogen defects are very mobile in BaTiO<sub>3</sub> perovskite and able to possess several configurations [140]. With increasing annealing temperature, this absorption intensity decreased and became 0 above 600  $^\circ\text{C}$ , which demonstrated that the hydroxyl defects could be eliminated with heat treatment at high temperature and were totally removed

above 600 °C [21, 128, 141]. On one hand, the release of hydroxyl induced the lattice distance contraction with increasing annealing temperature. However, in most cases where the crystalline nanoparticles were prepared with heat treatment above 600 °C, the lattice contraction observed in nc-BaTiO<sub>3</sub> was mainly caused by the variation in grain size [43, 44, 129].

In Raman measurements, it was found that these residual hydroxyl defects affected the behavior of the optical modes of nc-BaTiO<sub>3</sub>, particularly the 257- and 308-cm<sup>-1</sup> modes, which caused a mode shift in the frequency of the Raman mode of 257 cm<sup>-1</sup> toward 297 cm<sup>-1</sup> and inhibited the 308-cm<sup>-1</sup> mode in the as-prepared samples. With a decrease in the concentration of residual hydroxyl defects, the peak position shifted from 297 cm<sup>-1</sup> toward 257 cm<sup>-1</sup> with increasing annealing temperature to 600 °C [21, 33, 58]. In contrast, the 308-cm<sup>-1</sup> mode was unambiguously observed in two-phase coexisting barium titanate nanopowders, even in the LTHM as-prepared samples with a large concentration of hydroxyl defects [33, 49]. This different behavior of the 308-cm<sup>-1</sup> mode in the single phase and in two-phase coexisting barium titanate nanoparticles also contributed to the different hydroxyl configurations within the nanocrystal lattice. Moreover, a new Raman mode at 806 cm<sup>-1</sup> was observed owing to the hydroxyl absorbed on the nanoparticle boundary [21, 33].

Figure 6 presents typical Raman spectra for single-phase BaTiO<sub>3</sub> nanoparticles derived by the low-temperature hydrothermal method. It can be seen that the peak position of the 257-cm<sup>-1</sup> mode shifted upward to 297 cm<sup>-1</sup> in the as-prepared sample and shifted downward with a reduction in hydroxyl concentration in the BaTiO<sub>3</sub> nanoparticles. In the samples annealed above 600 °C, the 308-cm<sup>-1</sup> mode started to be clearly distinguished and the 806-cm<sup>-1</sup> peak disappeared, in agreement with infrared measurements on the hydroxyl defects. In the pure cubic BaTiO<sub>3</sub> nanoparticles, which were obtained with heat treatment above 600 °C, five modes centered at 184, 257, 308, 518, and 716 cm<sup>-1</sup> were recorded. In the tetragonal nc-BaTiO<sub>3</sub>, the intensity of the 184-cm<sup>-1</sup> mode decreased with increasing tetragonality and

**Figure 6.** Raman spectra of BaTiO<sub>3</sub> nanoparticles derived by low-temperature hydrothermal method and annealed at various temperatures. Reprinted with permission from [33], J. Yu et al., *Mater. Res. Soc. Symp. Proc.* 718, 177 (2002). © 2002, Materials Research Society.

became negative when the tetragonality reached the value of the bulk materials. Therefore, the intensity of the 184-cm<sup>-1</sup> mode was an effective probe to check the structural changes induced by grain size variation in nc-BaTiO<sub>3</sub> [10, 21, 33].

### 3.3. Complex Defects

In Section 2.1, it was pointed out that a homogeneous precursor played an important role in the chemical solution methods to obtain defect-free BaTiO<sub>3</sub> nanocrystals. Using high-resolution transmission electron microscopy (HRTEM) Jiang et al. found many internal defect textures, including (111) nanoscale multiple twinning and complicated (111) intergrowth defects, in some barium titanate nanoparticles derived by the SAG and sol-gel methods [56]. As an illustration, Figure 7 presents an example of an SAG-derived BaTiO<sub>3</sub> nanocrystal with a grain size of 10 nm, which contained a complex arrangement of defects on the (111) planes indicated by the arrow. At the same time, image processing showed a high density of small defects within the nanocrystal matrix. The density of small defects was estimated to be on the order of 10<sup>27</sup>/m<sup>3</sup> in the SAG BaTiO<sub>3</sub> nanoparticles prepared at 600 °C and decreased as the annealing temperature (i.e., particle size) increased. After annealing at high temperature (>1200 °C), no hexagonal intergrowth structure and (111) multiple twinning defects were observed, but the small defect density was still high. In the sol-gel-derived BaTiO<sub>3</sub> nanoparticles, the defect density was much lower than in the SAG-derived samples, but some still contained many internal defects, including the (111) multiple twinning. Based on the HRTEM results, the authors speculated that these defects of high density were the reason that the SAG BaTiO<sub>3</sub> nanoparticles remained in the cubic phase even with grain size up to 3500 nm.

In those cubic nc-BaTiO<sub>3</sub> including (111) twinning planar and intergrowth defects, Raman scattering measurements recorded three novel peaks at 153, 640, and 1059 cm<sup>-1</sup> besides the five modes of 184, 257, 308, 518, and 716 cm<sup>-1</sup>

**Figure 7.** High-resolution transmission electron microscopy image of a 10-nm SAG BaTiO<sub>3</sub> nanocrystal with complex set of twins on (111) planes (prepared at 650 °C). Reprinted with permission from [56], B. Jiang et al., *Physica B* 291, 203 (2000). © 2000, Elsevier Science.

characteristic of cubic nc-BaTiO<sub>3</sub>. Although the 153- and 640-cm<sup>-1</sup> modes were attributed to the nc-BaTiO<sub>3</sub> hexagonal phase [142], the HRTEM measurements did not detect any hexagonal nanoparticles. The 153- and 1059-cm<sup>-1</sup> modes were from BaCO<sub>3</sub> contamination. These (111) twinning and intergrowth defects existing in SAG nc-BaTiO<sub>3</sub> prepared below 950 °C were attributed to the existence of the low oxidation state of Ti<sup>3+</sup> [56, 63].

### 3.4. Phase Transformation Mechanism

To understand the structural changes, in particular, the grain size-induced tetragonal-cubic phase transition in nc-BaTiO<sub>3</sub>, three models were proposed.

#### 3.4.1. Surface Model

In nanoparticles, there are two significant factors affecting their physical properties: One is a macroscopic effect related to the surface tension of the nanoparticle, and the other concerns the grain size effect on microscopic interactions which induce ferroelectricity instability in perovskite oxides [5, 128, 143]. First, Zhong et al. developed a Landau phenomenological theory to treat the case of ferroelectric nanomaterials, in which a surface layer with degraded polarization was held responsible for the ferroelectric-paraelectric phase transition [144]. Numerical calculations showed that the spontaneous polarization decreased with decreasing particle size and eventually disappeared; that is, a size-driven phase transition took place. The ferroelectric critical size was defined as the size at which the ferroelectric tetragonal-paraelectric cubic phase transition takes place at  $T_c \rightarrow 0$  K. For BaTiO<sub>3</sub> nanoparticles, the ferroelectric critical size was predicted to be 44 nm, and for nc-PbTiO<sub>3</sub> to be 4.2 nm, which were on the same order as the experimental values. The size dependence of  $T_c$  was found to be inversely proportional to the grain size  $R$ :  $T_c \propto 1/R$ . Second, Uchino et al. analyzed the surface tension effect on the Curie temperature and obtained the same inverse-proportion relationship between  $T_c$  and  $R$ , whereas the experimental relationship of (3.2) obtained in BaTiO<sub>3</sub> and PbTiO<sub>3</sub> nanoparticles included the critical size,  $R_c$  [22, 139]. On the other hand, for covalent crystals, surface tension-like forces would always lead to lattice contraction in small particles [136]. Obviously, this prediction was contrary to the experimental results in nc-BaTiO<sub>3</sub>. So far, it can be seen that the surface model is insufficient to understand the Curie temperature change and lattice expansion in BaTiO<sub>3</sub> ferroelectric nanoparticles. The grain size effect on the microscopic cooperative phenomenon must be taken into consideration [22].

The core-shell model was proposed to explain the anomalous dielectric behavior and the structural phase transition in fine BaTiO<sub>3</sub> ceramics, in which each crystallite consisted of a regular ferroelectric core with a tetragonality gradient toward the outer surface range, surrounded by a cubic surface layer with low permittivity. The cubic surface layer was estimated to be approximately 5–15 nm thick [53, 117]. However, HRTEM measurements of lattice images of BaTiO<sub>3</sub> and PbTiO<sub>3</sub> nanoparticles did not reveal the existence of a cubic surface layer [56, 126].

#### 3.4.2. Defect Model

In the hydrothermal-derived BaTiO<sub>3</sub> nanoparticles, it was found that the synthesized BaTiO<sub>3</sub> nanoparticles were stabilized in the cubic phase by numerous residual hydroxyl defects, independent of grain size [126, 141, 145]. This stabilization was interpreted with the model of lattice defects, in which the dipoles were introduced by hydroxyl defects within the nanoparticles; the correlation size of the dipoles decreased greatly with increasing concentration of hydroxyl defects and, consequently, stabilized the cubic phase in the nc-BaTiO<sub>3</sub>. Nevertheless, the hydroxyl defects derived from wet chemical solution methods could be totally eliminated from the nc-BaTiO<sub>3</sub> matrix, while the cubic phase remained stable in nc-BaTiO<sub>3</sub> with grain size below the ferroelectric critical size [21, 128]. Furthermore, the hydrothermal method was demonstrated to directly produce about 100-nm large tetragonal BaTiO<sub>3</sub> nanocrystals, of which the hydroxyl concentration exceeded that in hydrothermal cubic BaTiO<sub>3</sub> nanopowders [50, 128]. These facts indicated that the hydroxyl defect model is not responsible for the stabilization of the cubic nanophase.

#### 3.4.3. Microscopic Interaction Model

Before discussing the microscopic interaction model, let us recall the main results on the origin of ferroelectricity and the nature of the ferroelectric-paraelectric phase transition of ferroelectric titanates. The first-principle theoretical investigations revealed that the long-range Coulombic interactions favor the ferroelectric distortion, but the short-range electric repulsions favor the nonpolar cubic structure, and those ferroelectric phases result from softening of the short-range electric repulsions by Ti 3d–O 2p hybridization [5, 6, 37, 38, 146–148]. Most recently, Kuroiwa et al. measured the charge density distributions of the tetragonal and cubic phases of BaTiO<sub>3</sub> and PbTiO<sub>3</sub> by the maximum entropy method/Rietveld analysis using synchrotron-radiation powder diffraction, and verified the hybridization between the Ti 3d states and O 2p states in the ferroelectric tetragonal phase. At the same time, a charge transfer was found between the Pb 6s states and O 2p states through the cubic-to-tetragonal phase transition but the Ba–O bond was always ionic, which suggested that PbTiO<sub>3</sub> has a larger ferroelectricity than BaTiO<sub>3</sub> [39].

In ferroelectric nanomaterials, when the grain size of the nanoparticles was comparable to the correlation length describing the long-range Coulombic interaction, the long-range interaction remarkably decreased with a decrease in grain size. In creating balance, both the Ti–O hybridization and the short-range electric repulsion were correspondingly reduced [32, 33]. For the partially covalent-ionic crystals, the reduction in hybridization meant a loss in the directional character of the interionic bonds and the crystal tended to assume a structure with comparatively higher symmetry [136]. In the cubic nc-BaTiO<sub>3</sub>, the reduction in Ti–O hybridization has been proved using X-ray photoelectron spectroscopy and *ab initio* simulation [129, 149]. In nc-BaTiO<sub>3</sub>, the binding energy of the Ba 3d<sub>5/2</sub> electron was measured as 779.3 eV, independent of nanocrystallite size, but the binding energy of the Ti 2p<sub>3/2</sub> electron slightly decreased with decreasing grain size below the critical size and was the same as that in the bulk crystal, 458.5 eV,

above the critical size. This decrease reflected the character change of Ti–O bonds from covalent to ionic below the critical size [129]. In particular, for the covalent–ionic BaTiO<sub>3</sub> nanoparticles, the reduction in Ti–O hybridization induced the lattice distance expanded and the ferroelectric tetragonal phase became unstable, then transformed to high-symmetrical cubic at some critical grain size. So far, it is seen that those structural changes caused by grain size in nc-BaTiO<sub>3</sub> are well prescribed using the model of grain size effect on long-range interaction and its cooperative phenomena. In tetragonal PbTiO<sub>3</sub>, owing to the additional Pb–O hybridization [39], the stronger covalent bonding resulted in a smaller ferroelectric critical size for the size-induced tetragonal–cubic phase transition than that for BaTiO<sub>3</sub>. This further demonstrates that the hybridization change plays a dominant role in structural changes of ferroelectric nanomaterials.

The first-principle calculations indicated that the tetragonal *c/a* lattice strain is quite significant for ferroelectric tetragonal distortion, which enhances the hybridization between the Ti 3d states and the O 2p states and helps stabilize the tetragonal phase. The ferroelectric–paraelectric phase transition in BaTiO<sub>3</sub> arises from a complicated coupling of a displacive soft-mode, order–disorder hopping between wells and lattice strain. Under high pressure, the volume dependence of soft-mode potential surfaces is consistent with the loss of ferroelectricity in titanate. Under compression, the multiple-well structure disappears, and a continuous transition at zero temperature occurs at the pressure where the well depths vanish [5, 6, 37]. As indicated by (5.2), theoretical and experimental studies both revealed that the tetragonal strain scales with the spontaneous polarization (ferroelectricity) in BaTiO<sub>3</sub> [150]. In the case of ferroelectric nanocrystals, the reduced tetragonality (as illustrated in Figs. 2 and 3) with decreasing grain size thus weakens the ferroelectricity in the tetragonal nanophase and reduces the hybridization, thereby driving the structure change to paraelectric cubic below the ferroelectric critical size.

In nanomaterials of GaN [151] and a large majority of partially covalent oxides [32, 136, 152], which includes technologically important systems such as ferroelectrics, ferromagnets, superconductors, and structural ceramics, a structural change from low symmetry to high symmetry and lattice expansion were also observed with decreasing nanoparticle size. Similar to the case of nc-BaTiO<sub>3</sub>, these results could also be well prescribed by the model of grain size effect on long-range interaction and its cooperative phenomena [33]. That is to say, the model of grain size effect on long-range interaction and its cooperative phenomena has universality for covalent–ionic nanomaterials. The reduction in electronic covalency intrinsically involved in this model may cause nanomaterials to possess some different properties from their corresponding bulk, such as superparaelectricity, quantum ferroelectricity (discussed below), superparamagnetism [153], and so on.

## 4. PROPERTIES

Since the long-range Coulomb interaction is strongly reduced in BaTiO<sub>3</sub> ferroelectric nanocrystals, it is quite natural that ferroelectric nanostructured materials exhibit

different electrical and optical properties from those of bulk crystals. In this section, the present results of the electrical and optical properties on BaTiO<sub>3</sub> nanostructured materials are summarized in Sections 4.1 and 4.2, respectively.

### 4.1. Electrical Properties

The grain size effect on the phase transitions and physical properties of ferroelectrics has been known since the 1950s. The properties of Curie temperature ( $T_c$ ), spontaneous polarization, coercive field, switching speed, dielectric constant, and so forth, were found to depend on the grain size [28, 144, 154]. As illustrated in Figure 5, the dielectric constant of BaTiO<sub>3</sub> ceramics increased with decreasing grain size, and a maximum value of  $\epsilon_r \sim 5000$  was observed with a grain size around 1  $\mu\text{m}$ . With further decreasing grain size into the nanometer scale,  $\epsilon_r$  remarkably decreased [9, 10, 25, 31, 116, 117, 130]. For nanoceramics with an average grain size of 400 nm, the room-temperature dielectric constant was measured as 3500 at 100 kHz, but for a grain size of 300 nm,  $\epsilon_r = 3000$  [10]. For sol–gel-derived 50-nm BaTiO<sub>3</sub> nanocrystalline film on platinized silicon substrates with a thickness of 1.5  $\mu\text{m}$ , the dielectric constant and loss tangent were measured as 430 and 0.015, respectively, at 10 kHz under ambient conditions.  $\epsilon$  increased from 430 to 470, but  $\tan \delta$  remained unchanged as the measurement atmosphere was changed from air to vacuum [23]. In sol–gel-derived BaTiO<sub>3</sub> nanocrystalline thick films with an average grain size in the range of 15–25 nm, the films with larger grain size exhibited stronger frequency dependence of the dielectric constant. For a film with a grain size of 25 nm, the room-temperature dielectric constant decreased from 401 to 349 as the frequency was increased from 1 kHz to 10 MHz. When the grain size was increased from 15 to 25 nm, the relative dielectric constant increased from 207 to 401 at 1 kHz [26]. For sol–gel-derived BaTiO<sub>3</sub> nanocrystalline thin films with a grain size of 25 nm, the dielectric constant and loss tangent were 230 and 0.02 at room temperature, respectively. The temperature coefficient of capacitance was  $625 \times 10^{-6}/^\circ\text{C}$  between  $-55^\circ\text{C}$  and  $125^\circ\text{C}$  at 1 kHz, which exhibited a better temperature capacitance stability [25].

As discussed in the model of grain size effect on long-range Coulomb interactions and its cooperative phenomena, the reduced grain size in ferroelectric nanomaterials suppressed the long-range cooperative order process so that the temperature dependence of the dielectric properties exhibited different behaviors from their bulk counterparts. This grain size effect on the dielectric properties of nanostructured BaTiO<sub>3</sub> was referred as to the superparaelectric effect [130].

For BaTiO<sub>3</sub> nanoceramics with an average grain size of 400 nm, spontaneous polarization  $P_s = 17 \mu\text{C}/\text{cm}^2$  and remanent polarization  $P_r = 4 \mu\text{C}/\text{cm}^2$  were obtained from the polarization–electric field hysteresis loop at room temperature. For nanoceramics with a grain size of 300 nm,  $P_s = 15 \mu\text{C}/\text{cm}^2$  and  $P_r = 2 \mu\text{C}/\text{cm}^2$ . In contrast, BaTiO<sub>3</sub> fine ceramics with a grain size of 1.2  $\mu\text{m}$  exhibited  $P_s = 19 \mu\text{C}/\text{cm}^2$  and  $P_r = 6 \mu\text{C}/\text{cm}^2$ . The coercive field was  $E_c \sim 200 \text{ kV}/\text{cm}$  for these nano- and fine ceramics [10]. For sol–gel-derived BaTiO<sub>3</sub> nanocrystalline film on platinized silicon

substrates with a grain size of 50 nm and a thickness of 1.5  $\mu\text{m}$ , the observation of good capacitance–voltage butterfly curve and hysteresis loop indicated ferroelectricity behavior, while  $P_r = \sim 2.0 \mu\text{C}/\text{cm}^2$  with  $E_c = \sim 27 \text{ kV}/\text{cm}$  were obtained at room temperature. With increasing temperature, the dielectric constant increases and goes through a broad maximum around 125  $^\circ\text{C}$  and then decreases with a further increase in temperature. This broad phase transition in the nc-BaTiO<sub>3</sub> with a grain size of 50 nm was characterized by a diffuse phase transition feature. Regarding the low-temperature dielectric property, there was a lack of any anomalies at the phase transition temperatures corresponding to tetragonal–orthorhombic and orthorhombic–rhombohedral phase transitions, except for a change in the slope of the temperature dependence of the dielectric constant below about 50 K [23]. For 50-nm BaTiO<sub>3</sub> nanocrystalline thin film on metallic LaNiO<sub>3</sub>-coated LaAlO<sub>3</sub> (100) single-crystal substrates, a good hysteresis loop with  $P_r = 8.3 \mu\text{C}/\text{cm}^2$  and  $E_c = 50 \text{ kV}/\text{cm}$  was observed. The dielectric constant slowly decreased from 127 to 117 and the loss tangent changed from 0.02 to 0.05 when the frequency was increased from 100 Hz to 1 MHz. The leakage current density for 400-nm-thick film was found to be less than  $5 \times 10^{-7} \text{ A}/\text{cm}^2$  at an electrical field of 100 kV/cm [24]. In contrast, bulk single-crystal BaTiO<sub>3</sub> has  $P_s = 26 \mu\text{C}/\text{cm}^2$  and  $E_c = 1.5 \text{ kV}/\text{cm}$ . Therefore, there occurred suppressed dielectric and ferroelectric behaviors but increased  $E_c$  in BaTiO<sub>3</sub> nanostructured materials.

In cubic BaTiO<sub>3</sub> nanoparticles, the present electrical measurements indicated a lack of polarization–voltage hysteresis loops. It was found that this paraelectric cubic nanophase remained stable over a relatively large temperature range, preliminarily determined to be 80 up to 1000 K [25, 72, 128]. Surprisingly, using electrostatic force microscopy, a local polarization was induced and reversed repeatedly on cubic BaTiO<sub>3</sub> nanorods as small as 10 nm in diameter. The retention time for induced polarization exceeded 5 days in an ultrahigh vacuum environment, which demonstrated the potential of nanorods for fabricating nonvolatile memory nanodevices [82]. Nevertheless, it should be noted that these electrical measurements on cubic BaTiO<sub>3</sub> nanocrystals are just preliminary.

The suppressed dielectric and ferroelectric behaviors but increased  $E_c$  in BaTiO<sub>3</sub> nanostructured materials were attributed to the finite grain size effect and clamping of the film to the substrate. In the past, the finite grain size effect was widely investigated and has been determined to be an intrinsic resource for ferroelectric nanocrystals. Both theoretical and experimental studies revealed the structural changes of a multidomain–single-domain transformation, a decrease in tetragonal distortion, and a size-induced ferroelectric tetragonal–paraelectric cubic phase transition with decreasing grain size [9, 10, 22, 32]. Shaikh et al. measured the dielectric constant and spontaneous polarization of fine BaTiO<sub>3</sub> ceramics with various grain size and estimated the critical size for the multidomain–single-domain transformation to be about 400 nm [116]. Using the thermodynamical free-energy method, Hsiang and Yen calculated this critical grain size to be about 80 nm, but their experimental measurements indicated it was larger than 100 nm [43].

The dielectric constant increment in fine BaTiO<sub>3</sub> ceramics was attributed to the domain structure change from the multidomain to the single domain with decreasing grain size. In PbTiO<sub>3</sub>, another important ferroelectric nanomaterial, transmission electron microscopy (TEM) measurements indicated it changed from the multidomain to the single domain when the grain size was less than 20 nm [137].

In perovskite-type oxide ferroelectrics, the tetragonal strain scales with the spontaneous polarization. Owing to the smaller strain of 1% in BaTiO<sub>3</sub> bulk crystal compared to 6% in PbTiO<sub>3</sub>, BaTiO<sub>3</sub> has a weaker ferroelectricity than PbTiO<sub>3</sub> [37]. In nc-BaTiO<sub>3</sub>, the tetragonality changed from  $c/a = 1.01$  to 1.00 with decreasing particle size, as illustrated in Figure 3. Compared with the bulk crystal, a reduction in the  $c/a$  ratio in nc-BaTiO<sub>3</sub> implies a smaller strain and leads to a weakening of the ferroelectric tetragonal [33, 74]. These grain size–induced structural changes in the ferroelectricity and paraelectric cubic phase were the cause of the dielectric constant reduction observed in BaTiO<sub>3</sub> nanocrystals. For BaTiO<sub>3</sub> nanoceramics with a grain size of 300–400 nm, both XRD and Raman data indicated that the reduced electric properties were due to the reduced tetragonality; for example, the  $c/a$  ratio was measured as 1.008 in nanoceramics with a grain size of 400 nm [10]. In dense nanoceramics and films, the nanoparticles are elastically constrained by the surrounding environment, which makes the structural analysis complex. To understand the precise nature of ferroelectricity at the nanoscale, it is necessary to prepare freestanding BaTiO<sub>3</sub> nanocrystalline particles and films [62].

In the BaTiO<sub>3</sub>/SrTiO<sub>3</sub> superlattices, Kim et al. observed an increase in both the dielectric constant and its nonlinearity (voltage tunability) with decreasing stacking periodicity within the critical thickness. A maximum zero-field dielectric constant of 1600 at 1 MHz and a large voltage tunability of 94% were observed at the periodicity of the (BaTiO<sub>3</sub>)<sub>2-unit-cell</sub>/(SrTiO<sub>3</sub>)<sub>2-unit-cell</sub> superlattice, in comparison with 74% in Ba<sub>x</sub>Sr<sub>1-x</sub>TiO<sub>3</sub> thin film [112]. The high dielectric constant and large voltage tunability make BaTiO<sub>3</sub>/SrTiO<sub>3</sub> strained superlattices very attractive for electrically tunable microwave devices. With varying layer thickness of the constituents, Tsurumi et al. found the [(BaTiO<sub>3</sub>)<sub>10-unit-cell</sub>]/[(SrTiO<sub>3</sub>)<sub>10-unit-cell</sub>]<sub>4</sub> and [(BaTiO<sub>3</sub>)<sub>10-unit-cell</sub>]/[(BaZrO<sub>3</sub>)<sub>10-unit-cell</sub>]<sub>4</sub> superlattices having much higher dielectric permittivities and refractive indices than other superlattices [98]. In contrast to symmetric superlattices, Shimuta et al. studied epitaxial asymmetric BaTiO<sub>3</sub>/SrTiO<sub>3</sub> strained superlattices that had unequal BaTiO<sub>3</sub> and SrTiO<sub>3</sub> layer thickness and found that the superlattice with a stacking periodicity of 15 unit cells BaTiO<sub>3</sub>/3 unit cells SrTiO<sub>3</sub> showed the largest remanent polarization  $2P_r$  of 46  $\mu\text{C}/\text{cm}^2$  but the dielectric constant was 240 at 1 MHz [109]. These experiments demonstrated that the strained superlattice is an effective approach to enhance the properties of the constituents by controlling the stacking periodicity, the thickness of the alternative layers, and their thickness ratio. Playing the role of the pressure effect, the lattice strain in the superlattices affected not only the ionic polarization but also the electronic structure or chemical bonding nature of the superlattices [98, 107, 112].

## 4.2. Optical Properties

In this section, second-harmonic generation, light emission, and up-conversion optical properties of BaTiO<sub>3</sub> nanostructured materials are summarized.

### 4.2.1. Second-Harmonic Generation

Owing to spontaneous polarization, pure or rare-earth-doped BaTiO<sub>3</sub> single crystals have strong electrooptic, nonlinear optical, and photorefractive effects. In bulk barium titanate, the nonlinear coefficients for second-harmonic generation (SHG) were  $d_{15} \approx 17.0$  pm/V,  $d_{31} \approx 15.7$  pm/V, and  $d_{33} \approx 6.8$  pm/V. Theoretical calculations revealed that the nonlinear electronic polarizabilities are very sensitive to changes in electron covalency and electron correlation in the transition metal oxides [40]. Compared with BaTiO<sub>3</sub> bulk crystals, the reduction in hybridization must decrease the optical nonlinear coefficients of BaTiO<sub>3</sub> nanocrystalline particles and thin films. For epitaxial BaTiO<sub>3</sub> nanocrystalline thin films with a grain size of 10–80 nm on MgO substrates, the SHG was investigated at an incident wavelength of 1.064  $\mu$ m. The effective  $d$  coefficient was measured as 2.13 pm/V for the  $c$ -oriented films and 1.5 pm/V for the  $a$ -oriented films [20]. Compared with the values of the bulk crystal, these values were much lower, in agreement with the theoretical prediction. Frey and Payne investigated the nanocrystallite grain size effect on SHG of BaTiO<sub>3</sub>. In the cubic BaTiO<sub>3</sub> nanoparticles, a measurable SHG signal was detected, but it was a factor of 10<sup>3</sup> weaker than that in the coarser grain of 10  $\mu$ m. When the nanocrystallite size increased above 50 nm, the SHG signal rose significantly. XRD and Raman scattering measurements indicated that the tetragonality increases with increasing grain size above 50 nm but only a local acentric lattice distortion occurs in the cubic nanoparticles [21]. From these facts, it was concluded that the SHG processes would be enhanced by large tetragonal distortion in BaTiO<sub>3</sub> nanocrystals. As discussed in Section 2.2, the tetragonal distortion in epitaxial single-crystal thin films can be tuned over a large range. Therefore, the strained epitaxial thin films are expected to exhibit better SHG performance with tunability.

### 4.2.2. Light Emission

Spontaneous light emission is one of the basic properties of nanocrystals due to the quantum size confinement effect, and it is a powerful tool to probe the electronic structure and impurity. In bulk ferroelectric BaTiO<sub>3</sub>, a complex broad luminescence band around 500 nm was observed under valence band-to-conduction band excitation. With increasing temperature, the photoluminescent intensity decreased and was quenched above the tetragonal-to-cubic phase transition temperature [155]. The self-trapped exciton mechanism was proposed to understand this light emission band in ferroelectric phases.

In nanocrystallites, the quantum size confinement effect would cause an increase in bandgap with decreasing grain size [18, 77]. Optical measurements indicated that the optical band edge blueshifted toward 3.68 eV for nc-BaTiO<sub>3</sub> with a grain size of 8 nm, and 3.53 eV with a grain size of 35 nm, compared to the value of 3.2 eV for bulk single

crystal [18]. There are no reports in the literature on the light emission properties of BaTiO<sub>3</sub> nanocrystals under excitation from the valence band to the conduction band. Under excitation by an Ar<sup>+</sup> laser, a weak yellow luminescence around 570 nm was first observed in sol-gel-derived BaTiO<sub>3</sub> nanoparticles [156]. Later, three photoluminescence bands centered at 543 nm (green), 574 nm (yellow), and 694 nm (red), respectively, were observed in the LTHM-processed slightly Ti-rich barium titanate nanoparticles with heat treatment at various temperatures; the results are reproduced in Figure 8 [49, 74, 75]. Yu et al. found that a hexagonal phase and BaTi<sub>2</sub>O<sub>5</sub> clusters embedded within BaTiO<sub>3</sub> nanoparticles played the role of color centers for the 543- and 694-nm emission bands, respectively, but the Ti defects contributed to the yellow emission band. Under various annealing temperatures, the peak position of each luminescence band did not shift, despite the luminescent intensity. This phenomenon was understood by combining quantum size confinement and dielectric confinement effects, which had the opposite effect on the energy level of the color centers as a function of nanoparticle size and thus kept them unchanged within the band gap. In the experiments with excitation of various powers, all three light emission bands were found, characteristic of the self-trapped exciton emission mechanism [49]. The mechanism of self-trapped exciton light emissions in the cubic BaTiO<sub>3</sub> nanophase can be understood by the embedded-molecular-cluster model [157], in which the local rhombohedral distortion and lattice expansion in cubic nc-BaTiO<sub>3</sub> fulfill the requirements to make excitons self-trapped on second-phase clusters or defects. In particular, when the annealing temperature was increased to more than 900 °C, the spectrum shape of the red band changed and could be fitted from one Gaussian distribution to two Lorentzian ones. This change was closely associated with the crystalline field change in the nc-BaTiO<sub>3</sub> cubic-tetragonal phase transformation induced by the grain size [158].

In Er-doped BaTiO<sub>3</sub> nanostructured materials with an average grain size of 25 nm, a typical erbium spontaneous luminescence, corresponding to the intra-4*f* transition from <sup>4</sup>I<sub>13/2</sub> to <sup>4</sup>I<sub>15/2</sub>, was observed at 1.54  $\mu$ m with a fine width

**Figure 8.** Room-temperature photoluminescence spectra for nc-BaTiO<sub>3</sub> annealed at various temperatures for 1 h. The photoexcitation line was 488.0 nm of Ar<sup>+</sup> laser with an output power of 200 mW at header. Reprinted with permission from [49], J. Yu et al., *Appl. Phys. Lett.* 77, 2807 (2000). © 2000, American Institute of Physics.

at half-maximum of approximately 45 nm under excitation of both 514- and 980-nm lasers [159]. The luminescent intensity and the  $1/e$  lifetime were closely dependent on the concentration of Er ions in the nanostructured materials. For the 3.0-mol% Er-doped BaTiO<sub>3</sub> nanomaterials, the 1.54- $\mu$ m emission decayed in a single exponential way with a  $1/e$  lifetime of approximately 5 ms. When the concentration was more than 3.0 mol%, the 1.54- $\mu$ m light emission was quenched. The quenching mechanism was explained by energy transfer and cross-relaxation processes between closely sited Er<sup>3+</sup> ions within the BaTiO<sub>3</sub> lattice, which are related to the up-conversion process discussed below.

### 4.2.3. Up-Conversion

Up-conversion to the visible spectrum from the near-infrared has been developing as an important approach for the generation of visible luminescence and short-wavelength lasing in some rare-earth-doped materials upon near-infrared excitation. Up-conversion is a nonlinear process, whereby two or more low-energy excitation photons are converted into one or two high-energy photons. It can find application in such as all-solid compact blue-green lasers pumped with near-infrared semiconductor laser diodes and infrared radiation detection by converting the invisible light into the visible range where conventional detectors are effective. In particular, Er<sup>3+</sup> has a favorable energy level structure with two transitions of  $^4I_{15/2} \rightarrow ^4I_{11/2}$  (at 980 nm) and  $^4I_{15/2} \rightarrow ^4I_{9/2}$  (at 810 nm), which can be efficiently pumped with high-power near-infrared semiconductor lasers to yield blue, green, and red up-conversion emissions. Compared with glasses and fluoride crystals, in which blue and red up-conversion emission and lasing have been realized, BaTiO<sub>3</sub> permits a high solid solubility of at least 10 at% at the Ti site of Er<sup>3+</sup> ions [14]. In addition, Er<sup>3+</sup> ions are homogeneously distributed throughout the depth of BaTiO<sub>3</sub> films. Thus, much higher overlap between Er<sup>3+</sup> distribution and optical field profile could be expected in the Er<sup>3+</sup>:BaTiO<sub>3</sub> film waveguides [54, 160].

In sol-gel-derived Er<sup>3+</sup>:BaTiO<sub>3</sub> nanocrystalline particles and thin films with an average grain size of 15–25 nm, three up-conversion emissions at 526 nm ( $^2H_{11/2} \rightarrow ^4I_{15/2}$ ), at 549 nm ( $^4S_{3/2} \rightarrow ^4I_{15/2}$ ), and at 670 nm ( $^4F_{9/2} \rightarrow ^4I_{15/2}$ ) were observed under excitation at 980 and 810 nm from both laser diodes and a xenon lamp, among which the transition  $^4S_{3/2} \rightarrow ^4I_{15/2}$  is spin-allowed so that the 549-nm emission was bright even to the naked eye [54, 159–161]. The absorption measurements in the ranges from 805 to 825 nm ( $^4I_{15/2} \rightarrow ^4I_{9/2}$ ) and from 960 to 1000 nm ( $^4I_{15/2} \rightarrow ^4I_{11/2}$ ) indicated that the laser diodes operating at 810 and 980 nm are efficient pump sources for the 549-nm up-conversion emission. Upon excitation at 980 and 810 nm, the predominant 549-nm emission had a different intensity and lifetime. The lifetime of the 549-nm emission increased sixfold with 980-nm excitation compared to that with 810-nm excitation, which resulted from the different population mechanisms. With the 980-nm excitation, both the excited state absorption (ESA) of individual Er<sup>3+</sup> ions and the cooperative energy transfer (CET) between two near Er<sup>3+</sup> ions

contributed to the 549-nm up-conversion emission. In contrast, the up-conversion emission under the 810 nm excitation was just through an ESA process. Therefore, the excitation around 980 nm was more effective for the 549-nm up-conversion emission from the Er:BaTiO<sub>3</sub> nanostructured materials [54, 160, 161]. For up-conversion lasing from Er:BaTiO<sub>3</sub> nanostructured materials, research is currently underway.

## 5. LATTICE DYNAMICS

### 5.1. Raman-Active Optical Modes

In the bulk BaTiO<sub>3</sub> paraelectric cubic phase, the space group  $O_h^1$  transforms as  $3T_{1u} + T_{2u}$  optical modes at the center of the Brillouin zone, which are triply degenerate. The long-range electrostatic forces split each of the optical modes into a doubly degenerate transverse optical (TO) mode and a singly degenerate longitudinal optical (LO) mode. The optical  $T_{1u}$  modes are infrared active, but the  $T_{2u}$  mode is neither infrared active nor Raman active [150, 162]. Nevertheless, two broad Raman modes centered around 250 and 515 cm<sup>-1</sup> were recorded in bulk BaTiO<sub>3</sub> single crystals and ceramics above  $T$  [95, 163, 164]. In the ferroelectric tetragonal phase, each cubic  $T_{1u}$  mode transforms as the  $A_1 + E$  irreducible representation and  $T_{2u}$  as  $B_1 + E$  of  $C_{4v}^1$ . The distinct Raman-active optical vibrations,  $3A_1(\text{TO}) + 3A_1(\text{LO}) + 3E(\text{TO}) + 3E(\text{LO}) + 1E(\text{LO} + \text{TO}) + 1B_1$ , were obtained for tetragonal BaTiO<sub>3</sub>. In single crystals, the first-order Raman modes at 36, 180, 305, 463, 470, 486, 518, 715, and 727 cm<sup>-1</sup> and two broad modes around 270 and 520 cm<sup>-1</sup> were obtained, while four modes at 270, 305, 516, and 719 cm<sup>-1</sup> and a negative intensity mode at 180 cm<sup>-1</sup> were obtained in ceramics [95, 162–164].

As illustrated in Figure 6, the depolarized Raman scattering measurements recorded five modes centered at 184, 257, 308, 518, and 716 cm<sup>-1</sup> in the single-phase cubic BaTiO<sub>3</sub> nanoparticles [21, 33, 58, 63, 95, 126]. In the cubic nanocrystal, of major importance was that the three first-order modes at 184, 308, and 716 cm<sup>-1</sup> were Raman active, even though these three modes typically conform to Raman selection rules in the bulk materials. These different lattice vibration properties indicated that the local structure of cubic nanocrystals was acentrically distorted, which relaxed the Raman selection rules. The second-harmonic generation and electron paramagnetic resonance spectroscopy measurements also revealed the occurrence of locally acentric distortion in the XRD-measured cubic nanoparticles [21, 53, 58]. Recent measurements showed that the change in the Ti–O bonding character of BaTiO<sub>3</sub> nanoparticles leads to elongation of both the Ba–Ti and the Ba–O bond lengths from 3.47 Å and 2.83 Å to 3.60 Å and 2.94 Å, respectively, while the Ti–O bond length remains nearly constant ( $\sim 2.0$  Å) [129]. Based on these bond lengths, the unit cell in cubic nc-BaTiO<sub>3</sub> has local rhombohedral distortion, but not the tetragonal or orthorhombic distortion assigned by other authors [21, 33, 63]. In the quantum phase transformations, the zero-point fluctuation energy is closely associated with the property of lattice dynamics. The first-order phonons being Raman active would have a strong influence on the

zero-point energy of the BaTiO<sub>3</sub> nanosystems and consequently, would shift the critical condition of phase transformation from classic to quantum [33, 158].

## 5.2. Soft-Mode Theory

In 1960, Cochran and Anderson independently pointed out that the ferroelectric–paraelectric structural phase transition in ABO<sub>3</sub> perovskite oxides was closely related to the dynamical behavior of the lowest frequency TO phonon mode, that is, the soft mode. Since then, the soft-mode theory has achieved great success in explaining ferroelectric phase transitions.

In the lattice dynamic model of displacive ferroelectric structural phase transitions, the dynamical behavior of ferroelectricity is closely associated with the softening of the lowest frequency TO mode at the center of the Brillouin zone, and its freezing corresponds to paraelectric–ferroelectric phase transition. As each transition temperature is approached, the frequency of the soft mode generally decreases and is described by the following relationship:

$$\omega_{\text{TO}}^2 = A(T - T_c)^{\gamma'} \quad (5.1)$$

where  $A$  is a constant: positive at  $T > T_c$  and negative at  $T < T_c$ . In cubic BaTiO<sub>3</sub>, the soft mode is the lowest frequency  $T_{1u}(\text{TO})$  mode, whose freezing induces the generation of ferroelectricity, but in the tetragonal phase, the lowest frequencies  $E(1\text{TO})$  and  $A_1(1\text{TO})$  are the soft modes, whose freezing induces the disappearance of ferroelectricity [1, 150]. The temperature dependence of the ferroelectric soft mode in ABO<sub>3</sub> reflects the variation of the anharmonic interactions due to the hybridization between transition metal d states and oxygen p states [165]. In the classical mean field region, the critical exponent  $\gamma' = 1$ , but when the quantum zero-point fluctuation prevails at low-temperature,  $\gamma'$  approaches 2, close to the quantum limit, and becomes 0 at  $T \rightarrow 0$  K [165, 166].

In addition to explaining the sequence of phase transitions, the soft-mode theory has been successful in other ways. In the ferroelectric phase of ABO<sub>3</sub> oxides, the spontaneous polarization  $P_s$  and spontaneous strain described by the tetragonality  $c/a$  are two important order parameters. In tetragonal BaTiO<sub>3</sub> and PbTiO<sub>3</sub> bulk materials, the connections between the temperature dependence of the soft-mode frequency  $\omega(A_1(1\text{TO}))$  and the spontaneous polarization and spontaneous strain were established [2, 150]:

$$\omega(A_1(1\text{TO})) \propto P_s \propto ((c/a) - 1)^{1/2} \quad (5.2)$$

The Curie–Weiss law characterizes the dielectric properties in the paraelectric phase of ferroelectric materials, and its general formulation is

$$\epsilon(T) = C(T - T_0)^{-\gamma_T} \quad (5.3)$$

where  $C$  is the Curie–Weiss constant and  $T_0$  is the Curie–Weiss temperature. In the classical regime, the critical exponent  $\gamma_T = 1$  was found for the static dielectric constant, but at relatively low-temperatures where zero-point quantum fluctuations prevented long-range order phase,

$\gamma_T$  approached 2, close to the quantum limit. With  $T \rightarrow 0$  K, the saturation of the low-frequency dielectric constant corresponded to  $\gamma_T = 0$ . These predictions have been experimentally demonstrated in incipient ferroelectrics such as SrTiO<sub>3</sub>, KNbO<sub>3</sub>, and KTaO<sub>3</sub> and normal ferroelectrics such as BaTiO<sub>3</sub> and PbTiO<sub>3</sub> [1, 2, 7, 166, 167]. Through the Lyddane–Sachs–Teller (LST) relationship, the Curie–Weiss law intrinsically reduces to the soft-mode theory [7, 166].

In ionic crystals, the LST relationship is

$$\frac{\epsilon(0)}{\epsilon(\infty)} = \frac{\omega_{\text{LO}}^2}{\omega_{\text{TO}}^2} \quad (5.4)$$

which relates the static dielectric constant,  $\epsilon(0)$ , and the high-frequency dielectric constant,  $\epsilon(\infty)$ , to the eigenfrequencies,  $\omega_{\text{LO}}$  and  $\omega_{\text{TO}}$ , of LO and TO phonons [1, 2]. The LST relationship has been proven quantitatively in the ferroelectric and paraelectric phases of ferroelectrics such as SrTiO<sub>3</sub>, PbTiO<sub>3</sub>, KNbO<sub>3</sub>, and KTaO<sub>3</sub>, and the dramatic change in the static dielectric constant is directly related to the soft-mode behavior [4, 150, 165, 166]. For example, in the case of tetragonal PbTiO<sub>3</sub>, the dielectric constant along the ferroelectric axis  $\epsilon_c$  is determined primarily by the lowest frequency  $A_1(1\text{TO})$  mode, and  $\epsilon_a$  perpendicular to the  $c$  axis by the lowest  $E(1\text{TO})$  mode at all temperatures upto  $T_c$  [150].

To date, it is accepted that BaTiO<sub>3</sub> is not a typical displacive ferroelectric [3, 4, 150]. In the tetragonal phase, the  $E(1\text{TO})$  soft mode was found to be highly overdamped, but the  $A_1(1\text{TO})$  soft mode was underdamped, both mixed with a certain amount of disorder character. Because of the large damping factor of the soft mode, it was very difficult to detect the soft modes by the conventional Raman spectroscopic method. At that time, the calculated  $\epsilon_{\text{LST}}$  from the soft mode was only about 25% of the experimentally determined  $\epsilon_c$  [150, 162]. In the 1990s, the femtosecond time-domain light-scattering spectroscopy technique was developed, which took advantage of determining the soft-mode frequency more accurately than conventional frequency-domain spectroscopy. Nevertheless, the static dielectric constant calculated via the LST relationship for BaTiO<sub>3</sub> bulk crystals still did not quantitatively agree with the present experimental value [4]. Dougherty et al. suggested reperforming dielectric measurements of BaTiO<sub>3</sub> to test the LST relationship, but the data are still lacking.

## 5.3. Finite-Size Effect

In the microscopic theory of displacive ABO<sub>3</sub> ferroelectrics, the dynamical behavior of the soft mode depends on the compensation of the long-range Coulomb force by the short-range electric repulsive and covalent forces. The hybridization between transition metal B ion d states and oxygen p states softens the ferroelectric soft mode and thus ferroelectric displacement can take place [5, 165, 168]. In ferroelectric nanocrystalline particles and thin films, the finite-size effect on the behavior of the soft modes also plays a central role in these changes in the structural and physical properties. When the grain size is comparable to the correlation length, both the long-range Coulomb forces and the short-range electric repulsive and covalent forces decrease with

decreasing nanocrystallite size, but the short-range forces decrease faster than the long-range Coulomb forces, and thus cause the  $A_1(1TO)$  and  $E(1TO)$  soft-mode frequencies to gradually decrease with decreasing grain size and finally to freeze out below a critical size. In accordance with (5.2), the reduction in soft-mode frequencies is accompanied by a weakening of the ferroelectricity and a decrease in tetragonality, and the soft mode freezing corresponds to the grain size-induced tetragonal–cubic phase transition [138, 139].

In  $PbTiO_3$ -based ferroelectric nanoparticles, with decreasing grain size, the room-temperature frequencies of the  $E(1TO)$  and  $A_1(1TO)$  soft modes were experimentally observed to decrease, but the linewidth increased, compared with those of the bulk materials [138, 169–171]. For example, in nc- $PbTiO_3$ , the  $E(1TO)$  soft mode shifted from  $83\text{ cm}^{-1}$  to  $72\text{ cm}^{-1}$  in frequency and increased from  $12\text{ cm}^{-1}$  to  $31\text{ cm}^{-1}$  in linewidth with decreasing grain size from  $50.5\text{ nm}$  to  $20\text{ nm}$  [170]. For nc- $PbTiO_3$ , with a grain size of  $50.5\text{ nm}$ , the squared frequency of the  $E(1TO)$  soft mode deviated from the straight-line dependence of pressure above  $4\text{ GPa}$ , which suggested that the  $PbTiO_3$  nanomaterials have a different phase transition from that of the bulk materials, where the  $E(1TO)$  soft-mode frequency decreased toward 0 as the pressure increased and all of the modes disappeared above  $11.63\text{ GPa}$  [170]. Varying the temperature and/or pressure, the partial softening and superlinear broadening of the  $E(1TO)$  soft mode implied that nanocrystalline  $PbTiO_3$  is no longer an ideal displacive ferroelectric, but mixed with an order–disorder feature [172].

For each grain size of  $PbTiO_3$  ferroelectric nanoparticles, taking (3.2) into (5.1), the temperature dependence of the  $A_1(1TO)$  soft-mode frequency was determined by the equation:

$$\omega^2 = A(T - T_c(\infty) + D/(R - R_c)) \quad (5.5)$$

On the other hand, the frequency of the soft mode decreased with decreasing nanocrystallite size, although they had the same dynamical behavior as described by (5.5) [138, 170]. This fact implies that the parameter  $A$  is a function of grain size, which decreases with decreasing grain size. Recently, the room-temperature spontaneous strain in nc- $PbTiO_3$  as a function of nanoparticle size was experimentally obtained:

$$c/a - 1 = E(1 - \exp(E(R_c - R))) \quad (5.6)$$

where the constant  $E = 0.065$  [32]. Under the first approximation ( $1 - e^{-x} \approx 1/x$ ), (5.6) can be simplified as

$$c/a - 1 \approx 1/(R - R_c) \quad (5.7)$$

Comparing (5.5) with (5.7), the relationship  $\omega^2(A_1(1TO)) \propto (c/a) - 1$  does not exist in the case of nc- $PbTiO_3$ . The reduced tetragonality ( $c/a$ ) in ferroelectric nanoparticles only provides partial contributions to the reductions in the soft-mode-frequency, dielectric, and ferroelectric properties. So far, it is concluded that the reduced tetragonal distortion is partially responsible for the suppressed ferroelectricity and related properties in ferroelectric nanoparticles, and the intrinsic grain size effect on the electronic structure plays a dominant role, especially in the variation of parameter  $A$ .

In quantum paraelectric  $SrTiO_3$  nanocrystals, the reduced long-range Coulomb forces would cause the frequency of the  $T_{1u}$  soft mode to increase with decreasing grain size, that is, soft-mode hardening. Raman and infrared spectroscopic measurements indicated that the zone center cubic  $T_{1u}$  soft-mode frequencies of the small nanoparticles were higher than those of the larger ones at low temperature [166, 173, 174]. The dielectric constant was measured as 770 with a grain size of  $44\text{ nm}$  but 350 with a grain size of  $12\text{ nm}$  at  $12\text{ K}$  and  $100\text{ kHz}$ . Compared with  $SrTiO_3$  bulk crystal, of which the static dielectric constant was about 20,000 below  $4\text{ K}$ , the quantum paraelectricity was strongly suppressed in  $SrTiO_3$  nanocrystals by the finite grain size. Through the LST relationship of (5.4), the soft-mode hardening observed in nanocrystals agreed with the dramatic reduction in the dielectric constant [173, 174]. For thick  $SrTiO_3$  films, the reduction in the dielectric constant was almost the consequence of the soft-mode hardening. But for thinner  $SrTiO_3$  films, the interfacial dead layer effect played a significant role in the reduction in the dielectric constant, in addition to the finite-size effect [166]. Moreover, the deviation from the classical Curie–Weiss law started at a higher temperature for smaller nanocrystallite size.

In ferroelectric  $BaTiO_3$  nanocrystals, the reduction in the p–d hybridization induced by the finite-size effect would no doubt influence the behavior of the soft mode [168]. Similar to  $PbTiO_3$  and  $SrTiO_3$ , the softening of the  $A_1(1TO)$  and  $E(1TO)$  soft modes in the tetragonal nanophase or the hardening of the  $T_{1u}$  soft mode in the cubic nanophase is also responsible for the reduction in the electrical properties of  $BaTiO_3$  nanocrystals. At present, there is a lack of experimental data on both the soft mode and the static dielectric constant with varying grain size for  $BaTiO_3$  nanocrystals.

#### 5.4. Quantum Ferroelectricity

For the displacive structural phase transitions in ferroelectrics such as  $BaTiO_3$ , the phase transition caused by variation of the parameters in a lattice dynamical system were investigated within the framework of both classical and quantum statistical mechanics [143]. For the ferroelectric–paraelectric transition Curie temperature  $T_c$ , it was found as a function of the interaction parameter  $S$ :

$$T_c(S) \propto (S_c - S)^{1/\phi} \quad (5.8)$$

where  $S$  is an interaction parameter—an external parameter such as pressure or chemical composition—that controls the interaction, and  $S_c$  is its value at  $T_c = 0$ . In the classical regime, the phase transitions were driven by thermal fluctuations, but when the  $T_c \rightarrow 0\text{ K}$ , quantum zero-point fluctuations, instead of thermal fluctuations, played a dominant role. The theoretical treatment predicted that  $T_c$  varied with the critical exponent  $\phi \equiv 2$ , close to the quantum limit, and  $\phi \equiv 1$ , close to the classical limit. The relationship  $T_c = A(S_c - S)^{1/2}$  is typical of quantum ferroelectricity,  $T_c = 0$  at  $S = S_c$  being the quantum limit. Conventionally,  $BaTiO_3$  was a normal ferroelectric with a critical exponent  $\phi = 1$  under low hydrostatic pressure or with a large concentration of strontium content. However, for  $BaTiO_3$  under a hydrostatic pressure of  $4\text{--}8\text{ GPa}$  and  $Ba_{1-x}Sr_xTiO_3$  with  $0.8 < x < 0.965$ ,

the critical exponent  $\phi$  changed to 2 [7, 167, 175]. That is to say, under these conditions, BaTiO<sub>3</sub> became a quantum ferroelectric and the nature of ferroelectric–paraelectric phase transition was controlled by quantum mechanics.

For BaTiO<sub>3</sub>, both theoretical and experimental results indicated the ferroelectric–paraelectric phase transformations change in nature from being controlled by classical mechanics to being controlled by quantum mechanics under high pressure (hydrostatic or chemical). In these pressure experiments, the interatomic distance played a crucial role in the pressure-established quantum ferroelectricity and paraelectricity. In the BaTiO<sub>3</sub> nanocrystals, as shown by Figures 2 and 3, the lattice parameter was a function of grain size and the ferroelectricity decreased with decreasing grain size. As indicated by (3.2), with decreasing grain size,  $T_c$  was shifted downward through room temperature, eventually tending toward 0 K at some critical grain size [22]. According to the scaling theory of phase transitions, the properties of ferroelectrics and the nature of the phase transition would be controlled by quantum mechanics under the condition of the polar order parameter being comparable with zero-point fluctuation [143]. Similar to the pressure effect, the grain size effect in ferroelectric nanomaterials could induce the spontaneous polarization to be reduced to 0, in accordance with (5.2) and (5.5), so that it might shift the critical conditions of classical-to-quantum ferroelectric and paraelectric phase variations. From the viewpoint of microscopic interaction, the predominant change in these phase transformations was found to be the reduction in the Ti–O hybridization, despite different birthrights—hydrostatic pressure, chemical pressure, grain size effect in nanomaterials. Based on these facts, nc-BaTiO<sub>3</sub> is expected in an analogous way to be quantum ferroelectric and paraelectric over some range of grain size [33, 158]. Equation (5.8) should also be suitable for nc-BaTiO<sub>3</sub>, where the grain size  $R$  can be used as the interaction parameter. In addition, preliminary measurements showed that the grain size effect in nc-BaTiO<sub>3</sub> plays an equivalent role of the pressure effect, spanning across the entire range of quantum ferroelectricity and paraelectricity of BaTiO<sub>3</sub> [7, 128]. Compared with the pressure effect, the grain size effect in nc-BaTiO<sub>3</sub> provides a method for stabilizing and utilizing those metastable phases in ambient environments. Of interest, in the experiments of pressure-induced phase transformation in CeO<sub>2</sub> nanoparticles, the critical pressure was reduced 28.1% and there was a larger volume change of 9.4% in the phase transformation than that for the bulk CeO<sub>2</sub> [176]. These facts supported in an experimental way the grain size effect in nanomaterials playing an equivalent role of the pressure effect.

The prediction of quantum behavior in nc-BaTiO<sub>3</sub> is significantly of interest for fundamental understanding of ferroelectric nanocrystals and technological applications, especially using its dielectric properties in such as infrared detection and electronic and photonic devices. However, in BaTiO<sub>3</sub> and PbTiO<sub>3</sub> nanoparticles with grain size above the critical size, the preliminary measurements revealed that the dependence of the Curie temperature on the grain size had a critical exponent  $\phi = -1$  [22, 139]. Taking  $R^{-1}$ , rather than  $R$ , as the interaction parameter, this sign discrepancy in the critical exponent may disappear. In the near future the nanocrystallite size–temperature phase diagram and the

temperature dependence of dielectric properties with various nanocrystallite size will be required.

In SrTiO<sub>3</sub> nanocrystals, electrical and Raman spectroscopic measurements revealed that the finite-size effect suppressed the zero-point quantum fluctuations and shifted the classical-to-quantum crossover towards higher temperature [174]. Since the finite-size effect plays the role of suppressing quantum fluctuation, the chemical pressure necessary for quantum ferroelectricity in Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> nanocrystals would be smaller than in the bulk case; that is, the critical composition  $x_c$  increases with decreasing grain size.

## 6. BARIUM STRONTIUM TITANATE

SrTiO<sub>3</sub> is a well known quantum paraelectric or incipient ferroelectric. It is in the cubic phase (space group  $Pm3m$ ) at room temperature and undergoes an antiferrodistortive structural phase transition to the tetragonal phase (space group  $I4/mcm$ ) at 105 K. This transition results from the freezing of one of the triply degenerate  $R_{25}$  modes at the Brillouin zone boundary. With decreasing temperature, the dielectric constant increases but becomes saturate at  $\epsilon(0) \approx 20,000$  below 4 K. Above 40 K, a zone center TO mode exhibits a softening behavior, which agrees with the temperature dependence of the static dielectric constant via the LST relationship. Below 40 K, zero-point quantum fluctuations preclude the freezing of this soft mode, and SrTiO<sub>3</sub> remains in the tetragonal paraelectric phase even to absolute 0 K, which is known as the quantum paraelectric phase [166, 177]. Moreover, it is possible to suppress the quantum fluctuations and induce polar ordering in SrTiO<sub>3</sub> by chemical substitutions of Ba, Ca, Pb, and <sup>18</sup>O, application of an electric field, or application of mechanical stress [167].

In Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> solid solutions, three phase transition temperatures of BaTiO<sub>3</sub> linearly decrease with increasing SrTiO<sub>3</sub> concentration up to  $x = 0.8$ . For the tetragonal–cubic phase transition, the Curie temperature obeys  $T_c(\text{K}) = 410 - 360x$ . When  $0.8 < x < 0.965$ , there is only one paraelectric–ferroelectric phase transition with  $T_c = 300(0.965 - x)^{1/2}$  (K). When  $x > 0.965$ , the ferroelectric phase transition is precluded by zero-point quantum fluctuations while barium strontium titanate exhibits a glasslike behavior [167]. For quantum ferroelectric Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> ( $0.8 < x < 0.965$ ) bulk crystals, the critical exponent  $\gamma_T$  of the Curie–Weiss law at  $x$  near 0.8 is equal to 1 and then grows to about 1.5 when  $x$  increases. Lattice contraction as a function of Sr concentration obeys Vegard’s law,  $a = 3.905x + 3.992(1 - x)$ . So the chemical pressure effect could be compared with the hydrostatic pressure effect, which has a similar pressure–temperature phase diagram [7, 167].

For Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> solid solutions, of technological interest is the room-temperature ferroelectric–paraelectric boundary around  $x = 0.3$ . They exhibit high room-temperature dielectric constant, high pyroelectric coefficient, and low dielectric loss, which have attracted considerable attention for applications such as dynamic random access memory (DRAM), microwave, and pyroelectric devices [167, 178].

In the remaining part of this section, the syntheses of Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> nanocrystalline thin film are reviewed. Then the dielectric and nonlinear properties are summarized.

Those factors affecting the film performance, including small grain size, film thickness, crystallographic orientation, lattice strain, and acceptor doping, are also discussed.

## 6.1. Syntheses

In principle, all the synthesis methods for BaTiO<sub>3</sub> nanostructured materials could be used without difficulty to prepare Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> nanostructured materials. Owing to the strong application background of Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> and the facility of the synthesis methods, the sol-gel [55, 178, 179], pulse laser deposition [180–184], and magnetron sputtering [185] methods were widely utilized to fabricate barium strontium titanate nanocrystalline thin films. In this section, the sol-gel methods are discussed and an alkoxide method proposed to prepare Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> nanoparticles.

Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> nanocrystalline particles and thin films were widely synthesized using the same sol-gel method used for synthesizing nc-BaTiO<sub>3</sub>, in which the desired stoichiometry was controlled by the ratio of strontium acetate to barium acetate. In a typical process, barium acetate and strontium acetate were mixed and then dissolved in acetic acid above 90° under stirring. 2-Methoxyethanol was utilized to adjust the viscosity of the solution. Titanium isopropoxide was then added to the solution. For films, the gel precursor was spin-coated onto the substrates before heat treatment. Finally, the dried and solidified gel was heat-treated to obtain crystalline nanoparticles and thin films. The crystallization temperature for perovskite Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> was 650 °C. With this technique, nanocrystalline barium strontium titanate thin films with an average grain size of 50 nm were obtained [55, 178, 179].

BaTiO<sub>3</sub> and SrTiO<sub>3</sub> nanoparticles were successfully produced using bimetallic alkoxide as the starting material [60, 174, 186]. Because Sr(OCH<sub>2</sub>OC<sub>2</sub>H<sub>4</sub>)<sub>2</sub> has a similar chemical behavior as Ba(OCH<sub>2</sub>OC<sub>2</sub>H<sub>4</sub>)<sub>2</sub>, the alkoxide method could be extended to synthesize (Ba, Sr)TiO<sub>3</sub> nanoparticles. Using Ti(*i*-OC<sub>3</sub>H<sub>7</sub>)<sub>4</sub>, Sr(OCH<sub>2</sub>OC<sub>2</sub>H<sub>4</sub>)<sub>2</sub>, and Ba(OCH<sub>2</sub>OC<sub>2</sub>H<sub>4</sub>)<sub>2</sub> as the starting materials and 2-methoxyethanol as the solvent, their stoichiometric mixture is refluxed to form a trimetallic alkoxide homogeneous precursor solution. Then hydrolysis is carried out by adding a mixture of deionized water and 2-methoxyethanol to the obtained precursor solution. Finally, the gelled precursor is pyrolyzed and calcined at high temperatures to obtain crystalline barium strontium titanate nanoparticles. On the other hand, similar to the case of nc-BaTiO<sub>3</sub>, crystalline barium strontium titanate nanoparticles may also be obtained by low temperature hydrolyzing of (Ba, Sr, Ti)-trimetallic alkoxides under highly alkaline condition [60, 186].

## 6.2. Low-Frequency Dielectric Properties

Ba<sub>0.7</sub>Sr<sub>0.3</sub>TiO<sub>3</sub> bulk material has a dielectric constant of approximately 5000 at 300 K. Parker et al. investigated the temperature and film thickness dependence of the dielectric constant of Ba<sub>0.7</sub>Sr<sub>0.3</sub>TiO<sub>3</sub> films on the platinized silicon substrate with a thickness ranging from 15 to 580 nm; the results are given in Figure 9. As the film thickness decreased, the maximum dielectric constant decreased from 660 to 110 at 4 kHz, which was more than one order of magnitude less

**Figure 9.** Permittivity as a function of temperature for six film thicknesses. The data are denoted by closed circles; the diffuse phase transition feature fit by open circles. The arrows denote the maximum value of permittivity. Tabulated with the arrow was the film thickness, the maximum permittivity, and the temperature at which the maximum permittivity occurred. Reprinted with permission from [187], C. B. Parker et al., *Appl. Phys. Lett.* 81, 340 (2002). © 2002, American Institute of Physics.

than the bulk value. The temperature at which the maximum dielectric constant occurred decreased from room temperature to 269 K for the 580-nm-thick film and to 102 K for the 40-nm-thick film. With decreasing film thickness, the temperature dependence of the dielectric constant anomalous peak became more broad. The film thickness dependence of the dielectric properties was explained in terms of a diffuse phase transition, in which the diffusivity increased with decreasing film thickness [187]. In Ba<sub>0.8</sub>Sr<sub>0.2</sub>TiO<sub>3</sub> nanocrystalline thin films on Pt/Ti/SiO<sub>2</sub>/Si substrates with an average grain size of 100 nm and a thickness of 400 nm, a broad tetragonal-to-cubic phase transition was observed around 35 °C, which was less than  $T_c = 80$  °C for the bulk material. Electrical measurements at room temperature showed a dielectric constant of 860 at 100 kHz,  $P_r = 6.5$   $\mu\text{C}/\text{cm}^2$ ,  $E_c = 41$  kV/cm, and a leakage current density of  $3.3 \times 10^{-7}$  A/cm<sup>2</sup> at 3 V [188]. In Ba<sub>0.8</sub>Sr<sub>0.2</sub>TiO<sub>3</sub> thin films, the tetragonal-to-cubic phase transition temperature was also observed to decrease with decreasing grain size [85, 188]. Similar to the case of BaTiO<sub>3</sub> nanostructured materials, the tetragonal-cubic phase transition temperature and dielectric constants of (Ba, Sr)TiO<sub>3</sub> nanocrystals were strongly suppressed by the reduced dimensionality, and an intrinsic finite-size effect and lattice strains introduced during film growth were proposed to understand these reductions in electrical properties [187, 189].

Owing to the strong anisotropy in ferroelectrics, the crystallographic orientation must influence the effective parameter normal to the film, as often reported in the literature. As an example, random and (100) oriented Ba<sub>1-x</sub>Sr<sub>x</sub>TiO<sub>3</sub> films with  $x = 0.33, 0.5, 0.67,$  and  $1.0$  were fabricated on base-metal (100) nickel tapes using a chemical solution deposition method. For randomly oriented films, zero-field room-temperature dielectric constants ranged from 250 to

420 at 100 kHz. But the films with enhanced (100) orientation exhibited zero-field dielectric constants of 980 to 1500, three times higher than the random films. The dielectric loss tangent was between 0.003 and 0.015 [190].

Taking advantage of the high dielectric constant, dynamic random access memories using barium strontium titanate thin film as the functional element were prepared for commercial use at the end of the 1990s.

### 6.3. Microwave Dielectric Properties

In heteroepitaxial  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$  thin films, lattice strain was introduced during growth owing to lattice and thermal expansion mismatch between these films and the substrates, and the dielectric properties were able to be tuned by controlling the internal lattice strain [180, 181]. In the case of  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{TiO}_3$ , the bulk cubic lattice parameter is  $a = 3.95 \text{ \AA}$  and the thermal expansion coefficient  $\alpha = 10.5 \times 10^{-6}/^\circ\text{C}$  at 300 K. On the (001) MgO substrate, the in-plane tensile stresses of heteroepitaxial  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{TiO}_3$  thin films were found to decrease with increasing film thickness from 14 to 130 nm and were fully relaxed above thickness 130 nm. The microwave dielectric constant dropped from 2350 for highly stressed thin films to 1700 for relaxed thicker films at 1 MHz [180]. For the pseudocubic  $\text{LaAlO}_3$  substrate,  $a = 3.79 \text{ \AA}$  and  $\alpha = 10 \times 10^{-6}/^\circ\text{C}$  at 300 K. Because of the different lattice match conditions between the MgO and  $\text{LaAlO}_3$  substrates, different lattice strains occurred in the epitaxial  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{TiO}_3$  thin films. In these epitaxial films, either a large dielectric tuning (75%) or a high dielectric  $Q = 1/\tan \delta$  (100–250) but not both at the same time were typically observed [182].

To tune the lattice strain, various thin buffer layers were developed for epitaxially growing barium strontium titanate thin films. Using a thin ( $\sim 5 \text{ nm}$ ) amorphous  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{TiO}_3$  buffer layer, the strains in the crystalline films were relieved, and the films exhibited both high dielectric tunability and enhanced dielectric  $Q$  [182]. Alternatively, by inserting a very thin  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$  ( $x = 0.1\text{--}0.7$ ) layer between the  $\text{Ba}_{0.6}\text{Sr}_{0.4}\text{TiO}_3$  thin film and the MgO (001) substrate, the lattice strain (described by the in-plane lattice constant/out-of-plane lattice constant ratio) in 400-nm-thick  $\text{Ba}_{0.6}\text{Sr}_{0.4}\text{TiO}_3$  epitaxial thin films was tuned from 0.9972 to 1.0051 by varying the interlayer composition. The dielectric constant varied between 512 and 1180 at a frequency of 1 MHz. On the  $\text{Ba}_{0.7}\text{Sr}_{0.3}\text{TiO}_3$  interlayer,  $\text{Ba}_{0.6}\text{Sr}_{0.4}\text{TiO}_3$  film showed a larger dielectric constant of 1180 and a tunability of 61% at a surface electric field of 80 kV/cm [181].

Silicon is a very technologically important substrate. Using a very thin yttria-stabilized zirconia buffer layer, epitaxial  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{TiO}_3$  thin films were successfully grown on the Si substrate using pulse laser deposition. The dielectric constant was as high as 1300 at 1 MHz when the lattice distortion of the in-plane lattice constant/out-of-plane lattice constant ratio was 1.007 [183].

For integrated film device applications, the better insulating (low leakage current density) quality is significantly attractive. In the metalorganic solution deposited  $\text{Ba}_{0.6}\text{Sr}_{0.4}\text{TiO}_3$  nanocrystalline thin films on a platinized silicon substrate, a typical resistivity was  $\rho = 0.04 \times 10^{13} \text{ \Omega cm}$

at an electric field of 100 kV/cm. However, the small concentration of acceptor dopants could dramatically modify the properties of the ferroelectrics. For instance, the 1-mol% La-doped  $\text{Ba}_{0.6}\text{Sr}_{0.4}\text{TiO}_3$  film (average grain size 50 nm and film thickness 150 nm) exhibited an enhanced resistivity of  $\rho = 31.4 \times 10^{13} \text{ \Omega cm}$  at 100 kV/cm. The dielectric constant, loss tangent, and tunability of the 1-mol% La-doped  $\text{Ba}_{0.6}\text{Sr}_{0.4}\text{TiO}_3$  films were 283 at 100 kHz, 0.019, and 21% at 200 kV/cm, respectively. The improved dielectric properties, low leakage current, and good dielectric tunability of the acceptor-doped barium strontium titanate thin films suggest their use in fabricating high-performance tunable microwave devices [55].

Owing to their large dielectric tunability and low dielectric loss, barium strontium titanate nanocrystalline thin films were widely used to fabricate electrically tunable microwave devices, such as phase shifters and harmonic generators. As an example, using sol-gel-derived highly oriented  $\text{Ba}_{0.6}\text{Sr}_{0.4}\text{TiO}_3$  thin films on a  $\text{LaAlO}_3$  (100) substrate, eight element coupled microstrip phase shifters were fabricated. An insertion loss of 8.435 dB, phase shift on the order of  $320^\circ$  ( $2.6\text{--}14.5 \text{ V}/\mu\text{m}$ ), and factor (phase shift/decibel of loss) of about  $38.0^\circ/\text{dB}$  were demonstrated [191].

### 6.4. Nonlinear Optical Properties

Similar to the dielectric properties, the nonlinear optical properties of  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$  thin films were also dependent on the strontium composition and the lattice strain.

For  $a$ -oriented  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$  thin films of thickness 200 nm on a (100)  $\text{LaAlO}_3$  substrate, Li et al. investigated the composition dependence of electrooptic properties at  $\lambda = 632.8 \text{ nm}$  of a He-Ne laser [184]. It was found that the linear electrooptic coefficient  $\gamma$  had maximum at  $x = 0.35\text{--}0.4$ . The quadratic electrooptic coefficient  $s$  initially decreased as  $x$  increased and reached a small plateau around  $x = 0.5$ . Both  $\gamma$  and  $s$  dropped to 0 when  $x > 0.7$ . For  $\text{Ba}_{0.7}\text{Sr}_{0.3}\text{TiO}_3$  film,  $\gamma$  was determined as 110 pm/V in the case of increasing electric field and 230 pm/V in the case of decreasing electric field;  $s = 0.55 \times 10^{-16} \text{ m}^2/\text{V}^2$ . For  $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{TiO}_3$  film,  $\gamma$  was 70 pm/V in the case of increasing electric field and 115 pm/V in the case of decreasing electric field;  $s = 1.3 \times 10^{-16} \text{ m}^2/\text{V}^2$ . Compared with  $\text{BaTiO}_3$ , the large electrooptic coefficients of  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$  ( $x = 0.3\text{--}0.5$ ) films make them well suited to integrated optoelectronic devices [27, 184].

For cubic  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$ , second-harmonic generation is unexpected since the crystal structure is centrosymmetric under ambient conditions. However, due to large lattice and thermal expansion mismatches between the  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$  film and the MgO substrate, the introduced lattice strains destroyed the inversion symmetry and induced second-harmonic generation. In a 30-nm-thick  $\text{Ba}_{0.48}\text{Sr}_{0.52}\text{TiO}_3$  epitaxial film grown on (001) MgO substrate, a tetragonal distortion induced by film strain was determined to be  $c/a = 1.015$ , and second-order nonlinear susceptibility was measured as  $d_{33} = 11.0 \text{ pm/V}$ ,  $d_{31} = 4.7 \text{ pm/V}$ , and  $d_{15} = 2.2 \text{ pm/V}$  at a fundamental wavelength of  $1.064 \text{ \mu m}$  [185]. As the strain decreased from 2.7% to 0.7%, corresponding to a decrease in the film thickness from 30 nm to 165 nm, the

second-harmonic signal decreased by a factor of 10. Therefore, the strain was the dominant factor controlling second-harmonic generation in  $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$  epitaxial thin films. Compared with  $\text{BaTiO}_3$  thin films [20], barium strontium titanate thin films have a large effective  $d$  coefficient, better chemical stability, and a higher dielectric constant as well.

## 7. APPLICATIONS

As discussed above, the grain size effect plays an important role in controlling the structural phases and properties of  $\text{BaTiO}_3$  nanostructured materials. Due to the grain size-induced tetragonal-cubic phase transition, the nanocrystalline  $\text{BaTiO}_3$  thin films with various grain sizes could find possible applications in integrated high-density memories ranging from dynamic random access memory using high dielectric constant to nonvolatile memory with spontaneous polarization being reversed between two opposite directions, surface acoustic wave devices, microactuators, and various electrooptic devices [29, 154]. Nanocrystalline  $\text{BaTiO}_3$  thick films of thickness up to several micrometers have potential applications in pyroelectric infrared microsensors and ultrasonic high-frequency transducers [26]. In the following,  $\text{BaTiO}_3$  nanostructured material applications in the fields of optical modulators, transducers and actuators, and thermal, humidity, and  $\text{CO}_2$  sensors are discussed in detail.

### 7.1. Optical Modulators

$\text{BaTiO}_3$  crystals have the highest known electrooptic coefficient  $\gamma_{51} = 820 \text{ pm/V}$  at 632.8 nm [19]. In epitaxial  $\text{BaTiO}_3$  thin-film waveguides on a  $\text{MgO}$  (001) substrate, a large effective dc electrooptic coefficient of  $\gamma_{\text{eff}} \sim 50 \pm 5 \text{ pm/V}$  and an electrooptic coefficient of  $\gamma_{\text{eff}} \sim 18 \pm 2 \text{ pm/V}$  at 5 MHz for  $\lambda = 1.54 \text{ }\mu\text{m}$  light were reported. The propagation loss in a 300-nm-thick planarized waveguide is typically 5 dB/cm for 1.5- $\mu\text{m}$  light [27]. Compared with barium titanate epitaxial thin films, the barium strontium titanate ( $x = 0.3\text{--}0.5$ ) epitaxial thin films exhibited a higher effective electrooptic coefficient, as discussed in Section 6.4. These experiments demonstrated the potential of  $\text{BaTiO}_3$  and  $(\text{Ba}, \text{Sr})\text{TiO}_3$  epitaxial thin films for low-voltage, highly confining, guided-wave electrooptic modulator structures. Moreover, thin-film devices offer unique characteristics superior to diffused waveguides fabricated on bulk ferroelectric crystals. The large index difference between the film and the substrate enables a high confinement effect in the waveguides, which creates the potential for high-speed, low-voltage electrooptic switching and for high energy density to be produced at moderate incidence power [159].

In sol-gel  $\text{Er}:\text{BaTiO}_3$  nanocrystalline thin films, optical waveguide double modes were observed with effective refractive indices of 2.122 and 1.868, respectively, at 632.8 nm of He-Ne laser [159]. These results were encouraging for the investigation of planar  $\text{Er}:\text{BaTiO}_3$  film waveguides and devices for optical amplifiers and laser applications. In most cases, the sol-gel-derived films were high loss and random oriented in nature, which resulted in a smaller electrooptic response compared with oriented films. Compared with the sol-gel methods, the MOCVD and laser

MBE techniques have more potential to fabricate high-quality optical waveguides with loss less than 1 dB/cm [54, 94, 192]. Epitaxial  $\text{BaTiO}_3$  optical waveguides and electrooptic modulators were fabricated with the MOCVD technique. Excellent modulation efficiency, frequency response, and losses as low as 3–4 dB/cm at 1.54  $\mu\text{m}$  were demonstrated [27, 94, 102, 192]. In the  $c$ -axis-oriented  $\text{BaTiO}_3$  epitaxial thin films on a  $\text{MgO}$  (001) substrate, the refractive index was  $2.378 \pm 0.002$  at 632.8 nm, and the waveguide loss was 2.9 dB/cm [103].

Nevertheless, future integrated optical circuits will require  $\text{BaTiO}_3$  thin films to be integrated with silicon or III–V compounds. To date, it is still difficult to prepare epitaxial  $\text{BaTiO}_3$  films directly on bare silicon substrates due to large lattice mismatch and severe interface diffusion. To obtain high-quality epitaxial ferroelectric thin films on those substrates, the approach using yttria-stabilized zirconia (YSZ) and  $\text{MgO}$  buffer layers was developed, and then epitaxial  $\text{BaTiO}_3$  and  $(\text{Ba}, \text{Sr})\text{TiO}_3$  thin films were obtained [183, 193, 194].

### 7.2. Transducers and Actuators

Piezoelectricity is the property of acquiring electric polarization under external mechanical stresses, or the *converse* property of changing dimension when subjected to external electric fields. The large piezoelectric coefficient, especially near the phase transition temperature, makes ferroelectrics attractive for transducers, which convert mechanical changes to electrical changes or vice versa. In some cases, the purpose of the transducer is to convert ac fields, or sudden change of field, into corresponding mechanical motions, as in ultrasonic generators, actuators, loudspeakers, or pulse generators. In other cases, a transducer uses piezoelectric effects to convert small motions into electric changes, as in ultrasonic detectors, strain-gauge, microphones, and devices to measure vibrations [2]. As illustrated in Table 1, ferroelectric  $\text{BaTiO}_3$  exhibits high piezoelectric coefficient potential for transducer and actuator applications.

According to (5.2), the spontaneous strain, which plays a dominant role in piezoelectricity, in ferroelectric  $\text{BaTiO}_3$  is proportional to the squared spontaneous polarization. Thus, the piezoelectric coefficient  $d_{31}$  in ferroelectrics is proportional to  $P$  [2, 150]. When the ferroelectrics are in the paraelectric cubic phase,  $P_s = 0$ , they have no piezoelectric effect. Therefore, cubic  $\text{BaTiO}_3$  nanostructured materials are precluded from application in transducers. The critical size of ferroelectricity is also the ultimate miniaturization level of piezoelectric  $\text{BaTiO}_3$ .

In  $\text{BaTiO}_3$  nanoceramics with an average grain size of 300 nm, the spontaneous polarization  $P_s = 15 \text{ }\mu\text{C}/\text{cm}^2$  at room temperature [10]. Although it was less than the  $P_s$  for single crystals and ceramics with a grain size of 1.2  $\mu\text{m}$ , in accordance with (5.2), nanoceramics still possess sufficient piezoelectric coefficient. In comparison with conventional ceramics, dense nanoceramics, nanocomposites, and thick films, which make use of nanoparticles as starting materials, facilitated versatile shapes. For various transducers, the chosen shape depends on the utilization field and required frequency. For example, a complex shape is required for

actuators, but a simple slab is required for ultrasonic frequency [2]. On the other hand, the high-dielectric-constant BaTiO<sub>3</sub> nanoceramics have a large electromechanical coupling factor—a measure of the proportion of electrical energy that can be stored elastically. Therefore, BaTiO<sub>3</sub> nanoceramics with versatile shapes could be applied for transducers and actuators with controlled oscillator frequencies and bands.

### 7.3. Thermal Sensors

The temperature dependence of spontaneous polarization, dielectric constant, or resistivity in ferroelectric BaTiO<sub>3</sub> and (Ba,Sr)TiO<sub>3</sub> was applied to fabricate bolometers for infrared detection, infrared imaging detection, and thermometers.

For pyroelectric bolometers, based on (5.1) and (5.2), the temperature dependence of spontaneous polarization in the ferroelectric nanoparticles can be written as

$$P_s \propto (|A|(T_c - T))^{\gamma/2} \quad (7.1)$$

where under  $\gamma = 1$  ambient conditions. By differentiating (7.1) with respect to temperature and substituting (3.2) into it, the pyroelectric coefficient of ferroelectric nanoparticles is obtained:

$$p = dP_s/dT \propto |A|^{1/2}(T_c(\infty) - D/(R - R_c) - T)^{-1/2} \quad (7.2)$$

From (7.2), it can be seen that the pyroelectric coefficient  $p$  could be enhanced by decreasing the ferroelectric nanoparticle size, owing to decreasing tetragonal–cubic phase transition temperature. But the parameter  $|A|$  was reduced greatly by decreasing grain size [138, 169–171]. Therefore, the resulting pyroelectric coefficient  $p$  was decreased in BaTiO<sub>3</sub> ferroelectric nanocrystals. For dielectric bolometers, the bulk dielectric constant changes anomalously near the ferroelectric–paraelectric phase transition, which obeys the Curie–Weiss law. However, in ferroelectric nanocrystals, this anomalous dielectric peak was suppressed to become flat, and even disappeared below a critical size, as illustrated in Figure 5. The preliminary measurements have demonstrated that the figure of merits, which is proportional to  $p$  and inversely proportional to  $\epsilon$ , in ferroelectric nanocrystalline BaTiO<sub>3</sub> and (Ba,Sr)TiO<sub>3</sub> was much lower than the value of bulk materials [85, 158, 187]. So the finite-grain-size effect precluded the small-grain-sized (Ba,Sr)TiO<sub>3</sub> nanocrystalline thin-film application for uncooled monolithic integrated ferroelectric thin-film infrared focal plane arrays [195]. To avoid this limit of small-grain-size effect on pyroelectric properties, (Ba,Sr)TiO<sub>3</sub> thin films with large grain size and columnar microstructure were prepared; they exhibited enhanced pyroelectric properties as expected [85, 188].

The vinylidene fluoride/trifluoroethylene [P(VDF-TrFE)] copolymers are useful pyroelectric organic materials without stretching and, thus, good candidates as solid-state imaging sensors. They have low thermal conductivity and can be fabricated into large-area thin films. Mixing ferroelectric nanoparticles and copolymer materials to form nanocomposites, improved pyroelectric performance was obtained [124, 125]. Because the piezoelectric coefficients

( $d_{33}$  as well as  $d_{31}$ ) of the ferroelectric and polymer phases have opposite signs, while the pyroelectric coefficients have the same sign, the piezoelectric contributions in composites from the two phases are partially cancelled, but the pyroelectric contributions are reinforced. Therefore, the ferroelectric nanoparticle/copolymer composite exhibits high pyroelectric activity but no spurious electrical signal due to mechanical strain or vibration owing to the minimized piezoelectric microphone effect, and is a promising candidate in the application field of integrated pyroelectric sensor arrays on silicon-based readout integrated electronic circuits. Based on the relationship between pyroelectric property and ferroelectric nanocrystallite size, it is necessary to choose large BaTiO<sub>3</sub> or (Ba,Sr)TiO<sub>3</sub> nanoparticles with good pyroelectric property and with grain size significantly smaller than the thickness of the nanocomposite films for pyroelectric sensor applications.

Usually, the pure BaTiO<sub>3</sub> ceramics were highly resistive at room temperature. Some donor-doped BaTiO<sub>3</sub> ceramics exhibited positive temperature coefficient of resistivity (PTCR) characteristics, which were used for infrared detection and temperature control [196, 197]. To optimize the sensor performance, the Ba or Ti elements were often substituted to tune the tetragonal–cubic phase transition temperature of BaTiO<sub>3</sub> ceramics over a large temperature range, for example, between  $-30$  °C and  $400$  °C [197]. With nanotechnology, the grain size in the nanometer scale can cause the tetragonal–cubic phase transition temperature of BaTiO<sub>3</sub> to decrease toward room temperature. On the other hand, the PTCR and anomalous dielectric properties were closely associated with the quality of grain boundaries [198, 199]. With low-temperature hydrothermal methods, the grain boundaries of BaTiO<sub>3</sub> nanoparticles could be easily modified [75]. Therefore, BaTiO<sub>3</sub> nanoceramics may find applications with the PTCR effect.

### 7.4. Humidity Sensor

The electrical conductance and capacitance of BaTiO<sub>3</sub> ceramics usually change in a humid environment due to water vapor chemisorption and physisorption and capillary condensation in the pores of the sensor element. Compared with conventional ceramics, BaTiO<sub>3</sub> nanoceramics have better humidity-sensing properties, such as lower resistance and higher sensitivity. Qiu et al. observed the resistance of nc-BaTiO<sub>3</sub> increasing with increasing grain size, for example, from 23 to 53 nm, while the linearity and slope in the high-humidity range were improved [48]. From the application point of view, the resistance for the resistive humidity sensor is better, ranging over  $10^6$ – $10^3$   $\Omega$ , for minimizing humidity hysteresis and increasing sensitivity and repeatability. To further improve the performance of nc-BaTiO<sub>3</sub> humidity sensors, Wang et al. proposed two methods of doping a certain amount of impurities into nc-BaTiO<sub>3</sub> and mixing some polymer humidity sensing materials with nc-BaTiO<sub>3</sub> to fabricate nanocomposite humidity sensors [47, 200, 201].

First, the experiments showed that doping Na<sub>2</sub>CO<sub>3</sub>, K<sub>2</sub>CO<sub>3</sub>, and sodium citrate modified the resistance of the nc-BaTiO<sub>3</sub> humidity sensor from  $10^6$  to  $10^3$   $\Omega$ , among which NaH<sub>2</sub>PO<sub>4</sub> was the best dopant for minimizing the humidity hysteresis of the BaTiO<sub>3</sub> sensor. The maximum humidity hysteresis of the sensor was 3% relative humidity (RH)

in the region of 30–90% RH [200]. Second, some polymer materials also show good humidity sensitivities such as long-term stability, repeatability, precision, and so forth. However, the polymer materials do not behave as well as ceramic and nanocrystal materials in complex environments, for example, in air with organic gas. Combining inorganic (ceramic or nanocrystal) materials with organic polymers may be expected to obtain better humidity-sensing materials. One example was to use polymer material of quaternary acrylic resin  $[(R)_nM^+X^-]$  mixed with nc-BaTiO<sub>3</sub> to form a nanocomposite. These nanocomposite materials exhibited much better sensing properties: The sensitivity was higher than that of pure nc-BaTiO<sub>3</sub>, and the maximum humidity hysteresis was about 3% RH in the range of 33–98% RH [47, 201].

### 7.5. CO<sub>2</sub> Sensors

In the fields of agricultural and biotechnological processes as well as air-conditioning systems and monitoring of exhaust gases, there is an increasing demand for CO<sub>2</sub> sensors. In addition to optical and electrochemical sensors, a new generation of low-cost solid-state CO<sub>2</sub> gas sensors based on nc-BaTiO<sub>3</sub> thick films is being developed. Nanocrystalline BaTiO<sub>3</sub> was used to fabricate CO<sub>2</sub> sensors owing to the semiconducting character that the conductance or capacitance changes due to adsorbed CO<sub>2</sub>. These sensors have the potential to further reduce production cost, increase sensor design versatility, and simplify integration with other gas sensors on the same substrate [202, 203].

Keller et al. systematically investigated the mechanical stability, sensitivity, reproducibility, detection limit, long-term stability, operating temperature, cross-sensitivity by interfering gases, and power consumption of nanocrystalline BaTiO<sub>3</sub>-based sensors [202]. It was found that nanocrystalline BaTiO<sub>3</sub>-based sensors had higher sensitivity to 0.01% CO<sub>2</sub> concentration, lower detection limit, minor influence of interfering gases, and reduced power consumption than microcrystalline sensors. The nanocrystalline BaTiO<sub>3</sub> thick films could also be applied as less power consuming CO<sub>2</sub> solid-state sensor devices for mobile CO<sub>2</sub> detection. In studying the CO<sub>2</sub>-sensing mechanism, the sensitivity was found to be closely related to lattice defects in the sensing layers—defect structures rather than the concentration of lattice vacancies [203]. Nevertheless, before entering the market, major drawbacks of semiconducting solid-state layers such as small long-term stability and signal drift must be overcome.

## 8. SUMMARY

In summary, perfect BaTiO<sub>3</sub> nanocrystalline materials ranging from 0D nanoparticles to 2D single-crystal films have been successfully fabricated. With the benefit of generalized solution-phase decomposition nanotechnology [51, 80, 81], fabrications of complex BaTiO<sub>3</sub> nanostructured systems (colloidal crystals) were also attempted, which would extend studying the properties and applications of nanostructured BaTiO<sub>3</sub>. Using BaTiO<sub>3</sub> nanocrystals as building block, strained superlattices, nanoceramics, and nanocomposites were also fabricated for technological applications.

The dielectric, ferroelectric, optical, and lattice dynamical properties of BaTiO<sub>3</sub> nanostructured materials could be tuned or enhanced by controlling the grain size and lattice strains. The finite-size effect on structural and physical properties was well understood with the model of grain size effect on long-range interaction and its cooperative phenomena. The finite-grain-size effect not only extended the application fields BaTiO<sub>3</sub> but also created some new fields such as optical modulators, transducers and actuators, and thermal and chemical sensors. Nevertheless, research is still needed to deepen our understanding of the grain size effect on those enhanced (novel) properties in BaTiO<sub>3</sub> nanostructured materials, such as low-temperature quantum ferroelectricity and paraelectricity, electronic structure changes, and soft-mode behavior with varying nanocrystallite size.

## GLOSSARY

**Ferroelectric critical grain size** The minimum grain size, below which the ferroelectricity disappears.

**Ferroelectric phase transition** A special class of structural phase transition where the transition from the high to the low symmetry phase is accompanied by the appearance of spontaneous polarization. They could be driven by external field applications of temperature, of pressure, of electric field, of composition substitution, and/or of grain size.

**Finite grain size effect** When the dimension of crystal is comparable with the feature length of some property, this property becomes dependent on the grain size and shape, which is named as finite grain size effect.

**Perovskite oxide** A family name of oxide materials having a chemical formula of ABO<sub>3</sub>. In the prototype cubic structure, the ionic A is at the corner, B at the bulk center, and O at the face center.

**Quantum ferroelectric phase transition** Instead of by thermal fluctuation, the ferroelectric phase transition from the paraelectric phase is driven by quantum fluctuation, of which the Curie temperature obeys the relation of  $T_c \propto (S - S_c)^{1/2}$ , changed from the classical law  $T_c \propto (S - S_c)$ .  $S$  is external parameter controlling interaction, and  $S = S_c$  at  $T_c$ .

**Soft mode** One of the lowest frequency transverse optical modes, of which the frequency is temperature dependent and reduces to zero as the transition temperature is approached, and at Curie temperature, the condensation of soft mode displacement determines the structure of the low temperature phase.

**Spontaneous polarization** The existence of electrical momentum in the noncentrosymmetric phases, which can be reversed or reoriented by application of external electrical field.

# Nanocrystalline Ceramics by Mechanical Activation

J. M. Xue, Z. H. Zhou, J. Wang

*National University of Singapore, Singapore*

## CONTENTS

1. Introduction
  2. Mechanically Activated Processes
  3. Mechanical Activation Devices
  4. Nanocrystalline Ceramic Materials
  5. Nanocrystalline Ceramics  
by Mechanical Activation
  6. Mechanical Crystallization and  
Precursor to Ceramic Conversions
  7. Summary
- Glossary  
References

## 1. INTRODUCTION

Ceramic materials are traditionally synthesized by solid-state reactions of the starting constituents (such as oxides, nonoxides, carbonates, and precursors) at elevated temperatures. It is, however, difficult to realize a nanocrystalline feature by the conventional ceramic process, as a high temperature calcination always leads to coarsening and aggregation of fine ceramic particles. Similarly, most of the wet-chemistry-based processing routes for ceramic materials have failed to deliver a true nanocrystalline structure, again due to the unwanted particle and crystallite coarsening and aggregation at the calcination temperature, which is unavoidably required for chemistry-derived ceramic precursors. In a fundamentally different approach, phase formation in mechanical activation is realized at room temperature, via one or more of the mechanically triggered chemical reactions, nucleation and growth from an amorphous state, decompositions, and phase transformations, depending on the specific ceramic material concerned. Little progress was made in synthesizing ceramic materials by mechanical activation until about 10 years ago when the potential of this novel

synthesis technique was demonstrated, although mechanical alloying for metals and intermetallics was devised more than 30 years ago. Over the past 5 years, there has been a surge in effort to employ mechanical activation for synthesis of a wide range of nanocrystalline ceramic materials including ceramic oxides, oxides of complex perovskite, spinel and layer structures, nonoxides, magnetic ceramics, electroceramics, and ceramic nanocomposites. While research focus on mechanical activation, on the one hand, is directed at synthesis of nanocrystalline ceramic materials, many of the underlying physical phenomena in association with mechanical activation have yet to be properly studied and made understood. On the other hand, mechanical activation promises a significant technological implication, whereby the currently employed multiple steps of phase-forming calcination/annealing at high temperatures for ceramic materials can be skipped, when the required nanocrystalline ceramic phases are realized at room temperature in an enclosed mechanical activation chamber. In this chapter, recent progress in mechanical activation for synthesis of nanocrystalline ceramic materials is reviewed and a number of new and unique phenomena brought about by mechanical activation in functional ceramics are discussed, together with a short discussion on the possible future development of this novel technique.

## 2. MECHANICALLY ACTIVATED PROCESSES

Mechanically activated processes are among the earliest phenomena created by humankind and the use of flint to trigger fires is perhaps one of the best known examples [1]. Mechanochemical reactions were documented and date back as early as several hundred B.C., when a number of chemical reactions were noted under the influence of one or more types of mechanical actions. However, mechanochemistry was not developed in a systematic manner until late 19th century, along with solid state chemistry, when the

effects of high pressure, mechanical impact, and combination of high pressure and temperature on the rates of solid state chemical reactions and phase transitions were studied [2]. Following the steady establishment of physical metallurgy in the first half of 20th century and then materials science, the potential of mechanically activated processes for materials synthesis was first demonstrated by Benjamin [3], who devised “mechanically alloying” for oxide-dispersed nickel- and iron-based super alloys. This marked a new era of successfully employing mechanically activated process in materials synthesis, and it was followed by the extension and application of this novel technique to a wide range of structural and functional materials, including intermetallics and metal matrix composites in the early stage of development, and then magnetic materials, semiconductors, and more recently nanocrystalline ceramic materials and ceramic matrix composites.

In the recent development history of mechanically activated processes, there existed a number of terminologies, each of which was adopted by the inventor of a specific fabrication technique [4]. In several cases, there is no clear boundary between two or more such terminologies. Mechanical alloying is used to describe a process where the powder mixture of different metals, alloys, or compounds is ultimately mixed together and the formation of a new alloy phase involves mass transfer. In comparison, mechanical milling refers to a milling process of homogenized compositions where mass transfer is not required. Therefore, it is often associated with milling of a pure metal or compound that is already in a state of thermodynamic equilibrium. Similarly, mechanical grinding refers to a milling process where mechanical milling is dominated by abrasion or shear stresses and chip formation. Mechanical disordering is specifically phrased for the milling process that is designed for destruction of the long-range order in intermetallics and production of either a disordered intermetallic or an amorphous phase. Mechanical crystallization describes the nucleation and crystallite growth triggered by a mechanical process from either an amorphous state or an amorphous precursor.

Mechanochemical synthesis/process is the general phrase that has been widely given to any high energy milling process of powdered materials involving one or more chemical reactions occurring during milling [5, 6]. Most of the mechanically activated processes for synthesis of nanocrystalline ceramic materials fall into this category. In mechanochemical synthesis, mechanical activation is employed to trigger the chemical reaction, structural change, and nucleation and growth of nanocrystallites from an amorphous state, leading to a product phase, with or without the need of a further thermal treatment at elevated temperatures. In combination with mechanical alloying, mechanochemical synthesis has been used to describe majority of the mechanically activated processes that have been devised and utilized in materials synthesis, while several other terms, such as reactive milling [7], rod milling [8], and mechanically activated self-propagating high temperature synthesis [9], can easily be categorized into either of these two general categories. Reaction milling, for example, pertains to the mechanical alloying process that is accompanied by one or more solid state reactions. Rod milling is a specific technique that was

developed in Japan to trigger the mechanochemical reaction by a predominant shear process, in order to reduce the level of contamination. Mechanically activated self-propagating high temperature synthesis refers to any mechanically activated reaction that is self-propagating in nature once triggered [10], which again can be categorized into the general terminology of mechanochemical synthesis. It must be pointed out that phase formation of several nanocrystalline ceramic materials, such as those via nucleation and subsequent crystallite growth from an amorphous state, is not a result of any chemical reactions that are described in the traditional mechanochemical process. Therefore, the terminology of mechanical activation is adopted in this chapter, which is aimed at covering most of the mechanically activated processes for synthesis of nanocrystalline ceramic materials.

### 3. MECHANICAL ACTIVATION DEVICES

Although syntheses of ceramic materials and many other types of materials have been successfully realized by various mechanically activated processes, there has been little specification and standardization with the types of mechanical activation devices and setups [4]. Conventional ball milling, which is commonly employed for mixing and blending of raw materials and refinement in particle and agglomerate sizes in ceramic industry, is generally unsuitable for mechanochemical synthesis, although certain phase transformations (such as those in PbO) and a number of chemical reactions can occur in conventional ball milling. Generally speaking, mechanical activation devices are those of high energy milling and modifications of high energy milling, which were originally designed for mechanical alloying. SPEX shaker mills and planetary ball mills are among the very few choices of commercially available high energy mills. SPEX Shaker mills are designed for a relatively small capacity of up to 20 grams and are therefore popularly adopted for laboratory investigation. They typically consist of one vial, containing the sample composition and activation media (typically of one or more high density balls made of ceramics or stainless steel), secured in clamps and swung energetically back and forth up to several thousand times per minute. The back and forth shaking motion of the vial is also combined with lateral movements. By simple calculation, ball velocity in SPEX Shaker mills is up to the order of 5 m/s, generating an unusually high impact force at a very high frequency.

Planetary mills, which are designed for relatively large quantities in the range up to a few hundred grams of powder per batch, are manufactured by Fritsch GmbH in Germany. Vials of planetary mills are arranged on a rotating support disk by a specifically designed drive mechanism to cause them to rotate around their own axes. There is a strong centrifugal force produced by the rotating vials around their own axes, together with that generated by the rotating support disk; both act on the vial contents and the activation balls. Because the vials and the supporting disk rotate in opposite directions, the centrifugal forces alternately act in like and opposite directions. This enables the activation balls to run against the internal walls of the vial, generating a friction effect, and at the same time the activation balls lift off and travel freely through the inner chamber of the vial and

collide against the opposing inside wall generating a strong impact effect.

An attrition mill, which is a modification of the conventional ball mill, consists of a vertically aligned drum with several impellers being set progressively at right angles to each other. The impellers energize the medium charge, causing impacts between activation media, between the medium and the drum wall, and between the medium, agitator shaft, and impeller. Attrition mills are capable of larger batch quantity (up to tens of kilos) than both planetary mills and shaker mills, although they are generally regarded as being of low energy type and unsuitable for successful mechanical activation syntheses in many cases.

There have been several new designs of mechanical activation devices, including rod mills, vibrating mills, and those shaker and planetary mills in combination with the application of an electrical discharge, magnetic field, temperature, and hydrothermal conditions, in an effort to combine mechanical activation with other processing controls [11–14]. Typical processing parameters that can be controlled in mechanical activation include the activation (or mill) speed, activation time, choices, size and combination of vial and milling media, media to powder weight ratio, activation media and atmosphere, activation temperature, and pressure.

#### 4. NANOCRYSTALLINE CERAMIC MATERIALS

Performance and functional properties of ceramic materials are critically dependent on a number of compositional and structural parameters in atomic, nanometer, and microstructural scales. Over the past four decades starting from the 1960s following the wide application of electron microscopes in materials characterization, there has been a steady accumulation of knowledge and understanding on the microstructure and microstructure–property relationships in ceramic materials. At the same time, in particular over the past two decades, research focus on ceramic processing has been shifting from the traditional solid state reactions to wet-chemistry-based syntheses, in order to refine the microstructure into nanometer scales. There are two major driving forces behind the current surge in pursuit of a nanocrystalline structure for ceramic materials: (i) the unique physical and functional properties arising from a nanostructure and (ii) a much lowered processing temperature for ceramic materials.

As a result of the significant refinement in particle size (for powdered ceramics) and grain size (for sintered bulk ceramics) into the nanometer range, surfaces, interfaces, and grain boundaries play a critically important role in determining the physical and functional behaviors of nanocrystalline and nanostructured ceramic materials, which can be considerably different from those of their counterparts with structural features in the micrometer scales. For example, a flexural strength of >2000 MPa and excellent superplasticity, which were traditionally considered as being impossible for brittle ceramic materials, have been demonstrated with both oxide ceramics (alumina and zirconia) and ceramic nanocomposites (e.g., alumina–SiC and  $\text{Si}_3\text{N}_4$ –SiC) [15–17].

Ultrafine ceramic powders consisting of well dispersed nanocrystalline particles of <100 nm in size have received considerable attention for technologically demanding application in micro- and nanoelectronics, materials processing and manufacturing, medicine and biotechnology, catalysts, new energy sources, and environmental protections. As a result of the much enlarged surface to volume ratio and one or more quantum and confinement effects, nanocrystalline ceramic particles exhibit many unique properties that can be fundamentally different from those of their coarse counterparts. Nanocrystalline ferrites of spinel structure are among many such well established examples. For example, zinc ferrite ( $\text{ZnFe}_2\text{O}_4$ ) in bulk ceramic form possesses a normal spinel structure with the tetrahedral A sites exclusively being occupied by  $\text{Zn}^{2+}$  ions. As such, the predominant magnetic interaction in  $\text{ZnFe}_2\text{O}_4$  is the weak B–B interaction (i.e., the negative superexchange interaction among  $\text{Fe}^{3+}$  ions in the octahedral sites) [18, 19].  $\text{ZnFe}_2\text{O}_4$  is therefore traditionally regarded as an antiferromagnetic with Néel temperature of about 10 K, above which it becomes paramagnetic. Several unusual magnetic phenomena have been observed in nanosized zinc ferrite particles synthesized via a number of different processing routes, including mechanical activation [20–24]. They exhibit unusually high magnetizations and higher Néel temperatures than those of bulk  $\text{ZnFe}_2\text{O}_4$ . Recent investigation has confirmed that this is related to a partially inverted spinel structure in the nanocrystalline  $\text{ZnFe}_2\text{O}_4$  particles, in which a small number of  $\text{Fe}^{3+}$  ions occupy the tetrahedral A sites, causing formation of magnetic clusters by the A–B interactions [25]. A similar structure disorder has been observed in nanocrystalline  $\text{NiFe}_2\text{O}_4$  derived from mechanical activation [26].

Employment of nanocrystalline ceramic powders as the starting materials can dramatically lower the sintering temperature of ceramic materials. While many ceramic materials are indispensable for functioning of almost all electronic, microelectronic, and data storage devices, integration of ceramic materials into wafer-based technology inevitably requires a processing temperature for ceramic materials be compatible to those for silicon and wafer technology. There is therefore a significant technological implication in lowering the sintering temperature of these ceramic materials. For example, use of an electroceramic material in co-fired multilayer devices requires the electroceramic composition be sinterable at a temperature below 1000 °C. A low enough firing temperature will apparently alleviate, if not completely eliminate, the detrimental interactions between alternative layers of ceramic and metal electrode at the co-firing temperature. For multilayer ceramic capacitors, for example, a large enough reduction in sintering temperature will lead to substitution of the very expensive electrodes of platinum and palladium, by much cheaper ones, such as those made of silver, nickel, copper, and their alloys [27].

To prepare nanocrystalline ceramic particles, many chemistry-based processing routes have been attempted, including for example, sol–gel [28], hydrolysis [29], hydrothermal reaction [30], and coprecipitation [31]. Chemistry-based processing techniques inevitably use high-purity inorganic, organic, and metallorganic chemicals as the starting materials, and they are associated with high production cost and low production yield. Furthermore, almost all the chemistry-derived

precursors require a calcination step at elevated temperatures, which unfortunately ruins almost all the advantages offered by chemistry-based novel processing techniques, including a very high specific surface area, ultrafine particle size, and narrow particle size distribution. Any thermal annealing and calcination inevitably causes crystallite coarsening and particle aggregation in the resulting ceramic powders. The occurrence of hard particle aggregates adversely affects subsequent compaction and sintering behaviors and leads to a low density and the occurrence of microstructural defects in sintered ceramic bodies. In the ceramic industry, one or more postcalcination conventional ball milling steps are often carried out, in order to modify the particle characteristics (e.g., particle and aggregate sizes, particle morphology) before subsequent shaping and then sintering at high temperatures. However, hard enough particle aggregates cannot be effectively eliminated by a conventional ball mill.

In a fundamentally different approach from the conventional ceramic processing and most chemistry-based synthesis techniques for ceramic materials, mechanical activation offers the following distinctions and advantages:

- (i) In mechanical activation, phase formation is realized by an input of mechanical activation, instead of the thermal activation (i.e., calcination and annealing at high temperatures) that is employed in the conventional ceramic processing and most chemistry-based synthesis routes.
- (ii) Mechanical activation is conducted at a much lower temperature, often at room temperature, than required in either conventional ceramic processing or wet-chemistry-based synthesis routes.
- (iii) Ceramic phases derived from mechanical activation exhibit a nanocrystallinity and particle sizes in the nanometer range, together with a minimized degree of particle agglomeration.
- (iv) Being conducted in an enclosed chamber and by skipping the thermal activation at elevated temperatures for phase formation, mechanical activation exercises a strict control on chemical and compositional stoichiometry, which is critically important for functional and electroceramic materials where volatile components are often lost at the solid state reaction or calcination temperatures.
- (v) Mechanical activation employs commonly available ceramic raw materials, such as oxides and nonoxides as the starting materials, and at the same time skips the phase-formation calcination and postcalcination comminution, leading to a much lower production cost than that of either conventional ceramic processing or a chemistry-based synthesis route.
- (vi) Nanocrystalline ceramic materials derived from mechanical activation demonstrate a number of unique structural and physical behaviors, such as structural metastability, cation inversion in spinel structure, and order-disorder transition in complex perovskites, which are not shown by the materials synthesized via either conventional ceramic processing or chemistry-based synthesis routes.
- (vii) As a result of the fundamentally different phase-forming mechanisms from those of conventional solid

state reactions in the conventional ceramic processing, mechanical activation can skip transitional and impurity phases, which are largely concerned with functional and electroceramic materials with complex perovskite, spinel, and layered perovskite structures.

- (viii) Mechanical activation can be employed to synthesize several nanocrystalline ceramic materials that cannot possibly be synthesized via either conventional ceramic or chemistry-based processing routes.
- (ix) As a result of the nanocrystallinity and ultrafine particle sizes, ceramic materials derived from mechanical activation exhibit a much lowered sintering temperature. For example,  $\text{PbZr}_{1-x}\text{Ti}_x\text{O}_3$  (PZT) derived from mechanical activation can be sintered at a temperature as low as 1000 °C [32].
- (x) There are a number of unique phenomena that have been observed in association with mechanical activation, including extension of solubility [33], formation of metastable structures [34], amorphization of a crystalline phase [35], phase transition [36, 37] order-disorder transformation [38], cation inversions [26], and crystallization from amorphous states and amorphous precursors [39–41].

## 5. NANOCRYSTALLINE CERAMICS BY MECHANICAL ACTIVATION

In syntheses of nanocrystalline ceramic materials by mechanical activation, one or more chemical reactions, phase transformations, decompositions, and nucleation and subsequent crystallite growth are associated with mixing, deformation, fracture, refinement, and amorphization of the starting materials, leading to formation of a product phase, with or without the need for further thermal activation at elevated temperatures. In comparison with the solid-state reaction in conventional ceramic processing at high temperatures, a distinct feature of mechanical activation is the realization of particle and crystallite sizes in the nanometer ranges. Nanocrystalline ceramic particles of as fine as 4 nm in size and varying particle morphologies (rounded, rod-like, and platelike) can be synthesized [42]. Several types of chemical reactions can be triggered by mechanical activation, including displacement reaction [43], oxidation [44], reduction [45], decomposition [46], and incipient reaction [47]. Depending on the nature of the starting material and experimental parameters chosen for mechanical activation, phase-formation mechanisms during mechanical activation can be fundamentally different from those in thermal activation.

Several very different phase formation mechanisms have been suggested for ceramic materials triggered by mechanical activation, including various mechanochemical reactions at the interface in microsecond or nanosecond duration of shock, impact, and collision in a highly activated state [37], local temperature-facilitated solid state reactions [39], nucleation at interface [40], and nucleation from the highly activated matrix and subsequent growth of crystallites [48]. It is commonly believed that mechanical activation can significantly increase the reactivity of a solid system, as a result of the refinement in particle and crystallite sizes and creation

of various structural and surface defects, and therefore diffusion and reaction kinetics are enhanced. This is supported by the much lowered reaction and phase formation temperatures that are brought about by mechanical activation. Mechanical activation can lead to a significant departure from the equilibrium state. In some cases, the free energy level raised by mechanical activation is above that of an amorphous state. The much refined particle and crystallite sizes, with or without presence of structure defects, enable chemical reactions which otherwise require high temperatures to occur. Thermodynamically, this is accounted for by the energy accumulation process during mechanical activation. A further contribution to the enhanced reactivity is the alleviation, if not elimination, of the diffusion barrier generated by the product phase that separates the reactants.

High temperature and pressure at the collision points can give rise to a new and product phase, although the overall temperature of the mechanical activation chamber normally does not exceed 100 °C in most cases. However, it is questionable whether the short interval of *in-situ* temperature at the collision points, which may be high enough to trigger many types of solid state reaction, will be sufficient for formation of a product phase of several nanometers in dimensions. In discussing the mechanisms of incipient reaction at solid–solid boundary under mechanical stresses, Senna [49] outlined the importance of coordination states, symmetry disturbance, and change in electronic states. Similarly, Boldyrev and Tkacova [2] considered the increase in solid density under a hydrostatic loading, which can cause a decrease in the width of forbidden band and conduction states. The process can be further facilitated by an appropriate combination of hydrostatic stress and shear component, which apparently occur in certain mechanical activation processes. One of the common features in all mechanical activation processes is the involvement of strain, which manifests itself by the shift of atoms from their equilibrium positions and the change in bond lengths and angles. Therefore, structural defects, amorphization and metastable states often occur prior to formation of the product phase with increasing degree of mechanical activation.

There is no doubt that the significant refinement in particle and crystallite sizes during the initial stage of mechanical activation creates newly formed, clean surfaces, which can quickly absorb and react with species that are in direct contact. In the presence of moisture or a liquid phase, hydrothermal processes can occur at the collision points, which can also lead to formation of a product phase [50]. This belief has encouraged the attempt to combine mechanical activation and hydrothermal reaction. In recent studies of mechanical activation for synthesis of electroceramic materials of complex perovskite structure [48], where multiple oxides are involved as the starting materials, a completely different phase formation process has been observed. Nucleation of nanocrystallites of perovskite structure occurs in a highly activated oxide matrix, where a significant refinement in particle and crystallite sizes together with a degree of amorphization have taken place. Subsequent growth of the nanocrystallites with further mechanical activation is a consequence of the equilibrium between the activation-driven buildup and destruction involving the entire masses of nanocrystallites. Constant collisions and rearrangement

of nanocrystallites provided by mechanical activation create opportunities for two or more of them to meet at favorable positions leading to growth in the crystallite size. At the same time, there is also a probability that the nanocrystallites are distorted and fragmented by mechanical activation.

While the phase-formation mechanisms and physical phenomena in many systems have yet to be properly understood, numerous nanocrystalline ceramic materials have been successfully synthesized by mechanical activation. They include simple oxides, such as  $\text{Al}_2\text{O}_3$ ,  $\text{ZrO}_2$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{ZnO}$ , and  $\text{CeO}_2$ , complex oxides of perovskite structure, spinel structure, aurivillius type compound and layered perovskite structure and their solid solutions, nonoxide ceramics such as nitrides, carbides, oxynitrides, sulphides, and ceramic nanocomposites. Table 1 lists examples of the typical nanocrystalline ceramic materials synthesized by mechanical activation. In the following, a brief review is given to each of these major types of nanocrystalline ceramic materials synthesized by mechanical activation.

### 5.1. Simple Ceramic Oxides

A large number of simple oxides, examples of which include  $\text{Al}_2\text{O}_3$  [51],  $\text{ZrO}_2$  [52–54],  $\text{Fe}_2\text{O}_3$  [55],  $\text{Gd}_2\text{O}_3$  [56],  $\text{CeO}_2$  [57],  $\text{SnO}_2$  [58],  $\text{ZnO}$  [59],  $\text{Cr}_2\text{O}_3$  [60],  $\text{Nb}_2\text{O}_5$  [60], and  $\text{TiO}_2$  [61], have been synthesized by mechanical activation. Starting with an inorganic salt, such as chloride, an oxide can be realized by a simple replacement reaction during mechanical activation, followed by a calcination/annealing at temperatures in the range of 150 to 600 °C. To synthesize nanocrystalline  $\text{Al}_2\text{O}_3$ , for example [51], an appropriate powder mixture of  $\text{AlCl}_3$  and  $\text{CaO}$  is mechanically activated, followed by calcination at progressively rising temperatures, leading to formation of  $\gamma\text{-Al}_2\text{O}_3$  within  $\text{CaCl}_2$  matrix at 350 °C and then  $\alpha\text{-Al}_2\text{O}_3$ . Nanocrystalline  $\text{Al}_2\text{O}_3$  particles are then recovered by washing off  $\text{CaCl}_2$ . Similarly, nanocrystalline  $\text{ZrO}_2$  [52] particles are produced by mechanical activation of  $\text{ZrCl}_4$  together with  $\text{CaO}$  ( $\text{NaOH}$  and  $\text{LiOH}$  can also be used) and the subsequent thermal annealing at 300 °C, leading to formation of zirconia particles of 5 to 10 nm in size and of metastable cubic structure. Other examples of simple oxides that have been successfully synthesized by the replacement reaction triggered by mechanical activation include  $\text{Fe}_2\text{O}_3$ ,  $\text{Gd}_2\text{O}_3$ ,  $\text{CeO}_2$ ,  $\text{SnO}_2$ , and  $\text{ZnO}$ , where the starting chemicals are corresponding chlorides in combination with an alkaline or oxide of an alkaline earth. Transitional and metastable phases may well be involved in some cases. For example [55],  $\text{FeOOH}$  can occur prior to formation of  $\alpha\text{-Fe}_2\text{O}_3$  during mechanical activation of  $\text{FeCl}_3$  together with  $\text{Ca}(\text{OH})_2$  and subsequent thermal annealing with rising temperature. To further modify the particle size and degree of particle aggregation of nanocrystalline oxides derived from mechanical activation, dispersion/dilution agents, such as  $\text{NaCl}$  and  $\text{CaCl}_2$ , have been proven effective.

In an analog to formation of simple oxides by thermal decomposition of corresponding hydroxides, decomposition of several hydroxides is obtainable by mechanical activation, leading to formation of nanocrystalline particles. For example, mechanical activation of  $\text{Zr}$ -hydroxides [62] results in formation of nanocrystalline zirconia particles of 4 to 10 nm

in sizes and of metastable tetragonal structure, in contrast to the monoclinic structure for ZrO<sub>2</sub> particles derived from thermal annealing of the hydroxide precursor. This is apparently related to the much refined crystallite size derived from mechanical activation, where the crystallite coarsening and particle aggregation that are always observed at a calcination temperature as low as 500 °C are avoided. Other successful examples of mechanical activation in decomposing ceramic precursors include ZnO [63] and Fe<sub>2</sub>O<sub>3</sub> [64]. For example, zinc oxide particles of 10 to 20 nm in size were successfully obtained, when zinc nitrate hydroxide hydrate precursor, (Zn<sub>5</sub>(NO<sub>3</sub>)<sub>2</sub>(OH)<sub>8</sub>·2H<sub>2</sub>O), was mechanically activated in NaCl for 15 hours, where NaCl was used as a drying and dispersion agent [63]. Several decomposition steps were triggered by mechanical activation prior to nucleation and subsequent growth of ZnO particles with increasing degree of mechanical activation. The nanocrystalline ZnO particles thus synthesized exhibited a well-established hexagonal morphology and are almost agglomeration-free, which were compared favorably with those derived from conventional calcination of the same precursor at 400 °C.

Extraction of zirconia from zircon, which is the principal mineral source for zirconia, is traditionally carried out at very high temperatures. When mechanically activated with calcium and magnesium [65], zircon undergoes decomposition to form zirconia and Ca- or Mg-silicates. Similarly, zirconia can be produced by mechanical activation of zircon together with oxides of alkaline earth metals [65]. Unlike the zirconia phase derived from high temperature calcination, nanocrystalline zirconia particles thus produced exhibit a metastable tetragonal structure, which undergoes phase transformation into monoclinic upon heating up to 1200 °C. The occurrence of metastable tetragonal structure is apparently related to the fine nanocrystallites derived from mechanical activation.

Alumina (Al<sub>2</sub>O<sub>3</sub>), which is one of the most studied ceramic materials and is widely employed in numerous structural and functional applications, is traditionally derived from bauxite, for example by the Bayer process [66] involving digestion and calcination at high temperatures. There exist several transitional phases of aluminum hydroxides/hydrates and oxides, which normally occur prior to formation of thermodynamically stable  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> at a high enough calcination temperature. On the one hand, as a result of the enhanced reactivity of bauxite brought about by mechanical activation, the extraction rate of aluminum hydroxides from bauxite is significantly improved in

the Bayer process. On the other hand, in the search for alternative routes for the aluminum hydroxide/hydrate to alumina conversion, which is traditionally realized by calcination at high temperatures, mechanical activation has been attempted by several investigators. To date, the experimental observations reported by different research groups are rather sketchy. For example, an identical sequence of phase transitions to those commonly observed in calcination of gibbsite was reported by Tonejc et al. [67], who employed high energy ball milling for mechanical activation, while others observed a rather different sequence of phase transitions between mechanical activation and thermal activation. These differences are accountable for by the differences in experimental setup and experimental parameters employed by different investigators. In a recent study conducted by Yong and Wang on gibbsite [68], it was observed that mechanical activation of monoclinic gibbsite  $[\text{Al}(\text{OH})_3]$  in nitrogen led to formation of nanocrystalline boehmite ( $\text{AlOOH}$ ) of orthorhombic structure, which cannot be converted into alumina by prolonging the mechanical activation process. Nanocrystalline boehmite phase started to appear at merely 3 hours of mechanical activation followed by a steady development in both phase purity and crystallite size with increasing mechanical activation time. Forty hours of mechanical activation produced in an essentially single-phase boehmite, together with nanocrystallites of  $\alpha\text{-Al}_2\text{O}_3$  of 2 to 3 nm in sizes dispersed in the boehmite matrix. Upon subsequent thermal annealing, mechanically activated boehmite transformed to  $\gamma\text{-Al}_2\text{O}_3$  at 520 °C and then to  $\alpha\text{-Al}_2\text{O}_3$  at around 1100 °C. The fine  $\alpha\text{-Al}_2\text{O}_3$  particles thus produced are 100 to 200 nm in size and exhibit a rounded particle morphology. This is in contrast to the calcination temperature of 1400 °C required for gibbsite that was not subjected to any mechanical activation, which undergoes transition at above 220 °C to boehmite and then to transitional phases of  $\delta\text{-Al}_2\text{O}_3$  and  $\theta\text{-Al}_2\text{O}_3$ , prior to formation of  $\alpha\text{-Al}_2\text{O}_3$ .

There are a number of other types of reaction that can be triggered by mechanical activation and lead to formation of simple oxides of nanocrystallinity. For example, CoO and NiO nanoparticles [44] can be formed by mechanical activation of corresponding metal elements in a highly oxidizing environment, where the oxidation is speeded up by mechanical activation. Mechanical activation of  $\text{Fe}_3\text{O}_4$  together with Al [69] leads to formation of a mixture of  $\alpha\text{-Al}_2\text{O}_3$ ,  $\text{FeAl}_2\text{O}_4$ , and  $\alpha\text{-Fe}$ . Reduction reaction of  $\text{FeTiO}_3$  by Si is obtainable at room temperature by mechanical activation [70, 71], leading to formation of nanocrystalline  $\text{TiO}_2$  in an amorphous  $\text{SiO}_x$ , together with intermetallic compounds and  $\alpha\text{-Fe}$ , depending on Si content in the starting mixture. These mechanical activation-driven processes consist of an initiation stage and subsequent reaction stage, where the length of initiation stage and subsequent reaction rate are largely controlled by the mechanical activation intensity. A similar mechanochemical reaction [72] has been reported for between  $\text{FeTiO}_3$  and Al during mechanical activation, producing nanocrystalline  $\text{Al}_2\text{O}_3$  together with intermetallic phases of  $\text{TiAl}_3$  and  $\text{Fe}_4\text{Al}_{13}$ .

## 5.2. Complex Ceramic Oxides

A number of complex oxides of nanocrystallinity, including those of perovskite structure, complex perovskite structure, aurivillius type and layered perovskite structure, and spinel structure and their solid solutions, have been successfully synthesized by mechanical activation of either constituent oxides or ceramic precursors, such as hydroxides and oxalates, or a mixture of these. Depending on the nature of the starting materials and the experimental setup for mechanical activation, there can be considerable differences in the types of mechanochemical reaction involved and the phase-formation steps during mechanical activation. In several cases, complex oxides of nanocrystallinity are formed as a result of one single step of mechanical activation, while in others a subsequent thermal annealing step is required before designed nanocrystalline ceramic phases are realized. As a consequence of the enhanced reactivity brought about by mechanical activation, phase-formation temperature for complex oxides can be significantly lowered.

Among the complex oxides of nanocrystallinity that have been successfully synthesized by mechanical activation, alkaline earth titanates, such as  $\text{BaTiO}_3$  and  $\text{SrTiO}_3$ , exhibit a perovskite structure.  $\text{BaTiO}_3$ , which is one of the most widely used electroceramic materials for numerous applications in electronics and microelectronics, is traditionally synthesized by the solid-state reaction between  $\text{TiO}_2$  and  $\text{BaCO}_3$  at temperatures above 1000 °C [73]. The conventional solid-state reaction between  $\text{TiO}_2$  and  $\text{BaCO}_3$  at high temperatures is associated with several fatal disadvantages. For example, the interfacial reaction between  $\text{TiO}_2$  and  $\text{BaCO}_3$  is accompanied by several intermediate phases, which often occur as unwanted impurity phases together with the product phase of  $\text{BaTiO}_3$ . The high calcination temperature that is required by phase formation in the solid state reaction always results in unwanted particle coarsening and aggregation, the presence of which adversely affects subsequent sintering and densification of  $\text{BaTiO}_3$ . It is therefore both scientifically interesting and technologically demanding to search for alternative synthesis routes for  $\text{BaTiO}_3$ . In an attempt to synthesize nanocrystalline  $\text{BaTiO}_3$  of perovskite structure, Xue et al. [74] carried out mechanical activation of  $\text{TiO}_2$  and BaO in a nitrogen atmosphere, leading to steady formation of  $\text{BaTiO}_3$  of 10 to 15 nm in crystallite sizes. Employment of the nitrogen atmosphere is to stop BaO from reaction with  $\text{CO}_2$  in air. In addition to BaO as the source material for Ba in  $\text{BaTiO}_3$ ,  $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$  was also used [75]. When mechanically activated together with  $\text{TiO}_2$  in acetone, nanocrystallites of  $\text{BaTiO}_3$  steadily resulted. The crystallinity of thus derived  $\text{BaTiO}_3$  was further enhanced by subsequent thermal annealing. There are several other examples of nanocrystalline titanates that have been synthesized by mechanical activation, including  $\text{MgTiO}_3$  [76, 77] and  $\text{PbTiO}_3$  [78–80]. For example, mechanical activation of PbO and  $\text{TiO}_2$  at room temperature led to formation of  $\text{PbTiO}_3$  (PT) of perovskite structure and nanocrystallinity. Figure 1 is a transmission electron microscopy (TEM) micrograph showing the nanoparticles of PT derived from mechanical activation of the constituent oxides at room temperature. They are 5 to 10 nm in size and spherical in particle morphology. While  $\text{PbTiO}_3$  was nucleated in the

**Figure 1.** A bright field TEM micrograph showing the nanoparticles of lead titanate ( $\text{PbTiO}_3$ ) synthesized by mechanical activation of  $\text{PbO}$  and  $\text{TiO}_2$  at room temperature.

highly activated matrix of oxides, strong deviation from compositional stoichiometry, vacancy generation, and occupation of B-sites by  $\text{Pb}^{2+}$  in the perovskite structure may well occur during mechanical activation.

Lead zirconate titanate (PZT), which is the classical piezoelectric, has recently been synthesized by mechanical activation of constituent oxides of  $\text{PbO}$ ,  $\text{ZrO}_2$ , and  $\text{TiO}_2$  at room temperature [32]. Unlike in the solid state reaction of these oxides at high temperatures, transitional  $\text{PbZrO}_3$  (PZ) and PT phases were not observed during mechanical activation of these oxides. This represents a significant step forward in synthesizing this technologically demanding material for a number of applications in sensors, transducers, and actuator devices using the low-cost oxides as starting materials. As will be discussed later, the phase-formation process of complex perovskites during mechanical activation is fundamentally different from that in the conventional solid-state reaction, where the process is controlled by one or more interfacial diffusions and reactions. In contrast, mechanical activation triggered the nucleation and subsequent crystallite growth of complex perovskites in a highly activated matrix of oxide composition. Owing to the unique nanocrystalline structures of PZT derived from mechanical activation, they can be sintered to a >99% theoretical density at a temperatures as low as 1000 °C, which is about 200 °C lower than what is normally required for this classical piezoelectric.

Another most remarkable example of mechanical activation in synthesizing nanocrystalline electroceramic materials of complex perovskite structure is  $\text{PbO}$ -based relaxor ferroelectrics [81].  $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$  (PMN), for example, is a relaxor-type ferroelectric of perovskite structure exhibiting some of the most desirable dielectric and electrostrictive properties for a number of applications in sensors and actuators [82]. Behind PMN, there is a big family of  $\text{Pb}$ -based relaxor ferroelectrics, typical examples of which are  $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ – $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$  (PMN–PZN) and  $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ – $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ – $\text{PbTiO}_3$  (PMN–PZN–PT). Constituent oxides are undoubtedly the starting materials of lowest cost for these relaxor ferroelectrics. It is,

however, impossible to synthesize a single phase PMN and PMN-based relaxor ferroelectrics of perovskite structure from their constituent oxides by one-step solid-state reaction at high temperatures [83]. Calcination of a powder mixture of  $\text{PbO}$ ,  $\text{MgO}$ , and  $\text{Nb}_2\text{O}_5$ , for example, always produces one or more transitional pyrochlore phases (notably  $\text{Pb}_3\text{Nb}_4\text{O}_{13}$  and  $\text{Pb}_2\text{Nb}_2\text{O}_7$ ), prior to formation of perovskite PMN phase. On the one hand, this is related to the difference in reactivity among the three oxides over a wide range of temperatures. On the other hand, there apparently exists a much larger interfacial area between any two of these three oxides than the common contact area where all three oxides are present, creating opportunities for the preferred interfacial reaction between  $\text{PbO}$  and  $\text{Nb}_2\text{O}_5$  to take place [84]. To overcome the much unwanted pyrochlore phases in PMN and PMN-based relaxors, multiple steps of calcination and postcalcination comminution are necessary in the well known Columbite method [83].

Figure 2 shows the X-ray diffraction (XRD) traces of mixed oxides of  $\text{PbO}$ ,  $\text{MgO}$ , and  $\text{Nb}_2\text{O}_5$  upon mechanical

**Figure 2.** XRD patterns of mixed oxides of  $\text{PbO}$ ,  $\text{MgO}$ , and  $\text{Nb}_2\text{O}_5$  mechanically activated for various time periods from 0 to 20 hours. O:  $\text{PbO}$ , ■:  $\text{Nb}_2\text{O}_5$ , ◆:  $\text{MgO}$ , ●: PMN. Reprinted with permission from [85], J. Wang et al., *Solid State Ionics* 124, 271 (1999). © 1999, Elsevier Science.

activation for various time periods up to 20 hours [85]. Sharp peaks of crystalline PbO, MgO, and Nb<sub>2</sub>O<sub>5</sub> are observed for the starting oxide mixture, indicating that little or no reaction took place during the conventional ball milling, which was employed for mixing of the constituent oxides. A few broadened peaks were observed when the oxide mixture was mechanically activated for 5 hours. The strongest one at a  $2\theta$  angle of  $\sim 29.1^\circ$  corresponds to the PbO (111) peak, which was seen as a sharp one before mechanical activation. This implies that the initial 5 hours of mechanical activation led to a significant refinement in particle and crystallite sizes, together with a degree of amorphization of constituent oxides. This is supported by a rise in the specific surface area from 1.20 m<sup>2</sup>/g for the oxide mixture that was not subjected to mechanical activation to 9.52 m<sup>2</sup>/g for the powder composition subjected to 5 hours of mechanical activation. The second strongest broadened peak at a  $2\theta$  angle of  $\sim 31.2^\circ$  and those at  $2\theta$  angles of 44.7 and 55.5° are newly formed. They are assigned to perovskite PMN (110), (200), and (211) peaks, respectively, suggesting that nanocrystallites of perovskite PMN phase had been formed as a result of the initial 5 hours of mechanical activation. The intensity of the perovskite PMN (110) peak increases with increasing mechanochemical treatment time, at the expense of the PbO (111) peak. In the composition mechanically activated for 20 hours, nanocrystalline PMN is the only XRD-detectable phase, as confirmed by the well defined peaks at  $2\theta$  angles of 21.9, 31.2, 38.5, 44.7, 50.2, 55.5, and 65.0°, respectively. There is also an apparent sharpening in PMN (110), (111), (200), (210), and (211) peaks when the mechanical activation time is extended to 20 hours, demonstrating that there is an increase in the crystallinity of perovskite PMN phase. Calculation using the Scherrer equation [86] on the basis of peak broadening of the perovskite (110) peak showed that the PMN nanocrystallites exhibited an average crystallite size of  $\sim 15$  nm upon 20 hours of mechanical activation, in comparison to  $\sim 9$  nm for the powder composition that was mechanically activated for 5 hours. Figure 3 is a bright field TEM micrograph showing the PMN nanoparticles that were synthesized by mechanical activation at room temperature of constituent oxides. Pyrochlore phases,

**Figure 3.** A bright field TEM micrograph showing the nanoparticles of lead magnesium niobate that were synthesized by mechanical activation of constituent oxides at room temperature.

such as Pb<sub>3</sub>Nb<sub>4</sub>O<sub>13</sub> and Pb<sub>2</sub>Nb<sub>2</sub>O<sub>7</sub> that are always observed as transitional phases in the temperature-driven solid-state reaction, are apparently not involved prior to formation of perovskite phase, while the perovskite nanocrystallites of lead magnesium niobate underwent a steady growth with increasing degree of mechanical activation.

It has been established that phase formation of PbO-based relaxor ferroelectrics from constituent oxides triggered by mechanical activation is not a result of one or more interfacial reactions as stated by the Roller model [87]. Instead, they occur via a nucleation process involving all three oxides in a highly activated oxide matrix, where a significant refinement in particle and crystallite sizes together with a degree of amorphization had taken place. There is a much smaller amount of common contact areas involving all oxides than the interfacial contact areas between any two of them (e.g., between PbO and Nb<sub>2</sub>O<sub>5</sub> particles). On the one hand, this, together with the high reactivity between PbO and Nb<sub>2</sub>O<sub>5</sub>, accounts for the occurrence of transitional pyrochlore phases in the conventional solid-state reaction when mixed oxides of PbO, MgO, and Nb<sub>2</sub>O<sub>5</sub> are calcined at elevated temperatures. On the other hand, it is very unlikely that the formation of nanocrystallites of perovskite PMN phase triggered by mechanical activation is a result of the interfacial reactions involving all three oxides without first going through any of the transitional pyrochlore phases. The subsequent steady growth of PMN nanocrystallites of perovskite structure with increasing mechanical activation time is a consequence of the equilibrium between activation-driven buildup and destruction involving the entire masses of perovskite nuclei [88]. Constant collisions and rearrangement of perovskite nuclei provided by mechanical activation create opportunities for two or more of these nuclei to meet at favorable positions leading to growth in crystallite size. At the same time, there is also a probability that the perovskite nanocrystallites are distorted and fragmented by mechanical activation.

Nucleation and subsequent growth of perovskite nanocrystallites triggered by mechanical activation of constituent oxides have also been observed in a number of PMN-based relaxor ferroelectrics. For example, mechanical activation of mixed oxides of PbO, MgO, ZnO, TiO<sub>2</sub>, and Nb<sub>2</sub>O<sub>5</sub> equivalent to stoichiometric composition of 0.9·[0.4Pb(Mg<sub>1/3</sub>Nb<sub>2/3</sub>)O<sub>3</sub>–0.6Pb(Zn<sub>1/3</sub>Nb<sub>2/3</sub>)O<sub>3</sub>]–0.1PbTiO<sub>3</sub> led to formation of perovskite nanocrystallites [89]. The multiple oxide composition would maximize the involvement of several transitional phases prior to formation of perovskite PMN–PZN–PT nanocrystallites, if phase formation triggered by mechanical activation proceeded via one or more interfacial reactions. In other words, it would be almost impossible not to go through one or more transitional phases if the phase formation of activation-triggered perovskite nanocrystallites is controlled by one or more interfacial reactions, while the chance to involve all five oxides at an interfacial location is minimum. Phase analyses at various stages of mechanical activation, however, demonstrated that no intermediate phases occurred prior to nanocrystalline PMN–PZN–PT phase with increasing mechanical activation time. A single perovskite phase was obtained at 20 hours of mechanical activation. Figure 4 is a high resolution TEM (HRTEM) micrograph together with the selected

**Figure 4.** A HRTEM micrograph together with the selected area diffraction patterns showing the nanocrystallites of perovskite PMN-PZN-PT in an amorphous matrix triggered by 10 hours of mechanical activation. area diffraction patterns showing the nanocrystallites of perovskite PMN-PZN-PT in an amorphous matrix triggered by 10 hours of mechanical activation [48]. They are well established perovskite crystallites of 5 to 10 nm in dimension dispersed in an amorphous oxide matrix. Measurement of lattice spacing (e.g.,  $d_{110} = 2.87 \text{ \AA}$ ) confirmed that these nanocrystallites were perovskite PMN-PZN-PT.

Mechanical activation is successful in synthesizing complex perovskites of nanocrystallinity that cannot possibly be synthesized by any other processing techniques. For example,  $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$  is a relaxor ferroelectric exhibiting a partially disordered perovskite structure and showing many of the most desirable dielectric and piezoelectric properties for a number of applications in sensors and actuators. However, the pursuit to synthesize a  $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$  (PZN) of perovskite structure via both traditional ceramic and chemistry-based novel processing routes over the last three decades has failed. The difficult-to-synthesize nanocrystallites of PZN have, however, been successfully synthesized by mechanical activation of either constituent oxides of  $\text{PbO}$ ,  $\text{ZnO}$ , and  $\text{Nb}_2\text{O}_5$  or a mixture of  $\text{PbO}$  and prereacted  $\text{ZnNb}_2\text{O}_6$  from  $\text{ZnO}$  and  $\text{Nb}_2\text{O}_5$  [90]. The activation-derived PZN exhibits a well established perovskite structure and a crystallite size in the range of 10 to 15 nm.

Bismuth titanate ( $\text{Bi}_4\text{Ti}_3\text{O}_{12}$  or BIT) and bismuth titanate-based electroceramics are examples of layered perovskites that have been successfully synthesized by mechanical activation. These electroceramic materials, which exhibit a high Curie temperature ( $\sim 675 \text{ }^\circ\text{C}$  for BIT) and excellent piezoelectric and dielectric properties, are promising candidates for high temperature piezoelectric and ferroelectric applications [91]. They are traditionally prepared by solid-state reaction among the constituent oxides at elevated temperatures. However, due to the high volatility of  $\text{Bi}_2\text{O}_3$  at

elevated temperatures, it is rather difficult to synthesize a bismuth-based ceramic of stoichiometry by the conventional solid-state reaction. Several bismuth titanate-based functional ceramics, including  $\text{Bi}_4\text{Ti}_3\text{O}_{12}$  [92],  $\text{SrBi}_4\text{Ti}_4\text{O}_{15}$  [93], and  $\text{CaBi}_4\text{Ti}_4\text{O}_{15}$  [94], have been synthesized by mechanical activation of mixed oxides at room temperature. Figure 5 shows the XRD traces of starting oxide mixture of  $\text{SrO}$ ,  $\text{Bi}_2\text{O}_3$ , and  $\text{TiO}_2$  together with those mechanically activated for 5, 10, 15, and 20 hours, respectively [93]. Sharp peaks of crystalline  $\text{Bi}_2\text{O}_3$  and  $\text{TiO}_2$  are observed with the starting oxide mixture, while  $\text{SrO}$  is not detected by XRD due to the relatively small amount involved. Upon 5 hours of mechanical activation, XRD peaks of these oxides are broadened. The small peak at a  $2\theta$  angle of  $30.5^\circ$  is newly formed, which is assigned to the  $\text{SrBi}_4\text{Ti}_4\text{O}_{15}$  (SBIT) (119) plane, indicating the formation of nanocrystalline SBIT by mechanical activation for 5 hours. Almost all the sharp peaks of oxides have vanished in the composition mechanically activated for 10 hours, and they are replaced by a few broadened ones. The  $\text{Bi}_2\text{O}_3$  (120) peak, which is seen as a sharp one in the powder mechanically activated for 5 hours, has broadened considerably. The disappearance of sharp peaks for oxides and subsequent formation of broadened peaks, with increasing mechanical activation time, suggest that a significant

**Figure 5.** XRD patterns of the mixed oxides of  $\text{Bi}_2\text{O}_3$ ,  $\text{TiO}_2$ , and  $\text{SrO}$  equivalent to SBIT subjected to mechanical activation for various time periods ranging from 0 to 20 hours. \*:  $\text{Bi}_2\text{O}_3$ , ▲:  $\text{TiO}_2$ , o: SBIT. refinement in particle and crystallite sizes, together with a degree of amorphization of mixed oxides, took place at the initial stage of mechanical activation. This is followed by nucleation and subsequent growth of SBIT nanocrystallites. As shown in Figure 5, diffraction peaks at  $2\theta$  angles of 23.1, 30.5, 39.8, 47.2, and 57.2° are established for the composition mechanically activated for 20 hours. They correspond to SBIT (111), (119), (0210), (220), and (319) planes, respectively, of the layered perovskite phase.

There are a number of other complex oxides of nanocrystallinity that have been successfully synthesized by mechanical activation of either constituent oxides or chemical precursors or a mixture of the two. They include  $\text{La}_{0.7}\text{Sr}_{0.4}\text{MnO}_3$  from constituent oxides of  $\text{La}_2\text{O}_3$ ,  $\text{SrO}$ , and  $\text{MnO}_2$  [95],  $\text{LaMnO}_3$  from  $\text{La}_2\text{O}_3$  and  $\text{Mn}_2\text{O}_3$  [96],  $\text{Al}_2\text{TiO}_5$  from  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  [97],  $\text{Sn}_{0.5}\text{Ti}_{0.5}\text{O}_2$  from  $\text{TiO}_2$  and  $\text{SnO}$  [98],  $\text{Bi}_3\text{NbTiO}_9$  from  $\text{Bi}_2\text{O}_3$ ,  $\text{Nb}_2\text{O}_5$ , and  $\text{TiO}_2$  [99],  $\text{LaFeO}_3$  from  $\text{La}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  [100],  $\text{LiCoO}_2$  from  $\text{LiOH}\cdot\text{H}_2\text{O}$  and  $\text{Co(OH)}_2$  [101],  $\text{ZrTiO}_4$  from  $\text{ZrO}_2$  and  $\text{TiO}_2$  gels [102],  $\text{LiMn}_2\text{O}_4$  from  $\text{MnO}_2$  with  $\text{LiOH}$  [103],  $\text{MgAl}_2\text{O}_4$  from  $\text{Mg(OH)}_2$  and  $\text{Al(OH)}_3$  [104],  $\text{CaTiO}_3$  from  $\text{CaO}$  and  $\text{TiO}_2$  [105],  $\text{Sr}_3\text{Ti}_2\text{O}_7$  from  $\text{SrO}$  or  $\text{SrCO}_3$  or  $\text{Sr(OH)}_2\cdot 8\text{H}_2\text{O}$  and  $\text{TiO}_2$  [106],  $\text{LaCrO}_3$  from amorphous  $\text{Cr}_2\text{O}_3\cdot n\text{H}_2\text{O}$  and  $\text{La}_2\text{O}_3$  [107], aurivillius type compounds from constituent oxides and precursors [108, 109], and fluorite type phases in the system  $\text{Bi}_2\text{O}_3\text{--Nb}_2\text{O}_5\text{--Ta}_2\text{O}_5$  [110]. Mechanochemical reactions responsible for formation of these oxides are dependent on the nature of starting materials and processing parameters chosen for mechanical activation. For example, mechanical activation of  $\text{TiO}_2$  together with  $\text{Mg(OH)}_2$  triggered an incipient reaction between them in association with dehydration of the hydroxide [111]. Use of hydroxide precursors or hydrated oxides as the starting materials can generate local hydrothermal environments responsible for formation of a product phase.

Silicates constitute a big family in the complex oxides, which are traditionally synthesized by conventional solid-state reaction at high temperatures. Mechanical activation has been applied to synthesis of several technologically demanding silicates, which otherwise require a very high calcination temperature. For example, mullite is a compound formed between alumina and silica at temperatures well above 1000 °C. Mechanical activation of constituent oxides and hydroxides (for example, gibbsite and silica gel) significantly lowers the crystallization of mullite [112], which often occurs via one or more transitional spinel phases in the conventional solid-state reaction. Mechanical activation of  $\text{MgO}$  and  $\text{SiO}_2$  produces a magnesium silicate of low crystallinity similar to what is formed under certain hydrothermal reaction conditions [113]. Magnesium silicate of well established crystallinity is obtained by subsequent thermal annealing. Hydrated calcium silicates can also be synthesized mechanochemically at room temperature where the presence of water and moisture employed play a significant role [114]. Mechanochemical reactions between kaolinite and several oxides (such as  $\text{ZnO}$  and  $\text{CaO}$ ) and nonoxides have been studied by several investigators. For example, cesium aluminum silicate and intercalation complexes occur as a result of mechanical activation of kaolinite together with  $\text{CsF}$  [115].

### 5.3. Nanocrystalline Oxide Ferrites

Nanocrystalline ferrites, magnetite ( $\text{Fe}_3\text{O}_4$ ), and maghemite ( $\gamma\text{-Fe}_2\text{O}_3$ ) were among the ceramic materials synthesized by mechanical activation in the early development stage of this novel technique. They were synthesized from corresponding oxides, hydroxides, precursors, and chemicals (such as chlorides) or a mixture of these. The types of mechanochemical reaction leading to formation of nanocrystalline ferrite phases include replacement reaction [116], decomposition [66], oxidation/reduction [117], and mechanical activation-induced nucleation and crystallite growth [118]. Very different magnetic behaviors are observed with these nanocrystalline ferrites derived from mechanical activation, as compared to those of their coarse/bulk counterparts and those materials derived from either conventional ceramic processing or wet-chemistry routes. For example,  $\text{ZnFe}_2\text{O}_4$  and  $\text{NiFe}_2\text{O}_4$  derived from mechanical activation demonstrate a much enhanced magnetization, as a result of the partially inverted spinel structure [26, 119].

Mechanical activation triggers a steady occurrence of nanocrystalline  $\text{ZnFe}_2\text{O}_4$  [120],  $\text{NiFe}_2\text{O}_4$  [121],  $\text{MnFe}_2\text{O}_4$  [122], and  $\text{Ni-Zn}$  ferrite [123] of particle size in the range of 5 to 20 nm from corresponding oxide mixtures, for example,  $\alpha\text{-Fe}_2\text{O}_3$  and  $\text{ZnO}$  for  $\text{ZnFe}_2\text{O}_4$ . Subsequent annealing at a temperature in the range of 600 to 800 °C enhances their crystallinity and magnetic properties in association with superparamagnetic to ferromagnetic transition. They can also be synthesized by mechanical activation of corresponding hydroxides, with or without involvement of certain transitional phases such as  $\text{Fe}_3\text{O}_4$  and  $\gamma\text{-Fe}_2\text{O}_3$ , depending on the selection of mechanical activation conditions [124]. A replacement reaction is apparently involved in mechanical activation of chlorides, such as  $\text{ZnCl}_2$  and  $\text{FeCl}_3$ , with  $\text{NaOH}$  for synthesis of  $\text{ZnFe}_2\text{O}_4$ , the crystallinity and magnetic behavior of which are largely controlled by the post-activation thermal annealing [22].

Several different combinations of starting materials have been experimented for synthesis of nanocrystalline  $\text{BaFe}_{12}\text{O}_{19}$  by mechanical activation, including  $\text{Fe}_2\text{O}_3$  and  $\text{Ba(OH)}_2$  [125],  $\text{BaCl}$  and  $\text{FeCl}$  [126], and co-precipitation-derived hydroxide precursors [127]. Formation of  $\text{BaFe}_{12}\text{O}_{19}$  of high crystallinity and hexagonal platelike morphology requires a postactivation annealing at a temperature in the range of 600 to 800 °C. Transitional phases, such as  $\alpha\text{-Fe}_2\text{O}_3$ ,  $\gamma\text{-Fe}_2\text{O}_3$ , and  $\text{Fe}_3\text{O}_4$ , can occur, prior to  $\text{BaFe}_{12}\text{O}_{19}$ , during mechanical activation and subsequent thermal annealing, depending on the nature of starting materials and processing conditions of mechanical activation. For example, when a co-precipitated hydroxide precursor is mechanically activated together with sodium chloride as a dispersion agent, nanocrystallites of  $\alpha\text{-Fe}_2\text{O}_3$  and spinel  $\gamma\text{-Fe}_2\text{O}_3$  of <10 nm in size occurred together with  $\text{BaFe}_{12}\text{O}_{19}$ . A single phase  $\text{BaFe}_{12}\text{O}_{19}$  of 50–100 nm in size and of platelike morphology is developed upon subsequent calcination at 800 °C [127]. Using  $\text{BaCl}$  and  $\text{FeCl}$  as the starting materials, mechanical activation in  $\text{NaOH}$  led to formation of a mixture of Fe oxides and hydroxides together with  $\text{NaCl}$  as a by-product [126]. Nanocrystalline  $\text{BaFe}_{12}\text{O}_{19}$  resulted upon subsequent calcination at 800 °C. Crystallite size and degree of agglomeration of thus derived  $\text{BaFe}_{12}\text{O}_{19}$  can be further tailored by employing  $\text{NaCl}$  as an effective dispersion agent.

Phase transformations among  $\alpha$ - $\text{Fe}_2\text{O}_3$ ,  $\gamma$ - $\text{Fe}_2\text{O}_3$ , and  $\text{Fe}_3\text{O}_4$  can be triggered by mechanical activation and are critically dependent on the oxygen partial pressure [128–131]. For example, mechanical activation of  $\alpha$ - $\text{Fe}_2\text{O}_3$  in vacuum can lead to complete transformation to  $\text{Fe}_3\text{O}_4$ , involving a significant refinement in crystallite size at the initial stage of mechanical activation prior to nucleation and growth of  $\text{Fe}_3\text{O}_4$  [128]. Mechanical activation of  $\gamma$ - $\text{Fe}_2\text{O}_3$  and  $\text{Fe}_3\text{O}_4$  in air gives rise to formation of  $\alpha$ - $\text{Fe}_2\text{O}_3$  [132].

Nanocrystalline ferrites derived from mechanical activation demonstrate very different structural and magnetic behaviors. For example,  $\text{MnFe}_2\text{O}_4$  derived from mechanical activation of  $\text{FeCl}$  together with  $\text{MnO}$  exhibits a unique core-shell structure, which consists of a ferrimagnetic core surrounded by a spin-glass shell, and therefore there occur a coupling and exchange between the spin in the core and that in the shell [132]. The most remarkable structural feature brought about by mechanical activation in nanocrystalline ferrites is the cation inversion. In bulk ceramic forms, spinel ferrites consist of close-packed face-centered cubic arrays of O anions, with the tetrahedral (A) and octahedral (B) sites partially occupied by metal cations. Due to the specific electronic configurations of cations and types of superexchange interactions among them, their magnetic properties are strongly dependent on the occupancy and exchange of cations in the two sites and among them. Unusual cation distribution has been observed in  $\text{ZnFe}_2\text{O}_4$ ,  $\text{MnFe}_2\text{O}_4$ , and  $\text{NiFe}_2\text{O}_4$  nanoparticles derived from mechanical activation [133–135]. This gives rise to a significant enhancement in magnetization and several other anomalous behaviors, although the exact reasons behind the inversion are yet properly established. Figure 6 [26] is a magnetization hysteresis loop measured at 5 K for  $\text{NiFe}_2\text{O}_4$  particles formed in silica matrix by mechanical activation of a gel precursor, where nanocrystallites of  $\text{Fe}_3\text{O}_4$  were first nucleated followed by incorporation of  $\text{Ni}^{2+}$  into  $\text{Fe}_3\text{O}_4$  leading to formation of  $\text{NiFe}_2\text{O}_4$  nanoparticles of  $\sim 8$  nm in size. Although magnetization is not saturated at a magnetic field of 9 T due to the surface strain arising from silica matrix,

**Figure 6.** Magnetization hysteresis loop, measured at 5 K, for gel composition of  $\text{NiFe}_2\text{O}_4$  mechanically activated for 30 hours. Inset shows the magnetization as a function of measuring temperature.

these  $\text{NiFe}_2\text{O}_4$  nanoparticles demonstrate an unusually high magnetization of 74.3 emu/g at 9 T.

In the inverse spinel structure of  $\text{NiFe}_2\text{O}_4$ , equal numbers of  $\text{Fe}^{3+}$  cations in tetrahedral (A) and octahedral (B) sites are coupled in an antiparallel arrangement. The net magnetic moment is therefore originated from the octahedrally coordinated  $\text{Ni}^{2+}$  cations. Displacement of an A-site  $\text{Fe}^{3+}$  ion with moment of  $5 \mu_B$  by a  $\text{Ni}^{2+}$  ion with moment of  $2.3 \mu_B$  gives rise to an increase in the net moment. The enhancement of magnetization shown in Figure 6 for  $\text{NiFe}_2\text{O}_4$  nanoparticles derived from mechanical activation arises from occupation of  $\text{Ni}^{2+}$  cations in the tetrahedral sites, which have been confirmed by Raman, Fourier transform infrared, and Mössbauer studies [26, 135]. The cation inversion also explains the shift in Curie temperature from 585 °C for bulk  $\text{NiFe}_2\text{O}_4$  to 530 °C for the nanocrystalline  $\text{NiFe}_2\text{O}_4$  particles. Since the  $\text{Fe}^{3+}$ (A)–O– $\text{Fe}^{3+}$ (B) interaction is the strongest one among those in nickel ferrite [136], any displacement of A site  $\text{Fe}^{3+}$  will reduce the overall superexchange interaction and hence decrease the Curie temperature. Furthermore, upon displacement of A site  $\text{Fe}^{3+}$  ions by  $\text{Ni}^{2+}$  ions,  $\text{O}^{2-}$  anions in the A sites are forced to shift in the direction to give space to  $\text{Ni}^{2+}$  ions of larger ionic radii. This leads to reduction in the cation(A)–O–cation(B) bond angles and hence weakens the superexchange interaction.

The observed disorder of cations for nanocrystalline  $\text{NiFe}_2\text{O}_4$  particles formed *in-situ* in silica matrix by mechanical activation occurs in conjunction with the phase formation process. As discussed, initial mechanical activation led to nucleation of  $\text{Fe}_3\text{O}_4$  nanocrystallites, which was followed by the incorporation of  $\text{Ni}^{2+}$ . Site occupancy of cations are affected by a combination of a number of parameters. Although  $\text{Ni}^{2+}$  possesses a high octahedral site preference energy, the electrostatic energy favors a normal spinel arrangement, as  $\text{NiFe}_2\text{O}_4$  has a deformation parameter  $\mu$  of 0.3823. The normal spinel configuration is more stable when  $\mu > 0.379$  [136]. Very often, however, the difference in total energy between the normal and inverse spinel distributions is very small. Therefore, when  $\text{Ni}^{2+}$  approaches an octahedral site that has already been occupied by  $\text{Fe}^{2+}$ , which also possesses a high octahedral site preference energy, it will be forced to occupy one of the nearest tetrahedral sites. This is particularly so when the incorporation of  $\text{Ni}^{2+}$  was triggered by mechanical activation, which can only promote short-range diffusion [137].  $\text{Ni}^{2+}$  then displaces the  $\text{Fe}^{3+}$  cations if the nearest tetrahedral sites are preoccupied by  $\text{Fe}^{3+}$  cations, which have zero octahedral site preference energy.

#### 5.4. Carbides, Nitrides, Nonoxides, and Nanocomposites

In parallel to the success of synthesizing ceramic oxides and complex oxide ceramics of nanocrystallinity, mechanical activation has been successfully applied to synthesis of several nonoxide ceramics, including carbides, nitrides, borides, and ceramic nanocomposites [12, 13, 138–144]. In several cases, mechanical activation of metallic elements together with carbon (graphite) and boron in a nitrogen environment produce corresponding carbides, borides, and nitrides. For example,

TiC [141] and TiB<sub>2</sub> [142] can be synthesized by mechanical activation of powder mixtures of elemental Ti and C and Ti and B, respectively, in a planetary ball mill using tungsten carbide balls as the activation media. The phase formation steps during mechanical activation consisted of diffusion of carbon or boron into titanium in the initial stage, whereby a small amount of TiC and TiB<sub>2</sub> was formed, followed by the mechanically triggered self-propagating reaction. Titanium nitride is produced by mechanical activation of titanium in nitrogen gas, where the reaction proceeded via a surface reaction between titanium particles and nitrogen and then diffusion of nitrogen into titanium under mechanical activation [143]. Nitridation of silicon at high temperatures (e.g., 1250 °C) is accelerated by factors of 9 and 23 by mechanical activation of silicon in either N<sub>2</sub> or NH<sub>3</sub>. This has been attributed to the enhanced reactivity of Si and the entrapment of N<sub>2</sub> by mechanical activation [144].

Nanocomposite compositions consisting of titanium nitride and titanium diboride of particle sizes in the range of 5 to 10 nm were obtained by mechanical activation of Ti together with BN [145]. Similarly, AlN–TiB<sub>2</sub> nanocomposites can be fabricated by mechanical activation of Ti and Al together with BN, followed by sintering or hot pressing in order to densify the nanocomposites [146]. A nanocrystalline mixture of WC and intermediate tungsten carbide phases was generated by mechanical activation of WO<sub>3</sub> together with Mg and graphite, where the mechanochemical reaction took place in two steps [147], namely, formation of  $\alpha$ -W as a result of explosive reduction of WO<sub>3</sub> by Mg and then the diffusion reaction between  $\alpha$ -W and C. The product therefore consists of WC nanoparticles of 4 to 20 nm in size dispersed in MgO matrix, which can be washed off using HCl solution. Prolonged mechanical activation of rutile (TiO<sub>2</sub>) together with aluminum in nitrogen produced a composite consisting of nanocrystalline alumina and titanium nitride, which undergo growth in crystallite and particle sizes upon subsequent annealing at 1200 °C [148].

In addition to carbides, nitrides, borides, and nanocomposites consisting of one or more carbide, nitride, and boride phases, other nonoxide ceramics and their nanocomposites that have been synthesized by mechanical activation include sulphides, silicides, and phosphates [149–158]. For example, mechanical activation of Ni together with P, and Al together with P, can lead to formation of nanocrystalline Ni- and Al-phosphides [154]. Bi<sub>2</sub>Se<sub>3</sub> and BiSe were synthesized by mechanical activation of Bi + Se mixtures in the molar ratio of 2:3 and 1:1, respectively [155]. Formation of ZnS is realized by mechanical activation of ZnCl<sub>2</sub> and CdS in CaCl<sub>2</sub>, which acts as a dispersion agent in refining the particle and agglomerate sizes [156]. Similarly, nanocrystalline cadmium sulphide (quantum dots) can be obtained by the displacement reaction between CdCl<sub>2</sub> and Na<sub>2</sub>S triggered by mechanical activation, giving rise to CdS and NaCl [157]. Zirconium silicides can be synthesized by a mechanically induced self-propagating reaction, which is analogous to the thermally ignited self-propagating syntheses, where the explosive formation of zirconium silicides is attributed to the relatively large heat of formation involved [158].

## 6. MECHANICAL CRYSTALLIZATION AND PRECURSOR TO CERAMIC CONVERSIONS

High sintered density and uniform microstructure/nanostructure are among the most desirable features for almost all ceramic materials, as far as most of the functional and structural applications are concerned. Synthesis of a fine and sinterable ceramic powder is the first and perhaps the most important step in realization of a high sintered density and desirable microstructure/nanostructure at lowered sintering temperatures. Phase formation by a conventional ceramic fabrication technique (i.e., solid-state reaction of constituent oxides/nonoxides at elevated temperatures) is unable to deliver a fine and sinter-reactive ceramic powder, due to the unavoidable particle coarsening and aggregation at the calcination temperature, in combination with several other apparent detrimental effects such as nonstoichiometry and occurrence of impurity phases. This explains why for the past two decades considerable research efforts have been directed towards synthesis of nanocrystalline ceramic powders via a number of chemistry-based routes. Unfortunately, as mentioned earlier, almost all ceramic precursors derived from wet-chemistry routes have to be calcined at a temperature in the range of 500 to 1000 °C, in order to materialize the precursor to ceramic convention. Calcination of a ceramic precursor at an intermediate temperature ruins almost all the advantages offered by chemistry-based novel synthesis techniques, as a consequence of the particle coarsening and aggregation in the calcined ceramic powders. In this context, there is no fundamental difference between conventional ceramic and chemistry-based processing routes, where the problems are caused by the unavoidable calcination at high temperatures. Therefore, realization of the precursor to ceramic convention via an alternative, low temperature route represents a major advance in ceramic processing.

Mechanical crystallization in Fe-based amorphous alloys at room temperature was extensively studied following the pioneering work of Trudeau and Schulz [39], who demonstrated that nanocrystalline metallic phases of crystallite size in the range of 2 to 5 nm were triggered to form in certain amorphous alloy compositions by an input of mechanical energy [40]. The feasibility of mechanical crystallization in ceramic composition and the precursor to ceramic conversion by mechanical activation have been successfully demonstrated with an amorphous hydroxide precursor of PZT prepared via a co-precipitation route [159]. Figure 7 shows the XRD traces of the co-precipitated hydroxide precursor upon mechanical activation for 5, 15, and 35 hours, respectively, together with that of the amorphous precursor that was not subjected to any mechanical activation. Only one strong and broadened peak is observed over the  $2\theta$  angle of 28 to 35° for the starting hydroxide precursor, indicating its amorphous nature. Five hours of mechanical activation apparently led to a steady formation of PZT nanocrystallites in an essentially amorphous PZT precursor, while the transitional PT and PZ phases were not observed prior to formation of perovskite PZT phase. The intensity and sharpness of perovskite PZT (110), (100), (111), (200), (210), (211), and

**Figure 7.** XRD traces of PZT precursor derived from co-precipitation when mechanically activated for various times ranging from 0 to 35 hours (O: PZT). Reprinted with permission from [159], J. M. Xue et al., *J. Amer. Ceram. Soc.* 82, 1641 (1999). © 1999, American Ceramic Society.

(220) peaks were further established when the mechanical activation was extended to 15 and then 35 hours.

Mechanical activation has also been successfully applied to the precursor to ceramic transition in several other oxide ceramic systems, including  $\alpha$ - $\text{Fe}_2\text{O}_3$ , ZnO,  $\text{CeO}_2$ ,  $\text{Al}_2\text{O}_3$ , and oxides ferrites. In general, oxide particles of nanocrystallinity and a minimized degree of particle aggregation are obtained, although the phase-forming mechanisms involved varied considerably from one material system to another. For example, formation of  $\gamma$ - $\text{Fe}_2\text{O}_3$  nanocrystallites triggered by mechanical activation, in an amorphous silica matrix from a sol-gel-derived precursor at room temperature, occurred by involving  $\text{Fe}_3\text{O}_4$  as a transitional phase. Prolonged mechanical activation led to a steady phase transformation from  $\text{Fe}_3\text{O}_4$  to  $\gamma$ - $\text{Fe}_2\text{O}_3$ , as confirmed by phase identification and measurement in magnetic behavior [118].

Mechanical crystallization in oxide glass has recently been demonstrated by Xue and Wang [160], who employed

two slightly different  $\text{PbNb}_2\text{O}_6$  glass samples, which were quenched from 1300 and 1350 °C, respectively, for experimentation. As a result of the much higher glass-forming ability of the oxide glass than that of a metallic glass, it is much more difficult to induce crystallization in the former than that in the latter. Nevertheless, mechanical crystallization was observed in the glass quenched from 1300 °C, where a density of  $\text{PbNb}_2\text{O}_6$  nuclei existed prior to mechanical activation. Mechanical activation promoted a steady growth in nanocrystallites of  $\text{PbNb}_2\text{O}_6$ , up to 15 nm in size. Due to the lack of  $\text{PbNb}_2\text{O}_6$  nuclei in the glass quenched from 1350 °C, mechanical crystallization was not initiated by mechanical activation. This has led the investigators to believe that the mechanical crystallization in  $\text{PbNb}_2\text{O}_6$  glass is nucleation-controlled. Although nucleation is thermodynamically favored at a low temperature, the inability of mechanical activation in triggering nucleation in the highly amorphous oxide glass is apparently due to its higher structural stability, as compared to that of Fe-Si-B based metallic glass.

## 7. SUMMARY

As a newly developed synthesis technique for nanocrystalline ceramic materials, mechanical activation can deliver the designed ceramic phase(s) and structure(s) by a single step of mechanical activation conducted in an enclosed activation chamber at room temperature. By employing the widely available oxides and nonoxides as the starting materials and skipping the multiple steps of phase formation at elevated temperatures that are always required in conventional solid state reaction, mechanical activation offers a lower manufacturing cost and a higher production yield, when compared to wet-chemistry-based synthesis techniques for ceramic materials. More importantly, mechanical activation delivers the much wanted nanocrystalline structures that cannot possibly be realized by either conventional ceramic processing or wet-chemistry-based synthesis techniques. In addition, a number of nanocrystalline ceramic materials derived from mechanical activation demonstrate unique structural metastability, extended solid solubility, and surface and structural defects (such as cation inversion in the spinel structures and order-disorder transitions in complex perovskites), which give rise to a number of unique electrical, electronic, magnetic, and functional properties.

On the one hand, phase formation processes triggered by mechanical activation are fundamentally different from those in the conventional solid-state reaction in many ceramic systems studied to date; mechanical activation can be used to synthesize ceramic materials that cannot possibly be synthesized by either conventional ceramic processing or wet-chemistry-based techniques. Nanocrystalline PZN of complex perovskite structure is one such good example [89, 90]. On the other hand, a number of solid-state phenomena that are traditionally triggered by thermal activation can be made to take place by mechanical activation, including phase transition, order-disorder transformation in complex perovskite structure, and precursor to ceramic phase conversions,

which are traditionally realized by calcination at elevated temperatures.

Mechanical activation has been successfully utilized to synthesize a wide range of nanocrystalline ceramic materials, including ceramic oxides, oxides of complex perovskite, spinel and layered perovskite structures, ceramic ferrites, nonoxide ceramics, and their nanocomposites. While phase formation triggered by mechanical activation is different from that in the conventional solid-state reaction, understanding the exact phase formation mechanisms in some of these nanocrystalline ceramic materials will apparently be one of the future developments in the study of mechanical activation. There are several unique phenomena that have been observed in association with mechanical activation, including the occurrence of metastable structures, order-disorder transformation in complex perovskites, and cation inversion in spinel structures. Both short-range and long-range structural disordering can be induced in certain Pb-based complex perovskites, for example in  $\text{Pb}(\text{Sc}_{1/2}\text{Ta}_{1/2})\text{O}_3$ ,  $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{-Pb}(\text{Mg}_{1/2}\text{W}_{1/2})\text{O}_3$ , by mechanical activation [38, 161]. There exists an equilibrium between mechanical activation and thermal activation in leading to the order-disorder transition in these perovskite structures, where mechanical activation induces disorder while thermal activation tends to recover the structural ordering. It will be considerably interesting to understand the exact physical principles behind these unique phenomena, as triggered by mechanical activation.

In order to further tailor the characteristics of nanocrystalline ceramic materials, mechanical activation can be combined with one or more other types of processing control. For example, mechanical activation can be assisted by an electrical discharge, magnetic field, hydrothermal conditions, and an effective integration of mechanical and thermal activations [11, 13, 14]. There is no doubt that this will also be one of the interesting areas for further development of mechanical activation.

Success of mechanical activation in synthesis of nanocrystalline ceramic material promises a significant technological implication, whereby the currently employed multiple steps of phase-forming calcination/annealing at high temperatures for ceramic materials can be skipped, when designed ceramic phases and chemical stoichiometry are realized at room temperature in an enclosed mechanical activation chamber. The scale-up of this novel synthesis technique to industrially useful batches will be technologically demanding and also a challenge in the future development of mechanical activation.

## GLOSSARY

**Complex ceramic oxide** Those oxides containing more than one type of cation in structure, including those of perovskite structure, complex perovskite structure, aurivillius type compound and layered perovskite structure, spinel structure, and their solid solutions.

**Mechanical activation** A mechanical process, typically involving one or more processes of mechanical impact, shear, straining, deformation, mixing, and fracture at room temperature, above or below room temperature, that can

activate the phenomena such as phase transformation, order-disorder transformation, structure change, surface modification, and in particular, formation of a new material phase as a result of the nucleation and crystallization triggered by such mechanical process. High energy mills are widely employed for mechanical activation.

**Mechanical amorphization/crystallization** Amorphization/crystallization triggered by a mechanical activation process.

**Mechanochemical synthesis** Materials synthesis involves one or more types of chemical processes/reactions triggered by a mechanical process, with or without the need for subsequent thermal annealing at elevated temperatures, in order to form the designed material phase/structure.

**Nanocrystalline ceramics** Those ceramic materials with microstructural feature in the nanometer scales, typically in the range of 1.0 to 100 nm.

**Simple ceramic oxide** Those oxides containing one predominant cation in structure, regardless of the structure types, with or without the involvement of other cations at a tracing level added as dopants. Typical examples of simple ceramic oxides are  $\text{ZrO}_2$ ,  $\text{CeO}_2$ ,  $\text{ZnO}$  and  $\text{Al}_2\text{O}_3$ .

## 1. INTRODUCTION

Polycrystalline diamond (PCD) film has excellent mechanical and tribological properties such as extreme hardness, chemical inertness, and high electric resistance [1–3]. Hence there is considerable interest in the synthesis of diamond film by various chemical vapor deposition techniques for wide range of applications from hard coating to electron emitting surfaces for flat panel display devices. However, the surface of these films is often very rough due to the polycrystalline nature with crystallite sizes of the order of micrometers. Such a rough surface causes excessive light scattering, reducing the optical transparency, causing high friction and wear losses on mating surface, and thereby limiting its use for various applications. Hence attempts were made to develop effective chemical etching and mechanical polishing techniques to get smooth diamond films. Because of chemical inertness and extreme hardness of diamond films, these techniques are not efficient and cost effective. Since one can change neither the microstructure nor the composition of diamond, the best way to get these desired properties will be to control the microstructure of diamond films [4].

Recently the nanocrystalline diamond (NCD) films have been recognized as an important class of structure in the family of diamond materials [4, 5]. It has been investigated that the microstructure of diamond films could be controlled so that crystallite size ranges from micrometer to nanometer. The size can be controlled continuously over this range by changing the gas phase chemistry of the plasma enhanced chemical vapor deposition technique. The enhancement in mechanical, electrical, and optical properties of NCD films over the PCD film has been achieved. This is due to the reduction in crystallite size of diamond particles. The decrease in crystallite size increases vastly the number of grain boundaries and the entire film becomes electrically conducting. Second, the reduction in crystallite size increases the smoothness of the NCD films. Such ultra-smooth films not only provide an opportunity for tribological applications but also their wide bandgap makes them suitable to act as ideal transparent film for optical components. The lower friction coefficient and higher hardness makes NCD a better material for coating mechanical tools. Thus controlling the microstructure of diamond films could bring many remarkable properties for various industrial applications [4].

There are a few articles related to the preparation of NCD films and several reporting the unique properties of NCD. A number of different deposition techniques and conditions have been used to get smooth films that are summarized below.

Gruen and co-workers reported the nucleation and growth of NCD film on silicon from hydrogen-poor argon plasma using fullerene as growth precursors [6, 7]. Deposition of NCD film was performed by introducing  $C_{60}$  into an argon microwave discharge in contact with a silicon wafer at 750 °C. The growth of NCD film was carried out on the substrates that were previously mechanically scratched with 0.1  $\mu\text{m}$  diamond powder. The deposition of NCD films was carried out with total argon pressure of 98 Torr,  $C_{60}$  partial pressure of  $10^{-2}$  Torr, flow rate of 100 sccm, and

microwave power of 800 W. It is difficult to get stable argon plasma in absence of  $\sim 1\%$  added hydrogen. The presence of 1 to 3% hydrogen in the carbon containing argon plasma does not appreciably affect the properties of the diamond films. The phase pure diamond films have been grown from  $C_{60}/Ar$  microwave plasmas and these films have nanocrystalline microstructure.

Zhou and co-workers prepared NCD films in an  $Ar-CH_4$  microwave discharge without addition of molecular hydrogen [8]. *N*-type single crystal silicon wafers with (100) orientation were used as the substrate, and mechanical polishing with fine diamond powder ( $0.1 \mu m$ ) was employed to enhance the nucleation density. The NCD films consist of a pure NCD phase with grain sizes ranging from 3 to 20 nm. The films have very smooth surfaces, which do not depend on the thickness of the film at least in the range of 1–5  $\mu m$ .

Erz et al. grew 800 nm thick NCD films with up to 10%  $CH_4$  in  $H_2$  [9]. Characterization was done with X-ray diffraction (XRD), Raman, and visible infrared spectroscopy. Incorporated diamondlike carbon (DLC) degrades the transmissivity, which in some samples reaches 93%. Meanwhile Konov et al. and Nistor et al. deposited 0.2–1  $\mu m$  thick films from  $CH_4/H_2/Ar$  mixtures that were characterized with XRD, high-resolution transmission electron microscopy (HRTEM), and Raman spectroscopy [10–13]. The percentage of Ar in the mixtures was always kept at 50%, while the  $CH_4/(CH_4 + H_2)$  ratio was varied. Grain sizes were found to be in the range 30–50 nm. TEM did not reveal amorphous carbon in significant quantities, but disordered  $sp^3$  and  $sp^2$  bonded amorphous carbon was detected, presumably located at grain boundaries. The diamond crystallites are highly defected with many twins and other planar defects.

Gu and Jiang prepared NCD films by continuous  $H^+$  ion bombardment of different energies induced by applying a negative substrate bias voltage in microwave plasma assisted chemical vapor deposition (CVD) [14]. The growth of NCD films was carried out on mirror polished *n*-type Si (001) wafers with a diameter of 50 mm and thickness of 300  $\mu m$ . They used a three-step process. In the first step, the Si wafer was etched *in-situ* in hydrogen plasma for 40 min at 860 °C. The second step involves bias pretreatment for the film nucleation at 845 °C in 5% methane in hydrogen plasma at 20 mbar and 840 W power, while the negative bias voltage was kept at  $-150$  V relative to the vacuum chamber, which was electrically grounded. In the last step,  $H^+$  ion bombardment assisted growth of diamond films was performed at different negative dc bias voltages (0–140 V), substrate temperatures (730–900 °C), and total pressures of 15–50 mbar. The nucleation density was about  $10^{10} \text{ cm}^{-2}$  after 17 min.

A series of NCD films was grown with grain size ranging from 4 nm to a few hundreds of nanometers using a microwave plasma enhanced chemical vapor deposition (MPCVD) technique by Chen et al. [5]. The deposition of NCD films was carried out on ultrasonically polished quartz substrates in a 5 kW microwave reactor. A mixture of semiconductor grade  $CH_4$ ,  $H_2$ , and  $O_2$  was used as source gas, wherein the fraction of methane was varied between 4 and 42%, while  $O_2$  was always kept constant at 0.1%. The total flow rate was 200 sccm, the chamber pressure was 22 Torr,

the microwave power was 1 kW, and the substrate temperature was maintained at 590–600 °C. Effects of the substrate pretreatment and the methane fraction in the source gas on the microstructure, surface roughness, and optical transmittance of the NCD films were studied. Specifically, comparison was made between two different sizes, 4 nm and 0.1  $\mu m$ , of the diamond powder used for substrate pretreatment. Interestingly, the films grown on substrates scratched with coarser powder (0.1  $\mu m$ ) are smoother and more transparent than those on substrates scratched with finer powder (4 nm) despite the similarity in the grain size of these two types of films prepared at high methane fractions. It is also observed that the major factor that controls the optical transparency is the surface roughness irrespective of the grain size as long as the  $sp^2$ -bonded carbon in the film is avoided.

Sharda et al. have grown the NCD films by biased enhanced growth in a MPCVD system on mirror polished Si (100) [15, 16]. No diamond powder or any other *ex-situ* treatment was performed prior to the depositions. A mixture of 5%  $CH_4$  in  $H_2$  was used at a pressure of 30 Torr with a microwave power of 1000 W for deposition of NCD films. The whole growth was performed for 1 hour in a single stage while applying a negative dc bias voltage of 260 V to the Si substrates with respect to the chamber that was grounded.

Hong et al. prepared NCD films on Si substrate from  $CH_4$ ,  $H_2$ , and  $O_2$  gas mixture by microwave plasma enhanced CVD and performed real time spectroscopic ellipsometry to understand the growth process of NCD films [17]. This study emphasizes the broad utility of the ellipsometric measurements to obtain accurate substrate surface temperature and characterization of the initial substrate damage that occurs upon seeding, the annealing of the substrate damage that occurs upon heating to the growth temperature, and the structure of the diamond film during the nucleation and bulk film growth regimes.

The effect of methane pressure on the film growth was studied by Fedoseev et al. [18]. The films deposited by Zarrabian et al. from an electron cyclotron resonance (ECR) plasma were found to consist of 4–30 nm crystallites embedded in DLC [19]. Magnetron sputtering of vitreous carbon leads to the nanocrystallites of 55 to 75 nm in size that were embedded in an amorphous carbon matrix. The sputtering was carried in Ar with 0–10% added  $H_2$ . Amaratunga et al. reported mixed phases using films containing 10–200 nm diamond crystallites embedded in a nondiamond carbon matrix [20]. In another report, ultrananocrystalline diamond films with up to 0.2% total nitrogen content were deposited by a MPCVD method using a  $CH_4(1\%)/Ar$  gas mixture and 1–20% nitrogen gas added. An enhancement in electrical conductivity of nitrogen doped NCD by five orders of magnitude was observed.

The surface morphologies of as grown NCD films have been studied by atomic force microscopy (AFM) [21]. Three-dimensional AFM images of the films with different thicknesses of 1 and 5  $\mu m$  illustrate that the NCD films produced from the  $Ar-CH_4$  plasma have very smooth surfaces. The surface roughnesses measured over an area of 5  $\mu m^2$  for these two films are 36.5 and 38.6 nm, respectively, suggesting thereby that the surface roughness of NCD films is largely insensitive to the film thickness, which is in

contrast to the conventional CVD PCD films prepared by an atomic hydrogen-rich microwave plasma. It is observed that the NCD film hardness depends on the methane content used for diamond deposition. The hardness of these films falls in the narrow range from 73 to 85 GPa that is lower by  $\sim 20\%$  than the value reported for the hardest direction (100) in natural diamond stones. A combination of high hardness and low surface roughness of the NCD films suggests the films to be perspective coatings for tribological applications. The transparency of NCD film is strongly dependent not only on the methane fraction but also on the pretreatment of the substrate. Optical transparency over 60% in the spectral range of 0.6–2.0  $\mu\text{m}$  is considered sufficiently high for most of optical applications. The NCD films also exhibit remarkable electron emission behavior. A high current density of  $4 \times 10^{-4}$  amps/cm<sup>2</sup> with turn-on field of  $\sim 1$  V/ $\mu\text{m}$  was reported for NCD films grown from C<sub>60</sub>(80%)–Ar(20%)–H<sub>2</sub> microwave plasmas. Similarly these NCD films were successfully deposited on sharp Si microtip emitters in order to enhance the electron emission properties of bare Si microtips. The Si tip emitter coated with 0.1  $\mu\text{m}$  thick NCD demonstrates a substantial reduction in the threshold field and an increase in the maximum emission current in comparison to the uncoated Si tip. The NCD films produced from C<sub>60</sub>–Ar plasma have several interesting electrochemical properties. These films have a wide working potential window, a low voltametric background current, and a high degree of electrochemical activity for several inorganic redox systems.

## 2. METHODS OF PREPARATION

In the conventional diamond films grown by CVD, the gas mixture of hydrocarbon–hydrogen is used. Typically NCD deposition requires a gas mixture of 1% CH<sub>4</sub> in 99% H<sub>2</sub>. It has been thought that atomic hydrogen is an absolutely essential ingredient of vapor from which the diamond films are grown. Atomic hydrogen is also generated by thermal decomposition or by collision processes in the plasma. There are various methods of preparation of NCD films among which plasma CVD and magnetoactive CVD are worth mentioning and most attractive. Various hydrocarbon precursors are available for the CVD processes of diamond films, among which the precursor having methyl group is favored for the preparation of diamond films. Methane (CH<sub>4</sub>), which dissociates into CH<sub>3</sub> in plasma and was preferred over other precursors such as CH<sub>4</sub> with hydrogen, produced diamond easily compared to other hydrocarbon precursors.

### 2.1. From Fullerene-Argon Microwave Plasma

The production in large quantities of the fullerenes [22] provides an opportunity to deposit diamond films from noble gas plasmas with very low hydrogen contents using C<sub>60</sub> as a precursor. The fragmentation mechanism of C<sub>60</sub> and kinetics of the process have been studied in detail [23] and it is observed that fragmentation of C<sub>60</sub> by photon, collisions with surfaces, or gas-phase collisions occurs primarily by the elimination of carbon dimer, C<sub>2</sub>. This is a highly reactive chemical species and is one of the carbon species resulting from

the sublimation of graphite. It is produced in microwave plasmas under nonequilibrium conditions from hydrocarbon molecules, resulting in supersaturated carbon vapor. With CH<sub>4</sub> as the precursor, the C<sub>2</sub> stationary concentration in argon microwave plasmas is higher than that of saturated carbon vapor by many orders of magnitude at the neutral Ar gas temperature 1600 K. At this temperature, CH<sub>4</sub> thermally decomposes to C<sub>2</sub>H<sub>2</sub>. The fraction of C<sub>2</sub>H<sub>2</sub> is then converted into C<sub>2</sub> during plasma processes by nonequilibrium processes. The dimer, C<sub>2</sub>, has a gas kinetic pseudo-first-order rate reaction with both CH<sub>4</sub> and C<sub>2</sub>H<sub>2</sub> and leads to likely formation of methylacetylene [24] and cyclobutene, respectively, as product. This high probability of formation of these products of reaction and successively larger hydrocarbon molecules is regarded as a process of homogeneous nucleation. As a result, there is a deposition of graphitic carbon. On the other hand, if the goal of the experiment is to deposit the diamond, that could be achieved by suppressing a gas-phase reaction of the sort described for heterogeneous nucleation on the diamond nuclei initially placed on the substrate *ex-situ*. Hence, there is a low probability of reactions by C<sub>2</sub> to form higher carbon clusters. Under these conditions, diamond could nucleate and grow using carbon dimer.

The growth of NCD films consisted of introducing C<sub>60</sub> into an argon microwave plasma at 750 °C on Si substrates [6, 7]. The Si substrates were mechanically treated with 0.1  $\mu\text{m}$  diamond powder. The deposition was performed for several hours with total argon pressure of 98 Torr, C<sub>60</sub> partial pressure of 10<sup>-3</sup> Torr, flow rate of 100 sccm, and microwave power of 800 W. It is difficult to operate and get the stable microwave plasma in the absence of 1% added hydrogen. The presence of 1–3% hydrogen in the carbon containing film does not appreciably affect the properties of diamond films, which are different from conventionally grown film with 1% CH<sub>4</sub> and 99% H<sub>2</sub>.

### 2.2. MPCVD

NCD films have been deposited on the quartz substrates by the MPCVD method [5]. A schematic diagram of the system employed during the work is shown in Figure 1 and consists

**Figure 1.** Schematic diagram of microwave plasma enhanced chemical vapor deposition chamber.

of a stainless steel four-way deposition vacuum chamber, a graphite holder that is attached to an induction heater, 5 kW microwave power supply, various gas lines connected to a vacuum chamber, and a vacuum pumping system. A mixture of semiconductor grade  $\text{CH}_4$ ,  $\text{H}_2$ , and  $\text{O}_2$  was used as a source gas, wherein the fraction of  $\text{CH}_4$  was varied between 4% and 42% and  $\text{O}_2$  was always kept constant at 0.1%. The total flow rate was 200 sccm, the chamber pressure was 22 Torr, the microwave power was 1 kW, and the substrate temperature was maintained at 600 °C during deposition. An independent radio-frequency (rf) heater was used to control the substrate temperature. During deposition, a single-color optical pyrometer was used to record the temperature from the front surface of the substrate.

The smooth films were deposited on the pretreated quartz substrates. The substrate pretreatment could be carried by first chemically cleaning the quartz plates with acetone and doubly distilled water and then these plates could be used for the ultrasonic polishing with diamond powder having grain sizes 4 nm and 0.1  $\mu\text{m}$ . The ultrasonic polishing of the quartz substrates is simple. This involves the preparation of suspension of diamond powder in acetone, placing the substrates in this suspension, and subjecting the beaker to ultrasonic vibration for at least 8 h.

### 2.3. Biased Enhanced MPCVD

The growth of diamond is considered to be taking place via surface processes of addition and subtraction of radicals from the gas phase [25, 26]. During the growth of diamond, ions enhance lattice disorders and also promote graphitic content in the deposit. On the other hand, in the growth of carbon films by hyperthermal species, ions with energy in the range 40–200 eV produce a high concentration of  $sp^3$  carbon in the film [27–30]. In this case, the growth is controlled by a subplantation mechanism, which relies on the shallow subsurface implantation of the carbon ions. Both of these routes of growth of carbon films are totally different. In the bias enhanced route the NCD films are deposited in a CVD diamond environment while continuously biasing the substrate to take advantage of both the processes in the growth. The CVD diamond conditions result in high etching rates of the nondiamond carbon from the surface processes while continuous biasing takes advantage of subsurface phenomena. This route is simply an extension of bias enhanced nucleation of CVD diamond and results in the growth of hard and smooth NCD films.

The NCD films could be grown in a MPCVD reactor on mirror polished silicon substrate placed on an Mo holder [15]. No diamond powder or any other *ex-situ* treatment is required prior to the deposition. The substrate is then immersed in methane and hydrogen plasma. A mixture of 5%  $\text{CH}_4$  in  $\text{H}_2$  should be used at a pressure of 30 Torr, with a microwave power of 1 kW for all the films. A negative dc bias voltage of 260 V should be applied to the substrate with respect to the chamber that is grounded. The whole growth of NCD film could be achieved in a single stage and requires a 1 hour duration without breaking the bias to the substrate. While holding the bias voltage constant throughout the deposition, bias current could be varied with time in the same fashion as commonly observed in biased

enhanced nucleation in the growth of CVD diamond; the current increases after some incubation period followed by saturation at longer deposition time. It is observed that there is an increase in the current attributed to enhancement in electron emission from the surface as highly emissive diamond is deposited on silicon.

### 2.4. Ar- $\text{CH}_4$ MPCVD

Atomic hydrogen plays a crucial role in the growth of PCD films by CVD using hydrocarbon as a carbon source [31, 32]. It is well known that atomic hydrogen from a hydrogen-rich reactant gas can terminate the carbon dangling bonds with a tetrahedral  $sp^3$  configuration and etch out nondiamond materials at the growth surface of diamond. The reduction in concentration of atomic hydrogen causes the growth of nondiamond phase or no diamond film deposition. Hence, argon has been used in place of hydrogen. A mixture of Ar (99 sccm) and  $\text{CH}_4$  (1 sccm) was used as the reactant gas for growth of NCD film. *N*-type single crystal silicon (100) wafers were used as substrates. These substrates were polished mechanically with 0.1  $\mu\text{m}$  diamond powder. During the entire film growth, the substrate temperature and input microwave power were 800 °C and 800 W, respectively. The films prepared in this work were 1 or 5  $\mu\text{m}$  thick. As grown films prepared from the Ar- $\text{CH}_4$  plasma, they consist of phase-pure crystalline diamond grains ranging from 3 to 20 nm in size independent of the NCD film thickness [21].

### 2.5. Hot Filament CVD

It has been shown that the addition of Ar into the  $\text{CH}_4$ - $\text{H}_2$  or  $\text{C}_{60}$  MPCVD can provide a route for controlling the microstructure of the diamond film, leading to thick and smooth NCD films at an Ar concentration of 90% [33, 34]. Due to the very high concentration of  $\text{C}_2$  species at higher percentage of Ar, it has been concluded that  $\text{C}_2$  dimer may be the growth precursor for NCD films in the MPCVD system. While most of studies on growth of NCD are focused on using MPCVD, there are only few reports on the use of the hot-filament CVD (HFCVD) system for the growth of NCD films. An interesting question is whether the chemistry observed in the MPCVD system for the growth of NCD films can be extended to HFCVD as the mechanism for gas activation is different in both these methods. Similarly the fraction of argon ions and electron density is significantly lower in the HFCVD system than the MPCVD system.

Lin et al. employed a conventional HFCVD system using curved tantalum wire arrays for the growth of NCD films [35]. A  $\text{CH}_4/\text{H}_2$  gas feed ratio that can yield the growth of high quality, well-faceted diamond film was used. Ar was then introduced in increasing concentration to the system in order to investigate the changes in microcrystallinity of the film as a function of Ar: $\text{H}_2$  ratio. The  $\text{H}_2$  and  $\text{CH}_4$  flow rates were fixed at 0.05 and 0.0013 l/min, respectively. The Ar/ $\text{H}_2$  ratio was adjusted by increasing the Ar flow rate from 0 to 0.43 l/min. In order to get a higher Ar: $\text{H}_2$  ratio, the  $\text{H}_2$  flow rate was reduced. The total pressure was kept at 60 Torr. The substrate temperature was held at 950 °C for Ar concentration below 92%. When higher Ar concentration was used, the substrate temperature was reduced to 870 °C to

avoid the deposition of graphite. The Si (100) wafer used in this work was supersonically scratched with diamond powder prior to the deposition of diamond films. The range of Ar concentration in the Ar-CH<sub>4</sub>-H<sub>2</sub> mixture that permits well-faceted diamond growth is up to 90%. At a concentration of 95.5%, there is a marked transition into NCD phase without graphitic phases. Such compositional mapping is one of the effective routes to prepare thick and smooth NCD films.

## 2.6. CVD of Camphor

It is well established that the methyl radical along with atomic hydrogen is key to growing the diamond films. A wide variety of precursor materials are available for the CVD processes of diamond films. Although any carbon containing precursor material may be used in the CVD technique, the preparation of diamond film is favored by the presence of a methyl group [36, 37]. Hence, methane, which dissociates into CH<sub>3</sub> in plasma, has been preferred over other precursor materials because CH<sub>4</sub> with hydrogen produced the diamond easily. Similarly the organic compounds, which can easily generate methyl radicals, may also be suitable for the growth of diamond films. Camphor (C<sub>10</sub>H<sub>16</sub>O) as the precursor material has been mentioned for the growth of NCD films. In camphor, there are three carbon atoms attached to three methyl groups while the remaining seven carbon atoms are associated with a ring structure.

NCD films were deposited by CVD of camphor and hydrogen (~75%) [38]. Camphor is a natural source which sublimates at room temperature and is soluble in alcohol, ether, acetone, and benzene. Figure 2 [38] depicts the schematic diagram of the apparatus used for CVD of camphor. The camphor vapor was passed through a heated stainless steel tube into a cylindrical deposition vacuum chamber. The heating tape was used over the stainless steel tube in order to prevent condensation of camphor vapor

**Figure 2.** Schematic diagram of the deposition system. Reprinted with permission from [38], K. Chakrabarti et al., *Diamond Relat. Mater.* 7, 845 (1998). © 1998, Elsevier Science.

before entering the deposition chamber. NCD films were deposited at 1.5 kV with 75 mA current at a chamber pressure of ~0.3 mbar on glass, quartz, and silicon substrates. The substrate temperature was varied within 573–713 K depending on the substrate material. The value of  $T_s$  for glass substrate was within 573–623 K, while for quartz it was within 573–713 K. The substrates could be heated to the desired temperature inside the substrate holder with proper insulation.

## 3. NUCLEATION AND GROWTH KINETICS

The preparation of pure and compact diamond thin films by MPCVD from CH<sub>4</sub>, H<sub>2</sub>, and O<sub>2</sub> gas mixture on non-diamond surfaces has a great potential for various commercial applications [39–41]. Such thin films can endow solid surfaces with one or more of the superlative properties of diamond, including resistance to wear and chemical attack, optical as well as infrared transparency, and high thermal conductivity. The limitations in achieving these prospective properties include: (a) the high substrate temperatures required for diamond nucleation with reasonable growth rates, (b) the surface pretreatments like abrasion with diamond powder for high nucleation density, and (c) the defective nature of the resulting nano- and/or PCD film. Diamond film deposited on nondiamond substrates exhibits a variety of difficulties related to their nano/polycrystalline structure, mostly in the appearance of a second phase of  $sp^2$  bonded C atoms. The transmission electron microscopy and Raman spectroscopy studies performed on the underside of a 20  $\mu\text{m}$  diamond film removed from its substrates revealed that diamond clusters are surrounded by  $sp^2$ -bonded C phase in the form of graphite crystals [42], while the growth side of these films exhibited the pure diamond phase. The formation of a defective region near the substrate interface has been attributed to heteroepitaxy [42] or to impurities that arise from the interaction of the plasma with the substrate during the nucleation stage [43]. Previous studies have revealed a 0.7 to 0.8 eV optical gap for the graphitic component of thin (0.2  $\mu\text{m}$ ) diamond films [44] consistent with the existence of  $sp^2$  bonded C atoms in clustered units sufficiently small so that a gap has developed [45]. A dominant graphite phase has also been detected in the grain boundary regions for 30–40  $\mu\text{m}$  thick diamond films prepared with excess CH<sub>4</sub> in the CH<sub>4</sub>/H<sub>2</sub> mixture. On the other hand, in the films prepared with an optimum CH<sub>4</sub>/H<sub>2</sub> mixture, this phase is no longer dominant and contains dilute  $sp^2$  C atoms within the diamond grains [46].

These pioneering studies of diamond thin films demonstrate that the atom fraction, physical location (intragrain or grain boundary), and nature (clustered versus dilute) of the dominant  $sp^2$  bonded C are sensitive parameters for the evolutionary stage of the film and the preparation conditions. The characteristics of the  $sp^2$  C phase and the void network are of greatest interest because such bonding and structural defects lead to degradation in the mechanical, optical, and electrical properties of diamond thin films deposited on non-diamond substrates. In view of this, real time monitoring of the deposition process becomes increasingly important in

order to quantify these characteristics as a function of film thickness and to exert greater control over the growth process for improved near-interface and bulk properties. Optical probes are beneficial in this role as they are passive and require no instrumentation internal to the reactor [47–50] because of the adverse environment of diamond deposition, highly reactive gases, high gas pressures, and high temperatures.

### 3.1. Real Time Spectroscopic Ellipsometry

Spectroscopic ellipsometry (SE) and optical emission spectroscopy (OES) are powerful, real time optical probes for characterizing film growth. Ellipsometry has an advantage over other optical techniques for characterizing the evolution of diamond thin films because it can provide the volume fractions of diamond,  $sp^2$  C, and void with good sensitivity in the films as thin as 40 Å [51, 52]. Hong et al. have applied real time SE to characterize the preparation of ~2000 Å thick NCD film on Si substrate by MPCVD [53]. Si wafers were seeded and placed on a graphite substrate platform. The platform is rf heated to a temperature that can be controlled independently of microwave power over a relatively wide range. In order to achieve a stable plasma configuration, a pure H<sub>2</sub> plasma was ignited with the substrate platform about 2 cm above the optical plane. The substrate platform was adjusted until optical alignment was achieved. CH<sub>4</sub> and O<sub>2</sub> were introduced, defining time zero in the data collections. The spectroscopic ellipsometer employs a polarizer rotating at 15.6 Hz that modulates the polarization state of an incident, collimated, white light beam generated by an Xe source. A fixed analyzer and a photodiode array based detection system should be used for the analysis of the polarization state change induced by the growing film over a range of photon energies [54, 55]. The resulting spectra consist of ~110 pairs of ellipsometry angles ( $\Psi$ ,  $\Delta$ ) from 1.5 to 4.5 eV and were obtained as an average of 40 rotations in an acquisition time of 2.6 s. In this time, ~1 Å accumulates at the maximum bulk layer deposition rate of 0.4 Å/s. The repetition time for the collection of successive spectra is adjusted to achieve sufficient thickness resolution for the growth rate measurements. The ( $\Psi$ ,  $\Delta$ ) spectra were analyzed by least-squares regression [56].

The nuclei studied in the first 5 Å of mass thickness  $d_m$  are simulated using a simplified single layer model consisting of a composite of diamond and  $sp^2$  carbon with void. The optical properties of this layer are calculated with the Bruggeman effective medium approximation (EMA) using a fixed nuclei composition established after  $d_m \sim 50$  Å. The outcome of the analysis in the first 5 Å is the physical thickness  $d$ , from which  $d_m = f_d d$  can be determined, where  $f_d$  is the diamond volume fraction. The continuous film is simulated as a two layer, roughness/bulk combination, where the surface roughness is modeled with the EMA as a 0.5/0.5 mixture of diamond/void, and the bulk layer is modeled as a composite of diamond,  $sp^2$  C, and void. The output of the analysis includes the bulk and roughness layer thickness,  $d_b$  and  $d_s$ , and the bulk composition, from which  $d_m = f_{ab} d_b + 0.5 d_s$ , where  $f_{ab}$  is the volume fraction of diamond in the bulk. The  $d_m$  versus time in the first 5 Å of the nucleation regime and in the bulk film growth regime

shows a linear fit that yields the deposition rates in terms of mass thickness. The mass thickness deposition rates are then plotted vs  $T^{-1}$  from 390 to 840 °C in Figure 3 [57]. A well-defined activation energy of  $8 \pm 0.5$  kcal/mol has been noted for diamond growth for  $390 \text{ °C} \leq T \leq 800 \text{ °C}$  in the bulk regime. Above 800 °C, a deviation from activated behavior could be observed, characterized by a maximum in the rate near 800 °C followed by a decrease with increasing  $T$ , and is attributed to a reduction in the incorporation probability. It should be noted that the 8 kcal/mol activation energy deduced in the bulk growth regime is close to the values obtained for diamond homoepitaxy on (100) and (111) surfaces [57]. This activation energy is attributed to  $sp^3$  C atom incorporation in specific atomic sites on these surfaces. Figure 3 shows larger scatter for individual depositions in the nucleation regime due to substrate seeding variation. During nucleation, the rates are  $10\text{--}10^2$  times lower than in the bulk regime with an apparent activation energy of  $17 \pm 2$  kcal/mol. The lower rates arise from growth at discrete nucleation centers, in which case only C-containing precursors that arrive within ~100 Å of a center can be incorporated. The higher activation energy is attributed to a decrease in the capture area as the nucleation density and precursor surface diffusion length decrease with decreasing  $T$ .

Figure 3 gives a clear understanding of the limitation of diamond film growth at low temperature. Lee et al. [57] suggested that the apparent activation energy of ~17 kcal/mol in the nucleation regime is a characteristic of the seeding process. Higher activation energies are expected with less effective seeding, and this explains values as high as ~30 kcal/mol [58, 59]. Figure 3 also demonstrates that the nuclei growth rate at  $T = 400$  °C is ~ $10^3$  times lower than the bulk rate at 800 °C. Of this factor of  $10^3$ , one order is attributed to the decrease in the average incorporation

**Figure 3.** Diamond growth rates in terms of mass thickness vs inverse temperature. The lines are the best linear fits for  $T > 800$  °C in the bulk growth regime, and to the full data set in the nucleation regime. The slopes of these lines yield the activation energies as shown. The broken line indicates a reproducible deviation from activated behavior. Reprinted with permission from [17], B. Hong et al., *Diamond Relat. Mater.* 6, 55 (1997). ©1997, Elsevier Science.

probability from 800 to 400 °C, another order is due to the fraction of the substrate area from which initial nuclei can collect impinging flux, and factors of 4 and 2 are due to the reduction in the nucleus capture radius and nucleation density, respectively. Thus considerable gains can be achieved in preparing diamond at reasonable rates on nondiamond substrates at low  $T$  by enhancing the density and area of the nucleation centers and retaining these characteristics as  $T$  is reduced. It is most probable that disordered  $sp^2$  or  $sp^3$  C embedded within the silicon during seeding is converted to NCD nuclei by H exposure in the initial stages of nucleation and that this process becomes more effective as  $T$  increases. Although gains in diamond film can be made at low  $T$  by increasing the precursor flux, a primary limitation is the low capture cross-sectional area of nuclei at low density on the substrate.

### 3.2. Optical Emission Spectroscopy

The diamond films were deposited on pretreated quartz substrates by the MPCVD technique as described in detail elsewhere [5]. In order to obtain information on plasma chemistry, OES was employed to monitor the  $H_2$ - $CH_4$  plasma. A monochromator with a focal length of 500 mm and grating of 1200/mm, which gives a resolution of 0.05 nm and a precision of about  $\pm 0.2$  nm/500 nm, was used for the OES measurements. Figure 4 [5] presents some typical optical emission spectra of the  $H_2$ - $CH_4$  plasma used for the NCD film deposition. The  $H_2$  spectrum consists mainly of emission from atomic H Balmer lines ( $H_\alpha$  and  $H_\beta$  lines at 656.3 and 486.1 nm, respectively) and excited  $H_2$  lines at around 460 and 590 nm. When methane was introduced into the system,  $C_3$  emission lines at around 400 nm,  $CH^+$  emission at 417 nm, CH lines at around 431 nm, and the  $C_2$  Swan bands around 469 and 515 nm appeared in the emission spectrum. Using the  $H_2$  line at 580.6 nm as reference, the relative intensities of emissions from the latter four species as a function of the methane fractions in the source gas are plotted in Figure 5 [5]. All emissions except that of  $C_2$

**Figure 4.** Some typical optical emission spectra of the  $H_2/CH_4$  plasma. Reprinted with permission from [5], L. C. Chen et al., *J. Appl. Phys.* 89, 753 (2001). © 2001, American Institute of Physics.

**Figure 5.** The relative intensity of the  $CH^+$  (▲),  $C_2$  (■),  $CH$  (●), and  $C_3$  (\*) emissions with respect to that of  $H_2$  as a function of the methane fraction in the source gas. dimer increased with increasing methane content, reached a maximum at around 20%, and decreased at higher methane content. Emission from  $C_2$  dimer, however, showed a continuing increase above 20% methane content. It can be seen from Figure 4 that the 515 nm  $C_2$  emission line was very pronounced at high methane content. Due to the fact that the emission intensity is a function of many factors including Frank–Condon factor, the density of states, various quenching effects, etc., a quantitative description of the observation is very complicated and is beyond the scope of this chapter. The gas-phase analysis by OES or any other single technique is far from complete since it is not possible to detect some important growth species such as  $CH_3$  by this technique. It is observed from these studies that the gas phase experienced substantial change when the methane fraction went from below to above 20%, with which the optical transmittance and surface roughness data [5] also exhibited similar crossover behavior.

Shown in Figure 6 [5] is the intensity ratio of two atomic hydrogen lines at 486.1 nm ( $H_\beta$ ) and 656.3 nm ( $H_\alpha$ ) as a function of the methane fraction in the source gas. It is quite clear from the graph that the intensity ratio of  $H_\beta/H_\alpha$ , which is related to the electronic temperature in the plasma, showed a maximum value at a methane fraction of 20% and declined rapidly with variation in methane content on either side. Once again, the electronic temperature exhibited a methane-fraction dependence similar to that of most emissions (except  $C_2$ ) as shown in Figure 5. From Figures 5 and 6, it is speculated that a change in major growth species might have occurred around a methane fraction of 20%. Most of the conventional PCD films were grown in low methane fraction. The major growth species  $C_2$  has been identified for the growth of NCD films using  $C_{60}$  as precursor under hydrogen-free or hydrogen-deficient environments [60]. For the conditions during this work [5], growth involving  $CH_3$  was expected since all depositions were carried out

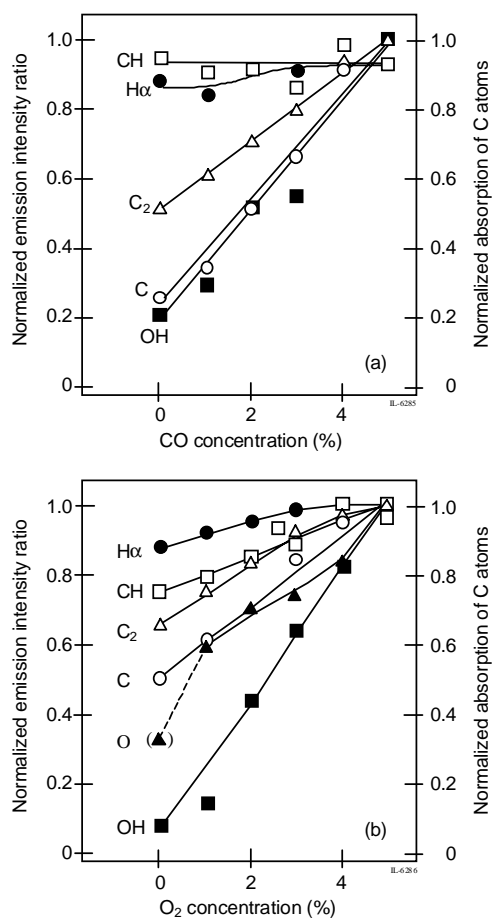

**Figure 6.** The relative intensity of  $H_{\beta}/H_{\alpha}$  as a function of the methane fraction in the source gas. Reprinted with permission from [5], L. C. Chen et al., *J. Appl. Phys.* 89, 753 (2001). © 2001, American Institute of Physics.

in  $H_2$ - $CH_4$  plasma. However, it is clear from OES studies that  $C_2$  dimer becomes the predominant growth species at methane fractions far above 20%.

### 3.3. Vacuum Ultraviolet Absorption Spectroscopy

The deposition of NCD film by using a low-pressure inductively coupled plasma (ICP) was employed by Teii et al. [61]. NCD films were grown at a pressure of 80 mTorr using  $CO/CH_4/H_2$  and  $O_2/CH_4/H_2$  gas mixtures. The densities of C atoms in ground state are measured by vacuum ultraviolet absorption spectroscopy (VUVAS).  $CO$  is employed as one of the simple gases that yield C atoms, through the primary reaction:  $CO + e^- \rightarrow C + O + e^-$ .

The emissive species observed in the  $CO/CH_4/H_2$  plasmas in the wavelength range of 300–800 nm were OH, CH, H,  $C_2$ , and Ar. In addition to these species, pronounced emissions from O were observed in the  $O_2/CH_4/H_2$  plasmas. The normalized emission intensity of OH, CH,  $H_{\alpha}$ ,  $C_2$ , and O [62, 63] and the normalized absorption of C atoms as a function of  $X_{CO}$  and  $X_{O_2}$  for a fixed  $X_{CH_4}$  of 5% are depicted in Figure 7 [61], respectively. It was very difficult to obtain sufficient absorption by C atoms when an emission line at 296.7 nm was initially used in (UVAS). It therefore follows from this that the absolute C atom density was lower than  $1 \times 10^{12} \text{ cm}^{-3}$ , the lower detection limit in this UVAS system [64]. The trend of the C atom density as determined by VUVAS was consistent with that by OES under experimental conditions, indicating thereby that the influence of collisional excitation processes was small. In Figure 7a, the  $H_{\alpha}$  and CH intensity ratios remain constant independent of  $X_{CO}$ , while the C atom absorption and OH and  $C_2$  intensity ratios increase in proportion to  $X_{CO}$ . To ensure that an increase in C and  $C_2$  was not due to an overall increase in the total carbon concentration in the feeding gas, a comparative experiment was performed by varying  $X_{CO}$  with the sum of  $X_{CO} + X_{CH_4}$  kept constant at 5%. This experiment gave similar results except for a slight decrease in the CH

**Figure 7.** Variations of the normalized emission intensity ratios of OH, CH,  $H_{\alpha}$ ,  $C_2$ , O, and the normalized absorption of C atoms (a) as a function of  $X_{CO}$  for a  $X_{CH_4}$  of 5%, and (b) as a function of  $X_{O_2}$  for a  $X_{CH_4}$  of 5%. Reprinted with permission from [61], K. Teii et al., *J. Appl. Phys.* 87, 4572 (2000). © 2000, American Institute of Physics.

intensity ratio probably due to a decrease in parent  $CH_4$ , informing thereby that the major origin of C and  $C_2$  is  $CO$ . In Figure 7b, the intensity ratios of OH, CH, H,  $C_2$ , and O as well as the C atom absorption increase with increasing  $X_{O_2}$ . Emissions from O for  $X_{O_2} = 0\%$ , arising from the impurity from quartz windows, were as low as the noise level. An increase in C atom absorption is ascribed to the result of sequential reactions induced by O atoms.

For the transition from upper state  $j$  to lower state  $i$ , the relationship between the emission line intensities  $I_{ji}$  and excitation temperature  $T_{ex}$  is given in detail elsewhere [65]. The relative excitational population of H atoms in the Balmer series as a function of excitation level for the three gas mixtures is shown in Figure 8 [61]. The emission line of  $H_{\epsilon}$  was not available because of its low signal-to-noise ratio. The distribution equilibrium of excitation levels of the  $H_{\alpha}$  atom Balmer series is not satisfied because the three sets of plots do not produce straight lines, in accordance with the previous study in the same pressure range [66]. The energy distribution is almost equivalent in any gas mixture, suggesting a common excitation process of H atoms. Furthermore, the overall emission intensities are equivalent in any gas mixture, indicating that the H atom density was

**Figure 8.** Energy distribution of the H atom Balmer series as a function of excitation level for the three sets of data in the 5%CH<sub>4</sub>-95%H<sub>2</sub>, 5%CO-5%CH<sub>4</sub>-90%H<sub>2</sub>, and 5%CO-95%H<sub>2</sub> plasmas. Reprinted with permission from [61], K. Teii et al., *J. Appl. Phys.* 87, 4572 (2000). © 2000, American Institute of Physics.

almost equivalent and the H atoms were produced mainly by dissociation of hydrogen molecules. These similarities for H atoms regardless of the gas mixtures imply that the H atoms were not responsible for the difference in the grown phases. Thus VUVAS analysis suggests that the C atoms resulting mainly from CO by electron impact dissociation increased the precursors to nondiamond phase by promoting gas-phase polymerization, while the OH radicals resulting predominantly by loss reactions of O atoms with H<sub>2</sub> and CH<sub>4</sub> were responsible for the enhancement of diamond growth. An excess amount of O atoms resulting from O<sub>2</sub> interrupt the formation of nuclei at the initial stage of the growth. Besides, the production path of C atoms induced by O atoms is also possible.

#### 4. SPECTROSCOPIC CHARACTERIZATION

NCD films are materials of a great potential use in various fields such as tools, optical windows, microelectromechanical systems (MEMS), etc., due to their remarkable properties. In recent years, attempts have been made to develop NCD films with a smooth surface and special attention has been paid to NCD films with characteristics of a small crystallite size. In order to understand and improve the properties of NCD films, it is desirable to relate the remarkable properties of NCD with their microstructure. The various techniques used for characterization of NCD are discussed next.

##### 4.1. Transmission Electron Microscopy

Transmission electron microscopy has been the most powerful technique for characterizing the microstructure of NCD and is widely used to obtain bonding information. Figure 9 [5] depicts a typical TEM bright-field image of a diamond film deposited on a nanometer-scratched substrate with a methane fraction of 4% [5]. A typical selective-area diffraction pattern (not shown here) of a nanometer-scratched sample prepared with a methane fraction of 41% indicates

**Figure 9.** Bright-field TEM image of a NCD film grown on nanometer-scratched quartz substrate with a methane fraction of 4%. Reprinted with permission from [5], L. C. Chen et al., *J. Appl. Phys.* 89, 753 (2001). © 2001, American Institute of Physics.

high degree of diamond phase. All the sharp diffraction rings can be indexed to the diamond structure. It is observed that diamond films consist of randomly oriented grains and that the substrate pretreatment has a strong effect on the average grain size of the resulting films. With a methane fraction of 4%, the average grain size of the micrometer-scratched sample was about 200 nm, whereas the corresponding value of the nanometer-scratched sample was only about 4 nm. As the methane fraction was increased from 4% to 41%, the grains of the micrometer-scratched samples became coarser and coarser. In fact, it is noted that the average grain size of the nanometer-scratched sample prepared at a methane fraction of 41% is quite similar to that of its micrometer-scratched counterpart.

High-resolution transmission electron microscopy has been utilized to understand the initial stages of diamond film growth [12, 67–69]. The detailed electron microscopic study [70] of NCD films grown from C<sub>60</sub> fullerene precursors showed that various planar defects such as twinning boundaries and stacking faults were observed in large crystallites found in the films. Similarly, measurements of the diamond crystallite size distribution using diffraction contrast TEM followed a gamma distribution with an average grain size of 15 nm [71]. Since the resolution of the TEM technique is limited by the small objective aperture, HRTEM has a great edge for reliable grain size measurements [72]. In addition, the TEM imaging techniques give additional information that can be used to determine the phase purity of NCD films. The selected-area electron diffraction is a powerful method to examine the phase composition of these films as short-range order in either sp<sup>2</sup>-bonded glassy carbon or predominantly sp<sup>3</sup>-bonded diamondlike amorphous carbon as they provide different diffraction intensities.

Gruen et al. have grown NCD films on (100) surfaces of n-doped silicon wafers using electrical biasing of the silicon substrate to initiate nucleation [4]. Growth was carried out at a rate of about 0.5–1 μm/h. Although NCD films have uniform morphology, two additional factors mandate the use of the HRTEM technique. When the packing density is high, the diffraction contrast due to orientational differences of the diffracting crystallites appears weak for

bright-field images. Also, the resolution of the diffraction-contrast method is quite low, and, therefore, it is difficult to resolve nanosized crystallite boundaries. For all the reasons mentioned above, reliable information on grain size could be determined from lattice images of nanodiamond crystallites. Mostly the (111) lattice planes are resolvable in the microscopes. Hence, the lattice images from those crystallites are oriented such that at least one set of their (111) lattice planes is parallel to the incident imaging electron beam. The crystallite size with high accuracy can be measured because of the low contrast from surrounding structures is close to random white noise. Although lattice images reveal individual crystallites at atomic resolution, the presence of amorphous carbons cannot be determined. When the crystallite size is reduced to the nanometer scale, the percentage of atoms located at the grain boundaries increases drastically with decrease of grain size. It is estimated that for NCD films, the fraction of atoms residing at grain boundaries can be as high as 10% when the average crystallite size becomes 3 to 5 nm. On the other hand, electron microscopy observations show that there is no graphitic phase between the grain boundaries. The presence of  $sp^2$  bonds suggests that carbons are  $\pi$ -bonded across sharply delineated grain boundaries limited to widths of 0.2–0.5 nm [73].

## 4.2. Electron Energy Loss Spectroscopy

Shown in Figure 10 [74] are high-resolution electron energy loss spectroscopy (EELS) spectra of the plasmon for  $C_{60}$  fullerene, amorphous, nanocrystalline, and polycrystalline diamond [74].  $C_{60}$  fullerene shows peaks around 6.5 eV which are  $\pi$ -plasmons due to the  $\pi$ - $\pi^*$  band transition

**Figure 10.** High-resolution EELS plasmon spectra for  $C_{60}$  fullerene, amorphous diamond, nanocrystalline powder, and crystalline diamond. Reprinted with permission from [74], H. Hirai et al., *Diamond Relat. Mater.* 8, 1703 (1999). © 1999, Elsevier Science.

[75, 76]; such peaks are not observed in the amorphous diamond, indicating thereby the absence of  $\pi$ -plasmons. Among the three diamond materials,  $\sigma$ -plasmon peaks that appear around 30–34 eV [77] are different in peak position and shape. Plasmon excitation of valence band electrons of EELS spectra is related to the dielectric function by an equation [78]. Applying the Kramers–Kronig equation, the real and imaginary parts of the dielectric function,  $\epsilon_1$  and  $\epsilon_2$ , can be estimated from the plasmon of EELS. The calculated  $\epsilon_2$  for the diamond materials is shown in Figure 11 [74]. The rise-up position of  $\epsilon_2$  corresponds to the bandgap.

For the natural crystalline diamond, the rise-up position is 5.5 eV, indicating excellent agreement with the established bandgap of diamond (5.5 eV). Two peaks appear at 8.2 and 12.7 eV, and the former is assigned to direct excitation of an electron at the  $\Gamma$  point, the latter being assigned to X and L positions, respectively [79]. For the amorphous diamond, the rise in peak is gradual and the rise-up position changes with the sample from 3.5 to 4.5 eV. In any case, the magnitude of the bandgap is smaller than that of crystalline diamond. A large peak at 7.2 eV, corresponding to point  $\Gamma$ , is observed. For the nanocrystalline powder, the rise-up position is at 3.0 eV and occurs very gradually. This implies that the present method of estimating  $\epsilon_2$  from the EELS plasmon is reliable. For the amorphous diamond, the magnitude of the bandgap is 3.5 to 4.5 eV, smaller than that of diamond. The variation in magnitude of the bandgap may be caused by the temperature distribution during the synthesis. In addition, the amorphous diamond exhibited the characteristic distribution in  $\epsilon_2$  and only  $\Gamma$  excitation at the point

**Figure 11.** Imaginary part of the dielectric function obtained from EELS spectra for diamond materials, showing different rise-up manners. Reprinted with permission from [74], H. Hirai et al., *Diamond Relat. Mater.* 8, 1703 (1999). © 1999, Elsevier Science.

appeared, while excitations at X and L points were not noticed or considerably weakened. X and L points, where the wave number vector has a certain value, are defined when the direction and periodicity exit in the material, whereas the  $\Gamma$  point is independent of direction and periodicity. The observed characteristics might have originated from the short-range structure of the amorphous diamond.

For the nanocrystalline powder the small bandgap of 3.3 eV and the gradual increase in  $\epsilon_2$  are probably generated from the disordered carbon layer surrounding individual nanometer-sized crystallites observed under high resolution TEM. It is quite likely to tailor the bandgap of diamond films by controlling the synthesis parameters.

### 4.3. X-Ray Photoelectron Spectroscopy

The NCD films with a thickness of 800 nm were grown by MPCVD and these films were implanted with nitrogen ions at energy of 110 keV [80]. During the implantation process, the temperature of the samples was controlled below 80 °C using a water-cooling device. X-ray photoelectron spectroscopy (XPS) was used to analyze the changes in surface structure and chemical state of the films before and after implantation.

Figure 12 [80] presents the XPS spectra for C 1s and O 1s states of the as-deposited film. The C 1s envelope has been deconvoluted into three components (Fig. 12a). The main peak at 284.5 eV can be attributed to contribution from C–C and C–H bonds [81]. The peak signals at 285.8 and 286.9 eV are indications of the presence of C–O

**Figure 12.** XPS spectra for: (a) C 1s and (b) O 1s states for the as-deposited film. Reprinted with permission from [80], T. Xu et al., *Diamond Relat. Mater.* 10, 1441 (2001). © 2001, Elsevier Science.

and C=O [82], respectively. Figure 12b is the O 1s spectra of the as-deposited film. A single-peak signal centered at 532.8 eV is evident, which may be assigned to the C–O bond [83]. The surfaces of as-grown CVD diamond films are typically terminated with hydrogen atoms [84]. However, the film grown as previously stated indicates that the O concentration on the surface reaches 9.83%, which implies that the terminals of dangling bonds of  $sp^3$  C–C atoms on the surface are occupied not only by hydrogen atoms but also by some oxygen atoms and absorption of hydrogen and oxygen may also exit on the surface [85]. Shown in Figure 13 [80] are the XPS spectra for C 1s and O 1s states of the film implanted with  $1 \times 10^{17}$  ions  $\text{cm}^{-2}$ . As compared with the unimplanted sample, distinct changes in the C 1s and O 1s spectra are observed. The C 1s core-level spectrum shifts to a higher binding energy, and the intensity of peaks for C–O and C=O shows an obvious increase (Fig. 13a). The O 1s lines are asymmetric, and more than one binding state is presented. Absorbed oxygen (529.6 eV), C=O (531.5 eV), C–O (532.8 eV), and absorbed  $\text{H}_2\text{O}$  (534.9 eV) [86] are shown in the O 1s spectrum of Figure 13b.

These studies show that nitrogen-ion implantation changes the surface chemical state of the NCD film. The C–H and C–O bonds on the surface of as-deposited films were broken by highly energetic nitrogen ions. Hydrogen and oxygen desorb from the diamond surface and yield unoccupied surface states, which cause the change in the surface state of the as-deposited film. These chemically unsaturated surface carbon atoms have free valences that may be saturated by chemisorption of foreign elements or may react with foreign elements to form bonded surface functional groups [87]. When the implanted samples are exposed in ambient atmosphere, the dangling bonds can be quickly

**Figure 13.** XPS spectra for (a) C 1s and (b) O 1s states for the film implanted with  $1 \times 10^{17}$  ions  $\text{cm}^{-2}$ . Reprinted with permission from [80], T. Xu et al., *Diamond Relat. Mater.* 10, 1441 (2001). © 2001, Elsevier Science.

occupied by OH, CO<sub>2</sub>, or H<sub>2</sub>O molecules and ions in air. In this way the surfaces of NCD films are covered by a layer of oxygen-containing groups after high fluence implantation, thereby resulting into the change in chemical state of oxygen on the surface.

#### 4.4. Raman Spectroscopy

It is well known that Raman spectra, that are sensitive to changes in translational symmetry, are very powerful for the study of disorder and crystalline formation in thin carbon films [88]. In Raman spectroscopy, a visible laser is used for excitation, and a sharp peak at 1333 cm<sup>-1</sup> appears in the spectrum. For NCD films, with decreasing the grain size, the grain surface area and grain boundary that mainly consist of amorphous sp<sup>2</sup> C phases increase. In the Raman spectrum, a broad D peak (disorder-induced mode) at 1350 cm<sup>-1</sup> will appear and possibly overlap the diamond peak at 1333 cm<sup>-1</sup> with increasing sp<sup>2</sup> C bonding. The high frequency stretch modes of sp<sup>2</sup> C atoms are overemphasized due to the π-π\* transition resonance effects [89], and the sp<sup>2</sup> C network exhibits resonance enhancement in the Raman cross-section since the local sp<sup>2</sup> C energy gap of approximately 2 eV is comparable to the energy of the incident photons. The sp<sup>3</sup> C atoms do not exhibit such a resonance effect because of the higher local gap of approximately 5.5 eV. Hence the Raman spectra obtained with visible excitation are completely dominated by the sp<sup>2</sup> C atoms [90]. Raman scattering in the UV region is promising for vibrational studies of sp<sup>3</sup> bonded C phase [91]. Advantages of using UV over visible photons include the suppression of the dominant resonance Raman scattering from sp<sup>2</sup> C atoms and increase in the intensity from sp<sup>3</sup> C bonding [92].

Figure 14 [93] is the Raman spectra of NCD films grown by the MPCVD technique at different temperatures [93]. The Raman spectrum of the NCD films mainly exhibits three features near 1150, 1350, and 1580 cm<sup>-1</sup>. The bands in the Raman spectra of these films near 1350 and 1580 cm<sup>-1</sup>, popularly known as D and G bands, are related to graphitic

**Figure 14.** Raman spectra of the films deposited at different temperatures: (a) 400 °C, (b) 500 °C, (c) 600 °C and (d) 700 °C. The samples were excited by a 488-nm Ar<sup>+</sup> laser. The three positions 1150, 1350 and 1580 cm<sup>-1</sup> correspond to nanocrystalline diamond, graphitic D and G bands, respectively. Reprinted with permission from [93], T. Sharda et al., *Diamond Relat. Mater.* 10, 1592 (2001). © 2001, Elsevier Science.

islands [90]. The D band appears due to small domain size in graphite. The band near 1150 cm<sup>-1</sup> is shown to be related to the calculated photon density of states of diamond and has been assigned to the presence of a nanocrystalline phase of diamond [94, 95]. It is observed from Figure 14 that the NCD feature is almost missing in the film grown at 400 °C, and this feature increases with temperature in the film grown at 500 °C and becomes quite pronounced in the films grown at 600 °C followed by a drastic decrease in its intensity at higher temperature. It has also been observed as a weak band in the microcrystalline diamond films along with a sharp peak near 1332 cm<sup>-1</sup> giving thereby the signature of crystalline cubic diamond [21, 96]. It is interesting to note that though the film grown at 600 °C shows an intense band related to NCD, it does not show any peak near 1332 cm<sup>-1</sup>. This is mostly due to uniformly distributed short-range sp<sup>3</sup> crystallites in the films [96, 97]. However, the higher intensities of the graphitic bands in the films grown at 600 °C, as compared to the intensity of NCD features, do not represent high amounts of sp<sup>2</sup> carbon in the film. This is because the cross-section of Raman scattering is 50–60 times higher for sp<sup>2</sup>-bonded carbon in comparison to sp<sup>3</sup>-bonded carbon [98]. This small amount of graphitic carbon in the film may exit between the nanodiamond grains [99]. The variation in the intensity of NCD peak can be taken as a qualitative measure of concentration of NCD grain in the film. It appears that the growth of NCD starts at 500 °C, becomes a maximum at 600 °C, and decreases at higher temperatures.

#### 4.5. Infrared

NCD films deposited by CVD of camphor on Si substrate were analyzed by infrared (IR) spectroscopy [38]. Figure 15 [38] shows the variation of transmittance with wave number of thermal CVD of diamond (curve a) and by rf + dc plasma CVD of CH<sub>4</sub> and hydrogen (curve b). It is observed from these figures that over the IR region, the transmittance of NCD is comparable to that of PCD film [100]. The transmittance of bulk diamond (curve c) is also shown

**Figure 15.** IR spectra of two representative films deposited on Si substrates: (a) deposited by CVD of camphor and hydrogen, (b) deposited by rf + dc plasma CVD of CH<sub>4</sub> + H<sub>2</sub>, (c) the spectrum of bulk diamond for comparison. Reprinted with permission from [38], K. Chakrabarti et al., *Diamond Relat. Mater.* 7, 845 (1998). © 1998, Elsevier Science.

in Figure 15. Clearly, the transmittance of bulk diamond is higher than that of NCD and PCD film. The reduction in transmittance of the CVD diamond is related to the formation of the initial layer of silicon carbide on Si substrate, while for bulk diamond the transmittance is higher as no such substrate effect is observed in this case. In addition, the two-phonon absorption is prominent in bulk diamond. The IR spectrum of CVD film exhibits two small peaks at wave numbers  $\sim 2325$  and  $1050\text{ cm}^{-1}$  that are due to  $\text{CO}_2$  and  $\text{SiO}_2$  absorptions. The CVD diamond films deposited by CVD of camphor +  $\text{H}_2$  have much lower average grain size of  $0.1\text{ }\mu\text{m}$  and smoother surface whereas the films deposited by rf + dc plasma CVD have large polycrystals with average grain size of  $\sim 3.2\text{ }\mu\text{m}$ . No prominent C–H absorption peak around  $2900\text{ cm}^{-1}$  was noticed in IR spectra indicating thereby a good quality of NCD films. On the other hand, the IR spectra of diamond films grown on Si substrates by MPCVD exhibit predominant C–H bands [101]. In particular,  $sp^3\text{-CH}_2$  symmetric stretch at  $2850\text{ cm}^{-1}$  and  $sp^3\text{-CH}_2$  asymmetric stretch at  $2925\text{ cm}^{-1}$  were identified.

## 5. PHYSICAL PROPERTIES

Diamond has unique and remarkable properties, for instance high hardness, low friction coefficient [102], high thermal conductivity [103], high chemical stability, and low or negative electron affinity (NEA) [104]. NEA enables electrons at the conduction band minimum to escape from the diamond without an energy barrier at the surface. However, diamond is a good insulator and therefore it is difficult to deliver electrons to the surface. Similarly diamond is a potential material for wear-resistant applications due to its excellent physical and chemical properties. However, conventional CVD diamond coatings that are deposited at high temperatures possess rough surfaces. The high surface roughness is a major problem when these diamond films are used for machining and wear applications. The successful growth of thin films of NCD at low deposition pressures opens up their large scale uses in tribological applications and field emission display devices.

### 5.1. Mechanical Properties

#### 5.1.1. Surface Roughness

The surface of PCD films is often very rough and hinders their use for optical and tribological applications. The consensus is that efficient ways must be developed to produce smooth diamond films wherein high  $sp^3$  content can be maintained. The NCD films appear promising toward this goal. It is well known that the key parameter to obtain smooth NCD films is the primary nucleation density of diamond nuclei on the substrate. Nucleation densities exceeding  $10^{10}\text{ cm}^{-2}$  can be achieved by ultrasonically scratching the substrate surface with fine-grained diamond powder [9, 105, 106]. A direct relationship between the grain size of diamond powder and primary nucleation density on the substrates, and consequently the optical transparency, has been observed. Other parameters such as the methane fraction in the source gas and the substrate temperature can also affect the morphology and the size of the crystallites. However, previous studies

have only focused on the variations in grain size of the diamond powder, keeping the methane fraction in the source gas either constant or varying it over only a small range. The optimized value of the optical transparency at  $700\text{ nm}$  and beyond was about 60% and the surface roughness was about  $20\text{ nm}$  [9, 105, 106]. The effects of both the grain size of diamond powder and methane fraction in the source gas over a wide range on the microstructure and the optical transmittance of the films have been investigated by these researchers.

The substrate pretreatment involved ultrasonic polishing of the substrates with diamond powder of two different grain sizes,  $4\text{ nm}$  and  $0.1\text{ }\mu\text{m}$ , for  $8\text{ h}$ , followed by standard chemical cleaning with acetone and de-ionized water. For convenience, hereafter the substrates treated with  $4\text{ nm}$  diamond powder will be designated as nanometer-scratched and those treated with  $0.1\text{ }\mu\text{m}$  diamond powder as micrometer-scratched. Both types of substrates were placed together in the deposition chamber. Notably, for no ultrasonic polishing at all or polishing for less than  $8\text{ h}$  with either of the powders, the resulting films were not continuous, indicating that the substrates were not uniformly and entirely scratched for less than  $8\text{ h}$  of treatment. The substrates were also cleaned in pure hydrogen plasma at  $1.5\text{ kW}$  for  $30\text{ min}$  before the depositions. Typical deposition time was about  $3\text{--}4\text{ h}$  to give a film thickness of about  $0.5\text{ }\mu\text{m}$ .

Typical surface profiles of NCD films grown at two methane fractions on nanometer- and micrometer-scratched substrates are presented in Figure 16 [5]. At low methane fraction, the micrometer-scratched sample had a rough surface whereas the nanometer-scratched sample was smooth. Under this specific condition, the average surface roughness is comparable to the respective average grain size, which in turn is directly related with the powder size used for substrate pretreatment. Surprisingly, this correlation between the average grain size and the surface roughness was not observed in the samples prepared at high methane fraction. For films deposited at 31% methane fraction, despite the similarity in the grain size distribution and the average grain size ( $\sim 30\text{ nm}$ ), the nanometer-scratched sample has a much rougher surface [root mean square (rms) of roughness  $\sim 100\text{ nm}$ ] than its micrometer-scratched counterpart with rms of roughness  $\sim 8\text{ nm}$ . Shown in Figure 17 [5] are some typical transmission spectra of these NCD films. It is observed that the transparency of NCD film is strongly dependent not only on the methane fraction but also on the pretreatment of the substrate. The optical absorption edge for most of the NCD films was quite similar to that for type IIa diamond. However, detail tailing near the absorption edge varied from sample to sample, presumably due to the structural imperfections of the films, as well as the internal light scattering at the grain boundaries. Optical transparency over 60% in the spectral range of  $0.6\text{--}2.0\text{ }\mu\text{m}$  is considered sufficiently high for most practical applications [105].

For comparison, a variation in the transmittance at  $700\text{ nm}$  as a function of the methane content of the source gas is depicted in Figure 18 [5]. Since most of the optical transmittance spectrum showed the influence of interference of the light in the film, the value of a smooth curve that represented the average behavior has been used. At lower methane fractions, the films grown on nanometer-scratched

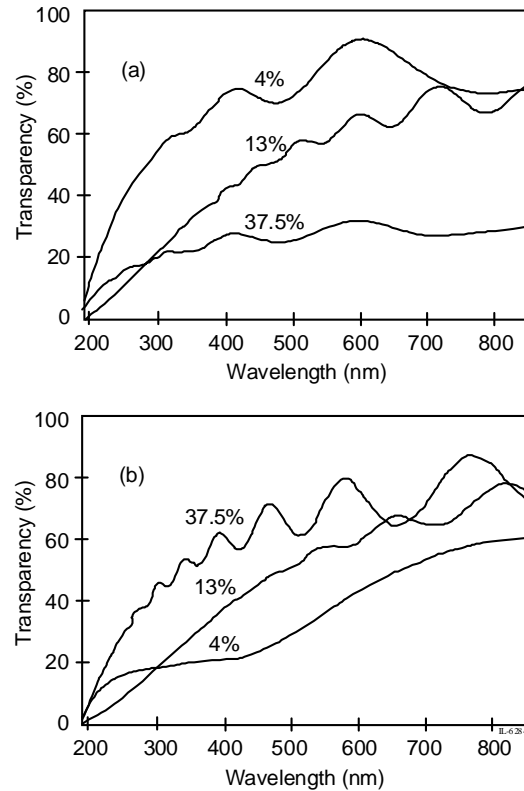

**Figure 16.** Surface profiles of NCD films grown at (a), (b) methane fraction of 4%, nanometer- and micrometer-scratched substrates, respectively; (c), (d) methane fraction of 31%, nanometer- and micrometer-scratched substrates, respectively. Both pairs of films have similar thickness of about  $0.55 (\pm 0.05) \mu\text{m}$ . Reprinted with permission from [5], L. C. Chen et al., *J. Appl. Phys.* 89, 753 (2001). © 2001, American Institute of Physics.

substrates were considerably more transparent than those on micrometer-scratched substrates. However, as the methane fraction increased, the difference between the transmittance of these two types of films diminished and actually reversed at a methane fraction of 20%, such that beyond this methane fraction, the films grown on micrometer-scratched substrates were more transparent than those on nanometer-scratched substrates. The films grown on micrometer-scratched substrates remained highly transparent until a methane fraction of 42%, while those on nanometer-scratched substrates became fairly opaque for methane fractions beyond 25%. Figure 19 [5] shows the plot between the optical transmittance at 700 nm and the inverse surface roughness and clearly reveals the existence of a region showing a linear relationship between the two parameters. In a second region, saturation of the optical transmittance of the films to 80% to 84% occurred despite continuing reduction in their surface roughness. Thus, the major factor that dictates the optical transmittance of NCD films is the surface roughness, instead of the grain size, provided that the contents of the  $sp^2$ -bonded carbon and the structural disorder were negligible.

### 5.1.2. Hardness

The indentation technique has been most widely used for the determination of hardness. This technique is suitable for films with higher thickness since the method requires

**Figure 17.** Optical transmittance spectra of the NCD films grown on (a) nanometer-scratched and (b) micrometer-scratched substrates at various methane fractions. Reprinted with permission from [5], L. C. Chen et al., *J. Appl. Phys.* 89, 753 (2001). © 2001, American Institute of Physics.

a penetration depth ( $h$ ) so that  $h < 0.1d$ , where  $d$  is the film thickness [107]. The stress/strain and hardness in thin films may be evaluated indirectly by measuring the physical properties that are influenced by the mechanical properties.

Chakrabarti et al. [38] studied the effect of mechanical stress on the optical absorption band tail to determine the strain ( $\delta a/a$ ) from the theoretical curve-fitting method. This being a nondestructive technique is often very useful since the film may be utilized for other applications.

If  $\alpha$  and  $\alpha_0$  are the absorption coefficients at any wavelength ( $\lambda$ ) and at the band edge, respectively, then a plot of  $\alpha/\alpha_0$  vs  $(Eg - h\nu)$ , as shown in Figure 20 [38], may be used to obtain the strain ( $\delta a/a$ ) in the film by using the curve-fitting procedure [108]. The stresses ( $S$ ) in the films were obtained from the relation

$$S = Y(\delta a/a)/(1 - \gamma)$$

with Young's modulus  $Y = 600$  GPa and Poisson's ratio  $\gamma = 0.11$ . The hardness ( $Hv$ ) in the films were obtained from [109]

$$Hv = 2.9[Y/(1 - \gamma)](100.0/x)^{-nc}(\delta a/a)^{1-nc}$$

where  $nc$  is the strain-hardening coefficient and  $x$  is the indentational strain. The values of  $S$ , ( $\delta a/a$ ), and  $Hv$ , for NCD films grown from CVD of camphor at various temperatures, were obtained and are in the range 1.9–8.4 GPa,  $(2-12) \times 10^{-3}$ , and 47–62 GPa, respectively [38].

## 5.2. Thermal Properties

### 5.2.1. Thermal Stability

To investigate the thermal stability of NCD films grown on mirror-polished Si substrates by biased enhanced MPCVD, the NCD films were annealed in an ambient Ar atmosphere at 200, 400, 600, and 800 °C [110]. The structural and

**Figure 20.** Plot of  $\alpha/\alpha_0$  vs  $(Eg - h\nu)$  for four representative films deposited on quartz substrates,  $\alpha_0$  being the absorption coefficient at the band edge  $Eg$ . Reprinted with permission from [38], K. Chakrabarti et al., *Diamond Relat. Mater.* 7, 845 (1998). © 1998, Elsevier Science.

mechanical properties of as-grown and annealed NCD films were evaluated. Shown in Figure 21 [110] are the Raman spectra of the as-grown and annealed samples of NCD films. The spectra consist of bands near 1150, 1350, 1500, and 1580  $\text{cm}^{-1}$ . The bands near 1350 and 1580  $\text{cm}^{-1}$  are D and G bands, respectively, and are related to graphitic islands. Another band near 1150  $\text{cm}^{-1}$  is assigned mainly to the presence of the nanocrystalline phase of diamond [15, 88, 90]. The band intensity near 1500  $\text{cm}^{-1}$  varies proportionally with

**Figure 21.** Raman spectra of the (a) as-grown and annealed samples at (b) 200 °C, (c) 400 °C, (d) 600 °C, and (e) 800 °C. Reprinted with permission from [110], T. Sharda et al., *J. Nanosci. Nanotech.* 1, 287 (2001). © 2001, American Scientific Publishers.

the band intensity near  $1150\text{ cm}^{-1}$  and is related to the disordered  $sp^3$  carbon in the films [12, 15]. The Raman results in this case indicate association of these Raman features closer to NCD. If these features were related to hydrogen, their intensity should have decreased with annealing temperature, because the hydrogen should have started to evolve from the samples after  $200\text{ }^\circ\text{C}$  [111]. On the other hand, if these features are related to  $sp^2$ -bonded carbon, their intensities should have increased with annealing temperature as the concentration of  $sp^2$  carbon increases with annealing temperature [111, 112]. Figure 22 [110] depicts the plot of the intensity ratio of the Raman features near  $1150\text{ cm}^{-1}$  to the graphitic G band as a function of annealing temperature. The ratio does not change significantly as a function of annealing temperature and shows an increasing trend up to  $400\text{ }^\circ\text{C}$  but saturates at higher temperatures to a lower value, which is identical to the value of the as-grown sample. Figure 23 [110] depicts the cubic crystalline diamond features in the XRD patterns of the NCD films, which also support to some extent the conjecture that the Raman feature near  $1150\text{ cm}^{-1}$  is related to NCD. In addition, the calculated interplanar spacings corresponding to the peaks at  $2\theta \sim 44.05^\circ$  and  $75.25^\circ \pm 0.20^\circ$  in XRD patterns of the films closely match the interplanar  $d$ -values of (111) and (220) planes of cubic diamond, respectively. The full width at half maximum of diamond peaks in the films is high as compared to the CVD grown microcrystalline films and these observations are well correlated with that of diamond nanocrystallites [21]. It should be noted that no XRD peaks associated with graphite or features related to amorphous carbon could be identified either in the as-grown films or in the annealed films. These results support the assignment of the Raman feature near  $1150\text{ cm}^{-1}$  to the presence of NCD. Similarly, the intensity ratio of the Raman NCD to the graphitic G band does not change much with annealing temperature, indicating thereby the structural stability of NCD films to temperatures as high as  $800\text{ }^\circ\text{C}$ .

**Figure 22.** Plot of the Raman intensity ratio of NCD ( $I_n$ ) to the graphitic G band ( $I_g$ ) as a function of annealing temperature. ### 5.2.2. Specific Heat Capacity

The specific heat capacity bears important implications on various parameters like thermal conductivity, diffusivity, and thermal expansion. The independent measurement of this quantity is important to gain an understanding of the thermodynamic behavior of NCD. The specific heat capacity of NCD samples has been measured by differential scanning calorimetry [113]. Shown in Figure 24 [113] is the plot of the specific heat at constant pressure  $C_p$  for the type IIb diamond stone, coarse-grained diamond, NCD, amorphous carbon, and reference data (solid line [114]) vs temperature. The  $C_p$  values of the coarse-grained sample are found to be lower than the reference data by less than 10% but are consistent with the measured  $C_p$  of the diamond single

**Figure 24.** Specific heat  $C_p$  of poly- and nanocrystalline CVD diamond, amorphous carbon and single-crystalline diamond (solid line: [114]) versus temperature. Reprinted with permission from [113], C. Moelle et al., *Diamond Relat. Mater.* 7, 499 (1998). © 1998, Elsevier Science.

crystal. The NCD sample exhibits a higher  $C_p$  at 50 °C and slightly lower values for  $T > 100$  °C. The accuracy of the experimental values for the NCD and amorphous sample is limited by the very small sample amount and is estimated to be about 15% based on repeated test runs. The  $C_p$  values of the amorphous carbon films are found to be increased by  $0.5 \text{ J g}^{-1} \text{ K}^{-1}$  compared to the reference data and are due to the different atomic short-range order and the  $sp^2:sp^3$  bonding composition in the amorphous structure. Additionally, the large amount of hydrogen homogeneously incorporated in the amorphous structure contributes to the increase of  $C_p$ .

The  $C_p$  data of the coarse-grained diamond and NCD sample deviate from the reference data by a maximum of 15%. Since the microstructure and hydrogen concentration considerably differ between them, it can be concluded that these properties have a negligible impact on the specific heat. These results are in good agreement with those of large-grained thick CVD diamond films [115]. The impact of nondiamond phases on the specific heat appears to be small. A residual volume fraction of amorphous carbon in the nanocrystalline sample should make a small contribution to  $C_p$ , with  $C_p$  of the second amorphous phase being increased by a factor of about 2. The fact that the specific heat data of the CVD diamond samples fall within a 15% interval around the reference data up to 300 °C implies that the temperature dependence of the thermal expansion coefficient should be the same as that of single-crystalline diamond.

### 5.3. Optical Properties

Figure 25 [38] presents the optical transmittance ( $T_r$ ) versus wavelength ( $\lambda$ ) traces of three NCD films deposited at different substrate temperature ( $T_s$ ) on quartz. It may be observed that the transmittance ( $T_r$ ) had a high value ( $\sim 93\%$ ) for  $T_s > 673$  K. The direct and indirect bandgaps ( $E_{gd}$  and  $E_{gi}$ ), estimated from the corresponding plots of  $(\alpha h\nu)^2$  vs  $h\nu$  and  $(\alpha h\nu)^{1/2}$  vs  $h\nu$  is presented in Figure 26 [38], where  $E_{gd} = 4.84$  eV and  $E_{gi} = 2.18$  eV. It may be noted that both the direct and indirect bandgaps were high and their values increased with increasing  $T_s$ . The surfaces of the as-deposited films were generally  $sp^2$  rich. The  $sp^2$  phases from the surfaces of the films could be removed either by etching in oxygen plasma or by using a chemical process [116, 117]. After etching, the absorption edge of the optical spectra became sharper than that of the as-deposited film as presented in Figure 27 [38]. There was also a substantial increase in the direct bandgap ( $E_{gd}$ ) due to the removal of the  $sp^2$  phase from the film surface by etching, although the change of indirect bandgap ( $E_{gi}$ ) was insignificant. The variation of bandgap energy due to removal of the  $sp^2$  phase etching was similar to that reported earlier for NCD films deposited by high pressure sputtering of vitreous carbon target [118] and for diamond films deposited by CVD of freon-22 and hydrogen [119]. In fact, the etching characteristics of diamond films may provide the information of  $sp^2$  graphitic and  $sp^3$  diamond structure in the film because the trigonal  $sp^2$  phase can be more easily etched than the tetragonal  $sp^3$  [120, 121]. The etch rate will be higher in films

having low  $sp^3/sp^2$  ratio and also the effect of the etching on the optical absorption edge will be higher in  $sp^2$ -rich film.

The refractive index ( $n$ ) of the films was estimated from the transmittance spectra.  $n$  varied within 1.3 to 1.5 in most of the as-deposited nanodiamond films showing practically no significant change with the variation of wavelength. The low value of  $n$  may be due to the presence of a significant amount of  $sp^2$  phases in the surface of the as-deposited film. Removal of  $sp^2$  by surface etching resulted in higher  $n$  values (i.e., within 1.8–2.2).

#### 5.4. Electrical Conductivity

Nitrogen doped ultrananocrystalline diamond (UNCD) films with 0.2% of total nitrogen content were synthesized by MPCVD, and temperature dependences of electrical conductivity of these films are reported [122]. These results are shown in Figure 28 [122]. In addition, Figure 28a shows secondary ion mass spectroscopy (SIMS) data for the total nitrogen content in the films as a function of the percentage of  $N_2$  gas added to the plasma. Along with these data is a plot of the room temperature conductivities for the same. The graph shows that the nitrogen content in the films initially increases but then saturates at  $\sim 2 \times 10^{20}$  atoms/cm<sup>3</sup> for 5%  $N_2$  in the plasma, which is  $\sim 0.2\%$  total nitrogen content. The increase in room temperature conductivity is dramatic and represents an increase by roughly five orders of magnitude over undoped UNCD films. The value of conductivity increases from  $0.016 \Omega^{-1} \text{cm}^{-1}$  for 1%  $N_2$  to  $143 \Omega^{-1} \text{cm}^{-1}$  for 20%  $N_2$ . The latter value is much higher than  $n$ -type diamond [123, 124] and is comparable to heavily boron-doped  $p$ -type diamond [125].

**Figure 28.** (a) Total nitrogen content (left axis) and room temperature conductivity (right axis) as a function of nitrogen in the plasma. (b) Arrhenius plot of conductivity data obtained in the temperature range 300–4.2 K for a series of films synthesized using different nitrogen concentrations in the plasma as shown. Reprinted with permission from [122], S. Bhattacharya et al., *Appl. Phys. Lett.* 79, 1441 (2001). © 2001, American Institute of Physics.

Figure 28b depicts the temperature dependent conductivity of nitrogen doped UNCD film over the temperature range of 300 to 4.2 K. This graph clearly exhibits finite conduction for temperatures even as low as 4.2 K. This behavior is also seen in heavily boron-doped diamond thin films. These graphs are indicative of multiple, thermally activated conduction mechanisms with different activation energies. Hall measurements have been carried on two samples. The carrier concentrations for the 10% and 20%  $N_2$  sample were found to be  $2.0 \times 10^{19}$  and  $1.5 \times 10^{20} \text{cm}^{-3}$ , respectively, and the carrier mobility of 5 and  $10 \text{cm}^2/\text{Vs}$  for 10% and 20%  $N_2$  samples, respectively. The negative value of the Hall coefficients indicates that electrons are the majority carriers in these films. It is proposed that conduction occurs via the grain boundaries. Nitrogen in microcrystalline diamond thin films usually forms a deep donor level with an activation energy of 1.7 eV [123]. It is therefore likely that the enhanced conductivity in UNCD is due to nitrogen doping

of the grains. The nitrogen in these films is present predominantly in the grain boundaries and not within the grains.

## 6. APPLICATIONS

The high optical transmittance, mechanical, and electrical properties of NCD films offer ample opportunities for applications in electron emitting cold cathodes, tribology, MEMS, electrochemical electrodes, surface acoustic wave (SAW) devices, and NCD coatings. A brief discussion of the results of research in these areas is provided.

### 6.1. Electron Emission

Field electron emission, which has important applications in the field of flat panel displays and high performance electron guns, has been a subject of extensive studies for many years. Early studies used sharp geometry [126] to attain the local field enhancement necessary to extract electron from materials with high work functions, such as Mo or W. This requires complex and expensive patterning and fabricating process. Another approach is to explore new materials with lower emission thresholds. In the past few years, diamond [125, 127] has attracted much attention. It is widely recognized that the property of NEA that can be displayed by diamond does not alone make this material ideal for low field electron emission applications. Few electrons exit in the conduction band of diamond, which is difficult to dope *n*-type, making transport of electrons from metallic contacts and emission of electrons from the diamond surface difficult. However, fine grain, highly defective diamond films have shown more promise, presumably due to the presence of a network of grain boundaries and a higher level of nondiamond carbon, which can increase the material's conductivity. These films, often called NCD films, are being investigated for field emission display devices [4].

The development of field emission flat panel displays (FEDs) has triggered very intense research especially in various kinds of carbon thin films because one of their properties is to emit electrons at relatively low applied electric field [127, 128]. A wide range of carbon films, such as amorphous and diamondlike carbon [129, 130], CVD diamond [125, 131], and single and multiwalled carbon nanotubes [132, 133], have shown field emission current in the mA range for applied fields below 10 V/ $\mu\text{m}$ . Cold cathode field emission has been demonstrated in CVD PCD films. In the undoped CVD diamond films, the space-charge-limited current limits the conductance of the bulk. As a result, grain boundaries, which are highly disordered and may contain codeposited graphitic impurities, have been suggested as the main conducting pathway. Because reduction in diamond grain size may increase the conducting pathways, it is possible to improve diamond field emission by depositing size controlled diamond films.

The field emission of CVD grown diamond films shows very analogous behavior to the emission of diamondlike carbon films. CVD diamond films of good quality characterized by a sharp and intense 1332  $\text{cm}^{-1}$  Raman peak seem to exhibit poor field emission properties. Zhu et al. [134] reported a relation between the quality of the diamond films measured by the full width at half maximum (FWHM) of

the Raman 1332  $\text{cm}^{-1}$  line and the field emission properties. By decreasing the crystalline quality and monitoring it by the FWHM of the 1332  $\text{cm}^{-1}$  Raman line, the threshold field to get an emission current of 1 nA decreases [134]. The NCD films show a very weak Raman line or even its absence and exhibit threshold field below 5 V/ $\mu\text{m}$ . Numerous models such as classical tip emission [135], emission from the conduction band due to a negative electron affinity [136], defect band emission [134], and field enhancement at conducting channels in an insulating matrix [137] have been suggested to explain the low field electron emission of CVD diamond films.

The current-voltage characteristics of NCD films were measured at a base pressure of  $10^{-8}$  Torr. The field emission measurements were performed using a Keithley 237 instrument with an incorporated high voltage. The emission current is collected by a graphite counter electrode placed 30  $\mu\text{m}$  above the anode. The experimental procedures for current density measurements were described in detail elsewhere [138]. Figure 29 [139] shows the typical electron emission characteristics of a NCD film deposited on nanometer-scratched (4 nm) substrate with methane of 20%. These films were grown for 4 h at 900  $^{\circ}\text{C}$  and demonstrate an emission current density of 15  $\text{mA}/\text{cm}^2$  at an applied field of 17 V/ $\mu\text{m}$  with turn-on field of 12 V/ $\mu\text{m}$ . Here the turn-on field expresses a value of field at emission current density of 0.01  $\text{mA}/\text{cm}^2$ . The field emission characteristics of the NCD films are further analyzed by the Fowler-Nordheim (FN) plot, a plot of  $\log I/V^2$  vs  $1/V$ , as depicted in Figure 30 [139]. The plot yields a straight line according to the FN equation [140],

$$J = \frac{A}{\phi} \left( \frac{\beta V}{d} \right)^2 \exp \left( \frac{-B\phi^{3/2}}{\beta V} \right)$$

where  $A$  and  $B$  are constants, current density  $J$  is in  $\text{A}/\text{m}^2$ , voltage  $V$  is in volts, anode-to-cathode distance  $d$  is in meters,  $\phi$  is the effective barrier height for electrons in eV, and  $\beta$  is the field enhancement factor that depends on the

emitter geometry. Consequently, a plot of  $\log(J/V^2)$  vs  $1/V$  yields a straight line with slope  $B\phi^{3/2}d/\beta$  indicating that the field emission property can be explained by a tunneling mechanism. The slope of the FN plot can be used to determine the work function of the emitter. These studies indicate that the NCD films would be suitable for application in electron emission devices as these devices operate at  $10 \text{ mA/cm}^2$ .

The field emission properties of the NCD films [138] can be explained by a conducting-tunneling mechanism. A model based on the graphite/nanodiamond mix-phase structure reported earlier [141] is considered. The NCD films used for field emission measurements were grown on silicon substrates. In such a structure, graphite plays the role of conducting channels from the silicon substrate to the film surface. While on the surface, it is assumed that the nanodiamond has a relatively low or even NEA as that of bulk. Thus electron will first tunnel through the nearby diamond edges and then emit from the diamond surface [127, 142]. There are two main parameters deciding the field emission. The first is the diamond grain size and the other is graphite content in the film. As electrons from the diamond/graphite interface must tunnel through a barrier between them, the diamond grain size is a critical factor determining the tunneling probability. For large-size diamond grains, electrons can only be emitted from regions close to crystal edges, which are thin enough for electrons to tunnel through. In contrast, for small-size diamond grains, electrons can be effectively emitted from a larger surface area, or even the whole diamond surface, thus greatly increasing the emission site density. The graphite content is another critical factor as the emission starts from the diamond/graphite interface. There is an optimum graphite content for maximizing the graphite/diamond interface area on the film surface. The optimal value of the graphite content is just enough to fill the gaps between the densely agglomerated diamond grains. Above this value, a decrease in graphite content will increase the diamond/graphite interface area and thus enhance field emission. But when the graphite content is below this value, a decrease in graphite content will decrease the interface area at the surface, and the field emission properties will drop. Moreover, a further decrease of the graphite content

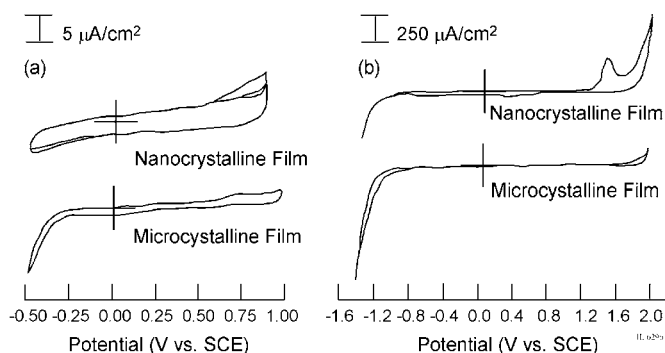

will make it insufficient to form conducting channels; thus the emission properties will be rapidly degraded. Recently, field emission from nitrogen-incorporated NCD films has also been reported [143]. All these studies indicate that NCD will be an excellent candidate for cold cathode materials for field emission devices.

## 6.2. Electrochemical Electrodes

The use of diamond in electrochemistry is a relatively new field of research that has begun to blossom in recent years [144, 145]. Conductive diamond possesses several properties that distinguish it from conventional  $sp^2$  carbon electrode, like glassy carbon, and makes it most promising for electroanalysis [146–148]. These distinguishing properties are (i) background current densities an order of magnitude lower than freshly polished glassy carbon, (ii) a working potential window of 3 to 4 V in aqueous media, (iii) an extremely stable surface structure resulting in better response precision and long-term response stability, (iv) a high degree of response activity for several aqueous-based analytes, and (v) weak adsorption of polar adsorbates such that the electrode material resists fouling and passivation. It has been demonstrated that untreated diamond outperforms freshly polished glassy carbon in terms of limit of quantitation, response precision, and response stability [146–148].

It is therefore necessary to understand the factors that influence electron transfer at conducting diamond thin film electrode. These electrode materials are challenging to investigate because these are typically polycrystalline with multiple crystallographic orientations, and because they contain extended and point defects, grain boundaries, and low levels of nondiamond carbon impurity. The multiple crystallites, defects, and possible nondiamond carbon phases could provide discrete sites for heterogeneous electron transfer. Within this context, NCD films are challenging as it is nearly pure diamond. Recently, the electrochemical properties of NCD thin films deposited from  $C_{60}/Ar$  and methane/nitrogen gas mixture were investigated [149].

Figure 31 [149] depicts the cyclic voltammetric  $i$ - $E$  curve for a nanocrystalline diamond film deposited from a  $C_{60}/Ar$  mixture and a boron-doped, microcrystalline diamond film deposited from a  $CH_4/H_2$  mixture. The voltammograms were obtained in  $1 \text{ M H}_2\text{SO}_4$  at  $50 \text{ mV/s}$ . The open circuit potential of the untreated nanocrystalline film was  $+174 \text{ mV}$  (vs saturated calomel electrode (SCE)). Figure 31a shows voltammograms for nanocrystalline and microcrystalline film between  $-0.5$  and  $1.0 \text{ V}$  (vs SCE). The curve for the nanocrystalline film is basically featureless within this potential range, and after the initial scan, the curves are reproducible in shape. The anodic current at  $0.1 \text{ V}$  is  $2.5 \mu\text{A/cm}^2$ , and this is significantly smaller than the cathodic current,  $20 \mu\text{A/cm}^2$  observed for polished glassy carbon. The open circuit potential for the untreated microcrystalline film was  $+205 \text{ mV}$  (vs SCE). The voltammogram for this film between  $-0.5$  and  $1.0 \text{ V}$  is not quite as featureless, as there are two small anodic and cathodic peaks at  $0.75$  and  $0 \text{ V}$ , respectively. These features are associated with a quasi-irreversible but as yet unknown surface redox process, probably at the nondiamond carbon impurities in the grain boundaries. The peak current ratio is near 1, so the

**Figure 31.** Cyclic voltammetric  $i$ - $E$  curves for a nanocrystalline diamond film deposited from a 1%  $C_{60}/Ar$  gas mixture and a boron-doped microcrystalline diamond film deposited from a 0.3%  $CH_4/H_2$  gas mixture over (a) a potential range from  $-0.5$  to  $1.0$  V (vs. SCE) and (b) a potential range from  $-1.6$  to  $2.0$  V (vs. SCE). The electrolyte was  $1$  M  $H_2SO_4$  and the potential sweep rate for (a) was  $50$  mV/s and for (b) was  $25$  mV/s. Reprinted with permission from [149], B. Faussett et al., *Electroanalysis* 12, 7 (2000). © 2000, Wiley-VCH.

surface sites that are being oxidized on the forward sweep are fully reduced on the reverse sweep. The anodic current at  $0.1$  V is  $0.7 \mu A/cm^2$ , which is a factor of 4 lower than the value observed for the NCD. It should be noted that the microcrystalline films show no evidence for any surface redox processes. The slightly higher background current for this particular nanocrystalline film has been mentioned due to the increased fraction of grain boundary carbon.

Figure 31b shows voltammograms for the nanocrystalline and microcrystalline films between  $-1.4$  and  $2.0$  V (vs SCE). The electrolyte was  $1$  M  $H_2SO_4$  and the potential sweep rate was  $25$  mV/s. The working potential window in this medium for the NCD film is ca.  $3$  V ( $\pm 250 \mu A/cm^2$ ) and is larger than the ca.  $2.5$  V window observed for freshly polished glassy carbon. The response shows a large anodic peak at  $1.5$  V and a smaller cathodic peak at  $0.4$  V. The anodic peak at  $1.5$  V is likely due to redox-active carbon in the grain boundaries. This indicates that some reduction of these surface carbon-oxygen functionalities must occur during the cathodic potential sweep in order to allow for their reoxidation on the subsequent forward sweep. The voltammogram for the boron-doped microcrystalline film, between  $-1.4$  and  $2.0$  V, reveals a working potential window of  $3.3$  V, which is slightly wider than observed for NCD films. The voltammogram shows an anodic peak at  $1.8$  V just prior to oxygen evolution; however, the peak charge is significantly less than that for the NCD films. This reflects the reduced coverage of redox-active grain boundary carbon on the microcrystalline films.

These studies indicate that NCD films prepared from  $C_{60}/Ar$  gas mixtures appear to have basic electrochemical properties similar to boron-doped microcrystalline diamond films with a wide working potential window and a low voltammetric background current. The potential application of NCD in electroanalysis seems to be due its nanocrystalline structure.

### 6.3. Tribology

The unique properties of diamond (i.e. the highest hardness, stiffness, and thermal conductivity as well as imper-

viousness to acidic and saline media) are exceptional and far exceed those of any other known material. The cleaved diamond surfaces exhibit one of the lowest friction coefficients of any known material. The combination of these qualities in a material is ideal for highly demanding tribological applications. The prospects for large-scale uses of diamond in tribology increased sharply when it was discovered that diamond can be grown as thin films at low deposition pressures by various methods [150–153]. High quality microcrystalline diamond films exhibit most of the desired properties of the natural diamonds. They are made up of large columnar grains that are highly faceted and generally rough. They tend to grow continuously rougher as the thickness of the deposited films increases. The generally rough surface finish of these films precludes their immediate uses for most machining and wear applications. When used in sliding-wear applications, such rough films cause high friction and very high wear losses on mating surfaces [154–156]. The rough surface can be polished by laser beams and fine diamond powders or by rubbing against a hot iron plate [157]. Despite the high interest in using diamond films for diverse tribological applications, their widespread utilization in the industrial world has not yet met expectations [158–160]. Recently, new methods have been developed for deposition of smooth NCD films [161] and the films afford ultralow friction and wear in sliding tribological applications.

As elaborated above, conventional diamond films are generally rough and consist of large grains. Depending on deposition conditions, these grains exhibit  $\langle 111 \rangle$  or  $\langle 100 \rangle$  crystallographic growth orientations. Figure 32 [162] depicts the friction coefficients of microcrystalline diamond films (surface roughness:  $0.35 \mu m$ , rms) and NCD (surface roughness:  $30$  nm, rms) films against  $Si_3N_4$  balls in open air and dry  $N_2$  [162]. After an initial run-in period during which friction is relatively high, the friction coefficient of the NCD film decreases rapidly to  $\sim 0.1$  in open air and to  $\sim 0.05$  in dry  $N_2$ , whereas the friction coefficient of the microcrystalline diamond film remains high and unsteady in both test environments.

Wear rates of  $Si_3N_4$  balls slid against the smooth NCD and rough microcrystalline diamond films in air and dry  $N_2$  are shown in Figure 33 [162] which clearly shows that the wear rates of balls slid against the NCD films are more than two orders of magnitude lower than the wear rates of balls slid against the rough microcrystalline diamond (MCD) films. The high friction coefficients of rough diamond films can be attributed to the abrasive cutting and plowing effects of sharp asperity tips on softer counterface pins, whereas the plowing effects created by smooth NCD films on counterface balls are minimal and thus exhibit lower friction. Previous studies also demonstrated a close correlation between higher surface roughness and greater frictional losses [155, 163, 164]. When the rough MCD films were polished and then used in sliding-contact experiments, very low friction coefficients were obtained [161, 163, 164].

Apart from physical roughness, surface chemistry and tribo-induced adhesive interactions can also occur and play a dominant role in the friction and wear performance of all diamond films [165]. The nature and extent of interactions may be controlled by the environmental species or by ambient temperature [166]. Mechanistically, the low-friction

**Figure 32.** Friction coefficients for rough MCD and smooth NCD films against  $\text{Si}_3\text{N}_4$  balls in (a) open air and (b) in dry  $\text{N}_2$ . (Test conditions: load, 2 N; velocity,  $0.05 \text{ m s}^{-1}$ ; relative humidity, 37%, sliding distance, 40 m, ball diameter, 9.55 mm.) Reprinted with permission from [162], A. Erdemir et al., *Surf. Coat. Technol.* 120–121, 565 (1999). © 1999, Elsevier Science.

nature of smooth or cleaved diamond surfaces has long been attributed to the highly passive nature of their surfaces [167, 168]. Specifically, it has been postulated that gaseous adsorbates, such as hydrogen, oxygen, or water vapor, can effectively passivate the dangling surface bonds of diamond. When the dangling bonds become highly passive, the adhesion component of friction is diminished [162]. Thus, unlike most other engineering materials, NCD offers

**Figure 33.** Wear rates of  $\text{Si}_3\text{N}_4$  balls slid against smooth NCD and rough MCD in air and dry  $\text{N}_2$  (test conditions: load, 2 N; velocity,  $0.05 \text{ m s}^{-1}$ ; relative humidity, 37%; sliding distance, 40 m; ball diameter, 9.55 mm). Reprinted with permission from [162], A. Erdemir et al., *Surf. Coat. Technol.* 120–121, 565 (1999). © 1999, Elsevier Science.

a combination of low friction and high wear resistance under a wide range of sliding-contact conditions. NCD coatings have been applied to seals using dc-biased substrates and an oxyacetylene torch [161, 169].

#### 6.4. Superhard Nanocrystalline Composites

Materials with Vickers hardness of  $\geq 40 \text{ GPa}$  are called superhard materials. The hardness of diamond depends on its quality and is typically in the range of 70 to 90 GPa. It is limited by dislocation sliding and crack propagation along the  $\langle 111 \rangle$  crystallographic direction [170, 171]. The theoretical strength of ideal single crystalline materials can be easily estimated from the critical stress, which is needed to cause shear sliding of lattice planes [172]. However, the practically achievable strength of single crystals and engineering materials is orders of magnitude smaller because plastic deformation and fracture occur due to inherent flaws, such as multiplication and propagation of dislocations and crack growth, which are present in the materials. The design of novel superhard materials is based on the formation of stable nanocomposite consisting of two or more phases, for example nanocrystals of hard transition metal nitride imbedded in an amorphous phase [173–175]. When such a nanostructure is formed by a thermodynamically driven segregation of transition metal nitride and silicon or boron nitride, it is fairly stable against recrystallization even at high temperatures of  $\geq 1000 \text{ }^\circ\text{C}$  [176, 177]. The resulting strong interface and compact grain boundaries avoid grain boundary sliding, which would otherwise limit the strength and hardness of nanocrystalline materials [178–181]. Beside the hardness, the nanocomposites also show a very high elastic recovery of 80% to 90% and toughness. The nanocrystalline diamond seems to be one of the promising superhard nanocomposite materials if the properties of NCD are properly tailored. The superhardness combined with a high elastic recovery and toughness will be very important for many practical applications.

Hardness of a material is a measure of its ability to resist deformation upon load. Hence, the meaning of hardness depends on the exact nature of that load resulting in various kinds of engineering scales of hardness, such as scratch, static contact indentation, or dynamic ones. The most universal measure of the hardness is the energy of the plastic or pseudoplastic deformation, which is calculated from the ratio of the applied load to the area of that deformation. Depending on the shape of the indenter used, various scales of the static hardness result. For the characterization of thin films the Vickers or alternatively Knoop hardness is most commonly used. During the measurement a diamond indenter of pyramidal shape with an angle between the opposite faces of  $136^\circ$  is pressed into a material with a given load  $L$  and after unloading, the area of the remaining plastic deformation  $A$  is measured. The hardness in GPa or  $\text{kg/mm}^2$  is then calculated from the equation  $H = \alpha L/A$ , where the constant  $\alpha$  depends on the type of the indenter which differs by the angles between the opposite faces of the diamond pyramid. Figure 34 [175] shows examples of indentation into a NCD and into ultrahard  $nc\text{-TiN}/a\text{-}$  and  $nc\text{-TiSi}_x$ ,  $x \approx 2$ . It should be noted that the measurements on super- and ultrahard materials including diamond show large scattering and, therefore,

**Figure 34.** Example of indentation into (a) NCD and (b) nc-TiN/a- & nc-TiSi<sub>x</sub> ( $x \sim 2$ ) coatings. The area between the lower (loading) and upper (unloading) curve corresponds to the energy of pseudoplastic deformation, the area between the loading curve and the y-axis corresponds to the total energy of deformation. Reprinted with permission from [175], P. Nesladek and S. Veprek, *Phys. Status Solidi A* 177, 53 (2000). © 2000, Wiley-VCH.

the obtained values of hardness should be considered as relative ones. Therefore, one can conclude from Figure 34 that the microhardness of the nc-TiN/a- and nc-TiSi<sub>x</sub> films is at least equal to that of the hardest diamond.

## 6.5. Conformal Coatings

The excellent mechanical properties of diamond suggest that diamond is one of the best materials for MEMS applications. In addition, the chemical inertness of diamond makes it a suitable as a corrosion protection material. Recently, NCD film growth has been demonstrated on various substrates of engineering interest [182]. The substrate of choice in most diamond deposition studies has been silicon while for metals, the thermal expansion mismatch between the diamond film and substrate gives rise to thermal stress, which often results in delamination of the film. Thus, one of the major barriers in obtaining a diamond film that is resistant to delamination is the inherent difference between the coefficient of thermal expansion between the diamond film and a metal substrate.

The desirable mechanical properties with coating containing NCD and/or amorphous carbon have been reported [183]. The combination of nanocrystalline and amorphous carbon components can result in coatings with high toughness, high hardness, and low surface roughness [183, 184]. These films are believed to consist of NCD grains imbedded in a primarily amorphous carbon matrix, which itself

has some  $sp^3$ -bonded carbon content. These coatings have been produced with hardness up to 80% that of natural diamond and yet still exhibit appreciable toughness uncharacteristic of a pure ceramic material [182]. NCD coatings can be tailored in their coating structure and mechanical properties by appropriate changes in CVD feed gas chemistry [182]. The relative concentration of CH<sub>4</sub> and N<sub>2</sub> is shown to strongly influence coating structure, hardness, and adhesion. This can provide an opportunity to choose a balance between coating hardness and toughness as required for a particular application.

There is general agreement that diamond film growth occurs most readily on pure metal that supports the formation of a stable carbide layer. There has been controversy as to whether the formation of a surface carbide film was a prerequisite for diamond growth. Ramanathan et al. [185] have studied the transition metals and found that diamond growth is supported by those metals that tend to produce stabilized  $sp^3$  carbon structures. Diamond film adhesion is critically linked to the thermal expansion mismatch between diamond and metal. At higher deposition temperatures more stress may be induced in the film, providing a higher driving force for film buckling or delamination. Ager and Drory [186] measured a residual compressive stress of about 7 GPa for a diamond film on Ti-6Al-4V that was in excellent agreement with the stress predicted from calculation. With such large residual film stresses it would be advantageous to be able to deposit diamond at low substrate temperature. It has been well established that adding small quantities of oxygen can lower the temperature range for which diamond can grow [187, 188]. A small amount of CO and O<sub>2</sub> diluted in H<sub>2</sub> has also resulted in high quality diamond growth at substrate temperatures in the range of 411 to 750 °C [189]. However, in high H<sub>2</sub>-dilution conditions, the deposition rate decreases rapidly with temperature. This is because the precursor radical that is widely believed to be responsible for diamond growth under high H<sub>2</sub> dilution is thermally activated [190, 191].

An interlayer can be used as a barrier to the diffusion of carbon into the substrate, thus providing sufficient carbon concentrations at the surface to nucleate diamond. The interlayer may also be used in order to minimize interfacial stresses and to provide an intermediate layer for bonding. Diamond deposition onto WC-Co and steel substrates has been achieved using a multilayer structure of silver and refractory metals with a resulting improvement in adhesion [192]. Such coating is typical of that required for good WC-Co cutting tool properties. Figure 35 [182] shows a thick NCD film grown on WC-Co that was prepared with a chemical treatment prior to coating and it depicts an extremely smooth and flat surface. Similarly, results of conformal coatings of NCD are very encouraging and a good degree of coating conformality has been reported wherein a hexagonal shaped silicon needle  $\sim 5 \mu\text{m}$  in diameter was successfully coated with  $\sim 2000 \text{ \AA}$  NCD [4].

## 6.6. SAW Devices

SAW devices have found several key applications in radio frequency and microwave electronics [193]. They offer a high degree of frequency selectivity with low insertion loss,

**Figure 35.** Thick NCD coating made on chemically treated surface of WC-Co cutting tool insert. Edge shown is a cutting edge of the tool. Reprinted with permission from [182], R. Thompson et al., in "Proceedings of the 1st ASM International Surface Engineering and the 13th IFHTSE Congress and Exposition" (O. Popoola et al., Eds.), 7–10 October 2002, Columbus, OH. © 2002, ASM International.

making them highly suitable for use as narrow band filters. SAW devices are particularly well adapted to microwave integrated circuits since they can provide a significant size reduction over purely electromagnetic devices. These devices are most typically implemented on piezoelectric substrates on which thin metal film interdigitated transducers (IDTs) are fabricated using photolithography. The use of diamond as a SAW substrate offers an attractive means for relaxing the lithographic criteria [194]. With a surface wave velocity  $\nu \sim 1 \times 10^{14} \text{ m s}^{-1}$ , diamond allows SAW device operation near 2.5 GHz with nominal  $1 \mu\text{m}$  linewidths. Since diamond is not piezoelectric, additional complexity is introduced by a requisite overlayer of a piezoelectric thin film, typically ZnO. Sound propagation in layered media may be highly dispersive and in general admits a multiplicity of allowed modes. Nevertheless, highly successful devices based on ZnO/polycrystalline diamond/Si layered structures have been reported [195–199].

NCD is a new form of diamond and differs from diamondlike carbon in that it contains relatively little hydrogen or  $sp^2$ -bonded carbon. The properties of NCD films like smooth surfaces and small crystallite size are most attractive and relevant for SAW applications, since standard PCD on Si is quite rough and must be smoothed by mechanical polishing before photolithographic processing can be attempted. Furthermore, one expects acoustic scattering at large angle grain boundaries in PCD, especially if lateral grain dimensions exist on length scales between acoustic wavelength and SAW device apertures and transducer separations. The use of NCD eliminates these concerns. SAW devices based on NCD have been fabricated [200] as shown schematically in Figure 36 [200]. This device was studied using a frequency and time domain method. Phase velocities were obtained from device resonant frequencies measured with a network analyzer. Figure 37 [200] presents a compilation of experimental results and calculations of the phase velocity  $\nu$  as a function of  $kh_{\text{ZnO}}$ . It is evident that several modes are allowed for a given value of  $kh_{\text{ZnO}}$ . The modes

**Figure 36.** Schematic diagram of the surface acoustic wave device multilayer structure. Reprinted with permission from [200], B. Bi et al., *Diamond Relat. Mater.* 11, 677 (2002). © 2002, Elsevier Science.

are highly dispersive at small values of  $kh_{\text{ZnO}}$  (i.e., the phase velocity is strongly dependent on  $kh_{\text{ZnO}}$ ). As expected, the lowest order mode tends toward the phase velocity of the Rayleigh wave on (0001) ZnO at large  $kh_{\text{ZnO}}$  but approaches the diamond Rayleigh wave velocity as  $kh_{\text{ZnO}} \rightarrow 0$ . It should be noted that the large phase velocity suggests that carbon within the grain boundaries is strongly bonded. Since surface waves are dominated by elastic shear strains, the grain boundary carbon is highly resistant to bond-bending forces. This indicates that most of the carbon is highly coordinated.

## 6.7. MEMS Devices

Thin film ferroelectrics are important for MEMS because of their strong piezoelectric effect and high energy density originating from the very high dielectric constant of ferroelectric materials [201, 202]. Further, these MEMS devices are fabricated primarily in silicon because of the available surface machining technology. A major problem with Si-based

**Figure 37.** Phase velocities as measured for surface waves on NCD, diamond ( $\blacktriangle$  $\blacklozenge$  $\blackstar$ ) and on large-grain polycrystalline diamond ( $\blacksquare$  $\bullet$ ). The solid line represent calculations of phase velocities based on single crystal diamond material parameters. The label denotes the Rayleigh mode indices for the layered medium. The dashed line shows the Rayleigh wave velocity on ZnO. Reprinted with permission from [200], B. Bi et al., *Diamond Relat. Mater.* 11, 677 (2002). © 2002, Elsevier Science.

**Figure 38.** Combined lithographic patterning and selective deposition methods. Reprinted with permission from [207], A. R. Krauss et al., *Diamond Relat. Mater.* 10, 1952 (2001). © 2001, Elsevier Science.

MEMS technology is that Si has poor mechanical and tribological properties [203, 204]. On the other hand, diamond is an ultrahard material with high mechanical strength, exceptional chemical inertness, and outstanding thermal stability. The friction coefficient of diamond is exceptionally low and the projected wear life is 10,000 times greater than that of Si, making diamond an ideal tribomaterial for MEMS components [205, 206]. Lubrication poses a major limitation on the design of MEMS devices since the usual methods of delivering lubricant to the interface between contacting parts are very difficult to implement. There are a number of ways in which diamond components can be fabricated for MEMS applications using thin film deposition methods [207].

One of the methods of obtaining the tribological benefits of diamond while exploiting the availability of Si fabrication technology is to produce Si components to near-net shape and then to provide a thin, low wear, low friction diamond coating [208–213]. This approach only works if the diamond film can be produced as a thin, continuous, conformal coating with exceptional low roughness on the Si component. Conventional diamond CVD deposition methods result in discontinuous films with a low density of large grains and poor ability to form thin conformal coatings on Si microstructures [214]. Recently, Krauss et al. successfully developed a fabrication technique [207] for conformal UNCD coating that is comparable to the lithography, galvanofarming, Abformung (LIGA) method and permits fabrication of complex three-dimensional shapes as opposed to the two-dimensional structures produced by Si microfabrication methods. The selective deposition represents a second method that may be used for the production of UNCD microstructures but has no analog in Si microfabrication technology. All diamond films require a nucleation layer, usually achieved by exposing the substrate to a suspension

**Table 1.** Mechanical properties of diamond thin films.

Thin films	NCD	UNCD	PCD	Ref.
Grain size	50–100 nm	2–5 nm	0.5–10 $\mu\text{m}$	[113]
Specific heat ( $\text{J g k}^{-1}$ )	0.68	—	0.54	[113]
Friction coefficient	0.06	—	0.35	[168, 207]
Surface roughness	50–100 nm	20–40 nm	400 nm–1 $\mu\text{m}$	[207]
Young's modulus	600 GPa	—	1200 GPa	[38, 207]
Hardness	62 GPa	—	100 GPa	[10, 38]

**Table 2.** Electrical properties of diamond thin films.

Thin films	NCD	UNCD	PCD	Ref.
Direct bandgap	4.84 eV	—	5.45 eV	[38, 74]
Indirect bandgap	2.18 eV	—	—	[38]
Field emission threshold field	1 $\text{V}/\mu\text{m}$	3.2 $\text{V}/\mu\text{m}$	22 $\text{V}/\mu\text{m}$	[8, 140]
Electronic bonding	up to 50% $sp^2$	2–5% $sp^2$	$sp^3$	[207]
H content	<1%	<1%	<1%	[207]

of fine diamond particles. It is possible to seed a selected portion of the substrate by (a) using photoresist to prevent exposure of selected areas to the diamond powder, (b) using diamond-loaded photoresist to produce a patterned nucleation layer, or (c) seeding the substrate uniformly and then selectively etching portions of the surface to remove diamond seeded areas. Alternatively, it is possible to use  $\text{SiO}_2$  as a mask [215–217], since diamond films grown from  $\text{CH}_4\text{--H}_2$  plasmas are normally unable to form on  $\text{SiO}_2$  substrates. The feature resolution that can be achieved by this method is limited by the grain size [216]. The lithographic patterning is the third method to produce diamond multiplayer structures. In this method, it is necessary to deposit a thin diamond film on a sacrificial release layer such as  $\text{SiO}_2$ . Methods have been reported [216, 217] to force the growth of conventional CVD diamond on  $\text{SiO}_2$ , typically by damaging the  $\text{SiO}_2$  surface by ultrasonic abrasion in a diamond powder suspension. Continuous diamond films have been achieved using this method for film thickness in the range 15–20  $\mu\text{m}$  although there are gaps between the film and the substrate, and the films are extremely rough [217]. Diamond films grown from  $\text{CH}_4\text{--Ar}$  plasmas are able to form directly on  $\text{SiO}_2$  substrates without the need for damaging the  $\text{SiO}_2$  layer since the gas-phase carbon dimer growth species in the UNCD process forms an intermediate SiC nucleation layer. The use of  $\text{SiO}_2$  as a sacrificial substrate layer for fabrication of multiplayer UNCD devices has also been demonstrated [207].

Thus by combining selective deposition and lithographic etching of blanket UNCD films, Krauss et al. fabricated multilevel diamond devices [207] using methods that are not feasible or require a large number of steps in Si. A scheme for fabricating a captive rotor using combined methods is shown in Figure 38 [207]. A blanket UNCD film is deposited on a Si substrate, followed by deposition of photoresist to yield the structure shown in Figure 38a. A  $\text{SiO}_2$  layer is then deposited and used as a hard mask in combination with an oxygen plasma etch to produce the structure shown in Figure 38b. A conformal  $\text{SiO}_2$  layer is then deposited, and the trenches are selectively seeded as shown in Figure 38c using one of the methods described in the previous paragraph. The seeded trenches are filled with UNCD, and the  $\text{SiO}_2$  layer is then removed by HF etch, leaving the wheel free within the retaining trench of the stator as presented in Figure 38d. Further UNCD growth results in both an increase in height and a lateral spread of the stator components, which act to capture the rotor within the track as shown in Figure 38e.

## 7. SUMMARY

NCD has many remarkable properties for variety of applications and these films have been recognized as an important class of structures in the family of diamond materials. With the advent of low pressure and temperature CVD techniques, it is now possible to control the microstructure, surface roughness, and optical transmittance of the NCD films. The grain size of the NCD films can be varied from 4 nm to a few hundred of nanometers. The OES investigations indicate that the nucleation and growth mechanism depends on a methane fraction. It is observed that C<sub>2</sub> dimer is the predominant growth species and plays a major role in the growth of NCD films.

The optical transmittance of NCD films is a strong function of the surface roughness but not the grain size of the NCD films. Ultrasoother and highly transparent NCD films can be grown on either nanometer- or micrometer-scratched substrates with either low or high, respectively, methane fractions. These smooth diamond films can be used in mechanical-seal applications, for protection against wear, and as abrasion resistant coatings in several demanding tribological applications. The field emission studies of NCD films showed a substantial reduction in emission turn-on voltage indicating their tremendous promise as a cold cathode material. In addition, these NCD films possess unique electrochemical behavior and also exhibit a great potential for application in SAW and MEMS devices. Thus in view of many interesting properties of NCD films that have been summarized in Tables 1 and 2, they proved to be one of the important emerging nanostructured materials with many potential applications.

## GLOSSARY

**Chemical vapor deposition (CVD)** A method for depositing some of the layers which function as dielectric, conductor, or semiconductor. A vaporized chemical containing atoms of the materials to be deposited reacts with another, liberating the desired material, which deposits on the substrate while the by-products of reaction are removed from the reaction chamber.

**Electron emission** The liberation of electrons from an electrode into the surrounding space, usually under the influence of a high electric field, light, or heat.

**Electron energy loss spectroscopy (EELS)** A technique for studying atoms, molecules, or solids in which a substance is bombarded with monochromatic electrons, and the energies of scattered electrons are measured to determine the distribution of energy loss.

**Field emission display (FED)** This is an array of a million or more electron guns, each exciting a single phosphor pixel. The electron guns are typically triodes.

**Hardness** The measure of a material's resistance to deformation by surface indentation or by abrasion.

**Specific heat capacity** The heat capacity per unit mass of material.

**Surface roughness** The finer irregularities of the surface texture that usually result from the inherent action of the production process or material condition.

**Thermal conductivity** For steady-state heat flow, the proportionality constant between the heat flux and the temperature gradient. Also, a parameter characterizing the ability of a material to conduct heat.

**Transmission electron microscopy (TEM)** A microscope that produces an image by using electron beams to transmit (pass through) the specimen, making examination of internal features at high magnification possible.

**Tribology** The science and technology of two interacting surfaces in relative motion and of related subjects and practices. The popular equivalent is friction, wear, and lubrication in surfaces sliding against each other, as in gears and bearings.

## ACKNOWLEDGMENTS

P. D. K. is thankful to Professor L. C. Chen, National Taiwan University, Taipei, Taiwan, and Professor K. H. Chen, Institute of Atomic and Molecular Sciences, Taipei, Taiwan, for introducing him to the field of nanocrystalline diamond. In addition, he gratefully acknowledges a Post-Doctoral Fellowship from the National Science Council, Taiwan and National Science Foundation–Nanoscale Interdisciplinary Research Teams, USA.

*Tsinghua University, Beijing, China*

## CONTENTS

1. Introduction
  2. Semiconductor  
Nanocrystalline Phosphors
  3. Doped Nanocrystalline Phosphors
  4. Conclusion
- Glossary  
References

## 1. INTRODUCTION

Phosphors are defined as solid, inorganic, crystalline materials that show luminescence upon excitation [1]. According to the excitation source, phosphors can be divided into photoluminescence phosphors, cathode luminescence phosphors, X-ray luminescence phosphors, electroluminescence phosphors, etc. The excitation sources are, respectively, photons, electrons with a high kinetic energy, X-ray, and electrons with a low kinetic energy [2].

Phosphors have been studied for a long time, and have been widely used in such areas as fluorescent lamps (FLs), X-ray photography, cathode-ray tube (CRTs), electroluminescence display (ELDs), and so on. With the development of nanoscience and nanotechnology, many investigations have focused on nanocrystalline phosphors, including semiconductor nanocrystals and doped nanocrystals. It is interesting to know what the differences are between the bulk and nanoscale phosphors in terms of their properties. In addition, there is currently a great deal of interest in the production of novel types of bright, high-resolution, and high-contrast emissive displays, such as high-definition TVs, field-emission displays, plasma displays, and electroluminescent devices. In these applications, the required properties are high purity, compositional uniformity, high luminous efficiency, low-energy excitation source, and small and uniform particle-sized powders [3, 4]. Nanocrystalline (<50 nm) luminescent materials are potentially well suited for the applications [5]. The demand of these new technologies has stimulated a search for new materials and synthesis techniques to improve the performance of phosphors.

In the early stage, most of the studies in nanocrystalline phosphors focused on semiconductor phosphors. This is because, when semiconductor particles become smaller than the Bohr radius, the so-called quantum-size effect occurs. As a result, these semiconductor nanocrystals not only provide many unique opportunities for studying physics in low dimensions, but also exhibit novel optical properties which are potentially useful for technological applications. It is important in both basic and applied research.

Recently, the number of scientific publications on the optical properties of transition or rare-earth metal-doped nanocrystals has increased. Some new nano-related phenomena, such as luminous efficiency, lifetime, quenching concentration, and so on, have been reported. Many new methods for the preparation of nanocrystalline phosphors have also been developed.

This chapter reviews recent work on the synthesis, luminescent properties, and potential applications of nanocrystalline phosphors. In Section 2, we discuss semiconductor nanocrystalline phosphors, and in Section 3, we discuss doped nanocrystalline phosphors.

## 2. SEMICONDUCTOR NANOCRYSTALLINE PHOSPHORS

Semiconductor nanocrystals (also known as quantum dots or QDs) have attracted a great deal of interest from all disciplines, including chemistry, physics, materials, and even biology, due to their attractive properties such as size-tunable optical properties [6, 7]. Furthermore, many promising technical applications in the field of biomolecular labeling [8, 9], solar cell [10, 11], laser [12], and light-emitting diodes [13, 14] have attracted commercial interest. Over the last decade, rapid progress has been made in the preparation of nanocrystal semiconductors. They mainly include the II–IV compounds (ZnS, CdSe, CdS) [15], III–V compounds (InP, GaAs) [16], IV–VI compounds (which mostly refers to some kinds of chalcogenides [17]), and Si [18]. In the following, we discuss them respectively. Because the II–VI and III–IV semiconductor nanocrystals share almost the same synthesis procedure and optical properties as CdSe, these two parts are discussed together.

## 2.1. II–IV and III–V Compounds

### 2.1.1. Synthesis

**Synthesis of CdSe Nanocrystals** In particular, II–IV and III–V compounds have attracted much attention because the preparation of nanocrystalline CdSe leads to an unprecedented degree of monodispersity and crystalline order [19]. Shape-controlled methods have been developed to prepare nanocrystals of different shapes [20, 21]. The investigation of the size-dependent optical absorption has been carried in detail [22]. In the following section, CdSe is used as an example for semiconductor nanocrystals. Its preparation, optical properties, and technical application are discussed. The synthesis of other II–IV and III–V semiconductor nanocrystalline phosphors is shown in Table 1.

There are two main synthetic methods for the preparation of nanosized CdSe. However, both need ligands to derivatize the surface to keep the nanocrystals stable in a solution. Stabilizing ligands must be present during growth to prevent aggregation and precipitation of the nanocrystals. The stabilizing molecules attach onto the nanocrystal surface as a monolayer through covalent, dative, or ionic bonds. Most of them use organic surface derivation in organic solution, and

others use organic or inorganic ones (such as cetyltrimethylammonium bromide, CTAB) in an aqueous solution, as shown in Figure 1.

The synthesis of colloid semiconductor nanocrystal CdSe is based on the pyrolysis of organometallic reagent (cadmium dimethyl,  $\text{Cd}(\text{CH}_3)_2$ ) with selenium (Se) powder by injection into a vigorously stirred flask containing a hot coordinating solvent (200–360 °C) [23]. The coordinating solvent can be amine, phosphonic acid, or phosphine oxide, which serves as a ligand/solvent for the synthesis of high-quality CdSe nanocrystals, as shown in Eq. (1):

Furthermore, fatty acids have also been developed as useful coordinating solvents. This method provides temporally discrete nucleation, and permits controlled growth of macroscopic quantities of nanocrystallites. Size-selective precipitation of crystallites from portions of the growth solution isolates samples with narrow size distributions

**Table 1.** Synthesis of other II–IV and III–V nanocrystals.

Semiconductor	Synthetic method	Size (nm)	Quantum efficiency	Ref.
CdSe	$\text{Cd}(\text{CH}_3)_2 + \text{Se-TOP}$ (in hot TOPO)	1.1–11.5		[40]
	$\text{CdCl}_2 + \text{Na}_2\text{Se}$ (CTAB as surfactant)	Nanorods		[41]
	$\text{Cd}^{2+} + \text{SeO}_3^{2-} + \text{N}_2\text{H}_4$ (hydrothermal method)	Nanorods and fractal		[42]
	$[\text{Cd}(\text{SePh})_2]$ thermolysis	3		[43]
	$\text{Cd}[\text{Se}_2\text{CNRR}']_2$ thermolysis	3–8		[44]
	$\text{CdO}$ [or $\text{Cd}(\text{C}_2\text{O}_4)$ ] + HPA (or TDPA, ODPA) + Se TOPO	Nanorods, tetrapods		[45]
CdS	$\text{CdC}_2\text{O}_4 + \text{Se}$	6–20 × 100–500 (nanorods)		[46]
	$\text{Li}_4[\text{Cd}_{10}\text{Se}(\text{Sph})_{16}]$ , pyrolysis	2–9		[47]
	$\text{S}$ (in THF) + $\text{CdCl}_2 + \text{KBH}_4$	4–8		[48]
	$\text{CdO} + \text{S} + \text{oleic acid} + \text{octadecene}$	1–6		[49]
	$\text{Cd}[\text{S}_2\text{CNRR}']_2$ , thermolysis	3–7		[50]
	$\text{Cd}(\text{NO}_3)_2 + \text{P}_2\text{S}_5$ in ethanol	Less than or equal to 6		[51]
ZnSe	$\text{Cd}(\text{CH})_3 + \text{S}(\text{TMS})_2$ in hot TOPO	2–3		[52]
	$\text{Li}_4[\text{Zn}_{10}\text{Se}(\text{Sph})_{16}]$ , pyrolysis	2–5		[53]
ZnS	$\text{Zn}(\text{CH}_3)_2 + \text{Se-TOP}$ (hexadecylamine/trioctylphosphine)	4.3–6	20–50%	[54]
	$\text{S}$ (in THF) + $\text{ZnCl}_2 + \text{KBH}_4$	4–8		
CdTe	$\text{Zn}[\text{S}_2\text{CN-Me}(\text{C}_6\text{H}_{13})_2]$ in hot TOPO			[55]
	$\text{H}_2\text{Te} + \text{Cd}(\text{ClO}_4)_2 + \text{RSH}$	2–5	40%	[56]
	$\text{Cd}(\text{CH}_3)_2 + \text{Te}$ (TOP + dodecylamine as solvents)	2.5–7	30–65%	[57]
ZnTe	$\text{Cd}^{2+} + \text{NaHTe} + \text{mercaptoacetic acid}$		18%	[58]
	$[\text{Zn}(\text{TePh})_2][\text{TMEDA}]$ with TOP in dodecylamine	4.2–5.4		[59]
InAs	$\text{InCl}_3 + \text{As}[\text{Si}(\text{CH}_3)_3]_3$ (TOP)	2.5–6		[60]
	$\text{In}(\text{Ac})_3 + \text{As}(\text{TMS})_3 + \text{octadecene}$			[61]
InP	$\text{In}(\text{PBut}_2)_3 + 4\text{-ethylpyridine}$	7.4		[62]
	$\text{InCl}_3 + \text{KBH}_4 + \text{P}$	11.3–20		[64]
	$\text{In}(\text{Ac})_3 + \text{P}(\text{TMS})_3 + \text{octadecene}$			[65]
	$[\text{R}_2\text{InP}(\text{TMS})_2]_2$ in hot TOPO and TOP	2–6.5		[66]
GaP	$\text{InX}_3$ ( $X = \text{Cl, Br, I}$ ) + $\text{P}(\text{SiMe}_3)_3$			[67]
	$\text{Na, P, and GaCl}_3$ in benzene	20–40 × 200–500 nanorod		[68]
	$(\text{Na/K})_3\text{P} + \text{GaCl}_3$ in 1,4-dioxane	11–21		[69]
GaAs	$[\text{R}_2\text{GaP}(\text{TMS})_2]_2$ in hot TOPO and TOP	2–6.5		[70]
	$(\text{Na/K})_3\text{As} + \text{GaCl}_3$ in 1,4-dioxane	6–36		[71]
	$\text{GaCl}_3 + \text{As}(\text{SiMe}_3)_3$ in quinoline	4.5		[72]

**Figure 1.** Two major surface modification schemes for the CdSe nanocrystals.

(<5% rms in diameter). Although numerous reports have been published in which CdSe was prepared using inorganic cadmium salts in an aqueous solution [24], the luminescence is much lower than organometallic synthesis. One possible reason is that the synthesis process operates at a much higher temperature, and may crystallize better than in an aqueous solution. It would be very helpful for the colloidal nanocrystals to have a good optical property [25].

It is well known that organometallic compounds are very unstable, apart from being toxic, expensive, and explosive. They are usually stored in the refrigerator inside a glove box. Fortunately, some alternative cadmium compounds have been developed via a different route. Simple inorganic and organic cadmium such as CdO [26] and  $\text{Cd}(\text{Ac})_2$  [27] can be candidates for the cadmium precursor. They are low-cost, safe, and easily controlled precursors. The resulting nanocrystal is nearly monodispersed without any exceptional size separation, and is reproducible. The reaction is simple and mild. Furthermore, the formation of nanocrystals with the concept of “user-friendly chemistry” was achieved by growing the nanocrystals in a mixture of octadecene (ODE) and oleic acid with CdO as the cadmium precursor [28].

Apart from spherical nanocrystals, the formation of nanocrystals of various shapes, including nanorods, -arrows, -teardrop, -tetrapod, and branched tetrapod-shaped nanocrystals, has also been achieved by adjusting the components of the coordinating solvent [21, 29]. The coordinating solvent is a mixture of pure trioctylphosphine oxide (TOPO) and hexylphosphonic acid (HPA). In general, experimental results show that the coordinating solvent TOPO must be technical grade if the semiconductor nanocrystal is synthesized using an organometallic precursor. In fact, TOPO and HPA are very similar. HPA can be called a ligand, which can be substituted by tetradecylphosphonic acid or octadecylphosphonic acid. The initial cadmium and selenium precursor ratio (Cd:Se ratio), the injection and growth temperature, and the concentration of the precursor all play key roles in determining the shape of the resulting nanocrystals and luminescent quantum efficiency. Usually, low temperature and a high precursor concentration lead to the formation of perfect nanorods.

In comparison with bulk semiconductors, there are more surface atoms for nanocrystals. Thus, the semiconductor nanocrystals are more likely to undergo epitaxial overgrowth than other inorganic compounds. Furthermore, there are many defective surface atoms unless they are passivated. To remove these defects, core/shell-type composite CdSe/ZnS

has been studied by several groups [30–32]. Overcoating the core of lower bandgap nanocrystals with a higher bandgap shell has improved the photoluminescence quantum yield by passivating surface nonradiative recombination sites. It has also been reported that the epitaxial growth graded CdS/ZnS shells on the colloidal CdSe nanorods [33]. The core/shell nanorods have increased the photoluminescence quantum yield and improved the photostability.

**Modification of CdSe** As mentioned earlier, nanocrystal CdSe is prepared in a coordinating solvent such as an amine, or a phosphine oxide with long alkyl tails. These organic reagents are usually called surfactants, a capping group, or ligands. They improve the stability of nanocrystals by adsorbing a monolayer on the surface. If nanocrystals lose the surface ligand, they will precipitate out, and the luminescence is totally lost. The ligands are usually hydrophobic. So the nanocrystal CdSe can easily be dispersed in many nonpolar solvents such as hexane, toluene, and pyridine.

Usually, it is necessary to modify the nanocrystals with a hydrophilic reagent if they are going to be dispersed in an aqueous solution. Some strategies have been pursued to develop hydrophilic nanocrystals [8, 34, 35]. The trick depends on supplying the nanocrystal surface with thiolated molecules having a free carboxyl group facing the solution that warrants water solubility. In general, the longer the alkyl chain is, the longer the modified nanocrystals remain dispersed in the aqueous solution. To improve the stability of thiol-coated nanocrystals in an aqueous solution, chelating agents were introduced for surface modification, instead of the commonly used monothiols [36]. In fact, all monothiol-coated CdSe nanocrystals have shown very profound photochemical instability in an aqueous solution [37]. The main reason is that the mercapto ligands on the surface can be oxidized photochemically to disulfides, which then leave the surface and expose the nanocrystal in air. The naked nanocrystals could also be photooxidized, and eventually precipitate out. So free thiols in a solution help to improve the stability of nanocrystals modified with hydrophilic thiols. According to the above mechanism of the photochemical instability of the thiol-coated nanocrystals, it is believed that a thick and densely packed ligand layer would be helpful in inhibiting the photooxidation. Organic dendritic ligands have been developed to stabilize nanocrystals [38]. They are hyperbranched organic molecules with thiol groups as the central focal point of the binding site for the cationic elements, and hyperbranched groups to inhibit oxygen diffusion to the surface of nanocrystals. The closely packed and tangled ligand shell provides sufficient stability to withstand the rigor of the coupling chemistry.

An alternative was reported in which CdSe nanocrystals were embedded in a polymerized silica shell [9, 39]. Mercapto silane was attached onto the surface, and a siloxane shell of 1–5 nm thickness was developed through pyrolysis of the silane reagent. The siloxane shell can be functionalized with thiols and/or amines on the surface. The silanized nanocrystal can be dispersed in buffer solutions in a wide pH range, even at a high salt concentration. The photoluminescence properties depend weakly on the pH of the solution due to the protection of the silicon shell. The silanized nanocrystals have quite a good quantum yield, and

are stable for months. They also have optical properties similar to that of thiol-coated nanocrystals. However, the thiol modification is much easier to carry out. The silanization process, although rather difficult to develop, results in better stability.

**Synthesis of Other II–IV and III–V Nanocrystals** The popular pyrolysis method with TOPO as the solvent medium has also been used by Alivisatos [8, 9] in the synthesis of InP (2–5 nm) or InAs nanocrystals (2.5–6 nm). The method was based on the reaction of  $\text{InCl}_3$  and  $X[\text{Si}(\text{CH}_3)_3]_3$  ( $X = \text{P}$  or As) in TOPO at elevated temperatures, as shown in Eq. 2:

The nanocrystals are highly crystalline, monodisperse, and soluble in various organic solvents. Improved size distributions have been obtained by size-selectively reprecipitating the nanocrystals. X-ray photoelectron spectroscopy (XPS) shows that the nanocrystals have a nearly stoichiometric ratio of indium to phosphorus, with the TOPO surface coverage ranging from 30 to 100%.

The synthesis of other II–IV and III–V nanocrystals is summarized in Table 1.

### 2.1.2. Optical Properties

**Optical Properties of CdSe** Due to the quantum-size effect, semiconductor nanocrystals exhibit many unique properties when their size is smaller than their Bohr radius (about 1–5 nm) [7, 73]. Semiconductor nanocrystals of different sizes show diverse properties. The optical absorption spectrum of semiconductor nanocrystals supplies accessible and straightforward information to evaluate the quantum-size confinement effect. An electron was excited from the valence band to the conduction band via absorbing a photon, which is associated with the bandgap energy ( $E_g$ ). The absorption of photons with energy similar to that of the bandgap,  $h\nu \geq E_g$ , leads to an optical transition producing an electron in the conduction band and a hole in the valence band.

CdSe semiconductor nanocrystals have a broad excitation range and a narrow emission range compared with temporal organic dyes. Their spectral width (full width at half maximum) usually spans 27–40 nm at room temperature, compared with 20 nm for a CdSe single crystal because of the inhomogeneous emission properties of the nanocrystals [74, 75]. Different from organic dyes, there is a

substantial Stokes shift in the luminescence of nanocrystals. The optimized excitation and emission filters for semiconductor nanocrystals can allow light passage for nearly the entire excitation and emission peaks, which permits detection of more fluorescence output than that of organic dyes. Semiconductor nanocrystals have a rather high cross section ( $\sim 10^5$  mol/cm), which means that they can efficiently absorb the light that is irradiated. And the photoluminescence quantum yield for the as-prepared nanocrystals increases by about 20% for bare dots, and by 30–50% for dots passivated with ZnS at wavelengths of 520 and 600 nm. Photoefficiency is lower at wavelengths below 520 nm or longer than 600 nm. [76]. It can be concluded that the semiconductor nanocrystals have a strong emission due to their large cross section and high quantum yield. The CdSe nanocrystals are rather stable against photobleaching. The emission wavelength of CdSe can be tuned from 450 (center) to 650 nm (center) by changing the particle size [77, 78]. It has been reported that light emission from single CdSe under continuous excitation turns on and off intermittently with a characteristic time scale of about 0.5 s [79–81]. The on/off time can change when a passivating, high-bandgap shell of ZnS encapsulates the nanocrystal.

### Optical Properties of Other II–IV and III–V Nanocrystals

The optical properties of other II–IV and III–V semiconductor nanocrystals are shown in Table 2.

## 2.2. IV–VI Compounds (Lead Chalcogenides)

Just as we reviewed earlier, II–IV and III–V semiconductor nanocrystals have been widely investigated. As for the IV–VI semiconductor nanocrystals, reports in this area mainly focus on lead chalcogenides, that is, PbS, PbSe, and PbTe. The growth of these semiconductor nanocrystals of uniform size distribution has been reported [89–92]. These nanocrystals are of interest because of their large Bohr radius (10 nm for PbS and 15 nm for PbSe), which permits quantum-size effects to be clearly visible, even for large particles or crystallites. These large Bohr exciton radii result in a strong confinement of the electron–hole pair. Nasu et al. [93] observed a significant bandgap shift from the IR region to the near-UV region, depending on the small size of the PbS crystallites. An enhanced photoluminescence was also reported [94] for PbS nanocrystals by Thielsch and co-workers. But reports on their optical properties remain scarce; studies in this area are preliminary; more work needs to be done.

**Table 2.** Optical properties of other II–IV and III–V semiconductor nanocrystals.

Semiconductor	Bandgap (bulk, eV)	Electron affinity (eV)	Bandgap (nanocrystals, eV)	Quantum efficiency (nanocrystals, %)
ZnSe	2.58	4.09		20–50 [82]
CdSe	1.74	4.95	1.88–3.62	20–85 [83]
CdTe	1.5	4.28	1.9–2.2	35–65 [84]
CdS	2.53	4.79	3.0–4.06 [85]	
InAs	0.36	4.9	1.05–1.55 [86]	8–20 [87]
InP	1.28	4.4	2.1–2.5 [88]	

### 2.3. Si

Since the strong room-temperature visible luminescence in porous silicon was discovered by Canham [95] in 1990, the study of the fabrication and light-emitting properties of various Si-based nanomaterials has received worldwide attention over the past few years. Si-based nanomaterials are some new photoelectronic and informational materials developed rapidly in recent years. These kinds of materials include nanoscale porous silicon, Si nanocrystalline-embedded SiO<sub>2</sub> matrices, Si nanoquantum dot, Si/SiO<sub>2</sub> superlattice, etc.

The synthesis of Si-based nanomaterials with high quality is very important in order to obtain efficient and stable luminescence. Thus far, various growth technologies have been developed, including chemical-vapor deposition [96, 97], Si-ion implantation [98], laser-ablation deposition [99], self-assembling growth [100], and so on.

When the Si nanocrystallite size is reduced, the bandgap will become large, and will create the quantum energy level in the conductor band and valence band. As a result, not only is the luminescent intensity increased, but also the peak energy is blue shifted [101]. Kanzawa et al. [102] measured the photoluminescence spectra of Si nanocrystals embedded in SiO<sub>2</sub> films as a function of size. They found that, as the average particle size decreased from 3.8 to 2.7 nm, the photoluminescence peak energy exhibited a blue shift from 1.42 to 1.54 eV, and its peak intensity increased progressively. This phenomenon was also observed by Takagi et al. [103]. They found that the luminescent intensity was inversely proportional to the square of the crystallite size from 2.8 to 5.6 nm.

## 2.4. Applications of Semiconductor Nanocrystals

Due to the attractive characteristics of colloid semiconductors, that is, variable emission colors, electron affinities, and ionization potentials, they have showed significant potential as luminescent chromophores ranging from biological luminescent tags, lasers, as well as light-emitting diodes to solar cells.

### 2.4.1. Biological Application

The fluorescent tag is a popular tool in biological detection. Organic dyes are most widely used in this area. Semiconductor nanocrystals have been applied as promising luminescent tags. Compared with the dyes, they have several potential advantages: a rather large Stokes shift, wide excitation and a relatively narrow emission peak (full width at half maximum, 20–30 nm), various emission wavelengths (400–2000 nm), a large extinction coefficient in the visible and ultraviolet range ( $\sim 10^5 \text{ M}^{-1} \cdot \text{cm}^{-1}$ ), high quantum yield (core-shell nanocrystals, >50%), a rather strong antiphotobleaching capability, and a relatively long luminescence lifetime ( $\sim 30$ –100 ns) at room temperature. Furthermore, semiconductor nanocrystals of different sizes may be excited with a single wavelength, resulting in many emission colors that may be detected simultaneously. The environment of semiconductor nanocrystals contributes little to their emission.

Consequently, semiconductor nanocrystals might be promising biological tags. There have been reports on immunoassay [104], immunohistochemical assay [105], live-cell detection [106], and multicolor detection [107].

### 2.4.2. Photovoltaic Device and Solar Cell

The semiconductor nanocrystals possess a relative large electron affinity and spectrally narrow luminescence compared to many traditional electroluminescent organic polymers. They show some desirable properties in that they can be spin coated, can be used on a large area. They are flexible, with potential thermal and electronic stability [108–109]. Consequently, the semiconductor nanocrystals have been made into bilayer light-emitting diodes with organic electroluminescent semiconducting polymers such as poly(p-phenylenevinylene). The device made from different sized semiconductor nanocrystals can emit from red to green with a relatively high conversion efficiency, a low operating voltage, and hundreds of hours of lifetime under constant current flow. As a class of electroluminescent materials, semiconductor nanocrystals offer many of the processibility advantages of polymers, along with potentially stable, long-lived operation. If the semiconductor nanorods are mixed with some conjugated polymers, they can be manipulated readily [110]. Tuning the length and diameter of the nanorods, the distance of electron transfer and the overlap between the absorption spectrum and the solar emission can be optimized. The power conversion efficiency of the reported device can be 1.7%.

### 2.4.3. Laser

Theoretically, semiconductor nanocrystals have some advantages as a gain medium, including temperature insensitivity, lower lasing threshold, and a gain profile concentrated into a much narrower luminescence spectrum. Such advantages have motivated the use of semiconductor nanocrystals as the medium of the laser. Semiconductor nanocrystal-based lasers with optical pumping have been successfully developed using nanocrystal-titania chemistry [111]. The output color of the laser can be selected by choosing appropriately sized nanocrystals, operating at room temperature or below. The experience with semiconductor nanocrystal thin-film systems has opened the possibility of UV and IR lasers using corresponding nanocrystals.

## 3. DOPED NANOCRYSTALLINE PHOSPHORS

In addition to semiconductor phosphors, there is another very important class of phosphors, called transition or rare-earth metal-doped phosphors. For the doped phosphors, transition or rare-earth metals act as luminescent centers. Since the wavelength of the characteristic luminescence of the doped metals hardly changes with size confinement, doped nanocrystals do not require the stringent control of size needed in semiconductor nanocrystalline phosphors. In fact, most of the phosphors employed in technological applications belong to doped phosphors. Such phosphors find

applications ranging from conventional fluorescent lighting to color TV picture tubes, X-ray photography, and so on. For example, the three components in trichromatic fluorescent lamps are  $\text{BaMgAl}_{10}\text{O}_7:\text{Eu}^{2+}$  (blue),  $\text{CeMgAl}_{10}\text{O}_{19}:\text{Tb}^{3+}$  (green), and  $\text{Y}_2\text{O}_3:\text{Eu}^{3+}$  (red) [112].

Nanoscale doped-phosphors are currently attracting a great deal of interest for both fundamental photophysics study, and important applications including display and sensor technologies [5, 113–115]. New synthetic techniques and effects of nanoscale confinement have motivated significant new interest in these materials [116, 117]. It is important and interesting to study the doped nanocrystalline phosphors.

So far, reports on doped nanocrystalline phosphors mainly focus on the following areas: (1) rare-earth metal-doped nanocrystals, such as  $\text{Y}_2\text{O}_3:\text{Eu}$ ,  $\text{Y}_2\text{O}_3:\text{Tb}$ ,  $\text{ZnS}:\text{Eu}$ ,  $\text{ZnS}:\text{Tb}$ ,  $\text{ZnS}:\text{Sm}$ ,  $\text{YVO}_4:\text{Ln}$ ,  $\text{LaPO}_4:\text{Ln}$ ,  $\text{ZnSiO}_4:\text{Ln}$  ( $\text{Ln} = \text{Eu}^{3+}$ ,  $\text{Tb}^{3+}$ ),  $\text{Y}_2\text{SiO}_5:\text{Eu}$ , and (2) transition metal-doped nanocrystals, such as  $\text{ZnS}:\text{Mn}$ ,  $\text{ZnS}:\text{Cu(I)}$ ,  $\text{ZnS}:\text{Cu(II)}$ ,  $\text{ZnS}:\text{Cu,In}$ , and  $\text{CdS}:\text{Mn}$ . In the following part, the preparation method, nanosize-related optical properties, and technical applications of doped nanocrystalline phosphor will be reviewed.

### 3.1. Rare-Earth Metal-Doped Nanocrystals

#### 3.1.1. Synthesis

The reported preparation methods include gas-phase condensation, flame-spray pyrolysis (FSP), coprecipitation, sol-gel, block copolymer, reverse microemulsion, combustion synthesis, colloidal chemistry, and hydrothermal method.

**Gas-Phase Condensation Method** Tissue and co-workers have prepared monoclinic nanocrystals by a gas-phase condensation method using  $\text{CO}_2$ -laser vaporization of  $\text{Y}_2\text{O}_3:\text{Eu}$  ceramic pellets, and condensing the nanocrystals from the gas phase [5, 118].  $\text{Y}_2\text{O}_3:\text{Eu}$  with an average diameter of 23 nm was obtained. The average production rate was 11 mg/h. The main problem of the method is, when the doped concentration of  $\text{Eu}^{3+}$  is above 0.7%,  $\text{Y}_2\text{O}_3:\text{Eu}$  and a secondary  $\text{Eu}_2\text{O}_3$  phase will occur due to a kinetic effect of the gas-phase condensation method.

**Flame-Spray Pyrolysis Method** There is also a well-established technology called flame-spray pyrolysis (FSP), which is used by the industry to produce nanocrystalline phosphors [119–121]. This process involves combusting aerosols of single-metal and mixed-metal metalloorganic alcohol solutions with oxygen or air in a reaction chamber at temperatures of 1200–2000 °C. By this method, rare-earth doped  $\text{Y}_2\text{O}_3$  nanocrystalline phosphors with a size of 60 nm have been prepared.

**Sol-Gel Method** For the sol-gel method, dilute solutions of metalloorganics or metal salts are reacted to form an irreversible gel, then dried and shrunk to an amorphous or weakly crystalline mass. This kind of method has been widely used to prepare different kinds of doped nanosized phosphors, including  $\text{Tb}^{3+}$  and  $\text{Eu}^{3+}$  doped  $\text{Zn}_2\text{SiO}_4$  [122],  $\text{Y}_2\text{SiO}_5:\text{Eu}$  [123],  $\text{Y}_2\text{O}_3:\text{Eu}$  [124],  $\text{SrAl}_2\text{O}_4:\text{Dy, Eu}$  [125], etc. Sharma et al. have synthesized nanocrystalline  $\text{Y}_2\text{O}_3:\text{Eu}$  by an improved sol-gel method in the presence of surface modifiers. The particle size gradually decreased from 6  $\mu\text{m}$

to 10 nm with an increase of the modifier from 0 to 10wt% with respect to  $\text{Eu}_2\text{O}_3/\text{Y}_2\text{O}_3$  [126].

The advantage of this method is that atomically mixed powders are obtained in the as-synthesized condition. However, these as-synthesized materials must also be heat treated to high temperatures to crystallize the desired phase. Also, the processing steps to prepare the precursor powders are complicated and time consuming.

**Homogeneous Coprecipitation Method** In this kind of method, urea or thioacetamide is used to produce  $\text{OH}^-$  or  $\text{S}^{2-}$ . Due to the characteristics of urea and thioacetamide,  $\text{OH}^-$  or  $\text{S}^{2-}$  may be increased very slowly and homogeneously throughout the whole solution. The gradual and uniform rise in  $\text{OH}^-$  or  $\text{S}^{2-}$  can result in the nucleation and growth of uniformly nanosized hydroxide or metal sulfide particles. Nanocrystalline  $\text{Y}_2\text{O}_3:\text{Eu}$  has been prepared by the homogeneous precipitation of  $\text{Y}^{3+}$  and  $\text{Eu}^{3+}$  with urea [127].

**Block Copolymer Method** This method uses copolymers as steric stabilizers. The copolymers form micelles, and serve as nanoreactors for the preparation of nanoparticles. For example, by utilizing polyacrylamide gel, nanosized  $\text{Y}_2\text{O}_3:\text{Eu}^{3+}$  [128] and  $\text{Y}_3\text{Al}_5\text{O}_{12}:\text{Ce}^{3+}$  (YAG) [129] have been prepared.  $\text{ZnS}:\text{Tb}$  nanocrystals [130] have also been synthesized in a similar way. This kind of synthesis scheme could be used with various combinations of metal salts to yield many different doped nanocrystalline phosphors. Also, the size of the nanoparticle can be controlled by adjusting the size of the micelle.

**Reverse Microemulsion Method** Reverse microemulsion is also called the reverse micelle method. In reverse microemulsion, the aqueous phase is dispersed as microdroplets, which are usually less than 100 nm. So the dispersed water droplets behave as nanoreactors for the synthesis of nanoparticles. By using this method, 10 nm  $\text{Y}_2\text{O}_3:\text{Eu}$  [131] nanoparticles with a narrow-size distribution have been prepared successfully.

**Combustion Synthesis Method (or Propellant Synthesis)** The combustion synthesis process involves the exothermic reaction of an oxidizer such as metal nitrate, ammonium nitrate, and ammonium perchlorate [132], and an organic fuel, typically urea, carbonylhydrazide, or glycine [3, 133]. During the process, the chemical energy released from the exothermic reaction between the metal nitrate and fuel can rapidly heat the system to high temperatures (>1600 °C) without an external heat source; at the same time, a large amount of gaseous product such as  $\text{N}_2$ ,  $\text{CO}_2$ ,  $\text{H}_2\text{O}$  is produced, which generates nanostructure phosphors with higher surface areas and high luminescence emission. Tao et al. have prepared nanoscale  $\text{Y}_2\text{O}_3:\text{Eu}$  phosphors by glycine-nitrate solution combustion synthesis [134]. An average particle size of 8, 40, 70, and 160 nm was obtained by adjusting the glycine-to-nitrate ratio.  $\text{Y}_3\text{Al}_5\text{O}_{12}:\text{Eu}$  (YAG:Eu) nanocrystalline phosphors are prepared by employing a combustion synthesis with urea as a fuel [135]. The size of the phosphor particles is in the range of 60–90 nm. The disadvantage of this method is that it can only be used to prepare oxide phosphors.

**Colloidal Chemical Methods** Colloidal chemical methods have often been utilized to prepare colloidal solutions of highly crystalline and well-separated nanoparticles. These methods have been widely used for the preparation of semiconductor nanocrystals, such as CdSe, as mentioned in Section 2. They have also been applied to the preparation of doped nanocrystals. Colloidal nanocrystals of  $\text{LaPO}_4\text{:Eu}$ ,  $\text{CePO}_4\text{:Tb}$  [136],  $\text{LaPO}_4\text{:Ce}$ , and  $\text{LaPO}_4\text{:Ce,Tb}$  [137] have been prepared by this method.

**Hydrothermal Method** Hydrothermal synthesis is a low-temperature and high-pressure decomposition technique that produces fine, well-crystallized powders.  $\text{YVO}_4\text{:Ln}$  (Ln = Eu, Sm, Dy) nanocrystals have been prepared via a hydrothermal method at 200 °C. Highly crystalline particles ranging in size from about 10 to 30 nm were obtained [138]. The authors have prepared  $\text{La}_2(\text{MoO}_4)_3\text{:Yb,Er}$  up-conversion nanocrystalline phosphors through the hydrothermal method [139].

For some time, a number of papers have reported on the preparation and luminescence of nanocrystalline rare-earth doped II–VI semiconductors, such as  $\text{ZnS:Tb}^{3+}$  [140],  $\text{ZnS:Eu}^{3+}$  [141], and  $\text{ZnS:Er}^{3+}$  [142]. Recently, Bol et al. repeated some of the experiments, and investigated the results systematically [143]. They concluded that it was not possible to incorporate rare-earth ions in the nanocrystalline semiconductors due to the large size, chemical differences, and the need for charge compensation for rare-earth ions. The observed rare-earth emission is really from the ions absorbed on the surface.

### 3.1.2. Optical Properties

**Emission Wavelength** Li et al. found that, when the size of nanocrystalline  $\text{Y}_2\text{O}_3\text{:Eu}$  [127] and  $\text{Y}_3\text{Al}_6\text{O}_{12}\text{:Ce}$  [144] became smaller, a blue shift was observed for the emission spectrum. For example, nanocrystalline  $\text{Y}_2\text{O}_3\text{:Eu}$  of different sizes with an average diameter of 43, 55, 68, 71 nm were prepared; the central emission wavelengths were, respectively, 610, 612, 614 and 614 nm.

**Luminous Efficiency** Bhargava reported [145] that the photoluminescence efficiency of nanocrystalline  $\text{Y}_2\text{O}_3\text{:Tb}^{3+}$  with a size between 2–4 nm was at least five times higher than that of bulk samples. He also proved that smaller nanocrystalline  $\text{Y}_2\text{O}_3\text{:Tb}^{3+}$  particles were far more efficient than larger ones or bulk-like samples. For the phosphor of  $\text{Y}_2\text{O}_3\text{:Eu}$ , Lee et al. [131] found that  $\text{Y}_2\text{O}_3\text{:Eu}$  nanoparticles produced by a reverse microemulsion method with an average size of 30 nm displayed a stronger photoluminescence intensity than the bulk samples. They attributed this fact to higher crystallinity and more densely packed crystal with few void spaces. Sharma et al. reported that the peak emission intensity of  $\text{Y}_2\text{O}_3\text{:Eu}^{3+}$  increased approximately five-fold as the average particle size decreased from 6  $\mu\text{m}$  to 10 nm [126]. Ihara and co-workers synthesized glass-coated  $\text{ZnS:Tb}$  and  $\text{ZnS:Eu}$  nanocrystals. They found that the photoluminescence intensities were about three times higher than those of bulk [146].

However, Li et al. [127] obtained a different result. Nanocrystalline  $\text{Y}_2\text{O}_3\text{:Eu}^{3+}$  has been prepared with a homogeneous precipitation method. The relative luminescent

intensity changed from 100 to 64% as the size decreased from 68 to 43 nm.

**Quenching Concentration** Nanosized phosphors doped with rare-earth elements have increased the quenching concentration. Tao et al. reported that the quenching concentration of  $\text{Y}_2\text{O}_3\text{:Eu}$  prepared by conventional synthesis is 6% mol europium, but for their nanoscale samples prepared by combustion synthesis, the quenching concentration was apparently 14% mol [134]. Li et al. found that the quenching concentration was 8% for nanocrystal  $\text{Y}_2\text{O}_3\text{:Eu}$  [147], as compared with 6% in bulk samples.

**Luminescent Lifetime** As for the lifetime of  $\text{Y}_2\text{O}_3\text{:Eu}$  nanocrystals, Tissue and co-workers have done much research. They observed that the fluorescent lifetime was obviously longer in the monoclinic  $\text{Y}_2\text{O}_3\text{:Eu}^{3+}$  nanocrystals than in the bulk material [5]. Li et al. also obtained the same result [148].

## 3.2. Transition Metal-Doped Nanocrystals

### 3.2.1. Synthesis

**Colloidal Chemical Method** For the synthesis of transition metal-doped nanocrystals, colloidal chemical methods have been widely used, and the most thoroughly investigated systems are manganese-doped zinc sulfide and cadmium sulfide. Liu et al. have prepared well-dispersed  $\text{CdS:Mn}$  nanocrystals in an aqueous solution by using mercapto acetate as a capping reagent [149], while our group has synthesized  $\text{ZnS:Mn}$  nanocrystals in a similar way by using histidine as a capping reagent [150]. In both methods, transparent colloidal solutions of  $\text{CdS:Mn}$  and  $\text{ZnS:Mn}$  nanocrystals were acquired. Bawandi and co-workers [151] synthesized TOPO-capped  $\text{CdSe:Mn}$  using two different manganese precursors. They found that almost all of the manganese resides near the surface in the doped sample obtained by using manganese salts as the manganese source, whereas by use of an organometallic complex  $[\text{Mn}_2(\mu\text{-SEMe})_2(\text{CO})_8]$ , manganese was incorporated in the lattice. Recently, TOPO-capped, nearly monodispersed  $\text{ZnS:Mn}$  and  $\text{CdS:Mn}$  nanocrystals were prepared by Malik et al. [152].

**Coprecipitation Method** Through this process, nanocrystalline  $\text{ZnS:Mn}$  was prepared by coprecipitation of zinc acetate and manganese acetate with sodium sulfide in methanolic media [153].  $\text{ZnS:Cu}^+$ ,  $\text{ZnS:Cu}^{2+}$  [154], and  $\text{ZnS:Cu,In}$  [155] nanocrystalline phosphors have been obtained by the chemical homogeneous precipitation of cation solutions, with  $\text{S}^{2-}$  as the precipitating anion, which was formed by the decomposition of thioacetamide.

**Reverse Microemulsion Method** By using this method,  $\text{ZnS:Mn}$  [156, 157],  $\text{ZnS:Cu}$  [157, 158], and  $\text{CdS:Mn}$  [159] nanoparticles with a narrow-size distribution have been prepared successfully.

### 3.2.2. Optical Properties

**Luminous Efficiency** In 1994, Bhargava et al. [160] first observed that nanocrystalline  $\text{ZnS:Mn}$  has a high luminous efficiency. The efficiency in these nanocrystals was measured to be 18%, as compared to 16% for the bulk.

**Table 3.** Nanocrystalline phosphors reported in the literature.

	Semiconductor	Size (nm)	Optical properties	Ref.
Semiconductor nanocrystalline phosphors	CdSe	1.1–11.5		[40]
		Nanorods		[41]
		Nanorods and fractal		[42]
		3		[43]
		3–8		[44]
		Nanorods, teprapods		[45]
	CdS	6–20 × 100–500 (nanorods)	Quantum efficiency 20–85%	[46]
		2–9		[83]
		4–8		[47]
		1–6		[48]
		3–7		[49]
		Less than or equal to 6		[50]
	ZnSe	2–3		[51]
		2–5	Quantum efficiency 20–50%	[52]
	ZnS	4.3–6	Quantum efficiency 20–50%	[53]
		4–8		[82]
	CdTe			[54]
		2–5	Quantum efficiency 40%	[55]
		2.5–7	Quantum efficiency 30–65%	[56]
	ZnTe		Quantum efficiency 18%	[57]
		4.2–5.4		[58]
	InAs	2.5–6		[59]
			Bandgap: 1.05–1.55	[60–61]
	InP	7.4		[86]
		11.3–20		[62]
			Bandgap: 2.1–2.5 eV	[64–65]
	GaP	2–6.5		[88]
20–40 × 200–500 nanorod			[66]	
11–21			[67]	
GaAs	2–6.5		[68]	
	6–36		[69]	
PbS	8–30	Spectral blue shift	[70]	
	Nanofilm	Bandgap blue shift from IR region to near-UV region	[71]	
PbSe		Enhanced photoluminescence	[89]	
		Quantum-size effect	[93]	
Si	Film	Enhanced photoluminescence	[94]	
	Porous silicon	Enhanced photoluminescence	[91]	
Doped nanocrystalline phosphors	Y <sub>2</sub> O <sub>3</sub> :Eu	3.8–2.7	Enhanced photoluminescence	[95]
		23	Longer fluorescent lifetime	[101]
		23		[5]
		60		[118]
		6 m, 10 nm	Enhanced photoluminescence (fivefold)	[119]
		43, 55, 68, 71	Emission blue shift decreased emission intensity	[126]
		10–30	Enhanced photoluminescence	[127]
		8, 40, 70, and 160	Quenching concentration increased to 14%	[131]
			Quenching concentration increased to 8%	[134]
			Long luminescent lifetime	[147]
			Enhanced photoluminescence (five times greater)	[148]
	Y <sub>2</sub> O <sub>3</sub> :Tb	2–4		[145]
	Zn <sub>2</sub> SiO <sub>4</sub> :Eu	40–100		[122]
	Zn <sub>2</sub> SiO <sub>4</sub> :Tb			
	Y <sub>2</sub> SiO <sub>5</sub> :Eu	50		[123]
Y <sub>3</sub> Al <sub>5</sub> O <sub>12</sub> :Eu	60–90		[135]	
LaPO <sub>4</sub> :Eu, CePO <sub>4</sub> :Tb	5		[136]	
YVO <sub>4</sub> :Ln (Ln = Eu, Sm, Dy)	10–30		[138]	
La <sub>2</sub> (MoO <sub>4</sub> ) <sub>3</sub> :Yb,Er	50	Enhanced up-conversion fluorescence	[139]	
Y <sub>3</sub> Al <sub>6</sub> O <sub>12</sub> :Ce		Emission blue shift	[144]	
ZnS:Tb and ZnS:Eu	2, 3	Enhanced photoluminescence (three times higher)	[146]	
ZnS:Mn	8.3		[150]	
	3.5–7.5	High luminous efficiency, short lifetime (4 ns)	[160]	

continued

Table 3. Continued

Semiconductor	Size (nm)	Optical properties	Ref.
	3–5	Normal lifetime of 1.9 ms	
	100	Low-voltage excitation	[169]
CdS:Mn	4		[149]
CdSe:Mn	5		[151]
ZnS:Cu	2–2.5		[154]
ZnS:Cu,In	2–3		[155]

**Luminescent Lifetime** Bhargava et al. also reported an ultrafast decay time for nanocrystal ZnS:Mn. The lifetime of the Mn emission was shortened from 1.8 ms in the bulk powder to 4 ns in the doped nanocrystalline phosphor, which is five orders of magnitude shorter than that of bulk ZnS:Mn [160].

However, it was later shown that lifetime shortening in nanocrystalline ZnS:Mn did not occur. The  $Mn^{2+}$  emission of nanocrystalline ZnS:Mn has a normal millisecond lifetime. To test the result, a systematic investigation was carried out by Bol and Meijerink [161]. From lifetime measurements and time-resolved spectroscopy, they concluded that the  ${}^4T_1-{}^6A_1$  transition of the  $Mn^{2+}$  had a normal decay time of about 1.9 ms. The short decay time reported by Bhargava was ascribed to a defect-related emission of ZnS, and was not from the decay of the  ${}^4T_1-{}^6A_1$  transition of the  $Mn^{2+}$  impurity. More recent work on ZnS:Mn [156, 162] and CdS:Mn nanocrystals [159, 163] confirmed this conclusion [156].

### 3.3. Application of Doped Nanocrystals

As we reviewed earlier, doped nanocrystalline phosphors have many new optical characteristics. Such a system offers numerous possibilities for the next-generation devices in the field of lighting, displays, sensors, bio tags, and lasers. In the following, we will discuss the application of display and bio tags in detail.

#### 3.3.1. Display Applications

The development of new types of flat-panel and projection displays has created a need for optical phosphors with new or enhanced properties [164]. For application in these areas, thermally stable, high-luminous-efficiency, radiation-resistant, fine particle size powders are required [3]. Nanophase and nanocrystalline materials, typically particles with diameters of 100 nm or less, offer new possibilities for advanced phosphor applications [165–167]. On the other hand, for display applications, multiple particle layers are required to achieve optimal light output [5]. Large particles require thicker layers, increasing the phosphor cost, and also producing more light scattering [168]. Small and uniform particles with high luminous efficiency are preferred for new flat-panel displays [3].

Dinsmore et al. [169] found that ZnS:Mn nanoparticles exhibit less current saturation than bulk phosphors, which is an important feature for use in field-emission displays. Furthermore, the nanoparticles were annealed at a temperature far below the processing temperatures of standard phosphors.

By using nanometer-sized rare-earth doped phosphors as layers, Chinese scientists have successfully manufactured a field-emission display recently. This display has the advantages of high definition, bright emission, sharp dynamic color image, large angle of view (nearly  $180^\circ$ ), and so on [170].

#### 3.3.2. Biological Application

Nowadays, most of the biological luminescent tags are organic dyes, such as rhodamine, FITC, Cy3, and Cy5. In comparison, the luminescence of doped phosphors is stronger, nonfading, not significantly influenced by pH or temperature, and has a longer lifetime [171]. Inorganic phosphors with a size of 100–300 nm, such as  $Zn_2SiO_4:Mn$ , As, ZnS:Ag, and  $Y_2O_3:Eu$ , have already been used for the detection of proteins and nucleic acids [171–173]. By using these kinds of labels, 10 fg protein and 300 fg nucleic acids have been detected. Nanosized phosphors with a narrow size distribution and high fluorescent efficiency are theoretically advantageous and favorable [172].

The uses of up-conversion phosphors as fluorescent labels for the sensitive detection of biomolecules have attracted even more interest recently [174, 175]. Phosphors that emit lower energy photons when excited by higher energy photons are down-conversion phosphors. For example, ZnS:Mn and  $Y_2O_3:Eu$  are well-known down-conversion phosphors. On the other hand, phosphors that emit higher energy photons after absorbing lower energy excitation photons are up-conversion phosphors. At least two low-energy photons are required to generate a higher energy photon. In comparison with organic dye labels, up-conversion phosphor fluorescent labels show very low background noise without photobleaching. By using up-conversion phosphor as labels, 1 ng/ $\mu$ L DNA could be detected, which is four times more sensitive than that labeled with cy5 [116].

## 4. CONCLUSION

Here, we have presented an overview of the synthesis and optical properties of nanocrystalline phosphors (see Table 3). The potential applications of these novel materials are also highlighted. For semiconductor nanocrystalline phosphors, a wide range of synthetic methods are now available. Particles with diameters in the range of 1–20 nm have been prepared, and quantum-size effects have been observed experimentally for many nanocrystalline semiconductors. However, most of the studies up to now have focused on II–IV and III–V compounds; there is still a major problem associated with the reproducible preparation of this kind of material that will be needed for technological applications, and the applications of semiconductor nanocrystals remain scarce, except for CdSe.

Studies of doped nanocrystalline phosphors, including synthesis, optical properties, and their applications, are discussed. Some new nano-related optical properties, such as high efficiency, high quenching concentration, and so on, have been reported. However, research in this area is preliminary; some results are quite confusing, and even contradicting. Most of the studies concentrated on a few of this kind of material, such as ZnS:Mn and Y<sub>2</sub>O<sub>3</sub>:Eu. There is still a lack of a guiding theory for the study of doped nanocrystalline phosphors. Systematic research needs to be done.

## GLOSSARY

**Down-conversion phosphor** Phosphor that emits lower energy photons when excited by higher energy photons.

**Emission spectrum** Wavelength distribution of the emission, measured at a single constant excitation wavelength.

**Excitation spectrum** Dependence of emission intensity, measured at a single emission wavelength, upon the excitation wavelength.

**Fluorescence** Emission of light by a substance immediately after the absorption of energy from light of usually shorter wavelength.

**Luminescent lifetime** Average fluorescence time between its excitation and its return to the ground state.

**Luminous efficiency** Also called quantum yields, is the number of emitted photons relative to the number of absorbed photons.

**Phosphors** Solid, inorganic, crystalline materials that show luminescence upon excitation.

**Up-conversion phosphor** Phosphor that emits higher energy photons after absorbing lower energy excitation photons. At least two low-energy photons are required to generate a higher energy photon.

## 1. INTRODUCTION

This review chapter is focused on the fabrication and characterization of layered Si-based nanostructures, which have been termed nanocrystalline silicon (nc-Si)–silicon dioxide superlattices [1]. Among the many semiconducting materials, silicon is well studied and certainly the most important material for commercial microelectronics. During the past several decades, the exponential growth of electronic chip complexity and drastic decrease of transistor dimensions have highlighted requirements for new directions in electronic device evolution and the potential applicability of Si nanocrystals for nanoelectronics and integrated light-emitters. The latter was stimulated by the discovery of efficient light emission in different forms of Si nanostructures [2] and by the demonstration of a Si-based light-emitting device prototype integrated into conventional microelectronic circuitry [3]. Hence, the interest in reliable fabrication

of Si-based nanostructures with control over the nanocrystal size, shape, and crystallographic orientation has been growing continuously over the last decade. Recently, the application of Si nanocrystals in electronic devices was suggested and proved by the demonstration of a Si nanocrystal nonvolatile memory and other devices utilizing the Coulomb blockade effect [4, 5].

Despite the strong interest in different forms of nc-Si, the fabrication of Si nanocrystals with control over the nanocrystal size and shape has been significantly less successful compared to other semiconducting materials. The latest advances in semiconductor nanocrystal fabrication have been based on chemical synthesis in II-VI materials [6] and the successful application of the Stranski–Krastanow growth mode in molecular beam epitaxy (MBE) for III-V semiconductors. Neither of these techniques is applicable for Si/SiO<sub>2</sub> structures. In general, crystalline Si (c-Si) and amorphous SiO<sub>2</sub> are quite different materials with large mismatches between their local crystallographic order and thermal expansion. Therefore, crystalline Si does not wet the SiO<sub>2</sub> surface, and standard heteroepitaxy based on MBE, chemical vapor deposition (CVD), or magnetron sputtering, produces highly disordered polycrystalline Si on SiO<sub>2</sub>-covered substrates.

Several attempts to introduce layered Si/SiO<sub>2</sub> nanoscale structures were reported in the mid and late 1990s, aiming for deep carrier confinement in Si nanocrystals due to high Si/SiO<sub>2</sub> barriers. Two major approaches were focused on (1) high-quality amorphous Si (a-Si)/amorphous SiO<sub>2</sub> (a-SiO<sub>2</sub>) structures [7, 8] and (2) layers of Si nanocrystals sandwiched between tunnel transparent, nanometer-thin a-SiO<sub>2</sub> separating layers [1]. In the former case, involving a-Si layer thicknesses between 1 and 2 nm, the ultrathin Si layers could not be crystallized even after extended annealing at high temperatures owing to the strain at the Si/SiO<sub>2</sub> interface [9]. Nevertheless, clear optical evidence of carrier confinement in the Si layers was obtained [7, 8, 10]. The other approach utilizes a unique property of the c-Si/SiO<sub>2</sub> interface, the same property that made the MOSFET the unique generic

device for modern electronics. Since crystalline (or nanocrystalline) Si and amorphous SiO<sub>2</sub> belong to different thermodynamic classes of materials, they do not mix but rather segregate at high temperatures. Therefore, an atomically smooth interface and very homogeneous growth of SiO<sub>2</sub> on c-Si can be produced by a simple technological procedure: namely, Si thermal oxidation. In general, controlled crystallization of amorphous Si/SiO<sub>2</sub> superlattices follows the same rules with only one exception: the a-Si layer must be crystallized before interstitial oxygen diffuses into the Si layer. It was realized almost immediately that rapid thermal annealing, which currently is a standard fabrication procedure for many semiconductor processes, is able to provide very fast crystallization of nanometer-thick a-Si layers. At the same time, an a-SiO<sub>2</sub> layer remains amorphous, because annealing at temperatures close to 1200 °C merely improves its stoichiometry.

This technological process (full details are presented in Section 2) is able to produce layers of Si nanocrystals sandwiched between a-SiO<sub>2</sub> layers or nc-Si/a-SiO<sub>2</sub> superlattices. In view of considerable prior research, the physical properties of these structures could be expected to be similar to those of grainy polycrystalline Si and should be affected by nanocrystal (or nanograin) boundaries. However, it turns out that many interesting and unique properties of nc-Si/a-SiO<sub>2</sub> superlattices stem from their vertical periodicity and nearly defect-free, atomically flat, and chemically abrupt nc-Si/SiO<sub>2</sub> interfaces [11]. In addition, by combining a less than 5% variation in a-Si layer thickness with control over the Si nanocrystal shape and crystallographic orientation [11, 12], a system of nearly identical Si nanocrystals can be produced and studied.

The aim of this chapter is to review in detail the fabrication of nc-Si/a-SiO<sub>2</sub> superlattices and their structural and optical (mainly Raman scattering and photoluminescence) properties. Recently, a number of surprising results (such as resonant tunneling and quantum carrier transport [13]) were obtained from investigations of the electronic properties of these structures. Carrier transport in layered structures of Si nanocrystals is a complex subject, and by itself could provide material for another chapter. Therefore, we only briefly mention here the most interesting and significant results on the electronic properties of nc-Si/a-SiO<sub>2</sub> superlattices.

## 2. SUPERLATTICE FABRICATION TECHNIQUES AND POST-TREATMENT PROCEDURES

Amorphous layered structures or amorphous superlattices have distinct advantages when compared to crystalline materials: since long-range order is not preserved, virtually any two materials can be deposited in the form of a heteropair or layered structure. However, the observation of desired physical phenomena such as Brillouin zone folding, band structure modification, and quantum carrier transport requires minimization of charge carrier scattering, and potential sources of such scattering are structural defects. Another important issue is a leaky and/or rough barrier. To avoid this problem, chemically abrupt and defect-free interfaces must be preserved. Since the great majority of amorphous superlattices studied to date were fabricated using

plasma enhanced chemical vapor deposition (PE CVD) [14–16], the most significant problem affecting the quality of these structures (a-Si:H/a-SiN:H, a-Si/a-SiC:H, etc.) is their diffused interfaces. Realizing this fact, Lockwood et al. [10] proposed to use MBE growth of a-Si in combination with ozone oxidation to achieve a perfect control over the a-Si layer thickness and abrupt a-Si/a-SiO<sub>2</sub> interfaces.

In 1995, Lu et al. [7] reported visible light emission at room temperature from ultrathin-layer a-Si/a-SiO<sub>2</sub> superlattices grown by MBE that exhibited a clear quantum confinement shift with Si layer thickness, as shown in Figure 1. According to effective mass theory and assuming infinite potential barriers, which is a reasonable approximation since wide-gap (~9 eV) 1-nm-thick a-SiO<sub>2</sub> barriers are used, the energy gap  $E$  for one-dimensionally confined Si should vary as  $E = E_g + (\pi\hbar^2/2d^2)[1/m_e^* + 1/m_h^*]$ , where  $E_g$  is the bulk material bandgap,  $d$  is the a-Si well thickness, and  $m_e^*$  and  $m_h^*$  are the electron and hole effective masses [10]. This simple model is a reasonable first approximation to compare with experiment for quantum wells. The shift in photoluminescence (PL) peak energy with a-Si well thickness is well represented by this equation, as can be seen in Figure 1, with  $E$  (eV) = 1.60 + 0.72 $d^{-2}$ . The very thin layers of Si ( $1 < d < 3$  nm) have a disordered, but nearly crystalline, structure owing to the growth conditions and the huge strain at the a-Si/a-SiO<sub>2</sub> interfaces [9]. The fitted  $E_g$  of 1.60 eV is larger than that expected for c-Si (1.12 eV at 295 K), but is in excellent agreement with that of bulk a-Si (1.5–1.6 eV at 295 K). These strong indications of direct band-to-band recombination were confirmed by measurements via X-ray techniques of the conduction and valence band shifts with layer thickness [7]. The fitted confinement parameter of 0.72 eV/nm<sup>2</sup> indicates  $m_e^* \approx m_h^* \approx 1$ , comparable to the effective masses of c-Si at room temperature [10]. The integrated intensity at first rises sharply with decreasing Si thickness until  $d \approx 1.5$  nm and then decreases again, which is consistent with quantum well exciton emission. The PL intensity is enhanced by factors of up to 100 on annealing and is also selectively enhanced and bandwidth narrowed by incorporation into an optical microcavity [8]. In a high-quality cavity, a very sharp

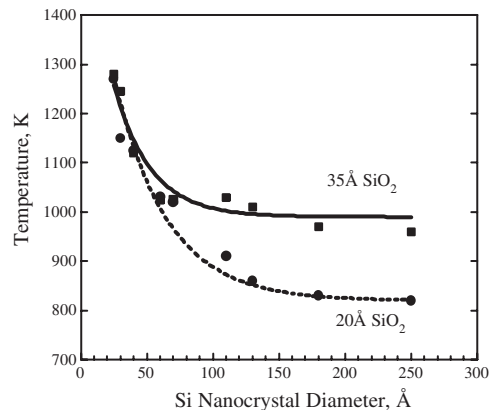

**Figure 1.** The PL peak energy (open circles) and integrated intensity (filled circles) at 295 K in (a-Si/a-SiO<sub>2</sub>)<sub>6</sub> superlattices as a function of the a-Si layer thickness. The solid line is a fit to the peak energy data using effective mass theory.

(17 meV full width at half maximum) PL peak has been observed [8]. Thus, in general, the wavelength of light emission in these structures can be controlled by the thickness of the a-Si layers and the design of the optical cavity within which they are contained.

The use of an a-Si layer as a quantum well is quite limited due to intrinsic structural defects. Silicon dangling bonds are the most well-known type of such defects [17], and they affect the quality of both the a-Si wells and a-Si/SiO<sub>2</sub> interfaces. Silicon dangling bonds in the a-Si matrix appear due to the absence of long-range order. The generally accepted model considers significant deviations in the Si bond angle and length and agrees with the fact that the a-Si density is typically 80% that of c-Si [18]. The model requires some critical thickness for the a-Si layer before the Si bonds are stretched enough to be broken. Therefore, the dangling bond density per unit volume is reduced in nanometer-thin a-Si layers compared to bulky, micron-thick layers of a-Si and the nanometer-thin a-Si layer density is 98% that of c-Si [9].

The fact that a-Si/a-SiO<sub>2</sub> superlattices are not defect-free structures stimulated a search for a post-treatment procedure that can reduce the defect density. Normally, structural defects that have been introduced by ion implantation or some other manufacturing steps can be eliminated using thermal annealing. Defect annealing utilizes the strong covalent nature of Si bonds and the ability of the crystal lattice to recover the initial, thermodynamically stable bond arrangement. Unfortunately, a-Si/a-SiO<sub>2</sub> superlattices cannot be treated the same way, because oxygen diffusion and the oxidation rate in a-Si is orders of magnitude faster at a given temperature compared to c-Si. Therefore, some intermixing of a-Si and a-SiO<sub>2</sub> may occur. Technically, an ideal solution is to have a stack of nanometer-thick layers of c-Si sandwiched between SiO<sub>2</sub> barriers. However, current technology is not able to provide the required dimensions and the interface quality for such structures and many approaches (e.g., SIMOX, smart-cut, and MBE growth of Si on dispersed SiO<sub>2</sub> layers) eventually failed to demonstrate the feasibility of reliable fabrication.

Several independent reports proposed thermal crystallization of nanometer-thick a-Si layers sandwiched between a-SiO<sub>2</sub> [19–21], and they indicated that the crystallization temperature (normally  $\leq 600$  °C for a micrometer-thick a-Si layer) increases significantly, and may reach 1000 °C or more for a-Si layers thinner than 2–3 nm. Detailed studies [22] supported the same conclusion, but they attributed such a strong increase in crystallization temperature to very strong strain within nanometer-thin a-Si layers sandwiched between layers of a-SiO<sub>2</sub>. A model has been developed [20, 23] that is able to describe the influence of strain at Si/SiO<sub>2</sub> interfaces, but it contains many empirical parameters. In fact, Figure 2, which compares the crystallization temperature for two series of samples having different SiO<sub>2</sub> thickness fabricated by magnetron sputtering, proves that a thicker SiO<sub>2</sub> layer actually introduces more strain into the layered Si/SiO<sub>2</sub> system. Therefore, the conclusion [22, 23] that the thickness of a partially disordered Si layer along such interfaces remains  $\sim 5$  Å even for completely crystallized structures may not be exactly correct. Most likely, as proved by several unsuccessful attempts to crystallize a-Si/SiO<sub>2</sub> superlattices

**Figure 2.** Crystallization temperature as a function of the Si nanocrystal vertical dimension in nc-Si superlattices with different thicknesses of a-SiO<sub>2</sub> separating layer.

fabricated by MBE and ozone oxidation [9], the values of the strain and crystallization parameters strongly depend on the local order of a-Si/SiO<sub>2</sub> structure, and such order may vary significantly for different fabrication techniques.

Compared to other a-Si/SiO<sub>2</sub> fabrication techniques, [e.g., radio-frequency (RF) sputtering and CVD], MBE in combination with ozone oxidation is the least desirable technique owing to its complexity. However, the alternatives to MBE fabrication are not able to produce abrupt a-Si/SiO<sub>2</sub> interfaces. Several experiments involving Auger microanalysis and transmission electron microscopy (TEM) showed the existence of a 20-Å-thick interface layer at a-Si/SiO<sub>2</sub> interfaces in samples prepared by RF sputtering [24]. Detailed studies have shown that such diffuse Si/SiO<sub>2</sub> interfaces may result in strong intermixing and the total destruction of the defined layered structures or superlattices after annealing (see Fig. 3).

In addition to these interdiffused a-Si/SiO<sub>2</sub> interfaces produced by CVD or sputtering growth methods, the quality of CVD or sputtered SiO<sub>2</sub> is known to be poor. Detailed analysis had shown that most of the SiO<sub>2</sub> structural defects originate from the formation of a columnar structure, which contains a large density of dangling Si bonds [25]. Such columns appear during growth due to the quasi-equilibrium (or low-rate) growth mode. To avoid the formation of the columnar structure, growth of amorphous materials (including a-Si and SiO<sub>2</sub>) should be done under highly non-equilibrium conditions. To achieve these conditions, CVD

**Figure 3.** TEM micrograph showing the result of thermal crystallization in an amorphous Si/SiO<sub>2</sub> superlattice with (a) initially diffuse ( $>20$  Å) and (b) abrupt ( $<5$  Å) Si/SiO<sub>2</sub> interfaces.

requires a specific range of gas flow, reaction temperature, and other growth parameters. Considering RF or magnetron sputtering, an increase in RF power generates highly energetic ions, which result in the destruction of the columnar structure. Figure 4 compares two samples of a-SiO<sub>2</sub> fabricated by RF sputtering using different RF power, and lower RF power visibly results in the formation of the unwanted columns.

The most basic figure of merit for these three growth techniques in a-Si/SiO<sub>2</sub> fabrication is the ability to control the growth rate and thus provide layers of both materials with angstrom precision. This is important for Si, because of the relatively large value of the reduced electron effective mass ( $\sim 0.5$  of the electron mass,  $m_e$ ), and a simple calculation shows that a desirable thickness for tunnel devices utilizing carrier confinement is of the order of 50 Å or less. It is even more important for SiO<sub>2</sub> barriers, because the large barrier offset of several electron volts constrains the barrier thickness to be thinner than 20 Å. Compared to the complex chemistry of CVD, RF or magnetron sputtering has the clear advantage of a physical deposition process, that is, a linear dependence in the deposition rate as a function of time at a given RF power. Sputtering, as in any other plasma induced process, is a self-cleaning procedure, and it can be done in a moderate vacuum of  $\sim 10^{-7}$  Torr. The process allows the simple cleaning of a target and substrate as a pre-deposition step. A modern sputtering system also provides very good stabilization of the plasma and is able to bring the deposition rate down to 100 Å per minute or even less.

Thermal crystallization of a-Si/SiO<sub>2</sub> superlattices can be carried out in a conventional, hot-wall furnace with control over the ambient conditions to avoid unwanted oxidation. At moderate temperatures (200–400 °C) it was found that the interstitial oxygen may quickly diffuse into a-Si and initiate a-Si/SiO<sub>2</sub> intermixing [26]. It also was noticed that CVD or sputtered SiO<sub>2</sub> introduces less strain into layered a-Si/SiO<sub>2</sub> structures, and this is most likely due to the lower density of sputtered SiO<sub>2</sub> layers compared to SiO<sub>2</sub> fabricated by ozone or thermal oxidation. By considering these issues, it was suggested [27] that the best growth choice would be sputtered or CVD deposited a-Si/SiO<sub>2</sub> layers, but thermal crystallization must be performed using rapid thermal annealing (RTA). The RTA approach was found to provide very efficient crystallization of nanometer-thick a-Si layers with thickness down to  $\sim 2$  nm [27]. It was also found that

the combination of RTA with subsequent furnace annealing results in the segregation of crystallized Si and amorphous SiO<sub>2</sub> layers, together with pronounced improvement in the nc-Si/SiO<sub>2</sub> interface abruptness and flatness. At the same time, thermal annealing at a temperature  $\leq 1200$  °C improves the a-SiO<sub>2</sub> layer stoichiometry and density, and reduces the number of defects at the Si/SiO<sub>2</sub> interfaces.

To summarize this brief review of Si/SiO<sub>2</sub> layered structure fabrication, amorphous Si/SiO<sub>2</sub> superlattices can be prepared by several techniques, but only one post-treatment process can bring them to the level of device-quality structures. This process is a properly controlled thermal annealing, and it results in (1) crystallization of a-Si, (2) enhancement of the Si/SiO<sub>2</sub> interface abruptness, and (3) reduction in the interface and intrinsic defect density (mostly Si dangling bonds).

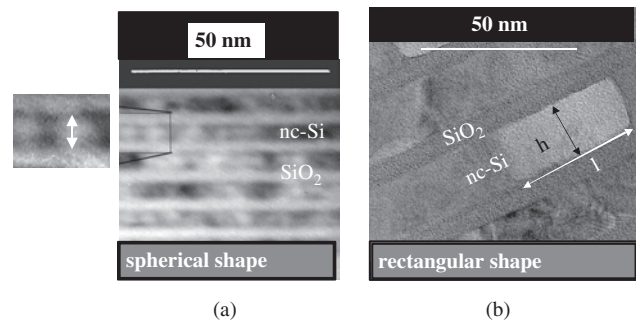

### 3. STRUCTURAL CHARACTERIZATION OF NANOCRYSTALLINE SILICON–SILICON DIOXIDE SUPERLATTICES

Ever since the first report on the successful fabrication of nanocrystalline Si superlattices [28], a wide variety of techniques have been proposed and employed to characterize these structures. The obvious initial focus was on transmission electron microscopy (TEM), which, despite its complexity, remains the most important technique to study nanocrystal geometry (size, shape, etc.) and crystallography. TEM is particularly difficult to perform in Si/SiO<sub>2</sub> structures, because of the relatively low contrast and significant probability of charging the SiO<sub>2</sub> layers. However, due to the considerable interest in Si-based nanostructures, considerable experience has been developed in the last decade, and a number of useful methods for sample preparation and image enhancement [29] finally allowed TEM to become a routine characterization method. In nc-Si/a-SiO<sub>2</sub> superlattices, TEM images have provided critical information and a number of important results will be presented below.

The TEM images in Figure 5 show a clear size-dependent trend in the Si nanocrystal shape: smaller Si nanocrystals with vertical sizes  $\leq 6$  nm are spherical or slightly elliptical but larger nanocrystals ( $\geq 10$  nm) clearly have a rectangular (or brick-like) shape. For the brick-shaped nanocrystals, the ratio between lateral and vertical dimensions is close to

**Figure 4.** Two examples of sputtered a-SiO<sub>2</sub> layers (a) with and (b) without columnar microstructure. The sample with columnar microstructure was prepared using a low ( $< 50$  W) RF power.

**Figure 5.** TEM micrograph showing examples of (a) spherical and (b) rectangular-shape Si nanocrystals termed “quantum dots” and “quantum bricks.”

2 : 1. A high-resolution TEM image of an individual, brick-shaped Si nanocrystal (Fig. 6) proves that the nc-Si/SiO<sub>2</sub> interfaces are flat and abrupt. This observation highlights at least two issues: (1) brick-shaped Si nanocrystals should have a better nc-Si/SiO<sub>2</sub> interface than spherically shaped nanocrystals; and (2) it is important to fabricate laterally extended Si nanocrystals with an even higher aspect ratio. Laterally extended Si nanocrystals can be considered and used as a Si quasi-well sandwiched between SiO<sub>2</sub> barriers. Figure 7 shows that by utilizing a series of annealing cycles in different ambient conditions (e.g., N<sub>2</sub> or diluted O<sub>2</sub> [12]), the aspect ratio in the Si nanocrystal lateral and vertical dimensions can be extended to  $\geq 3 : 1$ . Finally, nearly continuous Si layers with a thickness of  $\sim 25$  nm have been produced (Fig. 8), but some of them clearly show fluctuations in the brightness of the reflected electron beam indicating possible intrinsic defects.

TEM analysis shows that annealing in dry oxygen not only reduces the Si nanocrystal size but also changes the nanocrystal shape. Nanocrystals originally spherical in shape become more dome-like and larger in size; brick-shaped Si nanocrystals change very little. The modification in nanocrystal shape is extremely slow and requires hours of oxidation at a temperature  $\sim 1000$  °C confirming the strong resistance of Si nanocrystals to oxidation in dry oxygen. In contrast, wet oxidation is extremely aggressive and destroys Si nanocrystals very effectively. The precise mechanism of Si nanostructure oxidation is not understood, but most likely it is connected with different oxidation rates in different crystallographic directions. Figure 9 confirms this preliminary conclusion and shows that the originally brick-shaped Si nanocrystals after several minutes exposure to N<sub>2</sub>-diluted H<sub>2</sub>O vapor at 950 °C have been transformed into pyramids of different sizes but having the same angles.

Another interesting feature has been found in nc-Si/SiO<sub>2</sub> superlattices with a large number of periods ( $\gg 20$ ). In some parts of the initial layers of nanocrystals (closer to the Si substrate), large crystalline grains are observed (Fig. 10). These grains are seen as bright spots, which is due to a specific crystallographic orientation of these grains. These “broken” layers most likely appear due to strain forces. This strain is built in during crystallization, because of the significant difference in thermal expansion between Si and SiO<sub>2</sub>. Interestingly, this local distortion does not propagate throughout the nc-Si superlattices, and the rest of the structure is

**Figure 6.** A lattice image of a rectangular Si nanocrystal (i.e., quantum brick) showing nearly atomically flat interfaces with a-SiO<sub>2</sub>.

**Figure 7.** TEM images of a nc-Si/a-SiO<sub>2</sub> superlattice subjected to (a) initial two hours of annealing at 950 °C in dry nitrogen; (b) 15 min annealing at 750 °C in  $\sim 15\%$  nitrogen diluted water vapor followed by (a); (c) 30 min annealing at 750 °C in  $\sim 15\%$  nitrogen diluted water vapor followed by (a); (d) 45 min annealing at 750 °C in  $\sim 15\%$  nitrogen diluted water vapor followed by (a). From (a) to (d), the Si nanocrystal size slightly reduces in vertical dimension and significantly increases laterally.

**Figure 8.** Nearly continuous, nanometer-thin nc-Si layer produced by RTA followed by 30 min wet oxidation at 800 °C and 2 h annealing in dry N<sub>2</sub> at 1100 °C.

**Figure 9.** TEM micrograph showing pyramid-shape Si nanocrystals produced by 15 min wet oxidation at 950 °C in 15–20% diluted water vapor of initially brick-shape Si nanoclusters. The pyramid locations are indicated.

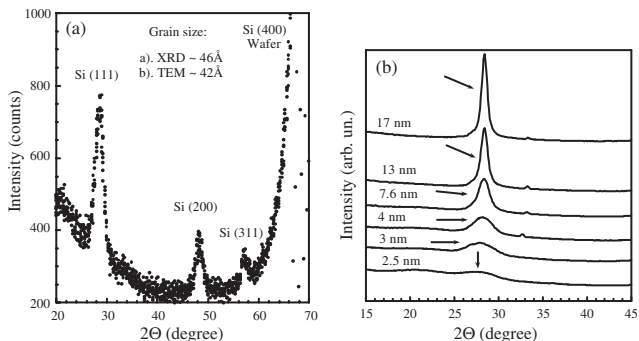

**Figure 10.** Multiperiod nc-Si/a-SiO<sub>2</sub> with areas of “broken” Si layers.

perfectly ordered. This observation proves that the ordered structure in nc-Si superlattices is robust and can survive during post-crystallization treatments and additional fabrication steps.

Among the many other characterization techniques, X-ray diffraction (XRD) shows reasonable agreement with TEM results (Fig. 11) using conventional analysis for the grain sizes [30, 31]. However, the quantitative application of XRD is limited to moderate sizes of Si nanocrystals (>2.5 nm). It is not clear if the reason for this limitation arises from a distortion of the lattice structure in small size Si nanocrystals, the presence of residual a-Si tissue, or something else.

#### 4. RAMAN SPECTROSCOPY OF NANOCRYSTALLINE SILICON–SILICON DIOXIDE SUPERLATTICES

Raman scattering in nanocrystals is a well-developed subject, starting with the work of [32] and [33] where a semiquantitative model considering a partial modification of the phonon selection rules was developed. Controlled crystallization is a fabrication method where Raman scattering can be a very informative characterization method, due to the easily observed difference between the spectra of amorphous

**Figure 11.** XRD data showing (a) peaks attributed to different crystallographic directions in Si nanocrystals and (b) the Si  $\langle 111 \rangle$  diffraction peak for Si nanocrystals of different sizes. (The X-ray measurements were kindly provided by (a) T. N. Blanton and (b) M. Zacharias.)

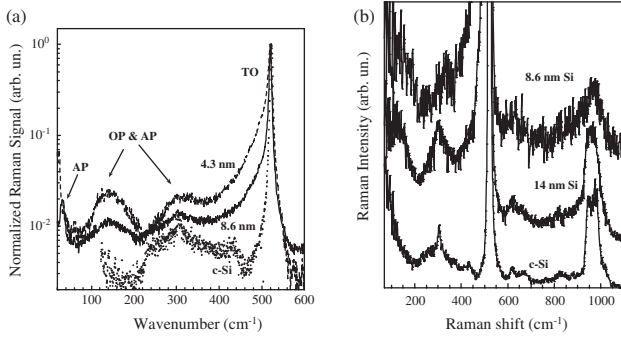

and nc-Si phases. Figure 12 compares the Raman spectra of several samples. In the as-prepared a-Si (11 nm)/a-SiO<sub>2</sub> superlattice, a strong Raman peak at  $\sim 470$  cm<sup>-1</sup> clearly indicates a purely amorphous phase. Rapid ( $\sim 30$  s) thermal annealing at 700 °C partially crystallizes the samples and a Raman contribution from both amorphous and nc-Si phases is shown by the two peaks at 485 and 520 cm<sup>-1</sup>, respectively. Rapid ( $\sim 30$  s) thermal annealing at 900 °C further reduces the contribution from the amorphous phase. Finally, furnace annealing for 30 min at 1050 °C completes the crystallization, and this can be verified from the Raman spectrum as a perfectly symmetric, slightly broader peak at 520 cm<sup>-1</sup>.

More detailed Raman measurements (Fig. 13) show that in smaller Si nanocrystals (from 14 down to 4 nm), several features associated with the disordered Si phase can be seen. The major feature related to small Si nanocrystals is a first-order, transverse-optical (TO) Raman peak at 520–500 cm<sup>-1</sup> (depending on the Si nanocrystal size) with a broad tail to the lower wavenumbers. Qualitatively similar broadening is observed for overtones related to combinations of acoustic and optical phonons at 150 and 300 cm<sup>-1</sup> as well as for the second-order Raman scattering at  $\sim 1000$  cm<sup>-1</sup>. The Raman data indicate not only the modification of phonon selection rules in small Si nanocrystals but also the presence of partial disorder, most likely due to the higher surface-to-volume ratio and stronger contribution from the nc-Si/SiO<sub>2</sub> interface. Following a semiquantitative analysis developed for a-Si [34, 35], we can consider that the degree of disorder is indicated by the intensity ratio between the major Raman peak at 520 cm<sup>-1</sup> and overtones ( $\sim 300$  cm<sup>-1</sup>) that are forbidden in perfect c-Si [36]. Figure 13 shows that this ratio between the Raman peaks at 300 and 520 cm<sup>-1</sup> increases as the Si nanocrystal size decreases.

The Campbell–Fauchet and other models that describe the changes in the phonon selection rules in nanometer-size Si nanocrystals have been criticized for being both a simplified theoretical approach and inconsistent with experiments [37–39]. However, it is not possible to combine all desirable considerations (nanocrystal size reduction, shape influence, strain, specific interface, etc.) in one model. It is also impossible to separate such effects as, for example, partial disorder due to a strained interface and phonon selection rule

**Figure 12.** Raman scattering in several samples of a nc-Si/a-SiO<sub>2</sub> superlattice annealed under different conditions, as indicated.

**Figure 13.** (a) Raman spectra and (b) details of second-order Raman scattering ( $\sim 1000 \text{ cm}^{-1}$ ) and overtones ( $\sim 300 \text{ cm}^{-1}$ ) for c-Si and Si nanocrystals of different sizes.

modification due to a nanocrystal size reduction. All these complications have made quantitative analysis of the optical phonon Raman spectra in Si nanocrystals difficult, if not impossible.

The fact that a nc-Si/a-SiO<sub>2</sub> superlattice is a layered, periodic structure with flat and abrupt interfaces stimulated interest in Raman measurements in the wavenumber range of acoustic phonons. We follow here the original Rytov model [40], which has been successfully applied to conventional MBE-grown superlattices [41]. In a more simplified picture, a superlattice made of alternating layers of nc-Si having thickness  $d_1$  and a-SiO<sub>2</sub> having thickness  $d_2$ , induces a new periodicity  $d = d_1 + d_2$  and leads to a reduction of the bulk crystal Brillouin zone in the superlattice growth direction. A new minizone is created with a maximum wavevector  $q_{mz} = \pi/d$ . Since the nc-Si/a-SiO<sub>2</sub> superlattice contains more than 10 atomic layers per period, it can be treated as an elastic medium and the elastic continuum model of acoustic vibrations can be used to calculate the superlattice phonon dispersion [40, 41]. According to this theory, the acoustic phonon dispersion in the superlattice is obtained by folding the acoustic phonon branches of the average compound into the superlattice minizone. For bulk acoustic phonons with frequencies less than  $100 \text{ cm}^{-1}$ , the dispersion is almost linear, and in the superlattice away from the Brillouin minizone center ( $q = 0$ ) and edge ( $q = q_{mz}$ ) it can be described by  $\omega = 2mv_{SL} \pi/d \pm qv_{SL}$ , where  $m = 0, 1, 2, \dots$  is the Brillouin zone folding index and  $q$  is the phonon wavevector. The superlattice sound velocity  $v_{SL}$  is given by

$$v_{SL} = d / [(d_1/v_1)^2 + (d_2/v_2)^2 + (\kappa + 1/\kappa) \cdot (d_1 d_2 / v_1 v_2)] \quad (1)$$

where  $\kappa = \rho_1 v_1 / \rho_2 v_2$ , and  $v_1$  and  $v_2$ ,  $\rho_1$  and  $\rho_2$  are the sound velocities and densities, respectively, in the nc-Si and a-SiO<sub>2</sub> layers. In the backscattering geometry, Raman scattering from phonons with wavevector  $q_p = 4\pi n_{SL} / \lambda$  is observed, where  $n_{SL}$  is the superlattice effective refractive index at the laser wavelength  $\lambda$ , defined as

$$n_{SL} = \xi n_1^2 + (1 - \xi) n_2^2 \quad (2)$$

where  $n_1$  and  $n_2$  are the corresponding refractive indices for the nc-Si and a-SiO<sub>2</sub> layers, respectively, and  $\xi = d_1/d$ . The case of  $m = 0$  corresponds to conventional Brillouin scattering from acoustic phonons ( $\omega_{Br} = q_p v_{SL}$ ). Each value

of the folding index  $m$  ( $m \neq 0$ ) gives rise to a doublet ( $\omega_{\pm m} = 2mv_{SL} \pi/d \pm \omega_{Br}$ ), which is the signature of the folded phonon modes in Raman scattering. In the exact continuum theory [42], small energy gaps appear in the phonon dispersion at the minizone center ( $q_p/q_{mz} = 0$ ) and edge ( $q_p/q_{mz} = 1$ ) due to a mismatch between the acoustic impedances  $\rho v$  of the nc-Si and a-SiO<sub>2</sub> layers. The gaps can be ignored when  $q_p/q_{mz}$  is not close to 0 or 1.

The a-Si/a-SiO<sub>2</sub> superlattices investigated by Raman spectroscopy were grown on a Si wafer by RF magnetron sputtering and plasma oxidation. The layer thicknesses for both a-Si and a-SiO<sub>2</sub> were kept constant throughout the superlattice. The a-Si layers were crystallized by RTA at  $900 \text{ }^\circ\text{C}$  for 60 s followed by quasi-equilibrium furnace annealing starting at  $750 \text{ }^\circ\text{C}$  with a  $10 \text{ }^\circ\text{C}/\text{min}$  temperature ramp-up to  $1100 \text{ }^\circ\text{C}$  (see [11, 12] for details). Rapid thermal and furnace annealing were performed in a nitrogen atmosphere. The layer thicknesses were determined using TEM.

Raman spectra were measured in a  $90^\circ$  scattering geometry with the sample surface inclined at an angle of  $12.3^\circ$  to the incident light, which is near to Brewster's angle in c-Si [41]. This configuration is close to exact backscattering inside the sample since the superlattice has a quite large refractive index ( $n_{SL} > 3$  as calculated below). The excitation source was an argon ion laser light giving wavelengths of 457.9, 476.5, 488.0, 496.5, and 514.5 nm. The scattered light was analyzed with low- and high-resolution double spectrometers. All measurements were carried out at room temperature in a helium atmosphere.

The Raman spectrum measured with a resolution of  $0.06 \text{ cm}^{-1}$  and 457.9 nm excitation is shown in Figure 14. Scattering from the longitudinal acoustic (LA) phonons with  $m = 0$  ( $\omega_{Br} = 3.4 \text{ cm}^{-1}$ ) and  $m = \pm 1$  ( $\omega_{-1} = 17.4 \text{ cm}^{-1}$  and  $\omega_{+1} = 24.3 \text{ cm}^{-1}$ ) can be easily identified. Brillouin scattering from LA and transverse acoustic (TA) phonons in the c-Si (100) substrate is also observed at 5.6 and  $3.9 \text{ cm}^{-1}$ , respectively. The observation of weak scattering from TA phonons is consistent with the small deviation from the exact backscattering geometry, for which Raman scattering from TA phonons in (100) Si is forbidden. The observation of

**Figure 14.** A high-resolution Raman spectrum in the vicinity of folded acoustic phonons (indices are shown) in a fully crystallized nc-Si/a-SiO<sub>2</sub> superlattice comprised of brick-shape Si nanocrystals.

Brillouin scattering is possible only in the case of a very low laser light-scattering background, proving that the sample had a very smooth surface and flat nc-Si/a-SiO<sub>2</sub> interfaces. The  $m = \pm 1$  doublet was also resolved in Raman spectra measured with a lower resolution of about 0.1 cm<sup>-1</sup> and excited by 457.9, 476.5, 488.0, 496.5, and 514.5 nm lines of the Ar<sup>+</sup> laser.

Using the experimentally determined  $d$  and  $\omega_{\pm 1}$ , it is possible to estimate the nc-Si/a-SiO<sub>2</sub> superlattice sound velocity. We found that  $v_{\text{SL}} = d(\omega_{+m} + \omega_{-m})/4\pi$ , averaged over the data obtained with different laser excitation lines, is  $7.5 \times 10^5$  cm/s. The reduced wavevectors of phonons participating in the scattering were calculated from  $q_p/q_{mz} = d(\omega_{+m} - \omega_{-m})/2\pi v_{\text{SL}}$ . Use of the different excitation wavelengths allows the observation of scattering from the LA phonons in the 0.26–0.31 reduced wavevector range of the Brillouin minizone. The assumption that the phonon dispersion is linear (i.e., the gaps can be ignored) is indeed justified by the above result: the light scattering involved phonons far from the minizone center or edge. Several measurements over the sample area of 2–3 cm<sup>2</sup> show very small deviation in the difference of the position of folded phonon peaks, and this difference indicates less than 5% variation in the superlattice thickness. Also, assuming that the sound velocity in the a-SiO<sub>2</sub> layers is identical to that in bulk a-SiO<sub>2</sub> ( $6.0 \times 10^5$  cm/s), the sound velocity in the Si nanocrystals is calculated as  $8.6 \times 10^5$  cm/s. This calculated sound velocity in nc-Si is close to the sound velocity in c-Si along the [100] direction ( $8.5 \times 10^5$  cm/s), compared with  $9.2 \times 10^5$  cm/s and  $9.4 \times 10^5$  cm/s along the [110] and [111] directions, respectively [43–45]. This result indicates that the Si nanocrystals might have some degree of preferential [100] orientation. This conclusion is not unreasonable, since under certain experimental conditions crystallized poly-Si films have [100] preferential orientation due to the fact that [100] is the fastest growing crystallographic direction [46]. The effective refractive index of the superlattice for different  $\lambda$  is calculated from  $n_{\text{SL}} = \lambda(\omega_{+m} - \omega_{-m})/8\pi v_{\text{SL}}$ . The refractive index in Si nanocrystals,  $n_1$ , then can be derived assuming that the refractive index of a-SiO<sub>2</sub>,  $n_2$ , is 1.46. The refractive index of nc-Si with an average nanocrystal size of 8.6 nm is noticeably lower than that of c-Si or a-Si.

Figure 15 shows moderate resolution ( $\sim 0.2$  cm<sup>-1</sup>) Raman spectra in the range of acoustic phonons for three samples of nc-Si/a-SiO<sub>2</sub> superlattices with different vertical sizes of the Si nanocrystals: 2.5, 4.2, and 8.5 nm. In agreement with the simplified theory of acoustic phonon dispersion in a layered structure, the Raman signal associated with folded acoustic phonons shifts to greater wavenumbers as the Si nanocrystal size decreases: from  $\sim 20$  cm<sup>-1</sup> for 8.5-nm Si nanocrystals to  $\sim 45$  cm<sup>-1</sup> for 2.5-nm Si nanocrystals. However, the structure of the observed Raman signal is then not clearly resolved, and that could be due to a decrease in quality of the nc-Si/a-SiO<sub>2</sub> interfaces. This decrease of the interface flatness is expected for the observed changes in Si nanocrystal shape: Si nanocrystals smaller than 7 nm are more spherical in shape compared to the brick-shape found in larger-size Si nanocrystals. In addition, these uncertainties in Si nanocrystal shape may be accompanied by some changes in other structural properties, for example, their crystallographic orientation.

**Figure 15.** Moderate-resolution low-frequency Raman spectra for samples of nc-Si/a-SiO<sub>2</sub> superlattices with different sizes of Si nanocrystals.

For many applications, it is very important to know and control the crystallographic orientations of Si nanocrystals. In particular, many physical effects (e.g., energy quantization) can only be observed for nanocrystals with similar crystallographic orientations, because of the sixfold symmetry of the electron energy dispersion in Si. Among other non-destructive and relatively fast analytical techniques, polarized Raman spectroscopy can be used directly to determine the crystallographic orientations of a Si film. We briefly review the theoretical approach developed in [47, 48] for the Raman polarization analysis and apply it to characterize nc-Si films.

Raman scattering is a two-photon process and the scattering intensity is determined by second-rank Raman tensors ( $R_{ij}$ , with  $i, j = x, y, z$ ). As a result, the Raman intensity depends on the orientations of polarization vectors of the incident and scattered light relative to the crystallographic axes of the sample. This means that the crystallographic orientation of the sample can be determined by examining the anisotropy of the Raman scattering intensity. Crystalline Si belongs to the O<sub>h</sub> point group of the 32 crystal classes, and the Raman-active optical phonon has F<sub>2g</sub> symmetry, which is triply degenerate. Raman tensors for the F<sub>2g</sub> mode in a crystal axis coordinate system are represented by

$$R_{yz} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & d \\ 0 & d & 0 \end{pmatrix}, \quad R_{zx} = \begin{pmatrix} 0 & 0 & d \\ 0 & 0 & 0 \\ d & 0 & 0 \end{pmatrix}, \quad R_{xy} = \begin{pmatrix} 0 & d & 0 \\ d & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad (3)$$

Raman polarization experiments are performed in the exact backscattering geometry, where the wavevectors of the incident ( $k_i$ ) and scattered ( $k_s$ ) light are normal to the crystal surface. In this configuration, changing the incident polarization direction has no effect on the percentage of incident laser light being absorbed by the sample. The Raman scattering intensity is given by

$$S = \eta \sum_j (e_i R_{ij} e_s)^2 \quad (4)$$

where  $\eta$  is a constant of proportionality related to the standard Raman cross section and depends on the frequency of the scattered light and the intensity of the incident laser light,  $e_i$  and  $e_s$  are unit polarization vectors of the incident and scattered light, respectively, expressed in the crystal axis coordinate system using  $\theta$ ,  $\phi$ ,  $\psi_0$ ,  $\psi$ , and  $\psi'$ . Angles  $\theta$ ,  $\phi$ , and  $\psi_0$ , relate the laboratory coordinate system (fixed with respect to the sample) to the crystal axis coordinate system and must be known to identify the crystallographic orientation of the sample. By definition,  $\theta$  is the angle made by the  $\langle 001 \rangle$  axis and  $k_s$ ,  $\phi$  is the angle between the  $\langle 100 \rangle$  axis and the projection of  $k_s$  onto the  $(001)$  plane, and  $\psi_0$  is the angle between the  $x$  axis of the laboratory coordinate system and the projection of the  $\langle 001 \rangle$  axis onto the  $xy$  plane. In addition,  $\psi$  ( $\psi'$ ) is introduced as the angle between the  $x$  axis and  $e_i$  ( $e_s$ ). Equation (4) can be rewritten in terms of the angle  $\psi$  as

$$I(\theta, \phi, \psi_0; \psi, \psi') = S/\eta d^2 \\ = A(\theta, \phi, \psi_0; \psi') + B(\theta, \phi, \psi_0; \psi') \cos 2\psi \\ + C(\theta, \phi, \psi_0; \psi') \sin 2\psi \quad (5)$$

The determination of the crystallographic orientation of the sample requires the measurement of its Raman intensity as a function of the angle  $\psi$  for at least two linear polarization directions of the scattered light. Usually, these two directions are chosen to be orthogonal to each other. When the polarization vector of the scattered light is parallel to the  $x$  axis ( $\psi' = 0$ ) or  $y$  axis ( $\psi' = 90$ ) in the laboratory coordinate system, Eq. (5) becomes

$$I_0 = A_0(\theta, \phi, \psi_0) + B_0(\theta, \phi, \psi_0) \cos 2\psi \\ + C_0(\theta, \phi, \psi_0) \sin 2\psi \quad (5a)$$

$$I_{90} = A_{90}(\theta, \phi, \psi_0) + B_{90}(\theta, \phi, \psi_0) \cos 2\psi \\ + C_{90}(\theta, \phi, \psi_0) \sin 2\psi \quad (5b)$$

By combining coefficients  $A_0$ ,  $B_0$ ,  $C_0$ ,  $A_{90}$ ,  $B_{90}$ , and  $C_{90}$ , and eliminating  $\psi_0$ , we obtain quantities that are functions of only  $\theta$  and  $\phi$ :

$$G(\theta, \phi) \equiv (\beta_+^2 + \gamma_+^2)/\alpha_+^2 = (k_1^2 + k_2^2)/k_0^2 \quad (6)$$

and

$$H(\theta, \phi) \equiv [(2\beta_- - \alpha_+ + 1)^2 + 4\gamma_-^2]/\alpha_+^2 \\ = [(k_3 - k_4)^2 + 4k_5^2]/k_0^2 \quad (7)$$

where  $\alpha_+ = A_0 + A_{90}$ ,  $\beta_+ = B_0 + B_{90}$ ,  $\gamma_+ = C_0 + C_{90}$ ,  $\alpha_- = A_0 - A_{90}$ ,  $\beta_- = B_0 - B_{90}$ ,  $\gamma_- = C_0 - C_{90}$ ;

$$k_0 = [4x(1-x) + 2 + (x-1)^2y]/2$$

$$k_1 = [-4x + (x+1)y](x-1)/2$$

$$k_2 = (1-x)[xy(1-y)]^{1/2}$$

$$k_3 = [4x(1-x) - 2 + (x+1)^2y]/2$$

$$k_4 = 1 - 2xy$$

$$k_5 = (1+x)[xy(1-y)]^{1/2}$$

with  $x = \cos^2 \theta$ ,  $y = \sin^2 2\phi$ .

Angles  $\theta$  and  $\phi$  are found by solving simultaneously Eqs. (6) and (7). The angle  $\psi_0$  can be found by solving

$$\alpha_- = k_1 \cos 2\psi_0 - k_2 \sin 2\psi_0 \quad (8)$$

With the restrictions  $\theta \geq 0$  and  $\phi \leq 90^\circ$ , six sets of  $(\theta, \phi)$  satisfy Eqs. (6)–(8). Determination of the angle  $\psi_0$  reduces the six sets  $(\theta, \phi)$  into three equivalent orientations  $(\theta, \phi, \psi_0)$  that are obtained by the rotation of the surface normal by  $120^\circ$  about the  $\langle 111 \rangle$  axis. For the  $(001)$  and  $(111)$  surfaces the variation of Raman intensity is given by

$$I_{001} = \sin^2(\psi + \psi' + 2\psi_0) \quad (9)$$

$$I_{111} = [\cos^2(\psi - \psi') + 2]/3 \quad (10)$$

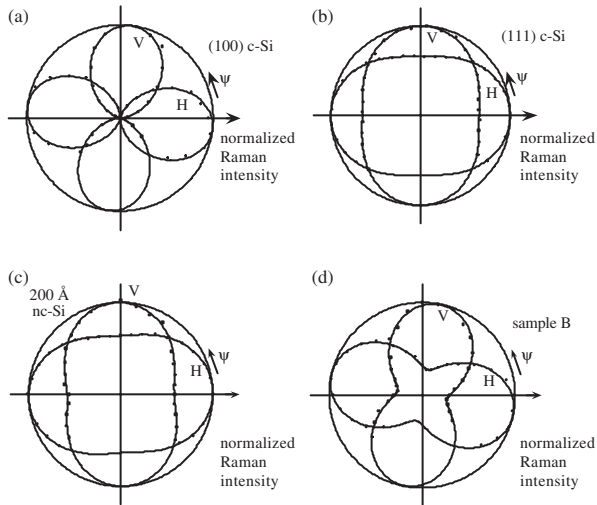

Any oblique incidence and scattering will have a negligible effect on the Raman polarization analysis of Si when one uses an objective lens with numerical aperture (NA) smaller than 0.5. This is because the refractive index of Si at 514.5 nm is 4.22 and the collection cone within the sample is only  $6.6^\circ$ .

The experimental setup for these measurements is quite standard. The 514.5-nm line of an Ar ion laser was focused on a sample surface by a lens of NA = 0.1. The scattered light was collected by an objective lens of NA = 0.5 and focused onto the entrance slit of a double spectrometer. The signal was detected by a photomultiplier with photon-counting electronics. A Glan–Thompson beam-splitting prism is used to produce linearly polarized light from the elliptically polarized light coming from the laser. A  $\lambda/2$  wave plate was used to rotate the polarization of the incident light. The sample was mounted on a movable X–Y stage and adjusted to be normal to the incident light. A sheet polarizer was used as an analyzer of the scattered light. A scrambler that compensates for the polarization-dependent transmission of the spectrometer was placed between the analyzer and the spectrometer entrance slit.

Raman polarization measurements were performed by varying the polarization of the incident light ( $\psi$ ) in  $10^\circ$  steps. The polarization of the scattered light is fixed at either perpendicular or parallel to the entrance slit of the spectrometer, that is, H (horizontal) or V (vertical) configurations, respectively. For each of the polarization configurations the spectrum in the 505–535  $\text{cm}^{-1}$  range was measured, the intensity of the background at 505  $\text{cm}^{-1}$  was subtracted, and the spectrum was numerically integrated. The spectral slit width of the spectrometer was  $\sim 1 \text{ cm}^{-1}$  and the Raman intensity was measured in 0.5- $\text{cm}^{-1}$  increments.

For Raman polarization measurements,  $(100)$  and  $(111)$  oriented single crystal Si wafers were used as test samples. Figure 16 shows their integrated Raman intensity in the radial direction as a function of the rotation angle of the polarizer ( $\psi$ ). Two sets of data (H and V) were collected for two orthogonal polarizations of the scattered light (along the  $x$  and  $y$  axes, respectively). The dots are experimental points fitted by Eqs. (9) and (10) (solid lines). The deviation between the calculated and nominal crystallographic orientations of Si  $(100)$  and  $(111)$  single crystals is found to be less than  $1^\circ$ .

For nc-Si/a-SiO<sub>2</sub> superlattices grown on c-Si substrates, a quantitative Raman polarization analysis is possible when

**Figure 16.** Polarization Raman diagram for (a)  $\langle 100 \rangle$  and (b)  $\langle 111 \rangle$  single crystal Si and (c) and (d) samples of crystallized nc-Si/a-SiO<sub>2</sub> superlattices.

the condition  $d_{\text{Si}} N \alpha(\lambda) \geq 1$  is satisfied ( $d_{\text{Si}}$  is a nc-Si layer thickness,  $N$  is a number of periods, and  $\alpha(\lambda)$  is the absorption coefficient of nc-Si). This condition ensures that the excitation light is completely absorbed within the nc-Si layers and no signal from the substrate will be detected: For a sample with 60 periods and a layer thickness of  $d_{\text{Si}} = 14$  nm,  $\alpha_{\lambda=514.5\text{nm}} = 1.465 \times 10^4 \text{ cm}^{-1}$ , where  $\alpha$  is the absorption coefficient of c-Si. Indeed, no difference in the shapes of normalized Raman spectra measured for orthogonal polarizations of the analyzer is observed. This proves that the Raman scattering is entirely determined by the nc-Si layers. Figure 16 shows the measured integrated Raman intensity as a function of a rotation angle of the polarizer (dots) for a sample having  $d_{\text{Si}} = 20$  nm. The solid lines are the curves obtained from a least-squares fit of the experimental data to Eq. (10). Using Eqs. (6)–(8) we find that  $\theta = 52^\circ$ ,  $\phi = 45^\circ$ ,  $\psi_0 = 13^\circ$ . This set of  $(\theta, \phi)$  angles is very close to the one defined by a  $\langle 111 \rangle$  surface:  $\theta = \arctan(\sqrt{2}) \approx 54.8^\circ$ ,  $\phi = \arctan(1) = 45^\circ$ . This result suggests that the majority of Si nanocrystals have their  $\langle 111 \rangle$  axis normal to the sample surface or, in other words, they have preferred  $\langle 111 \rangle$  crystallographic orientation.

The same Raman polarization analysis has been applied to samples with smaller Si nanocrystals ( $\sim 8.6$  nm in vertical dimension). Figure 16d shows the result, and our immediate impression (see Fig. 16) is that the Raman signal from the  $\langle 100 \rangle$  single crystal Si substrate is interfering with the signal from Si nanocrystals. The result of the numerical deconvolution of the Raman polarization signal is not accurate enough for any solid conclusions. However, a recent luminescence polarization analysis and additional structural measurements [49] indicate that Si nanocrystals smaller than 10 nm most likely have random crystallographic orientation. We will discuss the crystallographic orientation of smaller Si nanocrystals in a later paragraph on luminescence in nc-Si superlattices.

During studies of solid phase crystallization of a-Si films on amorphous substrates such as a-SiO<sub>2</sub>, it has been found that

crystallized a-Si films may exhibit a preferred crystallographic orientation only in cases when an orientation-dependent crystallization process (e.g., laminar crystallization along the a-Si/a-SiO<sub>2</sub> interfaces) takes place [50]. In c-Si, growth rates along  $\langle 113 \rangle$ ,  $\langle 110 \rangle$ ,  $\langle 112 \rangle$ , and  $\langle 111 \rangle$  crystallographic directions are 1, 1.5, 3, 5, and 24 times slower than the growth along the  $\langle 100 \rangle$  direction [51]. That difference is related to the number of Si atoms that are necessary to complete a crystal plane during the crystallization process. The crystallographic orientation of the crystallized a-Si film is strongly dependent on the density of nucleation centers, their location in the film, and the thickness of the film. Normally, crystallization of a-Si films on a-SiO<sub>2</sub> starts near the Si/SiO<sub>2</sub> interface where a large strain is present due to a difference in the thermal expansion coefficients of Si and SiO<sub>2</sub>. In the case of interface nucleation, crystallization of a-Si proceeds in columnar or laminar fashion, depending on the ratio between the film thickness  $h$  and the mean distance  $d$  between nuclei. When  $d \ll h$ , the crystallites grow in a three-dimensional way until they impinge on each other, then the growth continues in a one-dimensional way along a direction perpendicular to the Si/SiO<sub>2</sub> interface. In this case, the structure of the film is columnar and has a  $\langle 110 \rangle$  or  $\langle 112 \rangle$  crystallographic orientation, since the fastest growth occurs by the formation of twins along  $\langle 110 \rangle$  and  $\langle 112 \rangle$  axes. If  $d \gg h$ , crystallites grow in a three-dimensional way until they reach the surface and then the growth proceeds in a two-dimensional way. Nuclei with an orientation permitting a fast lateral rate of growth extend at the expense of other less favorably oriented nuclei. The resultant structure is laminar and has a  $\langle 111 \rangle$  orientation. When  $d \approx h$ , no preferred crystallographic orientation is expected because crystallites have the same chance to grow in any direction. It is quite possible that this particular scenario is realized in the case of Si nanocrystals smaller than 10 nm.

Our results show that the initial thickness of the a-Si film during crystallization controls not only the Si nanocrystal size but also the nanocrystal shape and crystallographic orientation. The shape of relatively large Si nanocrystals ( $> 10$ – $20$  nm) is rectangular and expanded laterally (i.e., bricks). In contrast, smaller Si nanocrystals ( $< 10$  nm) are nearly spherical. Also, our results have proved that brick-shape Si nanocrystals have preferred  $\langle 111 \rangle$  orientations while smaller, spherical nanocrystals are suspected to have random crystallographic orientation.

## 5. PHOTOLUMINESCENCE SPECTROSCOPY OF NANOCRYSTALLINE SILICON–SILICON DIOXIDE SUPERLATTICES

Intense interest in the optical properties of Si nanocrystals was stimulated by the initial report of a high-efficiency, room-temperature visible PL in porous Si [52], and by the subsequent discussions as to the origins of the PL [53–57]. This subject has already been covered extensively in many papers, reviews, and book chapters [2, 58, 59]. The aim of this review is to compare the PL properties of nc-Si/a-SiO<sub>2</sub> superlattices with similar data obtained in other materials containing Si nanocrystals (e.g., porous Si,

Si nanocrystals prepared by CVD, and ion implantation) and to examine the correlation between the Si nanocrystal structural (i.e., size, shape, and crystallographic orientation) and light-emitting properties. From the beginning of these studies it was obvious that one should start with relatively large-size ( $>20$  nm) Si nanocrystals of well-defined, brick-like shape and  $\langle 111 \rangle$  crystallographic orientation, and should continue toward much smaller, but less well controlled in shape, Si nanograins. Such a research strategy provided a unique opportunity to observe the transformation of phonon-assisted carrier recombination controlled by well-understood selection rules to a much less ordered process where phonons are still involved in carrier recombination but all selection rules are significantly relaxed. Figure 17 perfectly illustrates this statement where a set of narrow PL lines in a bulk Si sample where the dominant TO-phonon line practically does not move, but broadens and slightly changes the ratio between the TO-, TA-, and second TO-phonon lines in Si nanocrystals having sizes down to 8.6 nm in the vertical (growth) dimension. Continuing to decrease the Si nanocrystal size down to  $\sim 6$  nm, we observe a blue (toward higher photon energy) shift in the PL peak (which is at  $\sim 1.32$  eV) and significant broadening up to  $\sim 100$  meV in the PL full width at half maximum (FWHM). The phonon involvement can be recognized by the much less pronounced but still observable structure, with the main PL peak separated by  $\sim 60$  meV (TO-phonon) from a shoulder at lower photon energy (Fig. 17). A further decrease in Si nanocrystal size down to 4.2 nm results in a shift of the PL peak to 1.4 eV and an almost 200 meV FWHM. This PL looks quite different compared to PL from bulk Si and, at the same time, is similar to PL spectra observed in porous Si and Si nanocrystals prepared by ion implantation [58, 60]. The dependence of the PL peak position and FWHM as a function of Si nanocrystal size is summarized in Figure 18, showing a clear correlation between the PL broadening and PL peak blue shift. Note that the PL peak in smaller Si nanocrystals shifts to higher photon energy in a just slightly superlinear fashion, but the PL FWHM increases exponentially as the Si nanocrystal size decreases. To our surprise, we have found that the observed selection rule relaxation in PL

**Figure 17.** PL spectra from samples of nc-Si/a-SiO<sub>2</sub> superlattices with different sizes of Si nanocrystals, as indicated.

**Figure 18.** The PL peak energy and full width at half maximum (FWHM) as a function of Si nanocrystal size.

from small Si nanocrystals is very similar to the conclusions that we were able to draw from the Raman studies.

Considering the origin of this broad PL band, we concentrate on two major possibilities. After more than a decade of searching for a convincing experimental method of determining the origin of a broad and featureless PL in Si nanocrystals, the technique of resonant PL excitation has been widely recognized as the most useful one [58, 61]. The PL has been linked to carrier recombination in Si nanocrystals due to a clear indication of a phonon-assisted PL mechanism and the observation of structure in PL spectra where almost all of the characteristic Si phonons and their combinations are found [58]. Tuning the wavelength of optical excitation toward the PL band, the inhomogeneous PL broadening due to the Si nanocrystal size distribution is reduced [58]. In addition, resonant PL excitation may require phonon absorption due to the indirect nature of optical transitions in Si nanocrystals. These measurements have been described and performed in porous Si and other systems containing Si nanocrystals [58, 62]. In the case of nc-Si/a-SiO<sub>2</sub> superlattices, an additional contribution to the inhomogeneous broadening is, most likely, coming from the previously mentioned uncertainties in the shape and crystallographic orientation of small-size Si nanocrystals. This is particularly important for Si due to its indirect band structure and strong dispersion in the effective mass along different crystallographic directions.

From a technical point of view, the experiment requires a source of tunable excitation, which is usually a tunable laser (e.g., Ti:Al<sub>2</sub>O<sub>3</sub>), because the desired condition is to bring the excitation wavelength as close as possible to the PL line. This is demonstrated in Figure 19a, where a decrease of the excitation photon energy from 1.66 to 1.42 eV depicts a step-like structure more clearly. Figure 19b shows a higher-resolution PL spectrum under resonant excitation, and contributions from specific Si phonons and their combinations are indicated.

However, the fact that the PL lifetime has a strong temperature dependence (see Fig. 20) indicates that at least two competing mechanisms (most likely radiative and nonradiative) may contribute to the overall PL signal. Interestingly,

**Figure 19.** (a) An example of resonantly excited PL spectra in a nc-Si/a-SiO<sub>2</sub> superlattice with 42-Å-diameter Si nanocrystal showing better-resolved PL structure as the excitation photon energy decreases. (b) A high-resolution resonantly excited PL spectrum with energies of characteristic Si phonons indicated.

the PL kinetics appear single exponential compared to the more complex, usually stretched exponential behavior reported in Si nanocrystals prepared by other techniques [63]. Another indication that the PL may have a more complex rather than single origin comes from the data in Figure 21, where we compare PL spectra in a nc-Si superlattice with an average Si nanocrystal size of  $\sim 4.2$  nm. At low excitation power ( $0.05 \text{ W/cm}^2$ ), the PL peak is at  $\sim 1.4$  eV, but with the increase of the excitation up to  $10 \text{ W/cm}^2$ , the PL spectrum broadens and the PL peak shifts to  $>1.7$  eV. The observed broadening of the PL spectra has triggered a search for another technique that is able to separate different possible contributions to the luminescence in nc-Si superlattices.

To our surprise, the most interesting results with a very clear interpretation have been found in studies of the PL spectral response as a function of external magnetic and electric fields. Following the initial report that an external magnetic field increases the gap between singlet and triplet states in Si nanocrystals, the fact that the PL lifetime increases and intensity decreases in Si nanocrystals is quite well understood [64–66]. However, our studies show that in nc-Si superlattices this PL quenching is selective and

**Figure 20.** PL decay time in a fully crystallized nc-Si/a-SiO<sub>2</sub> superlattice with 42-Å-diameter Si nanocrystals showing a single exponential decay and a strong PL lifetime temperature dependence.

**Figure 21.** PL spectra in a nc-Si/a-SiO<sub>2</sub> superlattice with 42-Å-diameter Si nanocrystals under different excitation intensity.

affects only PL at wavelengths longer than  $\sim 750$  nm. The PL intensity at shorter wavelength does not show any quenching under an applied magnetic field as high as 9 T (Fig. 22). The observed selective quenching of PL in nc-Si superlattices proves that the PL origin is more complex than just a single mechanism based on the quantum confinement effect in Si nanocrystals.

The application of an external electric field is also an informative experiment due to quite different mechanisms of PL quenching, including direct exciton deformation and dissociation under an external electric field and exciton impact ionization. Different electric-field-induced PL quenching mechanisms have very different thresholds and field dependences. Therefore, we studied the PL dependence as a function of the applied electric field in nc-Si/a-SiO<sub>2</sub> superlattices. Our technique is based on the application of an AC

**Figure 22.** PL spectra in a nc-Si/a-SiO<sub>2</sub> superlattice with 42-Å-diameter Si nanocrystals in an applied magnetic field of different strengths. A selective quench of PL intensity is clearly shown.

electric field and detection of a modulated PL component using a lock-in amplifier. This technique is more sensitive compared to the standard technique where CW PL is influenced by an applied dc electric field. We have found that an electric-field-dependent PL spectral component is strongly correlated with magneto-PL measurements: the modulated PL component is red-shifted compared to CW PL at zero electric field, and the electric field modulates only the PL at wavelengths longer than 750 nm (Fig. 23). These data are in complete agreement with the magneto-PL measurements. Therefore, we can conclude that a portion of the PL in nc-Si superlattices at shorter wavelengths does not depend on the electric or magnetic field and most likely has a different origin than PL associated with confined excitons in Si nanocrystals. Additional support for this conclusion can be found in early work on porous Si showing that the PL peak follows the ratio between the numbers of Si-O and Si-H bonds in samples with different degrees of oxidation [67].

## 6. RESONANT CARRIER TUNNELING IN NANOCRYSTALLINE SILICON-SILICON DIOXIDE SUPERLATTICES

Amongst a wide variety of phenomena exhibited in semiconductor quantum transport, resonant carrier tunneling (RCT) and negative differential conductivity (NDC) due to a non-monotonic dependence of the carrier tunnel transmission through potential barriers has always been associated with nearly perfect semiconductor heterostructures and superlattices with a long carrier mean free path [68–70]. The question as to how RCT can be preserved in a structure with a partial disorder is important both for the physics of quantum structures and for practical quantum device applications [71–76]. A system with a controlled degree of disorder, combining for example a periodic potential in the  $z$  direction (i.e., the growth direction) with the presence of grain boundaries separating nanocrystals laterally in the  $xy$  plane, is a special case of general interest. A nc-Si superlattice fabricated by controlled crystallization of amorphous Si/SiO<sub>2</sub> layered structures forms a perfect example of such a system.

**Figure 23.** Strong red shift of the electric-field-modulated PL spectrum in a 20-period nc-Si/a-SiO<sub>2</sub> superlattice with 42-Å-diameter Si nanocrystals measured using a lock-in amplifier and an ac voltage of 15 V.

The flat and chemically abrupt SiO<sub>2</sub> layers of low defect density [77] separate the Si nanocrystals and provide vertical carrier confinement, which is a key condition for functional quantum devices. This structure has a well-defined order in the  $z$  direction, but is partially disordered laterally due to the nanograin boundaries and the limited degree of Si nanograin crystallographic orientation, as discussed earlier in this chapter. Using such a novel structure, the vertical carrier transport has been investigated and entirely unexpected effects such as narrow resonances in the conductivity, stable self-oscillations, and the strong influence of a low magnetic field applied in the  $z$  direction have been observed [13]. The surprising results show that even though there is significant carrier scattering, resonant tunneling and the formation of electron standing waves is still possible.

A typical sample for this work was prepared in the form of a 10-period nc-Si superlattice on an  $n$ -type, high-resistivity ( $\rho > 1$  k $\Omega$  cm) c-Si substrate, with a Si nanocrystal diameter of  $\sim 45$  Å and with  $\sim 15$ -Å-thick SiO<sub>2</sub> layers. The low-temperature (4.2 K) hole transport measurements were performed in the sandwich geometry. A He-Ne laser (632.8 nm) was used to generate electron-hole pairs, mostly within the depletion region of the positively biased Si substrate, and holes were extracted through the superlattice structure toward the negatively biased top Al contact. Standard direct current (dc) current-voltage (I-V) measurements were performed using a Keithley 595 electrometer. Measurements of alternating current (ac) differential conductivity were obtained using an HP 4192A impedance analyzer.

The experiments were carefully designed to avoid a nonuniform electric field, which may destroy the symmetry of barriers and reduce the effects of resonances. Using a superlattice-type structure confined in a  $p$ - $i$ - $n$  diode or Schottky barrier minimizes these effects. In addition, the use of light to generate carriers is a relatively nondestructive way to manipulate the carrier density without significant screening and distortion of the electric field uniformity. Finally, special attention was paid to transient conductivity characteristics. Resonant carrier tunneling in a structure with large (Si/SiO<sub>2</sub>) barriers is not an immediate phenomenon. In a practical device, resonant tunneling is time-dependent and needs a non-negligible time to become fully established. This process mainly requires the accumulation of tunneling carriers within the resonant well. Each electron localized within the well modifies the local potential, and a feedback mechanism, which often can be limited (at least in part) by the circuit resistance-capacitance time constant, increases the time of the resonant transition [78]. In the extreme case, this process may generate an oscillating current. Therefore, the dc current measurement should be accompanied by frequency- and phase-sensitive ac conductivity measurements.

Figure 24 shows a TEM micrograph of the investigated structure and a set of dc I-V characteristics measured under different levels of photoexcitation. The I-V curves clearly exhibit a step-like structure between 1 and 3 V of the applied reverse bias, with current steps shifted to slightly higher voltage as the excitation power increases (shown in the figure by the arrows). The observation of a step-like structure indicates the expected RCT in a multibarrier structure, which results from a non-monotonic dependence of the barrier tunnel transmission on the applied bias. However, in dc

**Figure 24.** Step-like direct current (dc) current-voltage (I-V) characteristics in a Si (45 Å)/SiO<sub>2</sub> (15 Å) 10-period superlattice with different levels of photoexcitation. The inset shows a TEM of a fragment of the sample. Reprinted with permission from [13], L. Tsybeskov et al., *Europhys. Lett.* 55, 552 (2001). © 2001, EDP Sciences.

conductivity measurements no fine structure was observed, which can be used in the identification of particular resonant transitions. Also, no NDC was found in these experiments, showing that carrier scattering in the structures is not negligible.

The measurements of ac differential conductivity  $\sigma_{ac}(V)$  proved to be much more sensitive. Figure 25a shows several traces of  $\sigma_{ac}(V)$  with different levels of photoexcitation (corresponding to different levels of carrier concentration) recorded at a frequency of 465 Hz. At the lowest level of excitation we detect a broad peak at  $V \approx 850$  mV with a full width at half maximum of about 600 meV. On increasing the carrier concentration, the peak is split and another peak rises near 1.3–1.5 V, which quickly becomes dominant. With further increase of carrier concentration, a sharp ( $\leq 100$  mV) asymmetric peak, the NDC regime, and an oscillating behavior near 2 V applied bias are found. At an even higher level of photoexcitation, the sharp peak and NDC regime could disappear, leaving a remnant in the form of a broad feature near 1.6 V and a sharp minimum at 2 V. The rich structure becomes less pronounced for temperatures above 20 K and practically cannot be detected at temperatures much greater than 60 K.

The expected time dependence of carrier tunneling in a barrier structure is demonstrated by the frequency dependence of the ac differential conductivity under experimental conditions close to the resonance condition (see Fig. 25b). The NDC regime has not been found for biases lower than 1.0 V. On increasing the applied bias ( $V \geq 1.8$  V), NDC is observed localized near 1 kHz. When a larger bias is applied, the NDC regime may occupy a broad frequency range, anywhere from 10 Hz to 10<sup>6</sup> Hz. Finally, at a large bias ( $V \geq 3.5$  V) NDC is no longer observed, which indicates that the system is out of resonance.

The observed step-like dc I-V characteristics, rich structure, and the NDC regime in the ac differential conductivity

**Figure 25.** (a) Differential alternating current (ac) conductivity as a function of the applied bias measured under different levels of photoexcitation. The NDC regime is shown by arrows. (b) Frequency dependence of the ac differential conductivity measured at the specified applied bias and light intensity. measurements convincingly show that the conductivity in nc-Si/SiO<sub>2</sub> samples exhibits a non-monotonic dependence as a function of the applied bias. However, the conductivity  $\sigma = e\mu n$ , where  $e$  is the electron charge, is a function of the carrier mobility  $\mu$  and carrier concentration  $n$ . It is well known that a non-monotonic carrier density dependence on the applied electric field also causes NDC, and an example of such a process is the electric field ionization of the Si/SiO<sub>2</sub> interface traps [79]. In general, the observation of NDC does not imply a resonant tunneling mechanism, and a test, independently probing tunnel transmission through the barriers, is necessary to prove the existence of RCT. This test can be performed using measurements of the longitudinal magnetoresistance for low applied magnetic fields.

Figure 26 shows that at nearly resonant conditions, the ac conductivity at low frequency ( $< 20$  Hz) displays a measurable magnetoresistance effect of the order of 10%. However, at higher frequency, where NDC takes place, the influence of the low magnetic field is much stronger, showing a complete destruction of NDC at a longitudinal magnetic field of less than 100 mT. The influence of a low magnetic field was investigated in a more sensitive fashion by employing an inductance-capacitance-resistance (LCR)-resonant circuit. Since the samples exhibit the NDC regime and  $N$ -shaped switching, a properly loaded LCR-resonant circuit allows stable self-oscillations, as can be seen in Figure 27. Any small changes in the circuit parameters affect the self-oscillations resonant conditions, and thus can be used to detect a weak magnetoresistance effect. Figure 27 shows that a very low ( $< 5$  mT) magnetic field applied in the  $z$  direction may strongly decrease the amplitude of the oscillations. Also, the applied magnetic field can generate beating effects, showing that self-oscillations with more than one frequency may coexist (see Fig. 27). This sensitive detection technique was applied to check the angular dependence of the magnetoresistance in the  $xz$  plane, but no significant angular dependence was found.

**Figure 26.** Frequency dependence of the ac differential conductivity measured at the specified longitudinal magnetic field. Arrows show the magnetoresistance effect at low frequency, which is similar to dc conductivity, and near the resonant frequencies. The zero level is shown by a dashed line. Why does a low magnetic field applied parallel to the current direction drastically affect the sample conductivity? In general, under such conditions only the transverse magnetoresistance should be detectable. However, it has been noted previously that the interface roughness in superlattices creates an additional lateral component in the initially vertical carrier transport [80], and this lateral conductivity would be responsible for the observed changes in current as a function of the parallel magnetic field. It is reasonable to assume that nc-Si/SiO<sub>2</sub> interface roughness and a variation in the Si nanocrystal crystallographic orientation complicate the carrier trajectories. Therefore, no significant magnetoresistance angular dependence can be anticipated. In addition, the self-oscillations beating and thus coexistence of several oscillation frequencies clearly indicate that

**Figure 27.** The influence of a weak longitudinal magnetic field under the experimental conditions indicated on self-oscillations: (a) self-oscillations suppression and (b) creation of self-oscillations beating. the sample conductivity may not be homogeneous over the entire sample area. In other words, instead of a single standing wave, carrier transport in the sample can be represented by a number of interfering modes. Performing dc conductivity measurements and averaging over all time-dependent processes, only a remnant of RCT with a step-like I-V response was observed. This consideration is fully consistent with the properties of RCT in conventional superlattices, where the peak-to-valley ratio in I-V measurements is strongly affected by scattering processes [69, 70]. The ac conductivity measurement, which by definition is a frequency- and phase-selective technique, allows one to focus on just a portion of the carrier transport that is associated with particular dwell time. This is why such a rich structure and the NDC regime could be found. The electron dwell time in 2D wells separated by a rectangular Si/SiO<sub>2</sub> barrier can be estimated using an approach outlined in [81] and [82] and a characteristic time of the order of  $\sim 10^{-3}$  s is obtained. In a more complex situation, such as where tunneling occurs between two Si quantum dots separated by a thin oxide layer, additional information about the electronic structure of the system is needed. This calculation has been performed taking into account the inter-dot interaction [83], and resulted in an electron dwell time of the order of  $\geq 10^{-3}$  s. These two dwell time numbers are close not only to each other but also to the experimental results (see Fig. 25). A broadening of the resonant frequency range (shown in Fig. 25b) evident under a larger applied bias most likely reflects several simultaneous processes such as a reduction of the Si/SiO<sub>2</sub> barrier effective height, which decreases the electron dwell time, and partial distortion of the symmetry of barriers with increasing contribution of phonon-assisted transitions, which increases the electron dwell time.

The low-magnetic-field ( $< 10$  mT) experiments indicate that carrier transport in nc-Si superlattices is, at least in part, phase coherent. The magnetic length for a wide ( $\sim 1$  mm) and short ( $\sim 600$  Å) sample can be estimated from  $l_m \sim (h/2\pi eB)^{0.5}$  [84, 85] as  $100 \text{ Å} \leq l_m \leq 1000 \text{ Å}$ . Phase coherence can be destroyed by the dynamic scattering that becomes significant at higher temperature due to the electron-phonon interaction and at higher carrier concentration due to the electron-electron interaction [86]. Assuming that the dynamic scattering at higher temperatures is due to the interaction between carriers and Si acoustic phonons, the temperature threshold for this process should be  $\sim 30$  K. Dynamic scattering due to carrier-carrier interaction should become noticeable when the carrier concentration becomes  $\geq 10^{14} \text{ cm}^{-3}$  (i.e., it becomes comparable with the Si nanocrystal volume density). Both of these general arguments are in good agreement with the experimental results.

Hole tunneling via Si nanocrystal quantized states is the major mechanism contributing to RCT in nc-Si/SiO<sub>2</sub> samples. This is verified from tight binding (TB) calculations [13] applied to various  $\langle 100 \rangle$  oriented Si nano-objects including (1) spherical Si nanocrystals with diameters of 33 Å and 40 Å; (2) a Si ellipsoid with 46 Å vertical and 65 Å lateral dimensions; and (3) a 42-Å Si quantum well sandwiched between tunnel transparent SiO<sub>2</sub> layers. To obtain accurately the hole states in  $\sim 40$ -Å nano-objects, the spin-orbit coupling was included in the calculation. An orthogonal  $sp^3$  TB model

with up to third nearest neighbor interactions and three-center integrals was used: the TB parameters given in [87] provide an accurate description of the bulk effective masses as well as the overall band structure. The eigenstates were calculated using an efficient conjugate gradient algorithm [87]. Results of these calculations are shown in Figure 28. To compare the calculations with experiment, the applied bias is divided equally between all 10 quasi-wells in the nc-Si/SiO<sub>2</sub> superlattice. Therefore, the voltage separating the two peaks ( $\sim 400$  mV) observed in the tunnel spectroscopy experiments corresponds to a  $\sim 40$ -meV energy separating the predominantly heavy and light hole states. According to these simulations of the experimental conditions, a part of the applied bias ( $\sim 30\%$ ) is dropped on the Si substrate, and thus the estimated energy separating heavy and light hole states is  $\sim 25$  meV. This result is very close to the energy calculated for a weakly isolated (laterally) Si  $\langle 100 \rangle$  ellipsoid with 46 Å and 65 Å vertical and lateral dimensions, respectively (see Fig. 28). Indeed, the TEM micrograph shown in the inset of Figure 24 confirms that the majority of Si nanocrystals possess a nearly elliptical shape.

The results presented in this section demonstrate that a great deal of information can be obtained from properly performed tunnel spectroscopy measurements based on ac conductivity. They have enabled the observation of discrete quantized energy levels in a Si nanocrystal. These energy levels have been suspected and discussed for a long time, but had never been experimentally observed before [88, 89]. Most importantly, this distinct observation of resonant tunneling in an imperfect Si/SiO<sub>2</sub>-based layered structure enables new efforts in the development of practical Si/SiO<sub>2</sub> quantum devices.

**Figure 28.** The electronic structure of the valence band in  $\langle 100 \rangle$  Si nano-objects obtained using TB calculations: Si ellipsoid with 46 Å vertical and 65 Å lateral sizes; 42 Å Si well sandwiched between tunnel transparent SiO<sub>2</sub> layers; and spherical Si nanocrystals with diameters of 33 Å and 40 Å. The first two hole energy levels are indicated for each nano-object. Reprinted with permission from [13], L. Tsybeskov et al., *Europhys. Lett.* 55, 552 (2001). © 2001, EDP Sciences.

## 7. SUMMARY

As has been mentioned earlier, the initial interest in structures based on Si nanocrystals was raised mostly due to their unusual optical properties, for example, visible PL with high quantum efficiency as reported first in 1990 [52]. The experimental fact that PL in Si nanocrystals as small as 2–3 nm remains slow and requires phonon assistance to conserve momentum, due to the indirect nature of their quasi-band structure, prevents their use in practical light-emitters utilizing intrinsic radiative transitions [90]. In contrast, recent work on complex or doped (e.g., Er<sup>+</sup> ions) Si nanocrystals and nc-Si superlattices is important due to the observation of an anti-correlation between the intrinsic PL and PL related to dopants [91]. However, at least two critical steps still need to be made: (1) a better understanding of the charge-transfer mechanism, and (2) a significant increase in the PL and EL quantum efficiency.

Following the first paper reporting the charging effect and possible applications of Si nanocrystals in memory devices [92], additional interest in their electronic properties has grown quickly. The fact that Si nanocrystals can be prepared in the form of a layered structure with precise control over their size, shape, and crystallography has also stimulated general interest in carrier transport in such systems. Despite such obvious imperfections as the grain boundaries that are separating laterally the Si nanocrystals, the periodic nature of the nc-Si/a-SiO<sub>2</sub> superlattices with tunnel transparent SiO<sub>2</sub> barriers controls carrier transport at low temperatures and many interesting and potentially important features such as sequential resonant tunneling, unusual magnetoresistance, and sustained oscillations can be observed [13]. In addition, it has been predicted that vertical quantum carrier transport can significantly be enhanced in structures where their nanocrystals display vertical self-alignment due to uniform strain propagation. So far, this work has been done primarily in epitaxial crystal growth (MBE, MOCVD, or CVD) of III-V and IV-IV semiconductors. The first successful attempt to achieve similar results in nc-Si/a-SiO<sub>2</sub> superlattices with a focus on the vertical self-alignment of Si nanocrystals is shown in Figure 29. Preliminary results indicate that quantum carrier transport in these structures is enhanced, and thus these structures can find applications

**Figure 29.** TEM micrograph showing vertical self-organization in a nc-Si/a-SiO<sub>2</sub> superlattice. Note the nearly pyramidal shape of the Si nanocrystals.

in practical electron devices. Therefore, it is quite possible that the most interesting results in the development of novel electron devices based on nc-Si superlattices are yet to come.

## GLOSSARY

**Absorption coefficient** A measure on an exponential scale of the degree of the attenuation of light propagating through a material.

**Brillouin scattering** As for Raman scattering, but very low energy excitations are involved, e.g., acoustic phonons.

**Epitaxy** Growth of materials atomic layer by atomic layer coherently on some single crystal planar substrate.

**Heterostructure** The joining of two dissimilar planar crystalline materials with a common in-plane lattice constant, usually produced by epitaxial growth.

**Minizone** A Brillouin zone of reduced size created within a superlattice along the growth direction.

**Nanocrystalline silicon** Single crystals of silicon of nanometer dimensions typically 110 nm in size.

**Photoluminescence** Light emitted by a material under illumination by light of usually shorter wavelength.

**Point group** A mathematical construct that describes the symmetry possessed by a crystal.

**Quantum well** A thin layer of a semiconductor in which charge carriers are confined by the higher band potential of the adjacent material.

**Raman spectroscopy** Inelastic scattering of light by vibrational or electronic excitations in a material.

**Resonant carrier tunneling** Quantum mechanical propagation of charge carriers through a potential barrier.

**Superlattice** Artificial lattice created in one direction by growing alternating layers of different materials on a planar substrate.

## ACKNOWLEDGMENTS

We would like to thank our many colleagues from the University of Rochester (P. M. Fauchet, L. Rothberg, and D. G. Hall), National Research Council of Canada (J. P. McCaffrey, J.-M. Baribeau, G. I. Sproule, and H. J. Labbé), the Technical University of Munich (F. Koch, M. Stutzmann, D. Kovalev, J. Diener, and V. Timoshenko), Motorola (B. E. White and S. Zollner), Kodak (T. N. Blanton), and other collaborators (M. Zacharias, G. Allan, C. Delerue, I. Aleiner, and B. Likhtman) for their help and diverse contributions. LT specifically thanks his former graduate student at the University of Rochester, Dr. G. F. Grom. He also thanks the German Academic Exchange Service (DAAD) for a 1999 summer research program in Germany and the National Science Foundation, Semiconductor Research Corporation, Motorola, Foundation at NJIT, and Army Research Office for financial support.

## 1. INTRODUCTION

Since the report of deposition using chemical transport method by Veprek and Marecek [1], hydrogenated nanocrystalline silicon (nc-Si:H), usually called hydrogenated microcrystalline silicon ( $\mu$ c-Si:H), has gathered much interest. The primary preparation method of nc-Si:H is plasma-enhanced chemical vapor deposition (PECVD) using highly diluted  $\text{SiH}_4$  in  $\text{H}_2$  [2–5]. In this method, dangling bond (DB) defects are decreased due to termination by hydrogen atoms. In addition, impurity doping can be done using phosphine gas or diborane gas as phosphorus or boron source, as well as in the case of hydrogenated amorphous silicon (a-Si:H) [6]. Moreover, doping efficiency of nc-Si:H is higher than that in a-Si:H. Dark conductivity of  $10^{-1} \text{ cm}^{-1}$  has been achieved by doping [7–9]. Due to the properties shown here, nc-Si:H has been a promising thin-film material for some optical devices such as solar cells [10–15] or thin solid transistors. As highly diluted  $\text{SiH}_4$  gas has been used as a silicon source, the deposition rate of nc-Si:H was extremely low; however, high-rate deposition of nc-Si:H films at low temperature has been reported [16]. This kind of work is thought to enhance the use of nc-Si:H thin films for devices. Recently, as another kind of low-temperature deposition

method, hot-wire chemical vapor deposition (HWCVD) has been extensively studied. In the method, a thermal and catalytic reaction between deposition source gas and tungsten hot-wire catalyzer that causes the film deposition instead of plasma decomposition of  $\text{SiH}_4$  is used for deposition of films [17–19].

Although the growth mechanism of nc-Si:H by the CVD method is still under discussion [4, 20–22], the structure of nc-Si:H has been studied and reported. The nc-Si:H is a heterogeneous material consisting of small crystallites with size on the order of 5 to 30 nm which are embedded in columns structure that is parallel to the film growth axis with a diameter of 50 to 200 nm [23, 24]. In such mixed phase structure, electron spin resonance (ESR) spectroscopy is an important method to study a particular electronic state, because the techniques are sensitive to the microscopic environment of this state.

In this chapter, ESR studies of nc-Si:H are reviewed. After the section of basics of ESR, the signal of conduction electrons, conduction holes, light-induced ESR, and dangling bond defects signals will be reviewed.

## 2. BASICS OF ELECTRON SPIN RESONANCE

ESR spectroscopy is a very important method to study the characteristics of paramagnetic species. In the case of nc-Si:H, ESR has been used for the study of silicon DB defects and carriers, mainly conduction electron (CE) in n-type materials. In the study of nanocrystalline or related material such as a-Si:H, ESR spectroscopy has been used in a great deal of work to estimate spin densities by intensity of corresponding signals. However, the ESR spectroscopy can also be used for the research of paramagnetic characteristics of the paramagnetic species in the material. The important information of ESR spectroscopy to clarify the characteristics of paramagnetic species in nc-Si:H are  $g$ -value, spin-lattice relaxation time, and line width. In this section, basic theories of these important data are explained.

The  $g$ -value is the magnitude of the electron Zeeman factor for the paramagnetic species considered. The  $g$ -value can be determined by the equation

$$E = g\mu_B B$$

In it,  $E$  is energy of microwave,  $\mu_B$  is Bohr magnetron, and  $B$  is magnetic field.  $g$ -value becomes 2.0023 in the case of free electron. In the case of actual paramagnetic species, the value becomes different because of the effect of local magnetic field. In the case of DB defects in a-Si:H or nc-Si:H, the effect of spin-orbit coupling is important. The spin-orbit coupling is caused by local magnetic field due to movement of electrons in its orbit. Thus, the  $g$ -value determined by spin-orbit coupling depends on the structure of the orbit. The effect of spin-orbit coupling is anisotropic; thus, it also depends on axis determined by magnetic field. Here, we assume the spin-orbit coupling of DB with a state in silicon. If we take a DB orbital along the  $z$ -axis, the anisotropic  $g$ -values are given by

$$g_{\parallel} = g_z = g_e$$

$$g_{\perp} = g_x = g_y = g_e \left\{ \delta_{ij} - \lambda \sum_{n=x,y,z} \frac{\langle \phi_{\text{DB}} | L_i | \varphi_n \rangle \langle \varphi_n | L_j | \phi_{\text{DB}} \rangle}{E_n - E^{\text{DB}}} \right\}$$

where  $g_e$ ,  $\phi$ , and  $E^{\text{DB}}$  are the  $g$ -value of free electron, the wave function of DB, and the energy of the DB, respectively.  $\varphi_n$  and  $E_n$  stand for the wavefunction and the energy of a coupling state.  $\lambda$  is a coupling constant of the spin-orbit interaction, which is  $149 \text{ cm}^{-1}$  in the case of silicon. The  $g$ -value observed in the spectra is

$$g = \sqrt{g_x^2 + g_y^2 + g_z^2}$$

Spin-lattice relaxation time is also one of the important characteristics for paramagnetic species. When ESR happens, the spin system absorbs the microwave with appropriate energy. Hence, the spin system can be thought as with high energy compared with its surroundings. The actual spin system undergoes interactions with the surroundings until its energy eventually is restored to the same as that of the surroundings through contact with it. As with any sufficiently simple thermodynamic system that receives an extra energy  $\delta U_0$  at  $t = t_0$ , it loses this excess energy to its surroundings with an exponential decay, described as

$$\delta U = \delta U_0 \exp[-(t - t_0)/T_1]$$

where  $\delta U_0$  is the excess energy at time  $t = t_0$ , and  $T_1$  is the characteristic time called relaxation time that corresponds to the energy flow rate magnitude from the spin system to the surroundings. Relaxation time  $T_1$  reflects the degree to which the spin system is connected to its surroundings.

Finally, we mention the line width of ESR signals. The spectral lines are classified into those that are homogeneously broadened and those that are inhomogeneously broadened. Homogeneous line broadening for a set of spins occurs when all the spins are in the same magnetic condition and have the same spin Hamiltonian parameters. This means all the spins have the same line shape of the signal. The line shapes of homogeneous broadening have a

lorentzian line shape. The actual homogeneous linewidth  $\Gamma$  is determined by the equation

$$\Gamma = \frac{1}{2T_1} + \frac{(1 + \gamma_e^2 B_1^2 T_1 T_2)^{1/2}}{T_2}$$

In the equation,  $T_1$  and  $T_2$  are the relaxation time of spins,  $B_1$  is oscillating magnetic field, and  $\gamma_e$  corresponds to

$$\gamma_e = \frac{g_e \mu_B}{\hbar}$$

The line width of homogeneously broadened lines depends on the relaxation time of the spins.

The inhomogeneous broadening mechanism distributes the resonance magnetic field frequencies without line broadening due to individual equivalent spins. The observed signal is a superposition of a large number of individual spin packets, all of which have slightly different  $g$ -values from each other. Even if the outer magnetic field is homogeneous, the inhomogeneous broadening is caused by various factors. With an anisotropic interaction in a randomly oriented system in a solid, the distribution of local magnetic field resulting from the anisotropic  $g$ -tensor gives rise to the inhomogeneous broadening. This corresponds to asymmetrical line shape in many cases. The DBs in the silicon are included in this case. Another factor that induces the inhomogeneous line shape is the unresolved hyperfine structure. This occurs when the number of hyperfine components located near nuclei is so great that no clear hyperfine structure is observed. In the hydrogen in the nc-Si:H, the line broadening due to the hyperfine structure by the hydrogen atoms may cause this broadening.

### 3. n-TYPE NANOCRYSTALLINE SILICON

In this section, ESR studies of doped n-type nc-Si:H are described. In the beginning of ESR studies of nc-Si:H, most of the studies published were devoted to n-type materials. In the n-type materials, the spectra are dominated by CE signal at  $g = 1.997\text{--}1.999$  rather than silicon DB defects signals. The studies of the CE signal are described in this section.

Before the first report of ESR study of n-type nc-Si:H, many works of related material such as n-type a-Si:H, crystalline silicon, and polycrystalline-silicon (poly-Si) have been reported. The first report of CE ESR signals in crystalline silicon was done by Portis and co-workers [25]. They described a lorentzian line of CE that has dependence of line width and reciprocal paramagnetic susceptibility on temperature. The ESR study of CE in crystalline silicon has been followed by a great deal of work [26–30]. For example, Feher reported a  $g$ -value of the CE of 1.99865–1.99885. Kodera reported the CE signals at averaged  $g$ -value of 1.99869 and hyperfine splitting of 41.7 G due to doped phosphorus atoms. In the case of doped poly-Si, ESR study of CE has been reported by Hasegawa et al. in 1979 [32]. In their work, the DB signal observed for phosphorus-doped samples disappeared by annealing at above 700–750 °C, where the sample crystallized, and a new signal that has similar  $g$ -value as CE in crystalline silicon has been observed at  $g = 1.997\text{--}1.999$ . ESR spectra of phosphorus-doped a-Si:H have also been reported by various workers [33–36]. For example,

Dersch observed a new signal at  $g = 2.0043$  beside the DB signal at  $g = 2.0055$  in the case of highly phosphorus-doped sample. The result is different from that in crystalline silicon or poly-Si. The signal broadens with increasing phosphorus doping due to hyperfine interaction with the phosphorus nuclei. A new signal with  $g = 2.0043$  is suggested to be due to electrons in localized conduction band tail states.

As an early ESR work of nc-Si:H, Hasegawa et al. have also reported the ESR spectra of undoped and phosphorus-doped nc-Si:H [37]. They observed the signals due to DB with  $g$ -value of 2.0049 when the doping level, gas flow rate ratio of  $\text{SiH}_4$  and  $\text{PH}_3$ , is below  $10^{-4}$ . In Figure 1, ESR spectra of phosphorus-doped nc-Si:H with various doping levels are shown. The CE signal at  $g = 1.9970$  has been observed in the sample at the doping level of  $10^{-3}$ . Other signals were observed at  $g = 2.0043$  in more highly doped samples than a doping level of  $10^{-2}$  with the decrease of crystalline fraction volume ratio observed by Raman spectra. The  $g$ -value of the signal is similar to that in localized electron near the tail of the conduction band in the a-Si:H. The DB signals observed in undoped or slightly doped samples have not been observed in phosphorus-doped sample with doping level more than  $10^{-3}$ . In the work, Hasegawa et al. [37] described the dependence of the ESR signals with  $g = 2.0049$ , 2.0043, and 1.997 on the doping level and rf power for films preparation. The result indicates that spin density of the signal with  $g = 1.997$  due to CE does not increase appreciably with increasing doping ratio above  $10^{-3}$ . The result is different from that in phosphorus-doped poly-Si in which CE signal increases with doping level.

**Figure 1.** ESR spectra measured at 77 K for nc-Si:H films deposited at various doping levels. Reprinted with permission from [37], S. Hasegawa et al., *Phil. Mag. B* 48, 431 (1983). © 1983, Taylor & Francis Ltd.

Finger and co-workers have reported the temperature dependence of nc-Si:H ESR spectra [38]. In Figure 2, ESR spectra of undoped and phosphorus-doped nc-Si:H at various temperatures from 10 K to 300 K are shown. Both samples show a resonance of DB at  $g = 2.0049$ – $2.0055$  with spin density of  $1$ – $2 \times 10^{17}$ . As the temperature is decreased, resonance of CE appears at  $g = 1.9981$ – $1.9985$  with characteristic asymmetric Dysonian line shape [27]. The signal due to CE becomes stronger with respect to the DB signal with a decrease of measurement temperature. The signal intensity of the CE follows the Curie law, that the signal intensity is proportional to  $T^{-1}$ , down to 10 K at below 200 K. The CE peak is not detectable above 200 K because of a strong line broadening. Finger et al. reported details of their ESR work of nc-Si:H in 1998 [39]. They have reported measurement of ESR spectra of the samples prepared with different n- and p-type doping at 40 K. Over a wide range of conductivities, they observed the DB and CE simultaneously in n-type nc-Si:H. The intensity of the CE signal, calculated from a gaussian line shape, shows a clear correlation with conductivity of the samples. This correlation supports the attribution of the signal at 1.998 as a CE.

Müller and co-workers also have reported the ESR of doped nc-Si:H [40]. In highly doped n-type sample (doping level of 17 ppm) at 20 K with high microwave power of 25 mW where all signal beside CE are saturated, the signal of hyperfine interaction of  $^{31}\text{P}$  has been observed as a shoulder of CE signals. The hyperfine splitting is about 110 G and the intensity ratio of hyperfine signal with respect to total CE signal is about 10%. In the report, they studied the dependency of  $g$ -value and line width of the CE signals on doping level. At higher doping level, the CE signal intensity significantly increases, whereas the DB signals are almost independent of doping condition. Therefore, the resonance of the DB signals becomes less visible with increase of doping level. They also have investigated dependence of  $g$ -value on conductivity. For the doped samples, the  $g$ -value of the CE signals is around 1.9980 at doping levels below 33 ppm and decreases continuously for

**Figure 2.** ESR signals of nc-Si:H at different temperatures. The spectra are normalized to similar peak-to-peak height. The  $g$ -value of the free electron ( $g = 1.9983$ ) and the dangling bond ( $g = 2.0052$ ) are indicated. Reprinted with permission from [38], F. Finger et al., *Phil. Mag. B* 70, 247 (1994). © 1994, Taylor & Francis Ltd.

higher doping level to 1.9972 at 133 ppm. The undoped samples have  $g$ -value of 1.9980–1.9985 with a large scatter due to the overlap with DB signals. The  $g$ -value also shows dependence on the measurement temperature. The  $g$ -value decreases with rising temperature between 4.5 and 300 K. The  $g$ -values observed in nc-Si:H are generally lower than what is reported for crystalline silicon ( $g = 1.9985$ – $1.9995$ ) [25–30] or poly-Si ( $g = 1.997$ – $1.999$ ) [32]. The peak-to-peak line width also shows dependence on the measurement temperature. Above 30 K, all samples with various doping levels from 1 to 133 ppm show a large increase in the CE line width with rising temperature. All samples exhibit line width of 9 G at 30 K and increased to 27–34 G at 300 K. They attributed the strong increase in line broadening with rising temperature for  $T > 60$  K to the corresponding decrease in spin-lattice relaxation time, because of their previous report of a steep decrease of  $T_1$  in nc-Si:H [41]. In their measurement, the minimum line width has not been observed at the lowest temperature but at 30 K. The line width increased again at the temperature lower than 30 K as well as in slightly doped crystalline Si [42–45]. In the case of crystalline silicon, Maekawa and Kinoshita explained the increase of line width by decrease of temperature by a change in the correlation frequency of the exchange interaction due to reduction of electron hopping rate between neighboring sites at lower temperature [42]. Maruyama and co-workers explained this phenomenon by condensation of the donor electrons into singlet ground states of donor cluster by coupling each other by antiferromagnetic exchange interaction [43].

Malten and Finger and co-workers have reported pulsed-ESR study of nc-Si:H [39, 41]. In the pulsed-ESR spectrum of n-type nc-Si:H, CE resonance dominates and DB signal is only visible as a shoulder. In addition, two hyperfine lines are observed as a shoulder with a hyperfine splitting of about 110 G. [They assigned as hyperfine] due to  $^{31}\text{P}$  nuclei, by comparison with phosphorus-doped a-Si:H and crystalline silicon samples. They also estimated spin-lattice relaxation time,  $T_1$ , by inversion recovery curves. The shape of recovery curve observed in nc-Si:H sample measurements is not simple single exponential form, because of overlapping with other resonance curves or distribution of relaxation time due to the structural disorder of the samples. They fit the recovery curve with stretched exponentials, which was reported by Durny and co-workers [46] and actually applied in the case of pulsed-ESR study of a-Si:H [47]. The fitting of the curve is in the form

$$I(t) = I_0 \left\{ \exp \left[ - \left( \frac{t}{T_1} \right)^\beta \right] - 1 \right\}$$

In this equation, the dispersion parameter  $\beta$  represents a distribution of relaxation time  $T_1$ . Obtained  $T_1$ , relaxation time of CE, is faster than that in DB by two or three orders at the temperature lower than 100 K.

Lips, Fuhs, and co-workers reported ESR study of band tail states and free electron in phosphorus-doped nc-Si:H in a study of metal-insulator transition (MIT) [48–50]. In the plot susceptibility of the CE line as a function of doping level, the susceptibility increases linearly with doping level below  $3 \times 10^{18} \text{ cm}^{-3}$ . In contrast, susceptibility increases sub-linearly above doping level of  $4 \times 10^{18} \text{ cm}^{-3}$ . At the MIT,

the paramagnetic susceptibility changes from Curie-type to Pauli-type [51]. This MIT occurs at a similar doping concentration as crystalline silicon, indicating that the donors are distributed homogeneously in the crystalline phase of the films. In degenerately doped films, they detect a Curie contribution to CE signal at spin density of  $4\text{--}8 \times 10^{18} \text{ cm}^{-3}$ . They assign this signal to tail states originating from disorder at the grain boundary.

In the case of a-Si:H, nitrogen-doping effect has been studied by Morimoto, Zhou, and co-workers [52, 53]. They found similarity between the nitrogen doping and that of phosphorus doping found in conductivity, and the photo-conductivity decay indicates that nitrogen can act as donor in a-Si:H. Although the nitrogen doping is also of substitutional type, the solid phase doping efficiency of nitrogen is estimated to be three orders of magnitude lower than that of phosphorus. In the case of nc-Si:H, nitrogen-doping effect has been studied by Ehara and co-workers [54–56]. In the nitrogen-doped nc-Si:H, conductivity was not increased, but rather decreased at higher doping level of  $10^{-1}$  because of structural change to amorphous. We also have studied ESR of nitrogen-doped nc-Si:H [55, 57]. Figure 3 shows the temperature dependence of the ESR spectra of undoped and nitrogen-doped nc-Si:H. As shown in Figure 3, both silicon DB and CE peaks have been observed at  $g = 2.005$ – $2.006$  and  $1.9975$ – $1.9985$ , respectively. In the undoped sample, signal intensity of the CE showed a maximum at 40 K and decreased at lower temperature. This may be interpreted as the interruption of the thermal excitation of electron. In the doped sample, the CE signal intensity exhibited a maximum at 20 K. The difference in the temperature dependence suggests that the doped samples have shallower donor levels. The result indicates that the nitrogen atoms work as an electron donor in the nc-Si:H, although the efficiency is far less than that of phosphorus as well as in the case of nitrogen-doped amorphous silicon.

The ESR signals of CE in another formed nanocrystalline silicon have also been reported. Young and co-workers have reported the ESR study of porous silicon (PS) at liquid helium temperature [58, 59]. They observed a new isotropic resonance center at  $g = 1.9995$  in both p-type and n-type PS. The paramagnetic center observed was identified due to the conduction band electrons in silicon nanocrystals by comparing its  $g$ -value with those of shallow donors in bulk silicon. Bardeleben and co-workers also reported  $n^{+}$ ,  $p^{+}$ , and p-type substrate supported and freestanding PS [60]. Signal of CE has been observed in  $n^{+}$ -type substrate supported PS as well as previous works at 40 K. However, the CE signal has not been observed in freestanding PS in spite of their careful search in the temperature range 4–300 K. In their possible explanation, they have considered that the strong hydrogen contamination range might have led to the passivation of the phosphorus donor.

#### 4. p-TYPE NANOCRYSTALLINE SILICON

ESR studies of p-type, boron-doped a-Si:H, as well as phosphorus-doped a-Si:H, have been reported by various workers [33–36]. Boron-doped a-Si:H shows a broad line at  $g = 2.01$  with line width of 20 G, beside the DB line. The signal attribution and line width have been assigned as holes in localized valence band tail states, and due to  $g$ -distribution, respectively. In contrast, ESR spectra of p-type, boron-doped nc-Si:H have not been well studied. Possible signals to be observed beside the DB are due to holes; however, it has been difficult in the p-type samples using continuous wave (CW) ESR measurement. Finger et al. reported absence of CE signal by CW-ESR spectrum of a boron-doped sample with doping level of 23 ppm [39]. This result is consistent with the doping effect. However, any peaks corresponding to holes have not been observed clearly.

The signals of holes induced by boron doping have been observed by pulsed ESR spectroscopy using an electron spin echo field sweep (ESE-FS) method [41, 61]. This measurement mode is preferable for measurement of broad signals, because it suppresses base line contributions. At lower temperature than 40 K, the spectra of p-type sample show a very broad line at around  $g = 2.1$  with peak-to-peak width of 500 G in addition to DB signal. In the case of a-Si:H, a possible origin of the peak, resonance of holes trapped in valence band tail states, shows different parameters ( $g = 2.01$  and width of 20 G). In crystalline silicon, the resonance of holes is only observed under external strain [62, 63] or extremely pure materials [64]. However, the observed signals under those conditions have some similarity with the broad peak of their work. Therefore, they tentatively attribute this broad resonance to hole states in the crystalline area of the material.

Another group also observed signal of holes by pulsed ESR spectroscopy in p-type nc-Si:H sample [65]. Kanschat et al. observed a broad structure of conduction holes (CH) at  $g = 2.08$  which they identify with holes trapped in valence band tail states. It is shown that the CH state behaves very similarly on illumination as the CE center.

#### 5. LIGHT-INDUCED ELECTRON SPIN RESONANCE

The light-induced ESR (LESR) is an effective method to study the transport mechanism or band structure of the material. In the case of a-Si:H, LESR signals of  $g = 2.004$  and  $g = 2.01$  are observed at low temperature beside the DB signal at  $g = 2.0055$  observed in dark. These signals have been tentatively attributed to conduction band tail electron ( $g = 2.004$ ) and valence band tail holes ( $g = 2.01$ ) based on the results of doping and photoluminescence experiments [33, 66–69].

The LESR spectrum of nc-Si:H was first reported in 1994 [38]. The light illumination by a 100-W halogen lamp enhances the free electron resonance at  $g = 1.9983$  in ESR of undoped nc-Si:H at 40 K. The signal of CE increased by a factor of about 3. Finger and co-workers reported details of LESR of nc-Si:H in [39]. In Figure 4, the LESR spectrum of an n-type nc-Si:H is shown with its dark ESR spectrum. In the figure, dark and LESR of a-Si:H are also shown for comparison. As shown in the figure, increase of both DB signal and CE signal is observed. The LESR-CE line is assigned to photoexcited CEs and increased DB signal can be due to newly appeared neutral DB changed from negatively charged DB by photoexcitation. The result observed in LESR of nc-Si:H is significantly different from the LESR of a-Si:H as shown in the figure.

Finger and co-workers also have studied the various kinds of LESR transient of nc-Si:H using white light and infrared light source. The LESR of nc-Si:H shows different transient characteristics from that in a-Si:H. After switching off of white light, decay of LESR signal has not been observed by infrared light illumination. The result is different from that in the case of a-Si:H. They have studied various transient characteristics of LESR intensity using sub-bandgap illumination. Lima and co-workers have also reported decay of LESR after illumination is discontinued [70]. In their case, the spin signal does not go to zero even after a few thousand seconds after the switch off of lamp, remaining around 20% of the original intensity. Although the time scales of the samples they measured are different from each other, the decay curve can be fitted using a model by Yan et al. [71] for

**Figure 4.** LESR together with dark ESR spectra of an n-type nc-Si:H sample, in comparison with a high-quality a-Si:H sample. Reprinted with permission from [39], F. Finger et al., *Phil. Mag. B.* 77, 805 (1998). © 1998, Taylor & Francis Ltd.

distant-pair recombination via tunneling between localized states.

Kondo and co-workers have reported light-induced phenomena in nc-Si:H [72]. They have measured excitation photon energy dependence of LESR response in nc-Si:H using lamp with monochromator at 5 K. The intensity of LESR decreases at 1.1 eV with decrease of the excitation energy, and this energy coincides with the crystalline silicon bandgap energy. They also reported details of temperature dependence of LESR signal intensity and concluded that the LESR signal does not arise from a mobile electron but from a localized electron trapped at a shallow level center close to the conduction band edge. They assigned the measured activation energy of 11 meV to the binding energy of the center. These shallow states that provide electrons probably originated from the conduction band tail caused by the structural disorder. They also have studied increase in the neutral DB density due to light exposure and suggested the defect formation correlates with the surface oxidation and surface band-bending model due to the oxidation.

The assignment of the peak at  $g = 1.998$  to shallow localized states close to the conduction band is also reported by Kanschä and co-workers [73]. They studied ESR, photoconductivity, and electrically detected magnetic resonance (EDMR) [74]. At low temperature, they have plotted increased density of CE centers by illumination and photoconductivity as a function of generation rate. If the CE resonance were due to free electrons, a linear relationship between increased CE spin density and photoconductivity would be expected. However, they observed almost the same dependence as that in a-Si:H [75]. Therefore, they assigned the CE states monitored at  $T = 30$  K to shallow localized states below the conduction band edge.

## 6. DANGLING BOND DEFECTS

Before the review of the ESR study of DB in nc-Si:H, ESR studies of DB in nc-Si:H related materials are reviewed for comparison. DB defects in crystalline silicon surface or Si/SiO<sub>2</sub> interface, P<sub>b</sub> center, which gives  $g$ -value of  $g_{\parallel} = 2.001$ – $2.002$ ,  $g_{\perp} = 2.008$ – $2.009$ , have been reported by some workers [76, 77]. ESR studies of DB in a-Si:H have also been reported. The asymmetric ESR signal of DB in a-Si:H is observed at  $g = 2.0055$  with peak-to-peak width of 5–7 G [66, 78]. Calculation of the  $g$ -value of a-Si:H DB using an interactive extended Hückel theory has been reported and the  $g$ -value of 2.0055 was explained by threefold-coordinated silicon atoms [79, 80]. Complicated ESR spectra of dislocations in crystalline silicon have been reported by a few groups [81, 82]. Hasegawa and co-workers have reported ESR spectra of poly-Si prepared by annealing of amorphous silicon films by low-pressure chemical vapor deposition (LPCVD) [83]. In the case of poly-Si,  $g$ -value of DB in the poly-Si depends on the annealing condition. The  $g$ -value observed depends on annealing time rather than temperature. The sample annealed for 24 h shows  $g$ -value of 2.0048 that is lower than the sample annealed for 2 h that has  $g$ -value of 2.0055–2.0057. The same group also reported ESR spectra of poly-Si prepared by PECVD [84]. The  $g$ -value and the stress strongly depended on the rf power and the thickness. In addition, the  $g$ -value of the DB

**Figure 5.** Dark CW ESR spectrum of nc-Si:H at 40 K. Included are numerical deconvolutions. Reprinted with permission from [40], J. Müller et al., *Phys. Rev. B* 60, 11666 (1999). © 1999, American Physical Society.

decreased from 2.0054 to 2.0042 with H<sub>2</sub> plasma annealing time [85]. These results are examined in terms of formation of different types of grain boundary that can be associated with a lattice deformation around the DB.

In the 1980s, a few groups reported ESR studies of nc-Si:H. Veprek and co-workers reported the ESR spectra of nc-Si:H sample prepared by the chemical transport method [86]. The spectra showed the peak of DB defect at  $g = 2.0055$ – $2.0059$  with the peak-to-peak width of 9 to 11 G. They analyzed that most of the samples have a line shape that could be approximated by a gaussian. However, line shape was not a simple gaussian or lorentzian function and appeared to be possibly a superposition of plural signals in some cases. The observed  $g$ -value of silicon DB is similar to that in a-Si:H ( $g = 2.0055$ ). However, the peak width was larger than that in a-Si:H (5–9 G). They determined the defects density in the films as between  $5 \times 10^{17}$  and  $2 \times 10^{18}$  by the spectra. However, they did not discuss the detail of the DB defect using the spectra. As far as the author knows, it is the first report of ESR study of DB in nc-Si:H.

Hasegawa and co-workers reported ESR of undoped nc-Si:H with a preferential orientation [87]. They prepared the undoped nc-Si:H sample at various substrate temperatures and rf powers. They reported that the increase in substrate temperature and decrease in rf power induce the change of orientation of nanocrystalline silicon from (111) to (220).  $g$ -value of ESR increased from 2.0048 to 2.0056 with increase in substrate temperature, and decreased from 2.0056 to 2.0049 by increase in rf power. This means change in orientation from (111) to (220) causes the increase in  $g$ -value. They explain the shift of  $g$ -value by change in morphology around the spin.

Finger et al. reported the temperature dependence of undoped and doped nc-Si:H [38, 39]. They observed asymmetric DB signal at  $g = 2.0049$ – $2.0055$  with spin density of  $10^{17}$ . They observed saturation effect in the DB signal at low temperature as a result of the increase in spin-lattice relaxation time. Later, they determined the spin-lattice relaxation time as  $10^{-4}$ – $10^{-2}$  s at the temperature of 20–100 K by measurement of pulsed ESR spectra. In the nitrogen-doped nc-Si:H, similar asymmetric signal of DB has been observed [55, 57]. Although the change in signal shape has been observed, it has been caused by structural change from nanocrystalline to amorphous, not by doped nitrogen.

In most of the ESR studies of nc-Si:H, the DB signals have been observed as an asymmetric line at around  $g = 2.005$ . Müller and co-workers reported the numerical fits for two-defect resonance of the asymmetric DB signal [40, 61]. The first center is supposed to be a silicon DB at  $g = 2.0052$ . The second center is signal at 2.0043. The origin of the second center was initially attributed to electron trapped in the conduction band tail, since  $g$ -value of this center is similar to that in n-type a-Si:H [33–36] and LESR of undoped a-Si:H [66–69]. However, this assignment is considered to be ambiguous, because the center is also observed in p-type nc-Si:H. Therefore, another explanation of the second center at  $g = 2.0043$  is needed. Müller suggested the attribution of the second center as the DB states in Si-rich Si-O layers as an attribution of the peak [88], because an increase of the signal at  $g = 2.0044$  in nc-Si:H samples was observed after exposure to air for several weeks [89]. Pulsed-ESR study of nc-Si:H, reported by Kanschat and co-workers, supported the existence of two centers [65]. They identified two DB-like structures at  $g = 2.0052$  and  $g = 2.0043$ . Whereas, the  $g = 2.0052$  signal is evenly distributed in the gap, the signal at  $g = 2.0043$  states is found to be localized in the lower part of the gap. Kondo and co-workers studied nc-Si:H DB to investigate its microscopic structure [90]. They have suggested DB at grain boundary with  $g$ -tensor of  $g_{\parallel} = 2.0022$  and  $g_{\perp} = 2.0078$  similar to the  $P_b$  center. They have simulated the DB signal in Q-band ESR spectra well by assuming randomly oriented grain boundary defects and DB in amorphous fraction. Lima and co-workers reported the simulation of asymmetric line shape of DB assuming a powder pattern of single center with  $g_{\parallel} = 2.0096$  and  $g_{\perp} = 2.0031$ , and a gaussian broadening of 3.2 G.

As another approach of ESR study of DB in nc-Si:H, our group studied X- and Q-band ESR spectra of various kinds of nanocrystalline silicon [91]. We have prepared unhydrogenated nanocrystalline silicon (nc-Si) [92, 93] and nanocrystalline silicon embedded in  $\text{SiO}_2$  (nc-Si in  $\text{SiO}_2$ ) [94–96] and compared their ESR spectra with that of nc-Si:H. ESR spectra of nc-Si at room temperature shows asymmetric DB signal at  $g = 2.0055$  with peak-to-peak width of 10–11 G. Although the peak width is larger, that  $g$ -value is similar to that in unhydrogenated amorphous silicon (a-Si) prepared by low-pressure Ar sputtering. However, in the Q-band ESR measurement, spectra of nc-Si show larger  $g$ -value ( $g = 2.006$ ) and significantly asymmetric signal compared with that in a-Si. In the case of the nc-Si in  $\text{SiO}_2$ , X-band ESR shows signal of DB at  $g = 2.005$ – $2.006$  with peak-to-peak width of 13 G. In Q-band ESR spectra, the signal of silicon DB has been observed at  $g = 2.006$ . In Figure 6, Q-band ESR spectra of silicon DB signal in nc-Si:H, nc-Si, nc-Si in  $\text{SiO}_2$ , and a-Si are shown. As shown in the figure, spectra of nc-Si:H and nc-Si have a similar shape beside the intensity of sharp signal of carbon contamination observed at  $g = 2.0026$ . We have simulated the broad DB signal in the Q-band ESR spectrum of nc-Si in  $\text{SiO}_2$ , using anisotropic distribution of  $g$ -tensor that  $g_{\perp}$  has larger distribution than  $g_{\parallel}$ , with  $g$ -value of  $g_{\parallel} = 2.0022$  and  $g_{\perp} = 2.0078$ . We suggested the DB structure corresponding to this simulation as distribution in  $C_{3V}$  symmetry.

Another kind of nanocrystalline silicon defect, DB in PS, has also been studied. Bhat and co-workers reported the

**Figure 6.** Q-band ESR spectra of unhydrogenated nanocrystalline silicon (nc-Si), hydrogenated nanocrystalline silicon (nc-Si:H), and nanocrystalline silicon embedded in  $\text{SiO}_2$  (nc-Si in  $\text{SiO}_2$  and a-Si).

ESR spectra of PS for various angles [97]. They observed the narrow signal of DB at 2.0052. Pokes and co-workers determined the DB density in the PS layer as roughly  $3 \times 10^{16} \text{ cm}^{-3}$  by measurement of ESR [98]. They observed anisotropic ESR spectra in the PS prepared using 0.1- $\Omega$  cm Si wafers. Rong and co-workers reported detail of  $g$ -value dependence on measurement axis and hyperfine by  $^{29}\text{Si}$  and attributed the defect in the PS as  $P_b$ -like centers [99]. Some groups reported the annealing effect of ESR spectra that induces the broadening of spectra by the increase in the strain of the back bonds. Meyer and co-workers reported the effect of rapid oxidation of PS to ESR spectra [100]. They observed two different types of defects after oxidation. One is isotropic and very similar to the DB in a-Si:H; the other is  $P_b$  center-like defects. Two signals show difference in the rotation pattern in the ESR signals. As a similar oxidation, heat treatment effect in air to ESR spectra has also been reported by Laiho et al. [101]. Plasma nitridation effect to ESR spectra of PS has also been reported by Yokomichi and co-workers [102]. They observed increase of  $P_b$  center density and decrease of PL intensity by plasma treatment.

## 7. OTHER DETECTION METHOD OF SPIN RESONANCE

Optically detected magnetic resonance (ODMR) study of nc-Si:H has been reported by Boulitrop and co-workers [103]. In their work, they have monitored the defect-related luminescence bands at 0.75 and 0.85 eV at 5 K. They detected quenching resonance at  $g = 2.0043$  and enhancing resonance at  $g = 1.9997$  and  $g = 2.016$ . The signals at  $g = 2.0043$  and  $g = 1.9997$  are similar to the DB signal and CE

signal observed by conventional ESR spectroscopy. The signal at  $g = 2.016$  has a very large line width of about 100 G.

As mentioned in Section 5, EDMR studies of nc-Si:H have been reported [49, 89]. Lips and co-workers have reported the bandtail states in phosphorus-doped nc-Si:H using ESR and EDMR [104]. They have shown that the CE states originate from both delocalized electrons in the impurity and conduction band as well as from trapped electron in bandtail states at grain boundary. Bronner and co-workers reported EDMR study of nc-Si:H before and after the electron irradiation [105]. Their measurement of EDMR spectra in the photocurrent mode shows an increased DB contribution and change in recombination path with sample irradiation. They find an EDMR signal attribute to recombination of CE in shallow traps and DB defects.

## 8. SUMMARY

In ESR spectra of nc-Si:H, signals of carrier (electrons or holes) and DB defect have been observed. Signals of the CE have been observed in undoped, phosphorus-doped, and nitrogen-doped samples at  $g = 1.997$ – $1.999$ . The CE signal is sharp and has a faster spin-lattice relaxation time than the DB signal. In the case of p-type nc-Si:H, it has been difficult to observe the signal of the conduction holes, because of the very broad line shape. However, the signals of holes can be observed at  $g = 2.01$  with line width of 500 G by pulsed-ESR spectroscopy. In the light-induced ESR spectra, enhancement of CE peak has been observed in undoped and phosphorus-doped samples. The ESR signals of DB defects have been observed at  $g = 2.005$ – $2.006$ . Several authors have attributed the asymmetric shape of the DB signal to the existence of two centers, silicon DB at  $g = 2.0052$  and oxygen-related center at  $g = 2.0043$ .

## GLOSSARY

**Hydrogenated amorphous silicon (a-Si:H)** The amorphous silicon in which some of the dangling bond defects are terminated by hydrogen atoms.

**Conduction electron (CE)** The electrons conduct in the Si.

**Dangling bond defect (DB)** The unpaired electrons of Si atoms that do not participate in the formation of Si-Si covalent bonds.

**Electron spin resonance (ESR)** One of the magnetic resonance techniques. ESR absorption corresponds to the energy difference of spin states in magnetic field.

**Light-induced electron spin resonance (LESR)** ESR under light illumination.

**Hydrogenated nanocrystalline silicon (nc-Si:H)** The material that contains nanocrystalline grain with the size of a few tens to a few hundred nanometers. In the material, some of the dangling bond defects are terminated by hydrogen atoms.

**Pulsed ESR** Electron spin resonance measurement using microwave pulse instead of continuous wave microwave.

## 1. INTRODUCTION

The development of novel materials and the assessment of their potential application constitutes a major fraction of today's scientific research efforts. In fact, there exist various major governmental research and development programs related to nanostructured materials. Furthermore, it is estimated that nanotechnology has grown into a multi-billion dollar industry and may become the most dominant single technology of the twenty-first century. To allow for this fact, this encyclopedia [1] encompasses a series of contributions devoted to a very prominent field of current materials research activities, namely, nanoscience and nanotechnology. The importance of these developments is reflected also in a number of recent books and articles reviewing this rapidly evolving field [2–10].

This article focuses on a specific class of such novel nano-scaled materials, nanocrystalline TiO<sub>2</sub>, and its photocatalytic properties. The title of this article encompasses three main terms (“(photo)catalysis,” “nanocrystalline,” and “TiO<sub>2</sub>”) which, individually, stand for very important areas of scientific research and of, perhaps even more important, technological applications. Their synergistic combination, as

indicated by the present theme, has stimulated great hopes in accomplishing thereby achievements with paramount benefits for human beings and the global environment. To outline the present state of that quest is the major goal of this article.

“Catalysis” is probably the most familiar of the three terms mentioned. A catalyst is incorporated in essentially everybody's automobile, with the goal of reducing or even eliminating the engine's toxic gaseous components by converting them into less harmful (albeit not necessarily benign) substances. As is the case in all catalytic reactions, the catalyst itself is not part of the reaction, but is expected to enhance its rate, that is, the velocity of the transformation from the original components (the “educts” in the chemist's terminology) into the final ones (the “products”). Hence, a catalyst is an entity that accelerates a chemical reaction without being consumed itself in the process. Without catalysts, various chemical reactions of great importance would proceed too slowly [11]. The economic significance of catalysis is enormous. In the U.S. alone, the annual value of products manufactured with the use of catalysts is roughly in the vicinity of one trillion dollars [12]. Indeed, more than 80% of the industrial chemical processes in use nowadays rely on one or more catalytic reactions [13]. A number of those, including oil refining, petrochemical processing, and the manufacturing of commodity chemicals (olefins, methanol, ethylene glycol, etc.), are already well established. But many others, as will be seen in this contribution, represent challenges requiring the development of entirely new approaches. But apart from their industrial importance, catalytic phenomena effect virtually all aspects of our lives. They are crucial in many processes occurring in living things, where enzymes are the catalysts. They are important in the processing of foods and the production of medicines. The reader may have noticed that we have as yet refrained from specifying the meaning of photocatalysis; which will be one of the major topics of this article. This term refers to a catalytic process that is triggered by illuminating the system by visible light or ultraviolet irradiation. Ideally, that light flux would be the sun's radiance.

Next we shall consider the meaning of “nanocrystalline.” First, it is noted that in today's science world rather inflationary used, the prefix “nano” refers to a fraction of

one part in one billion (10<sup>9</sup>) and, hence, its correct usage would require it being connected to some kind of unit (e.g., of length, time, energy, mass, etc.). In the present context (and in that of “nanotechnology”), “nano” most often relates to the dimension, that is, the size of an object. Therefore, nanocrystalline in the ensuing discussions will designate particles (of crystalline structure and, primarily, with the chemical composition of titanium dioxide) whose typical sizes are in the range of a few to several nanometers (nm), that is, of the order of the one billionth part of one meter. Obviously, these are extremely tiny objects and can be “seen” and studied only with the help of sophisticated analytical instruments like an electron microscope.

At first glance, it may appear that such tiny particles are a rather modern contrivance, but this is probably a premature conclusion. In fact, it is quite firmly established that nm-sized particles (mostly very refractory ones like corundum, diamond, or silicon carbide) are ubiquitous in the universe [14] and that they were already present at the time and the location of the formation of the solar system. This “stardust” originated from stellar outflows and supernova ejecta, which may have occurred eons before the gas and dust condensed into what is now the sun, the earth, and the planets. In fact, this dust has intrigued astronomers since the days of William Herschel who noted, in the 1780’s, the existence of small regions in the sky where there appeared to be a complete absence of stars [15]. These regions are most easily seen against the rich star-fields of the Milky Way. Evidence of the presolar origin of these nanocrystalline particles comes primarily from their isotopic abundance pattern [16], which deviates typically to such an extent from any other known matter that a terrestrial or solar origin is virtually impossible. (Most of these particles that have been investigated were extracted from primitive meteorites in which they were incorporated during the formation stage of the solar system; these did not experience any later modification and, hence, preserved the presolar dust particles unaltered [17].)

Only now, some billions of years later, mankind has initiated the manufacture and application of such nanocrystalline materials. Nanostructured materials with crystal sizes in the range of 5–50 nm of a variety of materials, including metals and ceramics, have been artificially synthesized by many different techniques in the past couple of years [2, 3, 5–7]. Such new ultrafine-grained materials have properties that are often significantly different and greatly enhanced as compared to coarser-grained or bulk substances. These favorable changes in properties result generally from their small grain sizes, the large percentage of atoms in grain boundaries and at surfaces, the large surface-to-bulk ratio, and the interaction between individual crystallites. Since these features can be tailored to a considerable extent, during synthesis and processing, such nanophase materials are thought to have great technological potential even beyond their current applications.

Let us finally turn to a brief discussion of the third term, “TiO<sub>2</sub>” (i.e., titanium dioxide). TiO<sub>2</sub> has three different crystal structures [18]: rutile, anatase, and brookite; only the former two of them are commonly used in photocatalysis. Like for many other metal oxides (also for titanium oxide) have the respective structural, optical, and electronic properties

been elucidated through several decades of intense scientific research (for a review see, e.g., [19]); some of them will be referred to in the course of the present overview. The feature probably most important in the present context is the fact that TiO<sub>2</sub> is a semiconductor with a bandgap of ~ 3.2 eV. On the other hand, TiO<sub>2</sub>, in its nanocrystalline form, constitutes an enormously important commercial product. In fact, the world production of titanium dioxide white pigments amounts to some 4.5 million tons per annum and the global consumption may be considered a distinct economic indicator. White pigments of TiO<sub>2</sub> have average particle sizes of around 200–300 nm, optimized for the scatter of white light, resulting, thereby, in a hiding power. Reducing the crystallite size (to ≤ 100 nm), the reflectance of visible light (vis) decreases and the material becomes more transparent; it is widely employed, for example, in paints, plastics, paper, or pharmaceuticals. Nanocrystalline TiO<sub>2</sub> exhibits, in addition, a pronounced absorption of ultraviolet (UV) radiation. Because of this high UV absorption and the concurrent high transparency for visible light, TiO<sub>2</sub> particles with a size of <100 nm have found widespread use in such diverse areas as sun cosmetics, packaging materials, or wood protection coatings. Hence, although perhaps not generally realized, TiO<sub>2</sub> is ubiquitous in our everyday life. Apart from this well-established range of usage, an increasing number of catalytic applications of nanocrystalline TiO<sub>2</sub> have emerged in recent years.

At this point, it appears appropriate to return to a more general view of the present topic. Nanostructured materials have generally the potential [3] for incorporating and taking advantage of a number of size-related effects in condensed matter ranging from electronic effects (so-called “quantum size effects”) caused by spatial confinement of delocalized valence electrons and altered cooperative (“many-body”) atom phenomena, like lattice vibrations or melting, to the suppression of such lattice-defect mechanisms as dislocation generation and migration in confined grain sizes. The possibilities to assemble size-selected atom clusters into new materials with unique or improved properties will likely create a revolution in our ability to engineer materials with controlled optical, electronic, magnetic, mechanical, and chemical properties for many pending future technological applications.

Among those nanocrystalline materials, semiconductors appear to play a pivotal role in such distinct fields as [20]:

- (i) heterogeneous photocatalysis;
- (ii) photoelectrochemistry, including electrochemical photovoltaic cells;
- (iii) photochemistry in zeolites, intercalated materials, thin films, and membranes (like self-assembled structures);
- (iv) supramolecular photochemistry.

This diversity is thought to be largely due to the fact that heterogeneously dispersed semiconductor surfaces provide both a fixed environment to influence the chemical reactivity of a wide range of adsorbates and, in addition, a means to initiate light-induced redox reactivity in these weakly associated molecules [21]. Upon photoexcitation of semiconductor nanoparticles, either in solutions or fixed to a suitable substrate, simultaneous oxidation and reduction reactions may

occur; molecular oxygen is often assumed to serve as the oxidizing agent. Such semiconductor-mediated redox reactions are commonly grouped under the rubric of heterogeneous photocatalysis [21].

In a heterogeneous photocatalytic system, photo-induced molecular reactions take place at the surface of the catalyst. Depending on where the initial excitation occurs, photocatalysis can be generally divided into two classes of processes [22]: In the case that the initial photoexcitation occurs in the adsorbate molecule, which then interacts with the ground state catalyst substrate, the process is referred to as a catalyzed photoreaction. On the other hand, when the initial excitation takes place in the catalyst substrate and the excited catalyst transfers an electron or energy into a ground state molecule, this process is referred to as a sensitized photoreaction [22]. Apparently, a considerable degree of synergism may be crucial when, for example, a transition metal oxide photocatalysts is combined with supramolecular spectral sensitizing ligand complexes used to harvest light and vectorially transfer photo-generated electrons and holes along selected energetic pathways.

In 1972, Fujishima and Honda reported [23] the photocatalytic splitting (i.e., the simultaneous oxidizing and reducing) of water upon illumination of a TiO<sub>2</sub> single-crystal electrode; in analogy to natural photosynthesis, they demonstrated the photoelectrolysis of water making use of a photoexcited semiconductor in what was essentially a photochemical battery. In that system, an *n*-type TiO<sub>2</sub> semiconductor electrode, which was connected through an electrical load to a platinum counter electrode, was exposed to near-UV light (cf. Fig. 1). When the surface of the TiO<sub>2</sub> electrode was illuminated with light of wavelength shorter than ~415 nm, photocurrent was observed to flow [23, 24]. Furthermore, oxygen evolution (i.e., an oxidation reaction) on the TiO<sub>2</sub> and hydrogen evolution (a reduction) on the Pt electrode was observed. The photoexcitation of TiO<sub>2</sub> injects electrons from its valence band into its conduction band; the electrons flow through the external circuit to the Pt cathode where water molecules are reduced to hydrogen gas and the holes remain in the TiO<sub>2</sub> anode where water molecules are oxidized to oxygen. These observations indicate that water can be decomposed by means of UV-VIS light according to the

following scheme

It appears to be generally accepted that this discovery boosted extensive research efforts in the era of heterogeneous photocatalysis [21, 25–27]. These studies, often carried out in an interdisciplinary fashion with the participation of physicists, chemists, and chemical engineers, focused on issues that are of great relevance both economically as well as ecologically like energy renewal and storage [28–30], the decomposition of organic compounds in polluted air and wastewaters [31–33], chemical energy generation [34, 35], and photovoltaic devices [36, 37]. Most of these either already proven or envisaged applications are intimately linked to the extraordinary properties of nanocrystalline TiO<sub>2</sub>. In fact, nanocrystalline metal-oxide semiconductors such as TiO<sub>2</sub> have been applied successfully in modern technologies including solar energy conversion, gas sensors, catalysis, and photocatalysis [38–42].

Following the first examination in 1977, using TiO<sub>2</sub> to decompose cyanide in water [43, 44], a great deal of effort has been devoted in recent years to developing heterogeneous photocatalysts with high photocatalytic activities for their applications in solving environmental cleanup and pollution remediation problems [31, 32, 45, 46]. Photocatalytic reactions on TiO<sub>2</sub> surfaces are very important in such environmental processes, as the oxidation of organic materials and the reduction of heavy metal ions in industrial waste waters. Apart from the utilization for water and air purification, TiO<sub>2</sub> photocatalysis has been shown useful for the destruction of microorganisms such as bacteria [47] and viruses [48], for the inactivation of cancer cells [46, 49], the clean-up of oil spills [50, 51], and other applications [45]; a more detailed account will be given later in this article.

As mentioned, TiO<sub>2</sub> is a semiconductor with a bandgap of 3.2 eV; when excited by light of energy equal to or exceeding that value, electrons are promoted from the valence band to the conduction band leaving positive holes in the valence band. These electrons and holes are capable of, respectively, reducing and oxidizing compounds at the TiO<sub>2</sub> surface. If the electrons and holes do not recombine (and produce heat), they can follow various reaction pathways; it is commonly accepted that the hole is quickly converted to the hydroxyl radical ( $\cdot\text{OH}$ ) upon oxidation of surface-adsorbed water and that the hydroxyl radical is the major reactant responsible for the oxidation of organic compounds. Typical reductive and oxidative reactions could be

**Figure 1.** Schematic arrangement for the photosplitting of water in an electrochemical cell (in the actual setup, both electrodes are immersed in an aqueous solution and the chambers are separated by an ionically conducting porous material). When the TiO<sub>2</sub> photoanode is irradiated with light, O<sub>2</sub> evolves from it, whereas H<sub>2</sub> evolves from the Pt counter-electrode, while electrons will flow through an external load.

the following [25, 52–54]

where  $M^{n+}$  is the oxidized compound and  $\text{R}_{(\text{ads})}$  the adsorbed organic species. Because the production of the hydroxyl radical is considered the decisive step, the determination and optimization of the corresponding quantum yield in illuminated TiO<sub>2</sub> is an important task [55, 56].

According to those concepts, TiO<sub>2</sub> nanoparticles are expected to show a unique surface chemistry due to their larger surface area [57]. The origin of the distinct photocatalytic activities exhibited by nanoparticles of TiO<sub>2</sub> is crucial in understanding the reaction mechanisms, for example, if they are purely due to the increased surface area or if they have to be addressed to the presence of distorted sites on the surface or to the whole lattice of the particles. In order to commercialize these treatment techniques, it is of great importance to improve the preparative methods of titania, because the photocatalytic activity and phase transition behavior of TiO<sub>2</sub> are significantly influenced by the preparative conditions [58–63]. As previously mentioned, these catalytic processes constitute a major issue of this work and will be outlined in the following sections.

The photocatalytic activity of TiO<sub>2</sub> is very useful not only in environmental purification by decomposition of organic substances, but also in the materials industry such as mirrors and glasses due to its self-cleaning [64] and antifogging effects. The latter has been attributed to the photo-induced hydrophilic nature of the surface [65, 66]. A further enhancement of the photocatalytic activity could be effected by means of composite TiO<sub>2</sub> materials; examples would be metal doping, mixing with insulating substances like SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub> [67], and monolayer coverage by SiO<sub>2</sub> [68].

Another prominent future application of nanocrystalline semiconductors is thought [69–71] to lie in photovoltaics, that is, the conversion of sunlight into electrical power. The limited reserves of fossil fuels and the increasing concern of global warming due to the greenhouse effect caused by the combustion of those fuels has triggered, in the last decades, widespread efforts into the development of photovoltaic devices. With an energy supply from the sun to the earth of  $3 \times 10^{24}$  Joule per year (about 10,000 times the global annual energy consumption), this enterprise appears all but unreasonable. In such solar cells, photon incident on a semiconductor can create electron-hole pairs, basically a result of the photoelectric effect, discovered by Becquerel already in 1839 [72]. At a junction between two different materials, this may establish an electrical potential difference across this interface. Until now, the material of choice for manufacturing such junctions has been (doped) silicon (crystalline or amorphous), with compound semiconductors also being considered more recently. While this traditional

approach clearly has room for further improvements, it may ultimately face limitations in terms of cost efficiency (manufacturing costs per unit of energy produced). Novel materials and fabrication schemes are therefore explored. A promising approach consists of electrochemical photovoltaic cells utilizing nanoporous semiconducting electrodes fabricated by lightly sintering nanosized TiO<sub>2</sub> particulates, followed by spectral sensitization with an appropriate dye.

Metal oxide particles with diameters of some 10 nm can be prepared as paste and spread out over a surface of fluorine-doped SnO<sub>2</sub> conducting glass to form a three-dimensional network of interconnected nanoparticles. These nanostructured metal oxide layers, and in particular those constructed from anatase titanium dioxide (TiO<sub>2</sub>), have aroused great interest because of their unprecedented properties as electrodes. They find application in dye-sensitized solar cells, which nowadays show light-to-electricity conversion efficiencies of 10% [69, 73–77]. The nature of electron migration in these electrodes has been debated in past years as the experimental results and their interpretation does not converge to a generally accepted model. Instead, the exact role of electron trapping and the concomitant screening of the electric field remain unclear. It is reported that soon after electrons are injected into the conduction band of TiO<sub>2</sub> a large fraction of them get trapped in surface states. Migration of these electrons must then proceed with a hopping-type process in which the electrons remain most of the time in localized states [78–83]. On the other hand, it is also reported that the injection of electrons into the conduction band shows the so-called “free-electron” absorption, which extends over a wide spectral range from the visible to the infrared [84–88]. This suggests that not all injected electrons become trapped but that a substantial fraction of them remain in the conduction band.

This article is organized in the following way: Section 2 outlines the electronic and charge-transfer processes as relevant for photocatalysis, with a special emphasis towards nanocrystalline TiO<sub>2</sub>. Since in photocatalysis and related applications the respective nanostructured materials are employed either in colloidal solutions or attached to a suitable support (e.g., as electrodes or thin films), both of these preparation techniques are discussed (Section 3). Furthermore, various approaches for surface and thin-film modification are described, as well as novel deposition methods and structures. The structural and electronic properties of nanocrystalline TiO<sub>2</sub> films are examined in Sections 4 and 5, respectively. The photocatalytic properties of nanocrystalline TiO<sub>2</sub> constitute the central theme of Section 6, highlighting the dependence of the photocatalytic activity on different parameters like film structure and phase, surface morphology, electronic properties, and the effects induced by various surface modifications. Representative examples of photocatalytic applications utilizing nanocrystalline TiO<sub>2</sub> materials are presented in Section 7. Finally, an extensive set of references is provided that should be useful for further study: although the number is substantial, no attempt was made, however, to be comprehensive; any such attempt might be bound to fail due to the rapidity with which this field is evolving.

## 2. ELECTRONIC AND CHARGE-TRANSFER PROCESSES IN PHOTOCATALYSIS

### 2.1. Electronic Excitations and Charge-Carrier Trapping

A photocatalytic process is initiated by the absorption of photons by a molecule or the substrate to produce highly reactive electronically excited states. The efficiency is controlled by the system's light absorption properties. Three fundamental steps are of relevance: (1) the electronic excitation of a molecule upon photon absorption, (2) the band-gap excitation of the semiconductor substrate, and (3) the interfacial electron transfer. Since a detailed account of these processes has been given in a lucid treatise by Linsebigler et al. [22], we shall briefly summarize here only the more important points, referring thereby partly to that work. The probability of an electronic transition can be calculated from quantum mechanical perturbation theory and is proportional to the square of the amplitude of the radiation field and the square of the transition dipole moment [89, 90]. The latter may be computed via the molecular wave function which, in turn, depends on the product of the electronic spatial wave function, the electronic spin wave function, and the nuclear wave function. Further arguments [89] lead to some general selection rules in terms of which electronic transitions are allowed and which might be forbidden. Typically, the excitation of a weak transition will not effectively induce a photochemical reaction, because few of the incident photons will be absorbed (low cross-section); however, an overall high reaction rate may still be possible in the case of a high quantum yield, that is, if the probability of product molecule formation per absorbed photon is high. The photochemical efficiency will also be determined by which deexcitation channels are dominant. In particular, the pertinent lifetimes of the involved processes are to be considered. Whereas the absorption of a photon occurs very rapidly on the order of  $10^{-15}$  s, deexcitation events are much slower, favoring the decay channel which minimizes the lifetime of the excited state.

The initial process for heterogeneous photocatalysis of organic and inorganic compounds by semiconductors is the generation of electron-hole pairs in the semiconductor particles. Once excitation across the bandgap has occurred, the lifetime is sufficient (in the nanosecond regime [91]) for the created electron-hole pair to undergo charge transfer to adsorbed species on the semiconductor surface from solution or gas phase. Figure 2 exemplifies these processes. The enlarged section shows the excitation of an electron from the valence band to the conduction band initiated by light absorption with energy equal or greater than the bandgap of the semiconductor. The figure also illustrates several deexcitation pathways for the electrons and holes. The electron transfer to adsorbed species or to the solvent results from migration of electrons or holes to the surface. At the surface, the semiconductor can donate electrons to reduce an electron acceptor (often oxygen in an aerated solution), corresponding to pathway *c* in Figure 2; conversely, a hole can migrate to the surface where an electron from a donor species can combine with the surface hole

**Figure 2.** Schematic illustration of the photoexcitation in a semiconductor particle followed by deexcitation events. CB and VB designate the conduction and valence band, respectively. For further details see text.

oxidizing the donor (pathway *d*). Competing with charge transfer to adsorbed species is electron and hole recombination, occurring either in the volume (pathway *b*) or on the surface of the semiconductor (pathway *a*); in both cases heat will be released. Naturally, electron and hole recombination is detrimental to the efficiency of a semiconductor photocatalyst. Modifications to semiconductor surfaces, such as metal addition, dopants, or combination with materials, can be beneficial in decreasing the recombination and concurrently increasing the quantum yield of the process.

An efficient means to retard the recombination of photoexcited electron-hole pairs may proceed via the trapping of charge carriers. The occurrence of surface and bulk irregularities resulting from the preparation process is associated with surface electron states; these may serve as charge carrier traps and can suppress the recombination of electrons and holes. The charge carriers trapped in such states are localized to a specific site on the surface or in the bulk; their population is dependent on the energy difference between the trap and the bottom of the conduction band. Experimental observations of such trapped states in TiO<sub>2</sub> will be reported later.

On the basis of laser flash photolysis measurements [45, 92], the characteristic times for the individual steps occurring during heterogeneous photocatalysis on TiO<sub>2</sub> have been derived. Whereas the primary process of charge-carrier generation is extremely fast ( $\sim$ fs), charge-carrier recombination may occur on time scales of 10–100 ns. Charge-carrier trapping can be very fast (100 ps) for the (reversible) trapping of a conduction-band electron in a shallow trap, but moderately fast ( $\sim$ 10 ns) for a deep trap or for the surface trapping of a valence-band hole, resulting in a surface-bound hydroxyl radical. Finally, interfacial charge transfer can be slow ( $\sim$ 100 ns) for the oxidation of an electron donor or very slow ( $\sim$ ms) for the reduction of an electron acceptor. In general, the valence-band holes are powerful oxidants (+1.0 to +3.5 V versus NHE depending on the type of semiconductor and pH), while the conduction-band electrons are good reductants (+0.5 to  $-1.5$  V vs NHE) [93]; most organic photodegradation reactions utilize the oxidizing power of these photo-generated holes.

## 2.2. Band-Edge Position and Band Bending

The ability of a semiconductor to undergo photo-induced electron transfer to adsorbed species on its surface is governed by the band energy position of the semiconductor and the redox potentials of the adsorbate. The relevant potential of the acceptor must be below (more positive than) the conduction band potential of the semiconductor. By contrast, the potential of the donor needs to be above (more negative than) the valence-band position of the semiconductor in order to donate an electron to the vacant hole. The band-edge positions of several semiconductors are depicted in Figure 3; the internal energy scale is given both with respect to the vacuum level (left scale) and for comparison to normal hydrogen electrode (NHE) in a solution of an aqueous electrolyte at pH = 1.

When a semiconductor is brought into contact with another phase (e.g., liquid, gas, or metal), the transfer of mobile charges across this junction occurs until electronic equilibrium is reached. This redistribution of charges involves the formation of a space-charge layer, that is, the charge distribution on each side of the interface differs from the bulk material (cf. Fig. 4). Depending on whether the electrons accumulate or deplete at the semiconductor side, an accumulation or depletion layer is formed, causing concurrently a shift in the electrostatic potential and a downward (or upward) bending of the bands in the semiconductor. The depletion of electrons may reach such an extent that their concentration at the surface decreases below the intrinsic level. As a consequence, the Fermi level is closer to the valence than to the conduction band; this situation is called an inversion layer, as the semiconductor is *p*-type at the surface and *n*-type in the bulk. These features are well documented [94] and will not be further discussed here. Of some interest in the present context is the situation encountered

**Figure 3.** Bandgap energies of various semiconductors in an aqueous electrolyte at pH = 1.

**Figure 4.** Space-charge layer of an *n*-type semiconductor in contact with another phase (e.g., an electrolyte or gas): (a) flat band situation, (b) accumulation layer, (c) depletion layer, and (d) inversion layer.

when an *n*-type semiconductor like TiO<sub>2</sub> is in contact with an electrolyte as in a photoelectrochemical cell [71]; such devices are thought to have great potential both in photovoltaics for producing electric current and as fuel cells for the generation of hydrogen via photo-cleavage of water. Because of these potential applications, the characteristics of the semiconductor-electrolyte interface have been investigated in great details [93, 95, 96].

In particular, the potential distribution within a spherical semiconductor particle could be derived [97] using a linearized Poisson–Boltzmann equation. As discussed in [69], two limiting cases are of special importance for light-induced electron transfer in semiconductor dispersions. For large particles, the total potential drop within the particle is

$$\Delta\Phi = \frac{kT}{2e} \left( \frac{w}{L_D} \right)^2 \quad (1)$$

where  $w$  is the width of the space charge layer and  $L_D = (\epsilon_0 \epsilon kT / e^2 N_d)^{0.5}$  is the Debye screening length [94], which depends on the dielectric constant,  $\epsilon$ , of the material and on the number density of ionized dopants,  $N_d$ . This potential variation is identical with that of a planar Schottky depletion layer [98]. For very small semiconductor particles (with radius  $R$ ) the potential drop within the particle becomes

$$\Delta\Phi = \frac{kT}{6e} \left( \frac{R}{L_D} \right)^2 \quad (2)$$

From the latter equation, it is found that the electrical field in nano-sized semiconductors will usually be small and that high dopant levels are required to produce a significant potential difference between the center and the surface. For example [69], in order to obtain a 50 meV potential drop in a nanocrystalline TiO<sub>2</sub> particle with  $R = 6$  nm, a concentration of  $5 \times 10^{19} \text{ cm}^{-3}$  of ionized donor impurities is necessary. Undoped TiO<sub>2</sub> nanocrystallites have a much lower carrier concentration and the band bending within the particles is therefore negligibly small.

### 2.3. Photo-Induced Charge-Transfer Processes on the Catalyst Surface

The principle of electron and hole transfer at the photoexcited semiconductor particle has already been alluded to previously in Fig. 2. Both free and trapped charge carriers participate in these interfacial redox reactions. Due to the quantization effects, by decreasing the particle's size, it is possible to shift the conduction band to more negative potentials and the valence band to more positive values. It was concluded [99] that the shift of the bandgap is proportional to  $1/R^2$ ,  $R$  being the particle size. Therefore, redox processes that cannot occur in bulk materials can be facilitated in quantized semiconductor particles. Figure 5 shows schematically such possible transfer reactions for an adsorbate at the surface of a semiconductor. When there are accessible energy levels in the substrate, an electron may be transferred from the donor (D) into a substrate level and then into the acceptor orbital as shown in Figure 5(a). This scheme operates in the photosensitization of semiconductor particles by dye molecules. An electron is injected from the excited state dye molecule into the semiconductor, which then reduces another adsorbate particle. Early experimental confirmation [100, 101] of these processes used the reduction of methyl viologen in colloidal semiconductor systems and the water splitting process. Later, such reductive processes have been investigated for many different systems (see, e.g., [102]); some illustrative examples will be presented in Section 6.

For an initial excitation on the semiconductor substrate (Fig. 5(b)), a positively charged hole is created at the band-edge of the valence band. An electron is transferred into

the empty acceptor orbital and, simultaneously, an electron is donated from the filled donor level to recombine with the original hole. This is a very general process for wide bandgap oxide semiconductors like TiO<sub>2</sub> and others. For example, the oxidation of many organic substances in colloidal suspensions has been investigated [102]. The energetics of the semiconductor valence band and the oxidation potential of the redox couple influence this photocatalytic oxidation. For example, the enhancement in the efficiency of halide oxidation at TiO<sub>2</sub> follows the sequence  $\text{Cl}^- < \text{Br}^- < \text{I}^-$ , correlating with the decrease in the oxidation potential. Again, some recent examples will be presented in Section 6.

The kinetic analysis [103] of electron transfer in colloidal semiconductor systems is often complex. Apart from the energetics of the conduction band of the semiconductor and the redox potential of the acceptor, factors such as the surface charges of the colloids, adsorption of the substrates, participation of surface states, and competition with charge recombination influence the rate of charge transfer at the semiconductor interface [102]. This fact is evident from the widely differing rates of experimentally observed charge transfer rates, with time scales ranging from picoseconds to milliseconds for different experimental conditions and various semiconductor systems.

### 2.4. Quantum-Size Effects

Size quantization effects in metals or semiconductors have attracted considerable attention in the past decade [104–107]. Semiconductor nanoparticles may experience a transition in terms of electronic properties from those typical for a solid to that of a molecule, in which a complete electron delocalization has not yet occurred. These quantum-size effects arise when the Bohr radius of the first exciton (an interacting electron-hole pair) and the semiconductor becomes comparable with or larger than that of the particle; the Bohr radius [94]

$$r_B = 4\pi\epsilon_0\epsilon\hbar^2/(e^2m^*) \quad (3)$$

depends on the dielectric constant  $\epsilon$  and the effective mass  $m^*$  of the charge carriers (electrons and holes). The latter is frequently radically different for holes and electrons and, in some cases,  $m^*$  is more than an order of magnitude smaller than the free-electron mass  $m_e$ . Hence, such quantum-size effects play a role for crystallites of approximately 1–10 nm in diameter. Under these conditions, the energy levels available for the electrons and holes in the conduction and valence bands become discrete and the effective bandgap of the semiconductor is increased. To a first approximation, the energy spacing between quantized levels is inversely proportional to the effective mass and the square of the particle diameter. A schematic energy diagram resulting from such confinement effects is shown in Figure 6.

Several attempts have been carried out to compute the electronic energy levels in such quantum dots [99, 108–110]. According to these concepts, the energy of the lowest excited state of a semiconductor particle with radius  $R$  is given approximately by

$$E(R) = E_g + \frac{\hbar^2\pi^2}{2R^2} \left[ \frac{1}{m_e^*} + \frac{1}{m_h^*} \right] - \frac{1.8e^2}{\epsilon R} \quad (4)$$

**Figure 5.** Sensitized photoreaction with (a) an initial excitation of the adsorbate, or (b) an initial excitation of the solid.

**Figure 6.** Schematic correlation diagram relating bulk-semiconductor electronic states to quantum crystalline states. Adapted from [110], M. G. Bawendi et al., *Annu. Rev. Phys. Chem.* 41, 477 (1990). © 1990, Annual Reviews.

Here  $E_g$  is the bandgap of the bulk semiconductor, the second term is the quantum energy of localization, increasing as  $R^{-2}$  for both electron and hole, and the third term is the Coulomb attraction [99]; whereas the Coulomb term shifts  $E(R)$  to smaller energy as  $R$ , the quantum confinement contribution increases  $E(R)$  as  $R^2$ . As a result, the apparent bandgap will always increase for small enough  $R$ . But while the shift can be appreciable ( $\sim 1$  eV) for small band gap materials like InSb, it might be considerably smaller ( $\sim 0.2$  eV) for semiconductors with a large bandgap like TiO<sub>2</sub> or ZnO [99]. Apart from a large effect on the optical properties (e.g., a change in color of the material due to the blue shift of the absorption), size quantization may also lead to major changes in the photocatalytic properties. While these effects have been studied in great detail for several compound semiconductor materials like CdS, ZnO, or PbS, related data for TiO<sub>2</sub> appear to be still rather limited.

## 2.5. Optical Properties

Semiconductors absorb light below a threshold wavelength  $\lambda_g$  which is related to the bandgap energy  $E_g$  by [93]

$$\lambda_g \text{ (nm)} = 1240/E_g \text{ (eV)} \quad (5)$$

Within the solid, the extinction of light follows an exponential law

$$I = I_0 \exp(-\alpha z) \quad (6)$$

where  $z$  is the penetration depth and  $\alpha$  is the reciprocal absorption length. For TiO<sub>2</sub>, for example,  $\alpha = 2.6 \times 10^4 \text{ cm}^{-1}$  at a wavelength of 320 nm; this implies that such light is extinguished to 90% after passing a distance of 390 nm in the semiconductor. Near threshold, the value of  $\alpha$  increases with increasing photon energy. Frequently, a proportionality of the type

$$\alpha h\nu = C(h\nu - E_g)^n \quad (7)$$

provides a satisfactory description of the absorption where  $h\nu$  is the photon energy.  $C$  is a constant scaling with the effective masses of the charge carriers, but is independent of the photon frequency. The exponent  $n$  has a value of 0.5 for a direct semiconductor and 2 for an indirect one [94]. Experimental data [111, 112] obtained on both anatase and rutile TiO<sub>2</sub> thin films indicated, however, that the actual situation might be more complex.

In colloidal solution, semiconductor particles reduce the light intensity of the incident beam both by scattering and absorption. In the absence of quantum-size effects the extinction spectrum is described by the Mie theory [113, 114]. This theoretical approach can be applied to an assembly of spherical particles if the interparticle distance is larger than the wavelength of the incident light (i.e., the particles scatter independently); if, furthermore, the particle size is much smaller than the wavelength, the energy-dependent absorption cross-section  $\sigma(\omega)$  for the irradiation of a solution containing the particles can be derived [115–117]:

$$\sigma(\omega) = 9V_p \frac{\omega}{c} \frac{\epsilon_s^{3/2} \epsilon_2}{(\epsilon_1 + 2\epsilon_s)^2 + \epsilon_2^2} \quad (8)$$

where  $\epsilon(\omega) = \epsilon_1 + i\epsilon_2$  is the complex, frequency-dependent dielectric constant of the semiconductor particle,  $\epsilon_s$  is the dielectric constant of the embedding medium (the solvent),  $V_p$  is the volume of a particle,  $\omega$  is the frequency of the incident light, and  $c$  is the velocity of light. For the case of a dilute system of particles with the number density  $n$ ,  $\sigma(\omega)$  can be related to the reciprocal absorption length  $\alpha(\omega)$ :  $\alpha(\omega) = n\sigma(\omega)$ . It follows that the imaginary part of the dielectric constant is a direct measure of the light absorption by the particles; it increases steeply near the absorption edge, that is, for  $\omega$  close to the threshold frequency. As noted in [69], Mie's theory has been widely employed to interpret the extinction spectra of colloidal systems [118]. For example, the brilliant ruby or yellow colors caused, respectively, by colloidal gold or silver particles are distinctly explained by this theory.

## 3. PREPARATION OF NANOSTRUCTURED MATERIALS AND THIN FILMS

Several distinct techniques have been utilized in recent years to synthesize nanocrystalline TiO<sub>2</sub> thin films by chemical, electrochemical, and organized assembly methods [69, 119–121]. A simple approach involves casting of the thin film directly from colloidal suspensions [122]. This method of preparation is relatively simple and inexpensive compared with other existing methods such as chemical vapor deposition or molecular beam epitaxy. Preparation of nanoclusters in polymer films and Langmuir–Blodgett films has also been considered. The sol–gel technique has been found to be useful in developing nanostructured semiconductor membranes with either a two-dimensional or three-dimensional configuration. Organic-template-mediated synthesis has been employed to develop nanoporous materials. The nanostructured materials are highly porous and can easily be surface modified with sensitizers, redox couples, and/or other nanostructured films.

### 3.1. Preparation from Colloidal Suspensions

Nanostructured semiconductor films of TiO<sub>2</sub> have been prepared frequently from colloidal suspensions [123–133]. By controlling the preparative conditions of the precursor colloids, it is possible to tailor the properties of these films.

Typically, these thin TiO<sub>2</sub> films exhibit interesting photochromic, electrochromic, photocatalytic, and photoelectrochemical properties that are inherited from the native colloids. The synthetic procedure involves the preparation of ultrasmall particles (diameter 2–10 nm) in aqueous or ethanolic solutions by controlled hydrolysis. The colloidal suspension is coated onto a conducting glass plate (an optically transparent electrode (OTE)) and dried; finally, the film is annealed at 200–400 °C in air for some 1–2 h. The conducting surface facilitates direct electrical contact of the nanostructured thin film. This simple approach of coating preformed colloids onto a surface and annealing generally produces an oxide film, which is robust and exhibits an excellent stability in both acidic and alkaline media, a feature very important in several potential applications. Generally, some optimization is required for thicker films and for higher colloidal concentrations in order to avoid cracking of the films upon drying. Further details of the methodology of preparation can be found in [134–136]. Transmission electron micrographs of nanostructured films prepared from colloidal suspensions show a three-dimensional network of oxide nanocrystals of particle diameter as small as a few nanometers. No significant aggregation or sintering effects are observed during the annealing process. X-ray diffraction analysis also confirms the crystallinity of these nanostructured films. Composite films, which in some cases may exhibit improved properties as compared to single-component films, can be manufactured by mixing two or more components prior to casting of the film.

Titania sol and gel prepared through the hydrolysis of tetrabutyl titanate in acid water solution are sensitive to ultraviolet (UV) irradiation and turn into blue color [137]. Electron spin-resonance measurement showed that the photochromism was ascribed to the presence of titanium (III) ions in the Ti-O-Ti network. The titanium (III) ions could be oxidized by the oxygen in the atmosphere, and then the sol and gel faded slowly. The absorption peaks in the optical absorption spectra of the titania gel were attributed to the transition of 3-dimensional electrons of a trivalent titanium in certain environments.

The morphology of TiO<sub>2</sub> particles affects their catalytic activity and electrical properties. In recent years, many methods for preparing TiO<sub>2</sub> nanoparticles and thin films have been studied [138]. TiO<sub>2</sub> nanocrystals prepared by the sol-gel method often have fully hydroxylated surfaces and these hydroxyl groups have a strong influence on the catalytic and photocatalytic properties such as electron-transfer rates and reducing properties [139]. In order to develop photocatalysts with high activities, it is very important to prepare porous anatase nanoparticles with a high specific surface area. Furthermore, the preparation method should be simple and should be a low temperature process. Mixtures of rutile and anatase precipitates could be obtained by the hydrothermal treatment of an alcohol solution of Ti alkoxide at 573 K [140], while anatase nanoparticles were prepared by heat treatment of a H<sub>2</sub>O-EtOH solution of TiOSO<sub>4</sub> at 373 K [141]. Thus, the anatase and rutile particles were usually formed in a solution by conventional soft chemical synthesis methods. The preparation of monodispersed oxide particles by the “sol-gel method” enables the manufacture of oxide particles through a gel state with a regulated

particle growth rate [142–144]. In a recent study [145], anatase nanoparticles were prepared in a Ti-peroxy gel without the collapse of the gel during the particle formation process. The gel was made from titanium tetraisopropoxide (Ti(O-iPr)<sub>4</sub>) and H<sub>2</sub>O<sub>2</sub>.

The crystallization rate of titania gels was found to be much higher in water than in methanol or *n*-hexane [146]; also, the crystallite size of anatase prepared in water was larger than those in organic solvents. Processing parameters very often control the crystallite size and phase. Nonagglomerated, ultrafine anatase particles have been generated by hydrothermally treating sol-gel-derived hydrous oxides [147]. The degree of crystallinity and purity of the synthesized materials may affect their structural evolution during any heat treatment.

TiO<sub>2</sub> thin films with different surface structures were prepared from alkoxide solutions containing polyethylene glycol (PEG) via the sol-gel method [148]. The larger the amount of PEG added to the precursor solution, the larger the size and number of pores produced in the resultant films. When PEG was added to the gel, the films decomposed completely during heat treatment. The adsorbed hydroxyl content of such porous thin films is found to increase with increasing amount of PEG. However, the transmittance of the films decreases due to the scattering of light by pores of larger size and a higher number in the films. Photocatalytic degradation experiments show that methyl orange is efficiently decolorized in the presence of the TiO<sub>2</sub> thin films by exposing its aqueous solution to ultraviolet light. However, in films deposited on soda-lime glass [149], diffusion of sodium and calcium ions from the glass into the nascent TiO<sub>2</sub> films was found to be detrimental to the photocatalytic activity of the resulting films. Sodium and calcium diffusion into nascent TiO<sub>2</sub> films was effectively retarded by a 0.3 μm SiO<sub>2</sub> interfacial layer formed on the soda-lime glass [149, 150].

TiO<sub>2</sub> thin film photocatalysts coated onto glass plates were prepared [151] by thermal decomposition of tetraisopropyl orthotitanate with a dip-coating process using alpha-terpineol as a highly viscous solvent. Two types of ligands—polyethylene glycol 600 and (ethoxyethoxy)ethanol—were added to the dip-coating solution as the stabilizer of titanium alkoxide and thin films were obtained after calcination at 450 °C for 1 h. The film thickness obtained with a single dipping was proportional to the viscosity of the dip-coating solutions. The thin films obtained were transparent with a thickness of 1 μm. The crystal form of the films was anatase alone. The thin films were formed with aggregated nanosized TiO<sub>2</sub> single crystals (7–15 nm), and the size of the TiO<sub>2</sub> crystals became smaller for the polymer-added systems.

Transparent anatase TiO<sub>2</sub>-based multilayered photocatalytic films synthesized via a sol-gel process on porous alumina and glass substrates showed a sponge-like microstructure and a mean crystallite dimension of ca. 8 nm [152]. Doping such films with iron(III) impeded the photocatalytic activity.

The effects of calcination on the microstructures of nanosized titanium dioxide powders prepared by vapor hydrolysis was investigated in detail [153–155]: Among the factors examined [153], large surface area and good dispersion of the powders in the reaction mixture are favorable to photoactivity. Conversely, prolonged calcination at high

temperatures is detrimental to photoactivity. Powders produced at higher temperatures are predominantly anatase and are generally more photoactive.

The formation, structure, and photophysical properties of functional mixed films of 5,10,15,20-tetra-4-(2-decanoic acid)phenyl porphyrin (TDPP) with TiO<sub>2</sub> nanoparticles formed from the two-dimensional sol-gel process of tetrabutoxytitanium (TBT) at the air/water interface was reported [156]. The composite multilayer films were assembled by transferring the mixed monolayer onto quartz plates. The sensitization of TDPP upon TiO<sub>2</sub> nanoparticles was confirmed by the spectral changes of UV-visible absorption and fluorescence of TDPP in the composite films. Furthermore the photosensitization greatly affected the photocatalytic activity of TiO<sub>2</sub> particles with respect to the degradation of methylene blue.

Crystalline titania thin films were obtained [157] on glass and various kinds of organic substrates at 40–70 °C by deposition from aqueous solutions of titanium tetrafluoride. Transparent films consisting of small anatase particles (~20 nm) exhibited excellent adhesion to relatively hydrophilic surfaces. Uniform coatings were successfully prepared on substrates with complex shapes such as cotton and felt fiber. Growth rate and particle size were controlled by both the deposition conditions and the addition of an organic surfactant. Organic dyes were incorporated into the anatase films using organic-dye dissolving solutions and a surfactant.

### 3.2. Chemical Precipitation

Rutile-phase nano-sized TiO<sub>2</sub> powders having a high specific surface area of 180 m<sup>2</sup>/g were prepared by homogeneous precipitation at ambient or very low temperatures (<100 °C) [158]. Ultrafine SnO<sub>2</sub>–TiO<sub>2</sub>-coupled particles could be synthesized [159] by homogeneous precipitation; they were employed for photocatalytic degradation of azo dye active red X-3B in aerated solution. The results show that a very rapid and complete decolorization of the azo dye can be achieved, and the photoactivity of the coupled particles is higher than that of pure ultrafine TiO<sub>2</sub>, and the optimum loading of SnO<sub>2</sub> on TiO<sub>2</sub> is 18.4%. The enhanced degradation rate of X-3B using coupled photocatalysts is attributed to increased charge separation in these systems.

### 3.3. Gas Condensation and Consolidation

Another method to synthesize nanostructured materials is by way of gas condensation followed by the *in-situ* consolidation under high-vacuum conditions [2]. This approach can produce ultrafine-grained materials which may exhibit size-related effects. The basic aspects of the generation of nanometer-sized materials via gas condensation are conceptually rather simple [2]: A precursor material, either an element or a compound, is evaporated in a gas maintained at a low pressure, usually well below one atmosphere. The evaporated atoms or molecules lose energy via collisions with the gas atoms and undergo a homogeneous condensation to form atomic or molecular clusters in the highly supersaturated vicinity of the precursor source. In order to maintain small cluster sizes, by minimizing further atom/molecule accretion and cluster-cluster coalescence, the clusters once

nucleated must be removed from the region of high supersaturation. Since the aggregates are already entrained in the condensing gas, this is readily accomplished by setting up conditions for moving this gas.

Typically, there are three fundamental rates that essentially control the formation of the clusters in the gas-condensation process [160]. These are

- (i) the rate of supply of atoms to the region of supersaturation where condensation occurs,
- (ii) the rate of energy removal from the hot atoms via the condensing medium, the gas,
- (iii) the rate of removal of the cluster upon nucleation from the supersaturated region.

The clusters that are collected via thermophoresis on the surface of a cold finger usually form very open, fractal structures. The clusters are held on the collector surface rather weakly, via Van-der-Waals forces, and are easily removed by means of a scraper. The material removed is consolidated in a compaction unit at typical pressures of 1–2 GPa; the scraping and consolidation are carried out under ultra-high-vacuum conditions *in-situ* after the removal of the gas from the chamber, in order to maximize the cleanliness of the particle surfaces and the interfaces that are formed.

### 3.4. Film Deposition by Sputtering and Vacuum-Based Techniques

Crystalline titanium dioxide films are often deposited by various techniques employing vacuum conditions, using, for example, RF magnetron [161–166], DC sputtering [167–171], chemical vapor deposition [172, 173], plasma spraying [174, 175], or related techniques [176, 177]. Rapid electroplating of photocatalytically highly active TiO<sub>2</sub>-Zn nanocomposite films on steel was achieved [178] and the gas-phase oxidation of CH<sub>3</sub>CHO was employed as an indicator of the photocatalytic activity. Not surprisingly, the film and surface morphologies and the crystallinity are strongly dependent on the total and the oxygen partial pressure, the deposition rate, and the phase composition; the resulting photocatalytic properties can be modified over a wide range by those parameters. Such films may show good uniformity of thickness over large areas, high optical transmittance (~80%) in the visible region, and considerable mechanical durability [169].

Transmission electron microscopy was used to study [179] the structure, morphology, and orientation of thin TiO<sub>2</sub> films prepared by reactive magnetron sputtering on glass slides at different substrate temperatures (100 to 400 °C). The microstructure and photocatalytic reactivity of TiO<sub>2</sub> films have been shown to be functions of deposition temperature. In the temperature range examined, all film samples have a porous nanostructure and the dimension of particles grew with increasing deposition temperature. Films are amorphous at temperatures of 100 °C and only the anatase phase forms at 200 °C and above. Films deposited between 200 to 300 °C show a preferred orientation, while films at 400 °C change into complete random orientation. Deposition at 250 °C yields high efficiency in photocatalytic degradation owing to the high degree of preferred orientation and nanocrystalline/nanoporous anatase phase.

Another frequently employed and convenient way for the preparation of TiO<sub>2</sub> thin films is pulsed laser deposition [180], although this technique does not produce nanocrystalline structures.

### 3.5. Surface and Film Modifications

The surface of as-deposited films has frequently been modified in the quest to enhance the catalytic activity. For example, Fe [181] or Sn [182] ions have been implanted into transparent and colorless TiO<sub>2</sub> thin films fabricated on microscope glass slides by DC magnetron reactive sputtering using Ar and O<sub>2</sub> as working gases. The efficiency of this procedure could not as yet be proven unambiguously. Apart from grain size, the presence of reactive species on the surface [183] may influence the photocatalytic activity. Implanted metal ions (V or Cr) were observed [184] located at the lattice positions of Ti<sup>4+</sup> in TiO<sub>2</sub> and were stabilized after calcination of the samples in an O<sub>2</sub> ambient at around 775 K. Spectroscopic studies showed that the presence of these substitutional metal ion species are, in fact, responsible for a large shift in the absorption spectra of these catalysts toward visible light regions. Porous anatase TiO<sub>2</sub> films were densified by Zn<sup>2+</sup> ion implantation up to the ion penetration depth [185]. After the subsequent annealing at 800 °C, the phase transformation from anatase to rutile accompanied with grain growth up to the film thickness was observed. In addition, the phase transformation was not induced by the annealing up to 800 °C with or without preceding Ar<sup>+</sup> ion implantation. Thus, the implanted impurity Zn assisted the phase transformation. Annealing in O<sub>2</sub> tends to reduce the rate of phase transformation and create ZnTiO<sub>3</sub>. Optical absorption above the photon energy of 2.9 eV was increased remarkably by the Zn<sup>2+</sup> or Zn<sup>+</sup> and O<sup>+</sup> ion implantation and subsequent annealing and is due to the phase transformation.

The presence of active species such as Ti<sup>3+</sup> and hydroxyl on the surface of ultrafine TiO<sub>2</sub> particles, prepared by a colloidal chemical approach and subjected to different heating treatments, was inferred [186] from optical absorption and photoelectron spectra; these species may enhance the photocatalytic activity of particles. Treating TiO<sub>2</sub> powder by a hydrogen plasma resulted in a reduction of the oxide particles and electrons trapped at the oxygen-defect sites were found [187]. Also laser ablation of TiO<sub>2</sub> photocatalysts aiming at the enhancement of the activity was reported [188].

Noble metal particles of Au, Pt, and Ir were deposited on nanostructured TiO<sub>2</sub> films using an electrophoretic approach [189]. The improved photoelectrochemical performance of the semiconductor-metal composite film was attributed to the shift in the quasi-Fermi level of the composite to more negative potentials. Continuous irradiation of the composite films over a long period causes the photocurrent to decrease as the semiconductor-metal interface undergoes chemical changes.

Doping of nanostructured TiO<sub>2</sub> both as particles and in thin films with a variety of metals has been reported, some common examples being Pt [190, 191], Pb [192], Au [193], or others [194]. A shift of the UV-vis absorption towards longer wavelengths was observed upon Pb doping, which indicates a decrease in the bandgap of TiO<sub>2</sub>. In TiO<sub>2</sub> films embedding Au nanoparticles [193], the specific resistance of

the films experienced a rising phase, followed by a dramatic drop with an increasing number of Au particles. Ultrafine Pt particles [191] were embedded into rutile TiO<sub>2</sub> particles by decomposing a colloidal organic-Pt complex, resulting in very narrow size distribution with a mean diameter of 3 nm. These nm-sized Pt particles were found to grow epitaxially on the TiO<sub>2</sub> crystallites with a well-defined crystallographic relationship.

Doping a nano-structured TiO<sub>2</sub> electrode sensitized with tetrasulfonated gallium phthalocyanine with tetrasulfonated zinc porphyrin (ZnTsPP) greatly enhances the photoelectric conversion at long wavelengths, with 20- and 60-fold improvement of the quantum efficiency at 680 and 700 nm [195].

Semiconductor/metal composite nanoparticles have been synthesized [196] by chemically reducing HAuCl<sub>4</sub> on the surface of preformed TiO<sub>2</sub> nanoparticles. These gold-capped TiO<sub>2</sub> particles (diameter 10–40 nm) were stable in acidic (pH 2–4) aqueous solutions. The role of the gold layer in promoting the photocatalytic charge transfer has been probed using thiocyanate oxidation at the semiconductor interface. More than 40% enhancement in the oxidation efficiency was found with TiO<sub>2</sub>/Au nanoparticles capped with low concentration of the noble metal.

Magnetic photocatalysts were synthesized by coating titanium dioxide particles onto colloidal magnetite and nanomagnetite particles [197]. The photoactivity of the prepared coated particles was lower than that of single-phase TiO<sub>2</sub> and was found to decrease with an increase in the heat treatment. These observations were explained in terms of an unfavorable heterojunction between the titanium dioxide and the iron oxide core, leading to an increase in electron-hole recombination.

TiO<sub>2</sub>-based powders, doped with a small amount of SiO<sub>2</sub>, were prepared by a sol-gel method and were subsequently heated to precipitate fine anatase crystals [198]. The obtained powders have large specific surface areas (~200 m<sup>2</sup>/g) and upon treating them chemically with aqueous NaOH, the photocatalytic property of the powders was extremely improved and the powders showed higher activity than the undoped TiO<sub>2</sub> powders.

In composite TiO<sub>2</sub>-SiO<sub>2</sub> thin films prepared by a sol-gel process, the refractive index and the photocatalytic activity decrease with increasing SiO<sub>2</sub> content in these films [199]. Alkoxide sol-gel processing has been investigated for the synthesis of stable SiO<sub>2</sub>-TiO<sub>2</sub> high-permeability catalytic membranes to be used in alkene isomerization [200]. Nanocrystalline TiO<sub>2</sub> was prepared on mesoporous silica both by sol-gel processes [201] and by an impregnation method with titanium complexes featuring different ligands [202].

Binary mixed oxide of Fe/Ti (1:1 composition) with homogeneous distribution of iron into the TiO<sub>2</sub> has been prepared by sol-gel impregnation using metal alkoxide precursors and firing at different temperatures (500, 700, and 900 °C) [203]. The mixed oxide exhibits excellent absorption in the visible spectral region (570–600 nm). The photocatalytic activity of the Fe/Ti oxide reduces to a large extent at a high sintering temperature of the sample due to the presence of a increasing amount of the inactive (Fe<sub>2</sub>/TiO<sub>3</sub>) pseudobrookite phase. Nanostructured TiO<sub>2</sub>/SnO<sub>2</sub> binary oxides were prepared by

combustion of stearic acid precursors [204], with metal precursors being dispersed in the stearic acid at the molecular level. It was found that preparative methods affected the crystalline structure of the powders and the anatase phase of TiO<sub>2</sub> was stabilized by the addition of SnO<sub>2</sub>.

Spray "painted" (spray deposited) titanium dioxide coatings were sensitized [205] with chemically deposited cadmium selenide thin films; the structural, optical, and photoelectrochemical characterization of these composite films indicate the importance of thermal treatments in improving the photocurrent quantum yields. Up to 400 °C, the effect of air annealing is to shift the onset of absorption to longer wavelengths and improve the photocurrent substantially.

Organic compounds may play a crucial role in chemical processes for ceramic coatings [206]. Organic compounds remained in a fixed position in the coating, which was prepared from the chemically modified titanium tetraisopropoxide solution and heated at temperatures as high as 673 K. It was not until the organic compounds decomposed to carbon dioxide and the gas phase was left from the coating that the nanostructure, consisting of nano-sized pores and anatase crystallites with preferred orientation, developed at 723 K.

Cobalt(II) 4,4',4'',4'''-tetrasulfophthalocyanine, covalently linked to the surface of titanium dioxide particles, TiO<sub>2</sub>-CoTSP, was shown [207] to be an effective photocatalyst for the oxidation of sulfur (IV) to sulfur (VI) in aqueous suspensions. Upon bandgap illumination of the semiconductor, conduction-band electrons and valence-band holes are separated; the electrons are channeled to the bound CoTSP complex resulting in the reduction of dioxygen, while the holes react with adsorbed S(IV) to produce S(VI) in the form of sulfate.

The photoactivity of the Pt/TiO<sub>2</sub> system in the visible region was improved [208] by the addition of the sensitizer ([Ru(dcbpy)<sub>2</sub>(dpq)]<sup>2+</sup>) [where dcbpy = 4,4'-dicarboxy 2,2'-bipyridine and dpq = 2,3-bis-(2'-pyridyl)-quinoxaline] leading to an efficient water reduction.

Photocatalytic properties for hydrogen production were investigated [209] on layered titanium compounds intercalating CdS in the interlayer, which were prepared by direct cation exchange reactions and sulfurization processes. The photocatalytic activity of the compounds intercalating CdS was superior to those of simple CdS and the physical mixture of CdS and metal oxides. The improvement might be attributed to the formation of microheterojunctions between the CdS nanoparticles and the layers of oxides.

### 3.6. Novel Deposition Methods and Structures

In recent years, there has been increased interest in studying and manufacturing nanoscaled TiO<sub>2</sub> materials as nanoparticles [210], nanowires [211], nanorods [212], whiskers [213], and nanotubes [214–217].

There are many synthetic routes for the creation of nanocrystals of oxides and the controlled hydrolysis of metal alkoxides is the most generalized solution-phase synthetic strategy [218]. Increased photocatalytic activity was reported recently for TiO<sub>2</sub> prepared by ultrasonic irradiation and glycothermal methods. This novel method [219] for preparing highly photoactive nanometer-sized TiO<sub>2</sub> photocatalysts

with anatase and brookite phases has been developed by hydrolysis of titanium tetraisopropoxide in pure water or a 1 + 1 EtOH–H<sub>2</sub>O solution under ultrasonic irradiation; the photocatalytic activity of TiO<sub>2</sub> particles prepared by this method exceeded that of Degussa P25 and was the first report that showed high photocatalytic activity of a photocatalyst containing an 80% anatase and 20% brookite phase.

A novel and convenient nonhydrolytic approach to the preparation of uniform, quantum confined TiO<sub>2</sub> nanocrystals, using an intramolecular adduct stabilized alkoxide precursor, was described recently [220]. In contrast to established aqueous sol–gel-techniques, the processing in hydrocarbon solvents at high temperatures allows access to very small free-standing crystallites, and opens up new possibilities for control over size distribution, surface chemistry, and particle agglomeration.

It has been reported that the columnar morphologies in sputtered TiO<sub>2</sub> films enhances the photocatalytic [221] and photovoltaic [222] efficiency. Following these studies, enhanced surface-reaction efficiency has been demonstrated in the photocatalysis of sculptured thin films of TiO<sub>2</sub> [223]. In obliquely deposited films with variously shaped columns such as zigzag, cylinder, and helix, the columnar thickness and spacing play an important role in the enhancement of the effective surface area, while the columnar shape is less important. The optimum morphology for a surface reaction has been obtained at the deposition angle of 70°, where the photocatalytic activity is 2.5 times larger than that at 0°. The morphology of these obliquely deposited thin films appears well suited for application as solar cells, electro- and photochromic devices, and photocatalysts.

The template method for synthesizing nanostructures involves the synthesis of the desired material within the pores of a nanoporous membrane or other solid. This approach has been used in several experiments [224–229] for the preparation of TiO<sub>2</sub> nanotubes and nanorods; typically, porous aluminum oxide (PAO) nano-templates were used.

Compact, continuous, and uniform anatase nanotubules with diameters in the range 50–70 nm were produced inside PAO nano-templates by pressure impregnating the PAO pores with titanium isopropoxide and then oxidatively decomposing the reagent at 500 °C [230]. Cleaning the surface of the template and repeating the process several times produced titania nanotubules with a wall thickness of ~3 nm per impregnation. The tube exteriors appeared to be faithful replicas of the pores in which they were formed.

Nano-TiO<sub>2</sub> whiskers were prepared by various techniques [213, 231]; using, for example, controlled hydrolysis of titanium butoxide [231] it was found that the nano-TiO<sub>2</sub> whiskers obtained were anatase and grew selectively in the [001] direction with a diameter of about 4 nm and a length of about 40 nm. Acetic acid played an important role in the oriented growth of nano-TiO<sub>2</sub> whiskers.

Highly ordered TiO<sub>2</sub> nanowire (TN) arrays were prepared [211] in anodic alumina membranes by a sol–gel method. The TNs are single crystalline anatase phase with uniform diameters around 60 nm. At room temperature, photoluminescence measurements of the TN arrays show a visible broadband with three peaks, which are located at about 425, 465, and 525 nm that are attributed to self-trapped excitons, *F*, and *F*<sup>+</sup> centers, respectively.

## 4. STRUCTURAL PROPERTIES OF NANOCRYSTALLINE TiO<sub>2</sub> FILMS

### 4.1. The Lattice Structure of Rutile and Anatase

Three different crystal structures of TiO<sub>2</sub> exist [18]: rutile, anatase, and brookite; only the former two of them are commonly used in photocatalysis, with anatase typically exhibiting the higher photocatalytic activity [232]. The structure of rutile and anatase can be described in terms of chains of TiO<sub>6</sub> octahedra. The two structures differ by the distortion of each octahedron and the actual pattern of the chains. Figure 7 depicts the unit cell structures of rutile and anatase crystals [233–235]. Each Ti<sup>4+</sup> ion is surrounded by an octahedron of six O<sup>2-</sup> ions. The octahedron in rutile shows a slightly orthorhombic distortion, whereas the respective octahedra in anatase are significantly distorted, resulting in a symmetry that is lower than orthorhombic. The Ti-Ti distances in anatase are greater (0.379 and 0.304 nm as compared to 0.357 and 0.296 nm in rutile) while the Ti-O distances are shorter than in rutile (0.1934 and 0.1980 nm in anatase versus 0.1949 and 0.1980 nm in rutile). In the rutile structure, each octahedron is in contact with 10 neighboring ones (two sharing edge oxygen pairs and eight sharing corner oxygen atoms), whereas in the anatase crystal each octahedron is in contact with eight neighbors (four sharing an edge and four sharing a corner). These differences in lattice structure result in different mass densities ( $\rho = 4.250 \text{ g/cm}^3$  for rutile and  $\rho = 3.894 \text{ g/cm}^3$  for anatase) and electronic band structures for the two forms of TiO<sub>2</sub>.

Synthetic titanium oxide crystallizes in two polymorphs: anatase and rutile. Anatase is metastable and transforms exothermally and irreversibly to rutile. Some properties of TiO<sub>2</sub> may strongly depend on its polymorphic phase. The anatase-rutile transformation is strongly influenced by the synthesis method, atmosphere, grain growth, and impurities. Some additives, such as ZrO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub>, retard the anatase-rutile transformation, whereas others, such as CoO and ZnO, accelerate such a process [236]. The anatase-to-rutile phase transformation of doped nanostructured titania was studied [237] using differential thermal analysis (DTA) and X-ray diffraction (XRD). The presence of Cu and Ni was found to enhance transformation as well as sintering.

**Figure 7.** Crystal structures of rutile (left) and anatase (right) TiO<sub>2</sub>.

On the other hand, La retarded both transformation and densification.

Transmission electron microscopy (TEM) is typically used to investigate the crystal size distribution, grain-boundary disorder, and defect structure in nanocrystalline TiO<sub>2</sub> materials prepared by the various techniques outlined in the previous section. In a recent study of films with an average grain size of 15 nm prepared by reactive sputtering [238], evidence of both ordered and disordered grain-boundary regions was found and planar defects were observed in grain interiors identified as (011) deformation twins. Also, crystallographic shear defects can occur as a result of aggregation of oxygen vacancies in understoichiometric titanium oxide. Figure 8 shows results of TEM investigations [239] of nanocrystalline TiO<sub>2</sub> films prepared from colloidal suspensions; the TiO<sub>2</sub> crystallites were nominally pure anatase phase with a size of 16 nm.

### 4.2. Structure of Crystalline TiO<sub>2</sub> Surfaces

The geometric structure of crystalline surfaces of TiO<sub>2</sub> has been studied predominantly on (macroscopically) large single crystals; in particular, the (110) surface of rutile, being thermodynamically the most stable one [240], has been investigated extensively by a broad variety of surface science tools [241–243]. Among the different questions addressed therein, a prominent one was related to the possible types of oxygen defects at the surface; in fact, three distinct oxygen vacancy sites were tentatively identified: lattice, single-bridging, and double-bridging vacancies [244]. With the widespread use of scanning-tunneling microscopy (STM), atomically resolved investigations of TiO<sub>2</sub> surfaces became feasible and a more detailed picture of the rutile (110) surface structure emerged [245–248]. Consistently, these studies corroborate the longstanding notion about the prominent importance of surface defects as the active sites for various types of chemical reactions [249–251], for example, for

**Figure 8.** Cross-section transmission electron microscopy image of a nanocrystalline TiO<sub>2</sub> anatase film. The nominal crystallite size is 16 nm.

the dissociation of water [252, 253]. The number of studies on the structural properties of anatase single crystals is considerably smaller, which appears to be largely due to the difficulties encountered in preparing such surfaces in a defect-free state. Nevertheless, a rather distinct picture of the anatase TiO<sub>2</sub> surface structure [254–257] and its properties in terms of adsorption/desorption reactivity [258–260] has been achieved.

The structure and composition of a nanocrystalline surface may have a particular importance in terms of chemical and physical properties because of their small size. For instance, nanocrystal growth and manipulation relies heavily on surface chemistry [261]. The thermodynamic phase diagrams of nanocrystals are strongly modified from those of the bulk materials by the surface energies [262]. Moreover, the electronic structure of semiconductor nanocrystals is influenced by the surface states that lie within the bandgap but are thought to be affected by the surface reconstruction process [263]. Thus, a picture of the physical properties of nanocrystals is complete only when the structure of the surface is determined.

To understand and improve the applications of titanium-oxide nanoparticles, it is extremely important to perform a detailed investigation of the surface and the interior structural properties of nanocrystalline materials, such as rutile and anatase with diameter of a few nanometers. Detailed experiments using X-ray absorption near-edge structure spectroscopy (XANES) demonstrated [264] that the presence of both defects and surface states strongly influence the X-ray absorption spectra, even though the first nearest-neighbor geometrical arrangement around the central Ti atom in both rutile and anatase is quite similar: the differences in the XANES spectra arise from the outer-lying atomic shells, indicating that “medium” to “long-range” effects play an important role to the near-edge features. In another study of this kind [265], a shorter Ti-O distance for surface TiO<sub>2</sub>, resulting from Ti-OH bonding was observed together with a minor disorder of the lattice in smaller nanoparticles. Nevertheless, the Ti sites largely remain octahedral even in particles with diameters of 3 nm. Because the interfacial electron/hole transfer occurs via surface Ti or O atoms, the observed structural changes around the surface Ti atoms in small TiO<sub>2</sub> particles could be responsible [265] for the unique photocatalytic properties.

A qualitative analysis of opaque nanostructured glass-supported TiO<sub>2</sub> films was carried out [266] using scanning force microscopy (SFM), and surface parameters such as average grain diameter, roughness exponent, and fractal dimension [267] were determined. The TiO<sub>2</sub> surfaces exhibit distinct roughness due to the large aggregates formed by the interconnected TiO<sub>2</sub> particles. Fractal dimension was found to range between 2.10 and 2.45, depending on the scanned range and the preparation method. The surface morphology of nanocrystalline materials prepared by compacting nanometer-sized clusters was investigated by SFM [268]; these materials had a grain size of 5–15 nm and contained about 10<sup>19</sup> interfaces per cubic centimeter. Upon heat treatment, grains were found to fuse together forming bamboo-like structures and then lined up as tubular structures.

The influence of the iron concentration in mixed-oxide (TiO<sub>2</sub> and Fe<sub>2</sub>O<sub>3</sub>) thin films prepared by reactive

radio-frequency sputtering on the structural properties of the layers has been studied [269]. This characterization allowed the correlation of the inhibition of the grain growth of titania to the presence of iron oxide and its segregation at grain boundaries. This behavior could be ascribed to a superficial-tension phenomenon. As a possible application of these thin films, it was observed that they were able to sense CO down to the level requested for environmental monitoring.

A study [270] of the structure and morphology of a titanium dioxide photocatalyst (Degussa P25) reveals multiphase material consisting of an amorphous state, together with the crystalline phases anatase and rutile in the approximate proportions 80/20. Transmission electron microscopy provides evidence that some individual particles are a mixture of the amorphous state with either the anatase phase or the rutile phase, and that some particles, which are mostly anatase, are covered by a thin overlayer of rutile that manifests its presence by the appearance of Moiré fringes. The photocatalytic activity of this form of titanium dioxide is reported as being greater than the activities of either of the pure crystalline phases, and an interpretation of this observation has been given in terms of the enhancement in the magnitude of the space-charge potential, which is created by contact between the different phases present and by the presence of localized electronic states from the amorphous phase.

## 5. ELECTRICAL PROPERTIES OF NANOCRYSTALLINE TiO<sub>2</sub> FILMS

Most studies into the carrier transport in nanocrystalline TiO<sub>2</sub> were carried out with the films in contact with electrolytes, mostly due to their use in highly efficient electrochemical solar cells, often called “Grätzel cells” [38, 71]. In this application, the pore surface is covered with an ultrathin organic dye layer and contacted with an electrolytic solution that penetrates the pore structure. The experimental work indicates [271–274] that in this configuration the electrolyte screens any electric field within the porous structure and establishes diffusion conditions for the carrier propagation. On the other hand, investigations in which the nanopores are in contact with an insulating medium (a gas or vacuum) may allow one to obtain quantitative insight into the electronic properties of the material and the basic feature of carrier transport. In a series of measurements [275–277] on the electron transport in nanoporous TiO<sub>2</sub> films with gas-filled, insulating pores employing Pt/TiO<sub>2</sub>, Schottky barrier structures indicate a barrier height of 1.7 eV, compatible with an electron affinity of 3.9 eV for the TiO<sub>2</sub> films. Below ~300 K, tunneling transport through the barrier occurs, resulting in barrier lowering effects. Carrier drift mobilities, recombination lifetimes, and their dependence on injection level in TiO<sub>2</sub> are reported. It is found that the mobility-lifetime product is independent of injection level, while drift mobility and recombination lifetime change strongly with injection. A trap-filling model appears as the most plausible model compatible with the experimental findings [277]. Comparison with recent experiments on nanoporous films in contact with electrolytes indicate that the transport and recombination mechanism is qualitatively similar for the two cases.

Various observations indicate that electron transport in the nanocrystalline TiO<sub>2</sub> dominates the transient response of the system. Transient photocurrent measurements reveal a very slow (~millisecond), multiphasic response to both continuous wave [278, 279] and pulsed [280–282] illumination. The characteristic rise or decay time of the response is dependent upon the intensity of the light source [278, 281–283]. Comparison with the transient response without electrolyte indicates that it is the TiO<sub>2</sub>, and not the electrolyte, which is responsible for the very long tail [284, 275]. A slow and multiphasic time dependence has also been observed in the rereduction of oxidized dye molecules in a redox inactive environment [285]; the same work indicates that the rate of dye reduction is controlled by the concentration of electrons introduced into the TiO<sub>2</sub> by externally applied bias. The wide range of time scales is consistent with the assumption that electron transport within the TiO<sub>2</sub> is the rate limiting step.

The slow processes are attributed to the trapping of electrons by a high density of localized states in the TiO<sub>2</sub>. Since the TiO<sub>2</sub> grains are normally crystalline [286], the localized states are believed to be concentrated at the grain boundaries and on the very large surface. There is evidence for intraband-gap states in bias-dependent optical absorbance spectra [287] and surface photovoltage spectra. It would, therefore, be extremely useful to correlate the density and nature of those states with the electronic transport properties of the material.

Investigating electron migration in nanostructured anatase TiO<sub>2</sub> films with intensity-modulated photocurrent spectroscopy [288], it was found that, upon illumination, a fraction of the electrons accumulated in the nanostructured film is stored in deep surface states, whereas another fraction resides in the conduction band and is free to move. These data indicate that the average concentration of the excess conduction band electrons equals about one electron per nanoparticle, irrespective of the type of electrode, the film thickness, or the irradiation intensity.

The photocurrent in thin film TiO<sub>2</sub> electrodes prepared by sol-gel methods was studied in [289] as a function of film thickness. Films with thickness smaller than the space charge layer were found to show a larger photocurrent than films with thickness larger than the space charge layer. It was concluded that the increase in photocurrent is due to the effective electron-hole separation throughout the whole film thickness and the reduction of bulk recombination. The use of TiO<sub>2</sub> thin-film electrodes for photocatalytic devices might therefore be useful to gain high device performance.

In a series of papers, Dittrich et al. carried out extensive investigations of the electrical conductivity in nanoporous TiO<sub>2</sub> films [290–296]. Studying the temperature- and oxygen partial pressure-dependent conductivity  $\sigma$  of rutile and anatase, they noted [292] that  $\sigma$  is thermally activated with  $E_A = 0.85$  eV, independent of the absolute value of  $\sigma$  and depends on  $p(\text{O}_2)$  by a power law for  $p(\text{O}_2) < 1$ –10 mbar. The electrical properties of reduced nanoporous TiO<sub>2</sub> are determined by surface chemical reactions which lead to the formation of shallow donor and deep trap states. Furthermore, this group examined in detail the photovoltage in nanocrystalline TiO<sub>2</sub> [293, 295] and the injection currents in these porous specimens [294, 296].

Such a power dependence of  $\sigma$  on the oxygen partial pressure was noted also in recent work [297] investigating electrical and defect thermodynamic properties of nanocrystalline titanium oxide. At high O<sub>2</sub> pressures,  $p(\text{O}_2) > 1$  mbar, the conductivity is constant, whereas at values  $p(\text{O}_2) < 10^{-14}$  mbar a steep increase of  $\sigma$  with decreasing pressure was found, following a power dependence  $\sigma \propto [p(\text{O}_2)]^n$  with  $n = -1/2$  [297]. The plateau of conductivity at high oxygen pressures can be interpreted as being a domain of ionic conductivity, an unexpected behavior for titanium dioxide. In a coarse-grained material, dominant hole conductivity is observed in this partial pressure range. This difference may be due to the high density of grain boundaries in nanocrystalline ceramics, which can be preferred paths for diffusion at reduced temperatures. Furthermore, an increase in ionic conductivity is also expected due to enhanced defect formation in the space charge regions adjacent to grain boundaries [298]. At low oxygen partial pressure, nanocrystalline TiO<sub>2</sub> exhibits enhanced electronic conductivity as compared to coarse-grained TiO<sub>2</sub>. The power exponent  $n = -1/2$  can be explained under the assumption that doubly charged titanium interstitials are formed. The intrinsic disorder of titanium dioxide is reputedly of the cationic Frenkel-type [299–302], although alternative defect models based on Schottky disorder are also described in the literature [303, 304]. In the domain of ionic conductivity, the activation energy of conduction is  $\sim 1.0 \pm 0.1$  eV [297], a value typical of migration enthalpies for ionic defects. By contrast, the activation energy in the reduction-controlled regime was found to be  $\sim 3.9 \pm 0.2$  eV.

In titanium oxide thin films prepared by a d.c. sputtering technique onto glass substrates with average grain sizes of 100–200 nm, the surface structure and phase morphology of the films was found [305] to depend on the deposition conditions. The current-voltage characteristics of these films are ohmic for values of applied voltage lower than 0.5 V. For higher values, the mechanism of electrical conduction is determined by space-charge-limited currents [306]; then, a power-law dependence was observed with  $n \sim 2.3$ –2.9. In much thicker Ti oxide films (1.9–8  $\mu\text{m}$ ) deposited by sputtering [307], both the surface roughness and the internal surface area increased with film thickness; this resulted in an enhancement of the incident photon-to-current efficiency.

Electrical and optical spectroscopic studies of TiO<sub>2</sub> anatase thin films deposited by sputtering showed [308, 309] that the metastable phase anatase differs in electronic properties from the well-known, stable phase rutile. (From the broadening of the X-ray diffraction peaks, the average grain size of the films is estimated to be in the range of 30–40 nm [308].) Resistivity and Hall-effect measurements revealed an insulator-metal transition in a donor band in anatase thin films with high donor concentrations. Such a transition is not observed in rutile thin films with similar donor concentrations. This indicates a larger effective Bohr radius of donor electrons in anatase than in rutile, which in turn suggests a smaller electron effective mass in anatase. The smaller effective mass in anatase is consistent with the high-mobility, bandlike conduction observed in anatase crystals. It is also responsible for the very shallow donor energies in anatase. Luminescence of self-trapped excitons was

observed in anatase thin films, which implies a strong lattice relaxation and a small exciton bandwidth in anatase. Optical absorption and photoconductivity spectra show that anatase thin films have a wider optical absorption gap than rutile thin films. The extrapolated optical absorption gaps of anatase and rutile films were found to be 3.2 and 3.0 eV, respectively, at room temperature.

The observation of space charge limited currents (SCLC) in nanoscaled pure and chromium-doped titania was reported [310] and both the free-charge carrier density and the trapped-charge carrier density were given.

Photoconductivity was also studied in compound systems; for example, in a TiO<sub>2</sub>-C<sub>60</sub> bilayer system the conductivity increases significantly in the fullerene upon irradiation at wavelengths <300 nm [311].

Although being an efficient photocatalyst for the detoxification of organically charged waste water, titanium dioxide suffers from the drawback of poor absorption properties because of a bandgap of 3.2 eV. Thus, wavelengths shorter than 400 nm are needed for light-induced generation of electron-hole pairs. That is the reason why doping with transition metal ions is interesting for inducing a reduction of the bandgap. However, this doping changes other physical properties such as lifetime of electron-hole pairs and adsorption characteristics [312].

## 6. PHOTOCATALYTIC PROPERTIES OF NANOCRYSTALLINE TiO<sub>2</sub>

Most experimental investigations reported a higher photocatalytic efficiency in the anatase TiO<sub>2</sub> phase; as a possible reason it was suggested that the recombination of the electron-hole pairs produced by UV irradiation occurs more rapidly on the surface of the rutile phase, and the amount of reactants and hydroxides attached to this surface is smaller than on the surface of the anatase phase.

The study of the photocatalytic activity of nanocrystalline TiO<sub>2</sub> materials is a longstanding research effort [313–315]; in most lab-scale experiments it was evaluated by means of the degradation observed for typical substances (e.g., aqueous methyl orange, methylene blue, etc.) upon exposure of the specimen to UV irradiation. In such a way, the possible influence of light intensity, structural properties, surface morphology, phase and chemical composition, resulting from various deposition or preparation methods, could conveniently be explored [316–320]. Furthermore, any correlation with the optical or electrical properties of the nanocrystalline films could thereby be investigated. In addition, alternative approaches have come under scrutiny. A new simple method for characterizing photocatalytic activity by measuring photo-generated transient charge separation at the surface of semiconductor photocatalysts was proposed [321]. In this technique, the charge separation generated by a pulse dye laser is obtained as a function of the incident laser energy; thereby, the photocatalytic activity and the type of surface reaction (reduction or oxidation) in titanium dioxide films were rapidly determined. In the following sections some examples of such studies will be given.

### 6.1. Dependence of Photocatalytic Activity on Film Structure and Phase

The photoactivities of ultrafine TiO<sub>2</sub> nanoparticles in anatase, rutile, or mixed phases were tested in the photocatalytic degradation of phenol [322]. For TiO<sub>2</sub> nanoparticles, mainly in the anatase phase and mixed-phases, the photocatalytic activities increased significantly with the content of the amorphous part decreasing. The completely crystallized rutile nanoparticles exhibited size effects in this photocatalytic reaction and the photocatalytic activity of rutile-type TiO<sub>2</sub> nanoparticles with a size of 7.2 nm was much higher than that with 18.5 nm or 40.8 nm and was comparable to that of anatase nanoparticles.

A modified sol-gel process was used [323] to prepare nano-structured TiO<sub>2</sub> catalysts of controlled particle size (i.e., 6, 11, 16, and 20 nm). The effect of TiO<sub>2</sub> particle size on gas-phase photocatalytic oxidation of toluene was examined under dry and humid conditions. Main reaction products were CO<sub>2</sub> and water, although small amounts of benzaldehyde were also detected. The smaller particle size (i.e., 6 nm) led to higher conversion and complete mineralization of toluene into CO<sub>2</sub> and H<sub>2</sub>O. Electronic and structural effects (i.e., size and ensemble effects) were responsible for the excellent performance of a 6 nm TiO<sub>2</sub> catalyst for toluene photodegradation. The dependency of the photoactivity on the crystallite size of anatase titania for the decomposition of trichloroethylene (TCE) was investigated [324]. It was found that the photoactivity of all titania samples was linearly increased as the crystallite size of the anatase phase increased, regardless of the preparation method, as long as there was no significant rutile phase.

The enhancement of the photocatalytic activity of TiO<sub>2</sub> was investigated as a function of added amount of other oxides to promote desired oxidation or reduction reactions [325]. Mixed oxides of Nb<sub>2</sub>O<sub>5</sub> or Li<sub>2</sub>O with TiO<sub>2</sub> were prepared by the sol-gel process. The target material of dichloroacetic acid (DCA) was chosen for oxidation reactions and K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> for reduction. While the Nb-oxide had a deleterious effect on the decomposition rate of DCA, the excess electrons due to the doping of Nb<sub>2</sub>O<sub>5</sub> into TiO<sub>2</sub> promoted the reduction process for Cr<sup>6+</sup>. Li<sub>2</sub>O (1 wt%) with TiO<sub>2</sub> was found to be the most efficient photocatalyst for DCA oxidation, resulting in photocatalytic activity of 50%.

A highly sensitive biochemical oxygen demand (BOD) sensor using a commercial TiO<sub>2</sub> semiconductor and photocatalytic pretreatment was developed to evaluate low BOD levels in river waters [326]. The photocatalytic oxidation was investigated as a function of irradiation times, TiO<sub>2</sub> concentrations, and pH. The optimal irradiation time was 4 min. The sensor response was increased with increasing pH and the responses obtained by photocatalysis to river samples were higher than those obtained without photocatalysis.

### 6.2. Influence of Surface Morphology and Defects

Photocatalytic reduction of CO<sub>2</sub> to organic compounds was carried out [327] in a semiconductor suspension system under simulated solar power using a TiO<sub>2</sub> catalyst. Experimental results show that the photocatalytic activity can be

improved by depositing Pd or Ru on the TiO<sub>2</sub> surface. Films of TiO<sub>2</sub> dispersed or coated with platinum were deposited on glass and Pt-buffered polyamide substrates, respectively, by magnetron sputtering [328]. The photocatalytic activity of the films was evaluated through the decomposition of acetic acid under UV irradiation. The Pt-dispersed TiO<sub>2</sub> film with approximately 1.5 wt% platinum shows a maximum activity due to the formation of anatase phase with a fine grain size. Platinum particles ~2 nm in thickness coated on anatase film greatly improves activity. The activity shows a step-like dependence of film thickness, where the critical thickness varies between 150 and 200 nm depending on the deposition temperatures. The correlation between defects and activity was verified by measuring either the temperature dependence of electric resistance or the shift of binding energy from X-ray photoelectron spectroscopy (XPS).

In crystalline TiO<sub>2</sub> films deposited by reactive RF magnetron sputtering on glass substrates without additional external heating, the photocatalytic activity was evaluated by the measurement of the decomposition of methylene blue under UV irradiation [162]. The results showed that crystalline anatase, anatase/rutile, or rutile films can be successfully deposited on unheated substrates. Anatase TiO<sub>2</sub> films with a more open surface, a higher surface roughness, and a larger surface area, formed at higher total pressures, exhibit the best photocatalytic activity. The photocatalytic activity of polycrystalline anatase TiO<sub>2</sub> films was found [329] to be affected by the crystalline orientation that depends on the deposition temperature; it was greater on the (112)-oriented than on the (001)-oriented film. The former film exhibited a columnar structure resulting in a larger surface area for photocatalytic reaction than the films with the (001)-preferred orientation. Furthermore, the introduction of structural defects associated with oxygen vacancies was found [169] to create some energy levels around the mid-gap, indicating that they could work as recombination centers of photo-induced holes and electrons, causing the decrease in photocatalytic activity. Therefore, the decrease in the structural defects associated with oxygen vacancies appears to be important for improving the photocatalytic activity of the films.

A marked difference of the photocatalytic activity between the TiO<sub>2</sub> films coated on quartz and glass substrates was confirmed [330], which would be interpreted in terms of the difference in the photocarrier's diffusion length induced by impurity Na<sup>+</sup> ions. These results lead to a conclusion that the crystallinity and defects of TiO<sub>2</sub> as well as the film thickness and surface area have a great influence on the photocatalytic activity. An enhanced photocatalytic activity of TiO<sub>2</sub> could be achieved also by deposition of the films on sulfonated glass substrates [331] or by using special support materials [332, 333].

Photo-oxidative self-cleaning and antifogging effects of transparent titanium dioxide films has attracted considerable attention for the past decade [334, 335]. In order to understand the photo-induced hydrophilic conversion on titanium dioxide coatings in details, it is inevitably necessary to understand the relationship between the photo reaction and the surface crystal structure; this can be done, for example, by an evaluation of the photo-induced hydrophilic conversion on the different crystal faces of rutile single crystals and also

polycrystalline anatase titanium dioxide [336]. Self-cleaning and antifogging effects of TiO<sub>2</sub> films prepared by magnetron sputtering were investigated [161, 163] in terms of the photocatalytic behavior by measuring the decomposition of methylene blue and the reduction of the contact angle between water and TiO<sub>2</sub> under ultraviolet irradiation. The phase conversion from the rutile to the anatase TiO<sub>2</sub> film leads to an enhancement of the activity; the anatase films with the best photocatalytic behavior are prepared at higher total pressures (>1.50 Pa) and characterized by a high decomposition efficiency, a contact angle about 10° after irradiation, and a good stability in darkness.

Titanium dioxide thin films prepared with various surface morphologies by metalorganic chemical vapor deposition were found to exhibit reversible wettability control by light irradiation [337]. These TiO<sub>2</sub> surfaces became highly hydrophilic by UV irradiation, and returned to the initial relatively hydrophobic state by visible-light (VIS) irradiation. The hydrophobic-hydrophilic conversion induced by UV light was ascribed to the increase in dissociated water adsorption on the film surface. By contrast, the conversion from hydrophilic to hydrophobic by VIS irradiation was caused by the elimination of water adsorbed on the surface due to the heat generated. Changes of the water contact angle between hydrophilic states and hydrophobic ones strongly depended on the roughness of the film surface.

The self-cleaning property of thin transparent TiO<sub>2</sub> coatings on glass under solar UV light was studied [338] for two compounds: palmitic (hexadecanoic) acid and fluoranthene, which are both present in the atmospheric solid particles. The removal rates of layers of these compounds sprayed on the self-cleaning glass were found to be sufficient for the expected application. The identified intermediates (about 40 for each compound) show the gradual splitting of the palmitic acid chain and the oxidative openings of the aromatic rings of fluoranthene. In the case of palmitic acid, the products give some indications about the photocatalytic mechanism. About 20% of the organic carbon contained in the initial compounds was transformed into volatile carbonyl products.

An extreme photo-induced hydrophilicity was achieved [339, 340] when TiO<sub>2</sub> films were covered by SiO<sub>2</sub> overlayers (with 10–20 nm in thickness). These multilayer films exhibited much more extreme hydrophilicity than a TiO<sub>2</sub> film without overlayer. The surface analyses revealed that the enhanced photo-induced hydrophilic surface of the multilayer films exhibited an improved photocatalytic activity towards decomposition of organic substances on their surfaces. An extreme light-induced superhydrophilicity was also reported [341] for mesoporous TiO<sub>2</sub> thin films (crystallite size ~15 nm, surface area ~50 m<sup>2</sup>/g, pore size ~3.6 nm). For such films, the water contact angle was found to be reduced essentially to zero upon UV-irradiation for a duration of about 60 min. In addition, the photocatalytic activity of those films could be enhanced by treating the substrate surfaces with an H<sub>2</sub>SO<sub>4</sub> solution [342].

In order to investigate the cathodic photoprotection of the steel from corrosion, stainless steel was coated with TiO<sub>2</sub> thin films, applied by a spray pyrolysis [343]. It was concluded that these coatings exhibit both a cathodic

photo-protection effect against corrosion and the frequently reported photocatalytic self-cleaning effect.

### 6.3. Influence of Electronic Properties

Detailed spectroscopic investigations of the processes occurring upon bandgap irradiation in colloidal aqueous TiO<sub>2</sub> suspensions in the absence of any hole scavengers showed [344] that while electrons are trapped instantaneously, that is, within the duration of the laser flash (20 ns), at least two different types of traps have to be considered for the remaining holes. Deeply trapped holes are rather long-lived and unreactive, that is, they are not transferred to the ions of model compounds for photocatalytic oxidation like dichloroacetate or thiocyanate. Shallowly trapped holes, on the other hand, are in a thermally activated equilibrium with free holes which exhibit a very high oxidation potential. The overall yield of trapped holes can be considerably increased when small platinum islands are present on the TiO<sub>2</sub> surface, which act as efficient electron scavengers competing with the undesired e<sup>-</sup>/h<sup>+</sup> recombination. While molecular oxygen, O<sub>2</sub>, reacts in a relatively slow process with trapped electrons, the adsorption of the model compounds on the TiO<sub>2</sub> surface prior to the bandgap excitation appears to be a prerequisite for an efficient hole scavenging.

### 6.4. Enhanced Photocatalytic Activity Via Surface Modifications

A driving force for research in heterogeneous photocatalysis using TiO<sub>2</sub> (and semiconductors in general) is the creation and application of systems capable of using natural sunlight to degrade a variety of organic and inorganic contaminants in wastewater or polluted air. As mentioned, the photocatalytic activity depends strongly, among other factors, on the wavelength range response. Since the bandgap of TiO<sub>2</sub> is ~3.2 eV, it is active only in the ultraviolet region which amounts to <10% of the overall solar intensity. Principally, there are several remedies to circumvent (at least partially) this limitation: (i) Deposition of metals on the semiconductor; (ii) using multicomponent semiconductors; (iii) surface modification with sensitizing dyes. The merits of these options will be outlined briefly in the following.

#### 6.4.1. Deposition of Metals on the Surface

The selectivity and efficiency of a photochemical reaction can be improved by modifying the surface with a noble metal. The deposition of metal particles on oxide surfaces has been the subject of several recent reviews [345–348] and therefore, there is, no need to duplicate it here. In terms of photocatalytic activity, a drastic enhancement has, for the first time, been observed for the photocatalytic conversion of water into hydrogen and oxygen upon a fractional coverage of the TiO<sub>2</sub> surface with platinum [349]. After excitation the electron migrates to the metal where it becomes trapped and electron-hole recombination is suppressed. The hole is then free to diffuse to the semiconductor surface where oxidation of organic species can occur. These processes are schematically depicted in Figure 9. The presence of the metal can be beneficial also because of its own catalytic

Figure 9. Metal-modified semiconductor photocatalyst particle.

activity. The Pt/TiO<sub>2</sub> system is probably the most frequently studied metal-semiconductor pair (see, e.g., [350, 351]); Figure 10 exemplifies the enhancement of the photocatalytic activity of nanocrystalline TiO<sub>2</sub> by platinumization [350]: three commercially available TiO<sub>2</sub>-catalysts, namely, Degussa P25, Sachtleben Hombikat UV100, and Millennium TiONA PC50, were platinumized by a photochemical impregnation method with two ratios of platinum deposits (0.5 and 1 wt%). The photocatalytic activities of these samples were determined using three different model compounds, EDTA, 4-chlorophenol (4-CP), and dichloroacetic acid (DCA). Platinumization resulted in all cases in an enhancement of the activity; Figure 10 shows the degradation of DCA as a function of illumination time (light intensity 23 W/m<sup>2</sup> at a wavelength of 320–400 nm) for pure TiO<sub>2</sub> and the two platinumized specimens. After 2 h of illumination, the initial concentration of 120 ppm total organic carbon (TOC) was reduced to 2.3 ppm at pH 3 employing the best photocatalyst, in this case, Hombikat UV100 with 0.5 wt% Pt. For this system, an initial photonic efficiency (i.e., number of degraded molecules per number of incident photons) of ~43% was obtained [350]. Apart from platinum, an enhanced photocatalytic activity has been also noted for other metals and semiconductors. Their influence on the photocatalytic activities has been studied in detail, for example, utilizing

Figure 10. Degradation of dichloroacetic acid (expressed as the relative change of TOC) with platinumized TiO<sub>2</sub> in comparison to pure TiO<sub>2</sub> as a function of illumination at pH 3. Data from [350], D. Hufschmidt et al., *J. Photochem. Photobiol. A: Chem.* 148, 223 (2002).

the following systems: Au-modified TiO<sub>2</sub> [352, 353], silver-modified titanium particles [354], transition-metal doped TiO<sub>2</sub> photocatalysts [355–357], or rare-earth-doped TiO<sub>2</sub> nanoparticles [358].

It should be noted in this context that various analytical techniques like transmission electron microscopy or scanning force microscopy are often very useful in determining the size of the particles and their distribution in the bulk and at the surface of these nanocrystalline materials.

#### 6.4.2. Composite Semiconductors

The advantage of composite semiconductors is usually twofold: first, to extend the photo-response by coupling a large bandgap semiconductor with another featuring a smaller one and, second, to retard the recombination of photo-generated charge carriers by injecting electrons into the lower lying conduction band of the large bandgap material. Two types of geometries have been employed: capping the nanocrystallites of one semiconductor with those of the second or bringing the nanocrystalline particles of the two materials into intimate contact. The principle of charge exchange and separation for both arrangements is illustrated in Figure 11. Let us consider the case of coupling CdS with TiO<sub>2</sub>; the energy of the excitation light is too small to directly excite the TiO<sub>2</sub> particle, but it is large enough to excite an electron from the valence band across the bandgap of CdS ( $E_g = 2.5$  eV) to the conduction band. According to the energetics, the hole produced in the CdS valence band remains in the CdS particle, whereas the electron transfers to the conduction band of the TiO<sub>2</sub> particle; this increases the charge separation and efficiency of the photocatalytic process. The separated electrons and holes are then free to undergo electron transfer with adsorbates at the surface. While the mechanisms of charge separation in a capped system are similar, in a capped semiconductor only one of the charge carriers is accessible at the surface for catalytic reactions. Several semiconductors have been studied

**Figure 11.** Photo-induced charge separation in composite semiconductor particles: (a) capped and (b) coupled semiconductor nanocrystallites. Photo-generated charge carriers move in opposite directions.

thoroughly in combination with TiO<sub>2</sub>: TiO<sub>2</sub>—CdS [359–361], TiO<sub>2</sub>—CdSe [362], TiO<sub>2</sub> coupled SnO<sub>2</sub> [363], TiO<sub>2</sub> capped SiO<sub>2</sub> [364], and some mixed-oxide systems like Fe<sub>2</sub>O<sub>3</sub>—TiO<sub>2</sub> [365] or ZrO<sub>2</sub>—TiO<sub>2</sub> [366].

#### 6.4.3. Surface Modification with Sensitizing Dyes

Surface sensitization of a wide bandgap semiconductor photocatalyst like TiO<sub>2</sub> via adsorbed dyes can increase the efficiency of the excitation step and, as a consequence, the activity. This process can also expand the wavelength range of excitation. Some common dyes that are used as sensitizers include erythrosin B, eosin, rhodamines, cresyl violet, thionine, porphyrins, [Ru(bpy)<sub>3</sub>]<sup>2+</sup> and its analogues, and many others (see, e.g., [102] for a more comprehensive list). The individual charge-transfer and excitation steps involved in the dye sensitizer surface process are exemplified in Figure 12. The primary excitation of an electron in the dye molecule occurs in either the singlet or triplet excited state of the molecule; if the oxidative energy level of the excited state of the dye molecule, with respect to the conduction band energy level of the semiconductor, is more negative, then the dye molecule can transfer the electron to the conduction band of the semiconductor. The surface accepts electrons from the dye molecules which, in turn, can be transferred to reduce an organic acceptor molecule adsorbed on the surface. The dye-sensitized semiconductor can also be used in oxidative degradation of the dye molecule itself after charge transfer; this appears to be an important process in view of the large quantities of dye substances in wastewater from the textile industries and others. In passing, it can be noted that the process of utilizing sub-bandgap excitation with dyes that absorb strongly in the visible for photosensitization is frequently employed in color photography and other imaging science applications. This approach of light-energy conversion is also similar to plant photosynthesis, in which chlorophyll molecules act as light harvesting antenna molecules.

Generally, the high porosity and strong bonding character of nanostructured TiO<sub>2</sub> (and other) semiconductor films facilitate the surface modification with organic dyes or organometallic complexes. For example, photoconversion efficiencies in the range 10–15% in diffused daylight have been reported [367] for nanostructured TiO<sub>2</sub> films modified with a ruthenium complex. The charge injection from a singlet excited sensitizer into the conduction band of a large bandgap semiconductor is thought to be an ultrafast process

**Figure 12.** Sequence of excitation and charge-transfer steps using a dye-molecule sensitizer. In the first step, the sensitizer (S) is excited by an incident photon of energy  $h\nu$  and an electron is transferred into the conduction band of the semiconductor particle; the electron then can be transferred to reduce an organic acceptor molecule (A) adsorbed on the surface.

occurring at a picosecond time scale; in the case of different organic dyes, it has been shown [368, 369] that charge injection takes place within 20 ps. A similar fast electron transfer has also been noted for [Ru(H<sub>2</sub>O)<sub>2</sub>]<sup>2+</sup> on a TiO<sub>2</sub> surface at very low coverage [370]. Progress in femtosecond laser spectroscopy opened a venue for investigations on even much shorter time scales. In fact, in recent studies charge carrier injection times in the range of 20–200 fs were reported [371–375] for various dyes on nanocrystalline TiO<sub>2</sub> particles.

Significant enhancement effects of electron acceptors (additives) such as hydrogen peroxide, ammonium persulfate, potassium bromate, and potassium peroxymonosulfate (oxone) on the TiO<sub>2</sub> photocatalytic degradation of various organic pollutants were observed already in early investigations [376]. The results showed that these additives markedly improved the degradation rate of 2,4-dichlorophenol. The enhanced photocatalytic oxidation of sulfide ions on phthalocyanine modified titania was ascribed [377] to the additional formation of superoxide radicals.

Sensitization of wide bandgap semiconductor electrodes by dyes absorbing visible light are routinely used also in dye-sensitized photoelectrochemical cells, in order to achieve high photon-to-current conversion efficiencies [378, 379]. The preparation and dynamics of interfacial photosensitized charge separation in metal oxides such as TiO<sub>2</sub> films has been reviewed [70, 71, 380]. Principally, the photo-physical reactions occurring in those dye-sensitized injection solar cells, which are based on a dye adsorbed onto a porous TiO<sub>2</sub> layer, are very similar to those relevant to photocatalysis. Because of their importance as an energy source, Figure 13 presents a schematic drawing [69] of such

a dye-sensitized nanocrystalline TiO<sub>2</sub> solar cell, depicting the relevant energy levels and the pathway for the photo-excited electrons. In this specific example, a ruthenium complex [367] was adsorbed as a dye onto the TiO<sub>2</sub> and an I<sup>-</sup>/I<sub>3</sub><sup>-</sup> redox couple was used in the electrolyte. Contrary to conventional semiconductor devices, in the dye-sensitized cells the function of light absorption is separated from the charge-carrier transport. The Ru-complex has to absorb the incident sunlight and to effect, via this energy, the electron-transfer reaction (numbers ① and ② in Fig. 13). Apart from supporting the dye, the TiO<sub>2</sub> film acts as an electron acceptor and electronic conductor: the electrons injected into the TiO<sub>2</sub> conduction band drift across the nanocrystalline film to the conducting glass support which functions as current collector (③ in Fig. 13). At the counterelectrode, the electron is transferred to the redox couple in the electrolyte (④) which, in turn, serves to regenerate the dye (⑤). The cell voltage observed under illumination, Δ*V*, is determined by the difference between the Fermi-level of TiO<sub>2</sub> and the electrochemical potential of the electrolyte (cf. Fig. 13 [69]).

## 7. PHOTOCATALYTIC APPLICATIONS OF NANOCRYSTALLINE TiO<sub>2</sub>

While many examples of the photocatalytic activity of nanocrystalline TiO<sub>2</sub> have been presented already in the foregoing sections, the following discussions will focus on novel and important (and sometimes large-scale) applications. A very prominent area appears to be environmental catalysis [31, 32, 45] which, in recent years, has expanded considerably beyond the traditional fields like NO<sub>x</sub> removal from stationary and mobile sources, or the conversion of volatile organic compounds (VOC). According to [381], these potential new areas include:

- (i) catalytic technologies for liquid or solid waste reduction or purification;
- (ii) use of catalysts in energy-efficient catalytic technologies and processes;
- (iii) reduction of the environmental impact in the use or disposal of catalysts;
- (iv) new ecocompatible refinery, chemical or nonchemical catalytic processes;
- (v) catalysis for greenhouse gas control;
- (vi) use of catalysts for user-friendly technologies and reduction of indoor pollution;
- (vii) catalytic processes for sustainable chemistry;
- (viii) reduction of the environmental impact of transport.

Hence, (photo)catalysis in environmental applications can be instrumental in promoting the quality of life and environment, in promoting a more efficient use of resources, and in promoting sustainable processes and products.

Because of the tremendous importance of those environmentally related areas, the use of nanocrystalline TiO<sub>2</sub> for such photocatalytic applications is illustrated in this section by means of selected examples. Before doing so, it is stressed that there exists at least one other rather important issue in this context. In fact, hydrogen production from aqueous solutions using semiconductor particles such as, CdS, TiO<sub>2</sub>, WO<sub>3</sub> as photocatalysts is envisaged to become a potential

**Figure 13.** Schematic outline of a dye-sensitized photovoltaic cell, showing the electron energy levels in the different phases. The system consists of a semiconducting nanocrystalline TiO<sub>2</sub> film onto which a Ru-complex is adsorbed as a dye and a conductive counterelectrode, while the electrolyte contains an I<sup>-</sup>/I<sub>3</sub><sup>-</sup> redox couple. The cell voltage observed under illumination corresponds to the difference, Δ*V*, between the quasi-Fermi level of TiO<sub>2</sub> and the electrochemical potential of the electrolyte. S, S\*, and S<sup>+</sup> designate, respectively, the sensitizer, the electronically excited sensitizer, and the oxidized sensitizer. See text for details. Adapted from [69], A. Hagfeldt and M. Grätzel, *Chem Rev.* 95, 49 (1995). © 1995, American Chemical Society.

major application of these materials, and new concepts and approaches are developed continuously. For example, a new photocatalytic reaction that splits water into H<sub>2</sub> and O<sub>2</sub> was designed [382] by a two-step photo-excitation system composed of a IO<sub>3</sub><sup>-</sup>/I<sup>-</sup> shuttle redox mediator and two different TiO<sub>2</sub> photocatalysts, Pt-loaded TiO<sub>2</sub>-anatase for H<sub>2</sub> evolution and TiO<sub>2</sub>-rutile for O<sub>2</sub> evolution. Simultaneous gas evolution of H<sub>2</sub> (180 μmol/h) and O<sub>2</sub> (90 μmol/h) was observed from a basic (pH = 11) NaI aqueous suspension of two different TiO<sub>2</sub> photocatalysts under UV irradiation (λ > 300 nm, 400 W high-pressure Hg lamp). An extensive review [383] assesses photocatalytic efficiencies with reference to hydrogen production by means of light energy in the presence and absence of loaded metals, electron-donors/acceptors, and hole scavengers.

### 7.1. Reduction/Removal of Toxic Gases

The conversion of nitrogen oxides to less toxic compounds is important both because of their toxicity and the global atmospheric pollution. NO<sub>x</sub> can be converted to N<sub>2</sub> and other nitrogen compounds by reduction. TiO<sub>2</sub>-loaded zeolites and the vanadium silicate-1 were found [384] to decompose NO under irradiation, in particular, TiO<sub>2</sub> included in zeolite cavities results in complete decomposition into N<sub>2</sub> and O<sub>2</sub>. Titanium oxide catalysts prepared within the Y-zeolite cavities via an ion-exchange method exhibit [385] high and unique photocatalytic reactivities for the decomposition of NO into N<sub>2</sub> and O<sub>2</sub>, as well as the reduction of CO<sub>2</sub> with H<sub>2</sub>O showing a high selectivity for the formation of CH<sub>3</sub>OH. It was also found that the charge transfer excited state of the titanium oxide species, (T<sup>3+</sup>-O<sup>-</sup>)<sup>\*</sup>, plays a vital role in these unique photocatalytic reactions. In yet another approach, an efficient catalytic reduction of NO at low temperature by means of NH<sub>3</sub> could be achieved using Mn-, Cr-, or Cu-oxides on a nanocrystalline TiO<sub>2</sub> support [386].

The NO<sub>x</sub> removal process was studied experimentally in a pulsed corona discharge combined with the TiO<sub>2</sub> photocatalytic reaction [387]. NO<sub>2</sub> was found to adsorb easily on the photocatalyst surface, whereas NO was hardly adsorbed. Addition of water vapor enhanced the NO<sub>2</sub> adsorption. It was concluded that the main role of the plasma-chemical reaction in this system is the oxidation of NO into NO<sub>2</sub>. A considerable part of NO<sub>2</sub> is adsorbed on the photocatalyst surface, and is transformed to HNO<sub>3</sub> through photocatalytic reaction with OH.

The photocatalytic degradation of VOCs in the gas phase constitutes another very important example in this range of applications. Utilizing variously prepared TiO<sub>2</sub> photocatalysts (e.g., deposited on glass fiber cloth, as pellets or as thin films), the photo-induced reactions of trichloroethylene, acetone, methanol, and toluene were investigated [388–390]. The photocatalytic degradation rate was observed [388] to increase with increasing initial concentration of the VOCs, but remained almost constant beyond a certain concentration. It matched well with the Langmuir–Hinshelwood (L-H) kinetic model [11]. For the influence of water vapor in a gas-phase photocatalytic degradation rate, there was an optimum concentration of water vapor in the degradation of trichloroethylene and methanol. Furthermore, water vapor enhanced the photocatalytic degradation rate of toluene,

whereas it inhibited that of acetone. As for the effect of photon flux, it was found that photocatalytic degradation occurs in two regimes with respect to photon flux: for illumination levels distinctly below 1000–2000 μW/cm<sup>2</sup>, the photocatalytic degradation rate increased linearly with photon flux, whereas for power densities above that value, the rate was found to scale with the square root of the flux. Figure 14 shows some of those data [388], depicting in panel (a), the degradation of methanol as a function of UV illumination time for five different initial concentrations. (Using TiO<sub>2</sub> anatase nanocrystallites with 7 nm diameter in a solution, in this work photocatalytic TiO<sub>2</sub> films were deposited onto glass substrates by dip-coating.) The reaction kinetics were found to follow the L-H model, in which the reaction rate  $r$  varies proportionally with the surface coverage  $\theta$  according to

$$r = k\theta = \frac{kKc}{1 + Kc} \quad (9)$$

where  $c$  is the concentration of the VOC and  $k$  and  $K$  are, respectively, the reaction rate constant and the adsorption equilibrium constant. Figure 14(b) exemplifies this finding, showing the initial reaction rates  $r_0$  derived from data like those in Figure 14(a) as a function of the respective initial methanol concentrations  $c_0$ . The solid line in Figure 14(b) is a fit to the data according to Eq. (9).

**Figure 14.** (a) Photocatalytic degradation of methanol with different initial concentrations as a function of UV illumination time (light intensity 2095 μW/cm<sup>2</sup> at a wavelength of 254 nm) at a H<sub>2</sub>O concentration of 0.38 mol/m<sup>3</sup> and a reaction temperature of 45 °C. (b) Initial reaction rates  $r_0$  as derived from the data in (a) versus the initial methanol concentrations; the solid line is a fit according Eq. (9). Data from [388], S. B. Kim and S. C. Hong, *Appl. Catal. B: Environ.* 35, 305 (2002).

## 7.2. Degradation of Organic Compounds

The degradation of organic compounds is probably the most widely used photocatalytic application of nanocrystalline TiO<sub>2</sub> and other semiconductor materials. In an aqueous environment, the holes created under UV irradiation are scavenged by surface hydroxyl groups to generate •OH radicals that then promote the oxidation of organics. This radical-mediated oxidation has been successfully employed in the mineralization of several hazardous chemical contaminants such as hydrocarbons, haloaromatics, phenols, halogenated biphenyls, surfactants, and textile and other dyes [102].

The possible photocatalytic decomposition of a broad range of organic compounds has been investigated using nanocrystalline TiO<sub>2</sub> particles. Detailed studies reported the oxidation of dissolved cyanide [391], the degradation of various kinds of acids [392–398], and of several herbicides [399–402], for the photocatalytic oxidation of toluene, benzene, cyclohexene, and benzhydrol [403–406] or for the 1,1'-dimethyl-4,4'-bipyridium dichloride decomposition [407]. In another application, a titanium oxide photocatalyst of ultra-high activity has been employed for the selective N-cyclization of an amino acid in aqueous suspensions [408]. Anatase crystallites of average diameter of ~15 nm were platinized by impregnation from aqueous chloroplatinic acid solution followed by hydrogen reduction. The catalyst was suspended in an aqueous L-lysine (Lys) solution and photoirradiated under argon at ambient temperature to obtain L-pipecolic acid.

The photocatalytic degradation and oxidation of phenol and phenol-based compounds has been examined quite frequently [409–414]. The decomposition of aqueous phenol solutions to carbon dioxide have been studied using natural sunlight in geometries simulating shallow ponds [415]. The photocatalyst was titanium dioxide freely suspended in the solution or immobilized on sand or silica gel. Photodegradation rates were approximately three times faster with the free suspension than with the immobilized catalyst under the same conditions, and were dependent on the time of year and the time of day. The seasonal variation correlated roughly with seasonal solar irradiance tabulations for the UV component of the spectrum. For 10 ppm of phenol, the maximum rate of solar degradation resulted in a decrease in concentration to 10 ppb in less than 80 min with total mineralization in 110 min.

An efficient degradation of aqueous phenol was achieved [416] by a new rotating-drum reactor coated with a TiO<sub>2</sub> photocatalyst, in which TiO<sub>2</sub> powders loaded with Pt are immobilized on the outer surface of a glass drum. The reactor can receive solar light and oxygen from the atmosphere effectively. It was shown experimentally that phenol can be decomposed rapidly by this reactor under solar light: with the used experimental conditions, phenol with an initial concentration of 22.0 mg/dm<sup>3</sup> was decomposed within 60 min and was completely mineralized through intermediate products within 100 min.

The photocatalytic degradation of various types of dyes appears to be another prominent and extensively explored application of nanocrystalline TiO<sub>2</sub> in environmental catalysis [417–423].

In a recent study [424], the photocatalytic degradation of five dyes in TiO<sub>2</sub> aqueous suspensions under UV irradiation has been investigated; it was attempted to determine the individual steps of such a degradation process by varying the aromatic structures, using either anthraquinonic (Alizarin S (AS)), or azoic (Crocein Orange G (OG), Methyl Red (MR), Congo Red (CR)) or heteropolyaromatic (Methylene Blue (MB)) dyes. Figure 15 exemplifies the photocatalytic degradation of three of these dyes (CR, OG, and MR) as a function of UV irradiation. The initial reaction rates were found to fall in the range from 1.9 μmol/l min (for CR) to 3.6 μmol/l min (for MR). In addition to a prompt removal of the colors, TiO<sub>2</sub>/UV-based photocatalysis was simultaneously able to fully oxidize the dyes, with a complete mineralization of carbon into CO<sub>2</sub>. Sulfur heteroatoms were converted into innocuous SO<sub>4</sub><sup>2-</sup> ions. The mineralization of nitrogen was more complex. Nitrogen atoms in the 3-oxidation state, such as in amino groups, remain at this reduction degree and produced NH<sub>4</sub><sup>+</sup> cations, subsequently and very slowly converted into NO<sub>3</sub><sup>-</sup> ions. For azo-dye (OG, MR, CR) degradation, the complete mass balance in nitrogen indicated that the central —N=N— azo group was converted into gaseous dinitrogen, which is the ideal issue for the elimination of nitrogen-containing pollutants. The aromatic rings were submitted to successive attacks by photogenerated •OH radicals leading to hydroxylated metabolites before the ring opening and the final evolution of CO<sub>2</sub> induced by repeated reactions with carboxylic intermediates.

The photocatalytic degradation of acid derived azo dyes in aqueous TiO<sub>2</sub> suspensions follows apparently first-order kinetics [425, 426]. The site near the azo bond (C—N=N-bond) is the attacked area in the photocatalytic degradation process, while the TiO<sub>2</sub> photocatalytic destruction of the C—N(=) bond and —N=N— bonds leads to fading of the dyes. The pH effect on the TiO<sub>2</sub> photocatalytic degradation of the acid-derived azo dyes varies with dye structure. Hydroxyl radicals play an essential role in the fission of the C—N=N— conjugated system in azo dyes in TiO<sub>2</sub> photocatalytic degradation. Metalized azo dyes were studied

**Figure 15.** Photocatalytic degradation of three different dyes, Congo Red (CR), Crocein Orange (OG), and Methyl Red (MR), given in terms of the concentration versus the time of illumination. Data from [424], H. Lachheb et al., *Appl. Catal. B: Environ.* 39, 75 (2002).

[427] under TiO<sub>2</sub> photocatalytic and photosensitized conditions in aqueous buffering solutions. The size and strength of intramolecular conjugation determines apparently the light-fastness of the dyes; the more powerful OH radicals in TiO<sub>2</sub> photocatalytic process are highly reactive towards the azo dyes.

### 7.3. Wastewater and Soil Remediation

The major causes [428] of surface water and groundwater contamination are industrial discharges, excess use of pesticides, fertilizers (agrochemicals), and landfilling domestic wastes. Typically, the wastewater treatment is based upon various mechanical, biological, physical, and chemical processes. After filtration and elimination of particles in suspension, the biological treatment is the ideal process (natural decontamination). Unfortunately, organic pollutants are not always biodegradable; a promising approach then relies on the formation of highly reactive chemical species, which degraded the more recalcitrant molecules into biodegradable compounds. These are called the advanced oxidation processes (AOPs). Although there exist differences in their detailed reaction schemes, their common feature is the production of OH radicals ( $\cdot\text{OH}$ ); these radicals are extraordinarily reactive species (oxidation potential 2.8 V). They are also characterized by a low selectivity of attack, which is a useful attribute for an oxidant used in wastewater treatment and for solving pollution problems. These photocatalytic degradation of wastewater employing nanocrystalline TiO<sub>2</sub> has been examined in various set-ups [429] and pilot-plant scale solar photocatalytic experiments have been realized [428].

Several recent studies reported on the removal or reduction of metals or metal-containing contaminants in wastewater, based on the principles outlined in the foregoing paragraph. Those investigations examined, for example, the removal of cadmium and mercury from water using modified TiO<sub>2</sub> nanoparticles [430, 431], the radical, mediated photo-reduction of manganese ions in UV-irradiated titania suspensions [432], the simultaneous photocatalytic Cr(VI) reduction and dye oxidation in a TiO<sub>2</sub> slurry reactor [433], or the removal of iron(III) cyanocomplexes [434].

While the efficient use of a photocatalytic process in the presence of TiO<sub>2</sub> to degrade many different types of pollutants in wastewater has been confirmed repeatedly, the question of how to efficiently separate and reuse TiO<sub>2</sub> from treated wastewater became a notable problem in the application of a TiO<sub>2</sub> photo-oxidation process. A recent study [435] aimed to develop an advanced process for dyeing wastewater treatment, in which dyeing wastewater was initially treated by an intermittently decanted extended aeration (IDEA) reactor to initially remove biodegradable matters and further treated in a TiO<sub>2</sub> photocatalytic reactor for complete decolorization and high chemical oxygen demand (COD) removal. Suspended TiO<sub>2</sub> powder used in the photo-oxidation was separated from slurry by a membrane filter and recycled to the photo reactor continuously.

Photocatalytic destruction of chlorinated solvents in water with solar energy was investigated [436] using a near-commercial scale, single-axis tracking parabolic trough system with a glass pipe reactor mounted at its focus. In

the photocatalytic degradation of industrial residual waters, the use of peroxydisulfate ( $\text{S}_2\text{O}_8^{2-}$ ) as an additional oxidant (electron scavenger) was observed to have an outstanding effect, producing an important increase in the degradation rate [437]. The impact of pH and the presence of inorganic ions and organic acids commonly found in natural waters on rates of TiO<sub>2</sub> photocatalyzed trinitrotoluene (TNT) transformation and mineralization was examined [438]. Raising the pH slightly increased the rate of TNT transformation, primarily as a result of an increased rate of TNT photolysis, but significantly reduced rates of mineralization due to increased electrostatic repulsion between the catalyst surface and anionic TNT intermediates. The presence of inorganic anions did not substantially hinder TNT transformation at alkaline pH, but mineralization rates were diminished when the anion either adsorbed strongly to the photocatalyst or was an effective hydroxyl radical scavenger.

Immobilized TiO<sub>2</sub> photocatalysts were used to sterilize and reclaim the wastewater of bean sprout cultivation from a continuous hydrocirculation system [439]. The photocatalysts effectively killed bacteria and degraded organic pollutants in the wastewater. Stimulation of bean sprout growth and suppression of decaying pathogens were also induced by the TiO<sub>2</sub> photocatalytic activity.

Photocatalytic decomposition of seawater-soluble crude oil fractions using high surface area colloid nanoparticles of TiO<sub>2</sub> under UV irradiation was explored [440]; although no mineralization occurred due to photolysis, important chemical changes were observed in the presence of TiO<sub>2</sub>, with the degradation reaching 90% (measured as dissolved organic carbon, (DOC)) in waters containing 9–45 mg C/l of seawater-soluble crude oil compounds after 7 days of artificial light exposure. During light exposure, transient intermediates that showed higher toxicity than the initial compounds were observed, but were subsequently destroyed. Heterogeneous photocatalysis using TiO<sub>2</sub> was considered to be a promising process to minimize the impact of crude oil compounds on contaminated waters.

TiO<sub>2</sub>-photocatalytic degradation of a cellulose effluent was evaluated [441] using multivariate experimental design. The effluent was characterized by general parameters such as adsorbable organic halogens (AOX), TOC, COD, color, total phenols, acute toxicity, and by the analysis of chlorinated low molecular weight compounds using GC/MS. The optimal concentration of TiO<sub>2</sub> was found to be around 1 g/l. After 30 min of reaction more than 60% of the toxicity was removed and after 420 min of reaction, none of the initial chlorinated low molecular weight compounds were detected, suggesting an extensive mineralization.

Photocatalysts, based on titanium dioxide, were used for the purification of contaminated soil polluted by oil [442]. Commercially produced slurry of titanium dioxide was modified with barium, potassium, and calcium. The experiments were performed under natural conditions in summer months (July and August) applying direct solar-light irradiation. The most active photocatalyst for soil purification was titanium dioxide modified with calcium.

Two different photocatalysts, namely, Hombikat UV100 (Sachtleben Chemie) and P25 (Degussa) have been used in batch experiments [443] to compare their ability to degrade the toxic components of a biologically pretreated landfill

leachate. A strong adsorption of the pollutant molecules was observed for both TiO<sub>2</sub>-powders, with a maximum of almost 70% TOC reduction for Hombikat UV100.

#### 7.4. Purification of Drinking Water

Pathogens in drinking water supplies can be removed by sand filtration followed by chlorine or ozone disinfection. These processes reduce the possibility of any pathogens entering the drinking water distribution network. However, there is doubt about the ability of these methods to remove chlorine-resistant microorganisms including protozoan oocysts. Titanium dioxide (TiO<sub>2</sub>) photocatalysis is a possible alternative/complementary drinking water treatment method and several studies [444, 445] reported a strong and swift photocatalytic inactivation of bacteria and bacteriophages in aqueous solutions. For example, the rate of disinfection was explored using TiO<sub>2</sub> electrodes prepared by the electrophoretic immobilization of TiO<sub>2</sub> powders with different crystallinity. These electrodes were tested for their photocatalytic bactericidal efficiency with *E. coli* K12 as a model test organism [446]. Similar studies were reported for natural water from a river [447].

Cyanobacterial toxins produced and released by cyanobacteria in freshwater around the world pose a considerable threat to human health if present in drinking water sources. Therefore, various treatments have been applied to remove these toxins. The effectiveness of TiO<sub>2</sub> photocatalysis for the removal of microcystin-LR from water has been established [448]. Not only does the process rapidly remove the toxin but also the by-products appear to be nontoxic. The photocatalytic process has also significantly reduced the protein phosphatase 1 (PP1) inhibition. Protein phosphatase 1 inhibition is potentially one of the most serious harmful effects to humans who may consume water contaminated by microcystins. Figure 16 shows some of these data, namely, the reduction of the microcystin-LR concentration and the PP1 inhibition as a function of the illumination time. The results indicate that about 86% of

**Figure 16.** Destruction and protein phosphatase (PP1) inhibition of microcystin-LR via TiO<sub>2</sub> photocatalysis as a function of the duration of UV illumination (xenon lamp with 480 W at a wavelength of 330–450 nm). Data from [448], I. Liu et al., *J. Photochem. Photobiol. A: Chem.* 148, 349 (2002).

microcystin-LR was destroyed within the first 5 min of photocatalysis, with 97% of the toxin removed in 20 min. The addition of 0.1% H<sub>2</sub>O<sub>2</sub> to the photocatalytic system was found [448] to further enhance the degradation rate: 99.6% of microcystin-LR was destroyed within 5 min and no toxin was left after 10 min of photocatalysis.

Photocatalytic inactivation of different bacteria and bacteriophages in drinking water at different TiO<sub>2</sub> concentrations with or without concurrent exposure to O<sub>2</sub> was studied in [449] using UV irradiation (5.5 mW/cm<sup>2</sup> at 365 nm). For example, for this light intensity, the most effective inactivation of *Escherichia coli* CN13 was obtained at 1 g/l suspension of TiO<sub>2</sub>, resulting in a reduction by five orders of magnitude in 5 min. Under the same experimental conditions, MS2 bacteriophage was reduced by four orders of magnitude, also in 5 min. The addition of O<sub>2</sub> into the experimental environment increased the inactivation of *Deinococcus radiophilus* by four orders of magnitude in 60 min.

#### 7.5. Miscellaneous Photocatalytic Applications

It may have become apparent from the foregoing discussions and examples that the solution of environmental problems constitutes one of the (if not the) major driving forces in research and development in photocatalysis using nanometer-sized TiO<sub>2</sub> (and other semiconductor) particles. Another one, of course, is the production of hydrogen from water splitting. Apart from these main applications, there exist, on the other hand, many attempts to explore novel areas for the photocatalytic use of nanocrystalline TiO<sub>2</sub> materials. To give a flavor of the diversity of these efforts, some selected (and mostly recent) examples follow.

Nano-sized titanium oxide (TiO<sub>2</sub>) thin films have been explored for alcohol-sensing applications. TiO<sub>2</sub> thin films with different doping concentrations were prepared on alumina substrates [450] using the sol-gel process using the spin-coating technique for ethanol and methanol alcohol. Experimental results indicated that the sensor is able to monitor alcohols selectively at ppm levels; the films are stoichiometric with carbon as the dominant impurity on the surface. The morphologies and crystalline structures of the films were studied by scanning electron microscopy (SEM) and XRD. X-ray diffraction patterns showed that the films are pure anatase phase up to an annealing temperature of 600 °C. As the annealing temperature increased to 800 °C, a small amount of rutile phase formed along with the anatase phase.

Optical waveguides were prepared by depositing a sol-gel-derived titania film onto a silica substrate [451]. The titania film is mesoporous, with pore sizes ranging from 3 to 8 nm. Deposition of the titania does not change the critical angle of total internal reflection. Thus, the titania-coated waveguides propagate light in an attenuated total reflection mode, despite the relatively high refractive index ( $n = 1.8$  in air) of the titania film relative to the silica substrate ( $n = 0.5$ ).

The light output of electric lighting gradually decreases due to stain buildup on lamps and covers during operation. Roadway, and especially tunnel lighting, experiences a large amount of contamination due to dust, carbon particles found in vehicle engine exhausts and other airborne contaminants,

which results in the rapid deterioration of the light output. Photocatalytic reactions caused by TiO<sub>2</sub> are known to decompose such stains. This reaction is caused by the absorption of UV light ( $\lambda \leq 400$  nm, corresponding to the bandgap of  $\sim 3$  eV) irradiated from lamps or the sun, and followed by oxidation. Extensive field tests revealed [452] that a fine film coating of TiO<sub>2</sub> on lamps and luminaires can effectively decompose various organic compounds such as vehicle exhaust gases, oil, nicotine, etc. This leads to an improvement of the luminous performance of installed lighting systems and reduces the cost of maintenance by approximately one-half.

It has been recently found [453] that photocatalytic TiO<sub>2</sub> coated with polycarbonate (PC) releases a huge amount of exothermic energy in the temperature range between 200 and 400 °C (ca. 1.85 kJ/g). The strong interaction between oxygen-deficient sites in TiO<sub>2</sub> and carbonyl groups of PC mediated by a good PC solvent is found to be a prerequisite for a release of the enormous amount of exothermic energy. This finding suggests that PC-coated TiO<sub>2</sub> powders or related oxides work as a combustion-assisting agent in a relatively lower temperature range and can be utilized for incineration applications in order to suppress the formation of extremely toxic dioxins.

A somewhat unusual application reported [454] the photocatalytic deposition of a gold particle onto the top of a SiN cantilever tip, employing the photocatalytic effect of titanium dioxide. When the titanium dioxide immersed in a solution including gold ions is subject to optical exposure, the excited electrons in the conduction band reduce gold ions into gold metal. Illumination by an evanescent wave generated with a total reflection configuration limits the deposition region to the very tip. In the experiments, 100–300 nm gold particles on SiN cantilever tips for atomic force microscopes were obtained. In a related vein, photo-induced deposition of copper on nanocrystalline TiO<sub>2</sub> films was proposed [455].

Solar photocatalytic oxidation processes (PCO) for degradation of water and air pollutants have received increasing attention. In fact, some field-scale experiments have demonstrated the feasibility of using a semiconductor (TiO<sub>2</sub>) in solar collectors and concentrators to completely mineralize organic contaminants in water and air [456]. Although successful preindustrial solar tests have been carried out, there are still discrepancies and doubt concerning process fundamentals such as the roles of active components, appropriate modelling of reaction kinetics, or quantification of photo-efficiency. Challenges to development are catalyst deactivation, slow kinetics, low photo-efficiency and unpredictable mechanisms. The development of specific nonconcentrating collectors for detoxification and the use of additives such as peroxydisulfate have made competitive use of solar PCO possible.

## GLOSSARY

**Charge transfer** The transfer of a charge carrier (electron or hole) from an excited semiconductor to an adsorbed species on its surface. This transfer may initiate a reaction (oxidation or reduction) in the adsorbed molecule.

**Dye-sensitized semiconductor** Adsorbing a suitable dye on the surface of a wide band gap semiconductor (like TiO<sub>2</sub>) can

enhance the efficiency of the excitation step and, hence, the catalytic activity.

**Electron-hole pair** The absorption of a photon of sufficient energy may excite in a semiconductor an electron from the valence band to the conduction band, thereby creating a hole in the valence band.

**Nanocrystalline** A material composed of individual crystallites which have a size in the range of nanometer (nm); 1 nm = 10<sup>-9</sup> m.

**Photocatalysis** A catalytic reaction triggered or enhanced by illuminating the system with visible or ultraviolet irradiation. This reaction involves normally the electronic excitation of the catalyst via the absorption of photons and an interfacial charge transfer to an adsorbed species. Typically, the photocatalyst is not consumed in the reaction.

**Photocatalytic degradation** The removal or reduction of (usually unwanted) substances via a photocatalytic reaction.

**Quantum yield** The probability of product formation per adsorbed photon in a photocatalytic reaction.

**Titanium oxide** Titanium dioxide with the nominal composition TiO<sub>2</sub> is a semiconductor with a band gap of  $\sim 3.2$  eV; it exists in three different crystalline modifications, two of which (anatase and rutile) are commonly employed in photocatalysis.

# Nanocrystals Assembled from the Bottom Up

Edson Roberto Leite

*Federal University of São Carlos, Carlos, SP, Brazil*

## CONTENTS

1. Introduction
  2. Transition Metal Nanocrystals
  3. Metal Oxide Nanocrystals
  4. Nanocrystalline Composites
  5. Characterization of Nanocrystals
  6. Summary
- Glossary  
References

## 1. INTRODUCTION

The physical and chemical properties of materials on the nanoscale (usually defined in the 1–100 nm range) are of immense interest and increasing importance for future technological applications. Nanoparticles or nanocrystals (in this work the words nanoparticles and nanocrystals are synonymous) generally display properties that differ from those of bulk material. The literature provides several examples of properties, such as magnetic and optical properties, melting point, specific heat, and surface reactivity, which can be affected by particle size [1–5]. A material's properties are usually very substantially modified in the 1–10 nm sizes. These changes are known as quantum size effects and their origin is directly related to the type of chemical bond in the crystal [6]. The correlation between properties and particle size has been known since the 19th century, when Faraday demonstrated that the color of colloidal Au particles can be modified, changing the Au particle size [7]. However, despite the subject's long history, interest in nanoparticles has grown considerably over the last decade. The driving force for this increase in research activity is the ability to control a material's properties by controlling the size and shape of crystals and the arrangement of such particles. These developments can lead to new technologies, including energy conversion [8–12], catalysis and sensors [13, 14],

ultrahigh density data storage media [15–17], nanoparticle light-emitting diodes [18, 19], and special pigments [20].

The future of these new technologies is strictly dependent on the development of synthetic routes to process metal, metal oxides, and semiconductor nanoparticles, as well as processes that allow such nanoparticles to be manipulated and controlled. This chapter focuses precisely on these two topics (i.e., the synthesis and control of nanoparticles). Special attention is given to particle growth control during high temperature heat treatment.

This chapter is dedicated to presenting a concise description of different wet chemical processes to synthesize metal and metal oxide nanoparticles by “bottom-up” methods and of how to control the shape, size, and particle growth of such nanocrystals. This chapter will also analyze the synthesis of nanocomposites. Nanocomposite processing will be considered as a route to control the particle growth, surface oxidation, and agglomeration of nanoparticles. The fact that the combination of different phases may result in a material with superior performance will be considered a secondary, albeit no less important, effect. Indeed, these two factors, control and synergetic effect, must be considered during the selection of material for nanocomposite processing.

Neither the synthesis of metal and metal oxide nanoparticles by high energy mechanical milling (“top-down” methods) or vapor phase nor the synthesis of semiconductor nanoparticles, such as II–IV semiconductors crystals, is discussed in this chapter, since the literature contains excellent papers and reviews on these subjects [21–23].

## 2. TRANSITION METAL NANOCRYSTALS

The “bottom-up” methods of wet chemical nanocrystal synthesis are based on the chemical reduction of the salts, or the controlled decomposition of metastable organometallic compounds in an organic or water solution. These reactions are always carried out in the presence of a large variety of stabilizers, which are used basically to control the growth of the initial nanocluster and to avoid particle coagulation

or agglomeration. The mechanism of nanoparticle formation is generally based on a process of nucleation, growth, and coagulation. This process was proposed by Turkevich and is based on the synthesis of metal nanoparticles by salt reduction [24–26]. This model still is valid and has recently been refined. A recent review authored by Bönemann and Richards [27] contains a good discussion about the refined model and supplementary references on this subject are also available.

Since nanocrystals are unstable from the standpoint of agglomeration and bulk, coagulation and agglomeration are the paths that nanoparticles follow to decrease their high surface area, thus becoming more stable. In the absence of any extrinsic impediment, the unprotected particle coagulates, basically under the action of van der Waals forces. To prevent the coagulation process from occurring, the particle surface can be protected by electrostatic stabilization and/or steric stabilization [28].

Electrostatic stabilization is based on the Coulombic repulsion between particles, promoted by a double layer composed of ions adsorbed on the particle surface. The electrostatic stabilization process can be modified by several parameters, such as ionic strength of the dispersing media, ion concentration, and the presence of neutral adsorbate, which may replace the adsorbed ion on the particle surface.

Steric stabilization is based on the steric hindrance caused by organic molecules that are attached to the particle surface, forming a protective layer that prevents particle coagulation or agglomeration. This type of stabilizing system can be viewed as a nanocomposite material, since the organic layer forms a nanometric scale second phase [29, 30]. Several kinds of protective groups can be used as steric stabilization agents, among them polymers and block polymers, P, N, and S donors (phosphanes, amines, thioethers), surfactants, organometallic compounds, and solvents. A detailed description of the several types of steric stabilizers used during the synthesis of metal nanocrystals is given in Bradley's review [31].

The synthesis of transition metal nanocrystals can be divided basically into two major groups: salt reduction and decomposition method. Examples of these methods are described in the following section.

## 2.1. Synthetic Methods

The salt reduction method is a process by which a reduction agent reduces the metal salt, in solution, to metal. These reactions can be done in water or in an organic solution. In an organic solution, the solvent can also act as a reduction agent. Alcohols are generally useful reduction agents, particularly alcohols containing  $\alpha$ -hydrogen. In this process, the alcohol is oxidized to the corresponding carbonyl group. An example of this kind of synthesis is the processing of palladium nanoparticles through the reduction of palladium acetate by methanol [32]. Teranishi and Miyake [33] reported on the reduction of  $\text{H}_2\text{PdCl}_4$  by alcohols to synthesize Pd nanoparticles, demonstrating that the mean diameter of Pd nanocrystals can be controlled from 1.7 to 3.0 nm in a one-step process by changing the amount of protective polymer, poly(*N*-vinyl-2-pyrrolidone) (PVP) and the kind and/or concentration of alcohol in the solvent. The

solvent they used was water. They also showed that the reduction rate of  $[\text{PdCl}_4]^-$  ions is an important factor in the production of smaller Pd particles. The reduction rate was controlled using different kinds of alcohol.

The reduction of metal salts by the addition of a reducing agent in a nonreducing solvent is a well-established synthetic route for the preparation of aqueous suspensions of metal nanocrystals. Faraday, for instance, used phosphorous vapor to promote the reduction of  $[\text{AuCl}_4]^-$  in aqueous solution to synthesize gold nanoparticles [7]. Different kinds of reducing agents have been used to process gold nanocrystals, allowing for the processing of particles ranging from 1 to 100 nanometers in diameter. Turkevitch and co-workers [24, 26] established the first reproducible standard protocol for the synthesis of gold nanoparticles. Their processing of gold nanoparticles by the reduction of  $[\text{AuCl}_4]^-$  with sodium citrate, for example, became a standard for histological staining applications [34] and for undergraduate experiments in surface and nanomaterials chemistry [35].

Platinum nanoparticles can also be synthesized by the reduction of metal salts, using a reducing agent [36, 37]. Van Rheenen et al. [37] demonstrated that the morphology of platinum particles could be controlled by controlling the synthetic parameters, such as temperature, protective polymer, time, pH, reagent concentration, and the sequence of reagent additions. These authors used various reducing agents and chloroplatinic acid as platinum salt.

An interesting synthetic route was recently developed based on the reduction of organometallic compounds by dihydrogen at low pressure and temperature [38–42]. The organometallic compounds used were low-valent alkene or a poly-ene complex of the desired metal. Using this process, well-dispersed nanoparticles of Ru, Pt, Ni, and Co with a narrow size distribution were synthesized. The particles were stabilized by the presence of PVP. Based on a similar process, Ould Ely et al. [43] synthesized nanoscale bimetallic  $\text{Co}_x\text{Pt}_{1-x}$  particles, using  $\text{Co}(\eta^3\text{-C}_8\text{H}_{13})(\eta^4\text{-C}_8\text{H}_{12})$  and  $\text{Pt}_2(\text{dba})_3$  (dba = bis-dibenzylidene acetone) as organometallic compounds. They found that the alloy's composition was determined by the initial ratio of the two organometallic precursors.

Recently, the so-called "polyol process" [44] has been used successfully to process magnetic nanoparticles with a very narrow particle size distribution [44–46]. This process is based on the reduction of metallic salt in solution, at a high temperature ( $100 < T < 300$  °C), by the addition of a polyol (such as ethylene glycol), resulting in nanometric particles. In this process, surfactants such as oleic acid are used to control particle growth and stabilize the nanoparticles.

Park and Cheon [47] discussed an interesting synthetic route to process solid solution and core-shell type cobalt-platinum nanoparticles via a redox transmetallation reaction, reporting they had obtained nanoparticles of solid solution and core-shell structures smaller than 10 nm. These alloys were formed by redox transmetallation reactions between the reagents without the addition of reducing agents. The reaction between  $\text{Co}_2(\text{CO})_8$  and  $\text{Pt}(\text{hfac})_2$  (hfac = hexafluoroacetylacetonato) resulted in the formation of solid solution, while the reaction between Co nanoparticles and  $\text{Pt}(\text{hfac})_2$  in solution resulted in " $\text{Co}_{\text{core}}\text{-Pt}_{\text{shell}}$ "

type nanoparticles. Narrow particle size distributions were achieved in both processes.

The organometallic compounds of transition metals usually display low thermal stability, decomposing into their respective metals even under mild conditions. Owing to these properties, organometallic compounds can be considered good sources to process metal nanoparticles.

Metal carbonyl pyrolysis has been used for the synthesis of several metal nanoparticles, although a broad particle size distribution is usually obtained [48, 49]. Park et al. [50] reported on the synthesis of iron nanorods and spherical nanoparticles using the thermal decomposition of  $\text{Fe}(\text{CO})_5$ , in the presence of surfactant. They found that rodlike particles, with a higher aspect ratio, could be obtained by changing the concentration of didodecyldimethylammonium bromide during the reaction process.

Alivisatos et al. [51] recently reported on the control of the size and shape of Co nanocrystals. A synthetic route, based on the principles applied to the synthesis and control of CdSe nanocrystals, was used [52]. These authors discussed the synthesis of Co nanoparticles with high crystallinity, narrow particle size distribution, and a high degree of shape control. The nanocrystals are produced by injecting an organometallic precursor [ $\text{Co}_2(\text{CO})_8$ ] into a hot ( $T \sim 180^\circ\text{C}$ ) surfactant mixture [oleic acid and trioctylphosphine oxide (TOPO)] under an inert atmosphere.

An interesting approach to synthesize metal alloy nanocrystals is the use of simultaneous salt reduction and thermal decomposition processes. Sun et al. [53] reported on the synthesis of iron–platinum (FePt) nanoparticles through the reduction of platinum acetylacetonate by a diol, and decomposition of iron pentacarbonyl [ $\text{Fe}(\text{CO})_5$ ] in the presence of a surfactant mixture (oleic acid and oleyl amine). Based on a similar approach, Chen and Nikles [54] synthesized ternary alloy nanoparticles ( $\text{Fe}_x\text{Co}_y\text{Pt}_{100-x-y}$ ), using a simultaneous reduction of acetylacetonate and platinum acetylacetonate and thermal decomposition of  $\text{Fe}(\text{CO})_5$  and obtaining an average particle diameter of 3.5 nm and narrow particle size distribution.

The decomposition of the organometallic compounds can be promoted by different energy sources, such as acoustic waves (sonochemistry). Sonochemistry stems from acoustic cavitation—the formation, growth, and implosive collapse of bubbles in the liquid. These phenomena can generate high temperatures and high cooling rates [55, 56], creating a favorable environment to promote the decomposition of organometallic compounds and the synthesis of nanoparticles. Suslick et al. [57] used this approach to synthesize Fe nanocrystals. They used  $\text{Fe}(\text{CO})_5$  as the precursor, promoting sonochemical decomposition (by ultrasonic irradiation) in the presence of PVP as stabilizer and obtaining Fe nanoparticles with a mean particle size of 8 nm.

As previously described, the synthesis of metal nanocrystals is based on a colloidal process whereby a metallic salt or an organometallic compound, in solution, is reduced to a metal by a reducing agent (salt reduction method) or by thermal decomposition (thermal decomposition method). The reduction is developed in the presence of a stabilizer (electrostatic stabilization and or steric stabilization). These additives have two basic functions: to control particle growth and to prevent particle agglomeration.

These processes are based on nucleation, growth, and agglomeration, or coagulation. As illustrated in Figure 1, the general process of metal nanocrystal synthesis can be divided, for didactic purposes, into five steps. The first step (step I) consists of the reduction of the metallic precursor ( $\text{M}^+\text{X}^-$ ), which results in metal atoms ( $\text{M}^\circ$ ). These metallic atoms, ions, and metallic clusters will interact (step II), resulting in a metallic cluster growth process. Steps I and II are reversible. When the cluster grows to a critical size (step III), the process becomes irreversible (thermodynamic condition). Particle size can be controlled with the aid of stabilizers (step IV). The presence of only one stabilizer can result in a spherical particle. The origin of this morphology is thermodynamic. In fact, the cluster will grow in a geometrical arrangement in order to minimize the surface energy. The presence of two simultaneous stabilizers, on the other hand, may give rise to a preferential growth process caused by the preferential adsorption of one of the stabilizers. This process, which leads to the formation of anisotropic particles such as nanorods, occurs under a kinetic condition. Particle agglomeration, basically, is prevented by steric stabilization under the influence of the molecules attached to the particles' surface (step V). Step V is essential to control nanoparticle deposition. Thus, colloidal metal dispersion can be used as a building block to produce functional materials [58]. This nanocrystal-based self-assembly process is governed by particle–particle and particle–substrate interaction. The nanocrystal self-assembly process requires a monodispersion system (particle size deviating by less than 10% from the average size) [59] and can be achieved by solvent evaporation [53, 60] or polymer-mediated nanocrystal assembly [61].

Needless to say, the process described in Figure 1 is ideal. One of the major obstacles to achieving good control over metal colloidal synthesis is in separating the nucleation from the growth process. A positive advance in this direction is the synthesis of CdSe nanocrystals, in which nucleation is separated from the growth process by rapidly injecting the precursor in a solvent at high temperature [62, 63]. This approach has become the most suitable thermal decomposition method and has been applied successfully in the synthesis of Co nanocrystals [51], as discussed in Section 2.1.

**Figure 1.** Schematic representation of the general process of metal nanocrystal synthesis.

## 2.2. Properties

When we talk about metal nanocrystal, two major application fields come to mind: catalysis and magnetic materials. In this section, we will present some examples of metal nanocrystal properties in these fields.

The magnetic properties of nanocrystals differ in several aspects from their bulk properties. These differences stem from the large fraction of atoms located on the surface or at the interface, leading to a local environment that differs greatly from that of the internal atoms. Hence, the intrinsic and extrinsic properties of nanostructured materials must be different. Besides these modifications, a second phenomenon must be considered as well. Unlike bulk ferromagnetic materials, which are composed of multiple ferromagnetic domains, a sufficiently small ferromagnetic particle consists of a single magnetic domain. These two effects can lead to new magnetic properties that can help the development of ultra-high-density magnetic recording, particularly on metal thin film media.

Metal thin film media are generally processed by physical deposition techniques, which usually require postdeposition annealing. This annealing treatment can result in loss of control over particle size and particle size distribution due to particle growth [64]. The use of nanoparticles as building blocks to fabricate magnetic thin films, via self-assembly, appears to be a good alternative to process metal thin film media [53, 61]. Sun and co-workers [53] showed that ferromagnetic FePt nanocrystal superlattices are chemically and mechanically robust and can support high-density magnetization reversal transitions.

The development of metal nanoparticles whose particle size, size distribution, and composition is strictly controllable can result in high performance catalysts. The preparation of metal nanoparticles prior to deposition on a support can provide fine control over the composition and microstructure [65]. Such control is difficult with the traditional impregnation/reduction catalyst preparation. Polymer-protected precious metal nanoparticles have been used with good results in the hydrogenation of unsaturated organic molecule catalysts [66–68].

Transition metal nanoparticles have recently become a fundamental component for the synthesis of carbon nanotubes. This synthesis can be done by noncatalytic and catalytic methods [69]. When the growth method of nanotubes by chemical vapor deposition (even of single-walled carbon nanotubes) is used, there is strong evidence that carbon nanotubes grow via the base-growth mode, with the catalytic nanoparticle acting as seed for the growth [70, 71]. In fact, the size of the nanoparticle determines the diameter of the nanotube [72]. In the catalyst method, Ni, Fe, and Co are the transition metals that can serve as catalysts for carbon nanotube growth [73]. The catalyst method produces large quantities of very long carbon nanotubes [74].

## 3. METAL OXIDE NANOCRYSTALS

Metal oxides represent an important class of materials with a variety of technological applications. Several reports in the literature describe the effects of size on the various properties of this class of materials. Nanocrystalline metal oxide

semiconductors such as TiO<sub>2</sub>, SnO<sub>2</sub>, and ZnO, for example, display a quantum confinement effect, with enlargement of the bandgap as the particle size decreases [75–77]. Colloidal nanocrystals with quantum size effects are promising building blocks for novel electrical and optoelectronic devices [2, 78]. The ferroelectric phenomena in complex ferroelectric oxides are suppressed when the particles are reduced to a critical size [79–81]. Ceramic materials with nanometric scale microstructures display superior mechanical properties and enhanced electronic conductivity [82, 83].

Based on the above analysis, the development of metal oxides of nanometric dimensions can result in devices and materials with superior performance. However, these developments are directly related to the development of synthesis methods that allow for controlled particle size, particle morphology, and deposition. Once again, the “bottom-up” methods of wet chemical nanocrystal synthesis are apparently the most viable approach to achieve such control. Compared to the control attained in the synthesis of metal and II–IV semiconductor nanocrystals, the control of metal oxide nanocrystals is still in its earliest stage, particularly insofar as the synthesis of complex metal oxide nanocrystals (oxides formed of more than one cation) is concerned.

The synthesis of metal oxide nanocrystals by wet chemical processes can be divided basically into two major groups: (a) chemical synthesis method based on the hydrolysis of metal alkoxides or metal halides; (b) chemical synthesis based on the nonhydrolytic method. Examples of these methods are described in the following section.

### 3.1. Synthetic Methods

The chemical synthesis of metal oxide nanocrystals based on hydrolysis falls into two major groups: hydrolysis of metal alkoxides and hydrolysis of metal halides and other inorganic salts. Following I give a description of these two groups.

Metal alkoxide compounds are defined as compounds that have metal–oxygen–carbon bonds. Si(OC<sub>2</sub>H<sub>5</sub>)<sub>4</sub>, for instance, which is known as tetraethyl orthosilicate (TEOS), is an alkoxide compound. This class of compound is highly reactive with water. Because the hydroxyl ion (OH<sup>−</sup>) becomes bonded to the metal of the organic precursor, this reaction is called hydrolysis. Reaction 1 shows a typical hydrolytic reaction of an alkoxide compound,

where M represents Si, Ti, Zr, Al, and other metals, R is a ligand such as an alkyl group, and ROH is an alcohol. Hydrolytic reactions are strongly dependent on water content and catalysts. Due to the high reactivity of alkoxide compounds with water, hydrolytic reactions must be carried out in an atmosphere devoid of water vapor and the solvents used must have a very low water content. A partially hydrolyzed metal alkoxide molecule can react with other partially hydrolyzed molecules by a polycondensation reaction, as described in the following equations.

This type of reaction leads to the formation of an inorganic polymer or a three-dimensional network formed of metal oxianions. The described process is called metal alkoxide-based sol-gel. The literature contains excellent reports providing in-depth analyses of this method [84, 85].

The sol-gel process allows for very good chemical homogeneity and offers the possibility of obtaining metastable phases, including the amorphous phase. This process normally promotes the formation of amorphous metal oxides, which require thermal or hydrothermal treatment to promote crystallization. Several factors affect the sol-gel process, including the kind of metal alkoxide, pH of the reaction solution, water:alkoxide ratio, temperature, nature of the solvent, and stabilizers [84]. By varying these parameters, particles can be synthesized with controlled size, morphology, and agglomeration. When the metal alkoxide's hydrolytic reaction rate is too fast, particle size and morphology are more difficult to control. A good alternative to overcome this problem is to use organic additives, which act as chelating ligands (carboxylic acids,  $\beta$ -diketones, and others) and decrease the precursor's reactivity [86].

The sol-gel process can generally be divided into three steps, as illustrated schematically in Figure 2: (1) precipitation of hydrous oxide particles; (2) control of hydrous oxide particle coagulation; and (3) crystallization of the hydrous oxide particle. Thus, the sol-gel process requires control of the particle size and morphology during the precipitation and coagulation steps and during the heat or hydrothermal treatment to promote crystallization. These three steps are now discussed in detail.

The precipitation of amorphous metal oxide (step 1) is controlled by a nucleation growth mechanism. The nucleation mechanism used in this step is well described by the LaMer and Dinegar theory [87]. Following this model, the supersaturation of hydrous oxides increases continuously (by a change in temperature or pH) until a critical concentration is reached. In this condition, nucleation occurs very rapidly and leads to precipitation. Precipitation decreases the supersaturation to levels below the critical concentration,

preventing further nucleation and precipitation. After nucleation occurs, the nuclei thus formed grow, reducing the concentration until an equilibrium concentration is achieved.

The solubility ( $S$ ) of the particle formed during nucleation is related to the particle's size ( $d$ ) by the Ostwald-Freundlich equation,

$$S = S_0 \exp(4\gamma_{SL}V_m/RTd) \quad (4)$$

where  $S_0$  is the solubility of the flat surface,  $\gamma_{SL}$  is the solid-liquid interfacial energy,  $V_m$  is the molar volume of the solid phase,  $R$  is the gas constant, and  $T$  is the temperature. This dependence controls the nucleation and the growth process. After the nucleation step, the smaller particles show a tendency to dissolve, increasing the supersaturation, which may cause reprecipitation of the larger particles. This mechanism, which controls particle growth, is known as Ostwald ripening.

Controlled hydrolysis is one of the most popular methods for processing silica spheres in the range of 10–1000 nm. The method was developed by Stöber et al. [88] and is based on the hydrolysis of TEOS in a basic solution of water and alcohol. Particle size depends on the reactant concentration, that is, the TEOS/alcohol ratio, water concentration, and pH ( $>7$ ). This method has been extended to other metal oxide systems with similar success, particularly for  $\text{TiO}_2$  synthesis [89, 90].

The hydrous oxide particles precipitated by the hydrolysis of an alkoxide compound have the same tendency to agglomerate as that described under item 2 for metal colloid systems. Different stabilizers can be used to stabilize these particles and prevent coagulation (step 2). These stabilizers control coagulation by electrostatic repulsion or by steric effects [28], similarly to the metal colloid systems.

There is not only a similarity but also a fundamental difference between the approach used to control coagulation in the sol-gel process and that used for metal nanocrystal systems. In the sol-gel process, the surface charge is controlled by the protonation or deprotonation of the hydrous oxide particle surfaces (M-OH). Thus, the charge-determining ions are  $\text{H}^+$  and  $\text{OH}^-$ . The ease with which protonation or deprotonation occurs depends on the metal atoms and can be controlled by the pH. The pH at which the particles are neutrally charged is called the isoelectric point. At the  $\text{pH} >$  isoelectric point, the particles are negatively charged [see Eq. (5)] while, at the  $\text{pH} <$  isoelectric point, the particles are positively charged [see Eq. (6)]:

Electrostatic stabilization is most commonly employed in the water solution system, while steric stabilization can be more effective in organic media [91, 92]. A steric stabilizer can be used to control the condensation reaction during the precipitation of hydrous oxides. In this case, the stabilizer is added during the hydrolysis step [93–96]. Peiró et al. [97] recently reported on the synthesis of  $\text{TiO}_2$  anatase phase with a nanorod morphology ( $9 \times 5$  nm size) using controlled hydrolysis of tetraisopropyl orthotitanate and tetrabutylammonium hydroxide as a steric stabilizer agent.

**Figure 2.** Schematic representation of the sol-gel process. For more details about each step, see Section 3.

The crystallization process (step 3) can be considered the critical step in the sol-gel process when a crystalline phase is desirable. If an amorphous phase is the final target, as in the case of SiO<sub>2</sub> nanoparticle processing, the synthesis ends with step 2. However, for crystalline materials, a heat or hydrothermal treatment is necessary to promote the crystallization of the amorphous hydrous oxide which is formed during hydrolysis. Such subsequent treatments can lead to particle growth and modify the particles' morphology.

In the case of crystallization by heat treatment, the hydrous oxide colloidal suspension must be dry before the treatment. During the heat treatment, normally done in an electric furnace, crystallization occurs by a nucleation growth process and can be described by the standard nucleation growth theory [84, 98].

Since the amorphous phase crystallizes via the nucleation-growth process, particle size and growth can be controlled based on the separation of the nucleation phenomena from the growth process. However, during crystallization, each hydrous metal oxide particle can generate several nuclei, rendering it very difficult to control particle morphology and shape. Figure 3 shows a high-resolution transmission microscopy (HRTEM) image of the nucleation of several PbTiO<sub>3</sub> nuclei in an amorphous inorganic nanoparticle. This figure shows the particle before and after crystallization induced by an electronic beam. The polynuclei process generates polycrystalline particles rather than freestanding ones. Controlling the generation of polynuclei in a single amorphous particle is the main challenge involved in obtaining crystalline metal oxide freestanding nanoparticles through the sol-gel process or by any other process that requires crystallization by heat treatment at high temperatures. The origin of the polynuclei process occurring during sol-gel amorphous precursor crystallization is assumed to be related to the preferential heterogeneous nucleation process (surface and interface nucleation) in detriment to homogeneous crystallization (bulk nucleation). The presence of hydroxyl groups and other defects on the particle surface can contribute to reduce the Gibbs free energy for crystallization, rendering the surface crystallization more favorable than the bulk crystallization. Since crystallization occurs in a scenario of high driving force (high temperature of heat treatment),

**Figure 3.** HRTEM image of the nucleation of several PbTiO<sub>3</sub> nuclei in an amorphous inorganic nanoparticle. (a) Amorphous particle before the crystallization (inset shows the electron diffraction pattern typical of amorphous materials) induced by the electron beam (300 kV); (b) the same particle after the crystallization process (inset shows the electron diffraction pattern of the crystalline materials).

surface crystallization must occur first, followed by bulk crystallization, giving rise to a particle with several nuclei. A possible way to avoid this problem is to suppress surface crystallization by using an inhibitory surface layer. If crystallization occurs at a temperature that favors bulk crystallization, a single nucleus can be generated, resulting in a freestanding particle. This approach was used recently to process freestanding lead zirconate titanate (PZT) nanoparticles [99]. Liu and co-workers [99] used a sol-gel process based on controlled hydrolysis and a two-step heat treatment. They first applied a 12-h treatment in Ar atmosphere at 700 °C, which formed a surface layer rich in carbonaceous materials on the nanoparticles, inhibiting surface nucleation. A second treatment was carried out at 500–600 °C, in air, to burn out the carbon residue. Freestanding PZT nanoparticles with a mean particle size of 17 nm were reported.

Freestanding particles are desirable in a variety of fundamental studies and in some technologies, particularly for ferroelectric metal oxides such as PbTiO<sub>3</sub> (PT), Pb(Zr,Ti)O<sub>3</sub> (PZT), BaTiO<sub>3</sub> (BT), among others. Freestanding and single crystalline nanorods of BT and SrTiO<sub>3</sub> (ST) were recently obtained [100, 101]. The approach used in both these studies to obtain this type of material was the injection of a bimetallic alkoxide compound into a solvent at high temperature (100–280 °C), in which the hydrolysis took place (injection-hydrolysis method). Murray et al. [100] synthesized BT nanoparticles with diameters ranging from 6 to 12 nm based on this approach, controlling the particle size by the bimetallic alkoxide (BaTi(OR)<sub>6</sub>)/oleic acid ratio. Park and co-workers [101] reported on the synthesis of BT and ST single crystalline nanorods using a similar process. The origin of nanorod morphology is not yet well understood. Nonetheless, the above-described approach appears to promote and control crystallization with no extra heat treatment, allowing for good control of particle size and morphology.

Another alternative approach to avoid the heat treatment process is to promote crystallization under hydrothermal conditions, a process that is widely used in the synthesis of zeolites [102, 103]. Ying and Wang [104] used hydrothermal treatment to promote the crystallization of anatase and rutile phases, using an alkoxide sol-gel route and achieving the crystallization of anatase TiO<sub>2</sub> phase with a mean particle size of 10 nm at 180 °C, as well as the synthesis of ultrafine rutile TiO<sub>2</sub> phase obtained by hydrothermal treatment in an acidic medium.

The hydrolysis of metal halides and other inorganic salts is a method widely employed to process metal oxide nanoparticles, such as TiO<sub>2</sub> [105, 106], doped and undoped SnO<sub>2</sub> [107–111], ZnO [112, 113], ZrO<sub>2</sub> [114, 115], Y<sub>2</sub>O<sub>3</sub> [116], and others. This process is less sensitive to water content, requiring less control than the hydrolysis of metal alkoxide. In fact, the hydrolytic process normally occurs in a water solution. In solution, the metallic salt generates the anion (Cl<sup>-</sup>, F<sup>-</sup>, NO<sub>3</sub><sup>-</sup>, and others) and the cation (M<sup>n+</sup>). The cation is normally hydrolyzed by pH changing. Hydrolysis promotes the precipitation of an insoluble amorphous hydrous metal oxide. Thus, the steps illustrated in Figure 2 to describe the metal alkoxide hydrolysis-based sol-gel process can also be used to describe the sol-gel process based on inorganic salts. Equations (7) and (8) describe the reaction involved during

the hydrolysis of inorganic salt in water solution. Precipitation will occur by increasing the pH or the  $[\text{OH}^-]$  concentration

The synthesis based on this approach requires the same control described earlier for the sol-gel method related to the hydrolysis of metal alkoxide. However, control of the atmosphere and water content in the solvents is much less demanding.

Again, the major problem of the metal salt hydrolysis approach is the crystallization step, since a heat treatment or hydrothermal treatment is necessary to promote crystallization. The synthesis of metal oxides based on the hydrolysis of inorganic salts or metal alkoxides, with a high degree of crystallinity at room temperature, still represents a challenge.

The best route to obtain good crystallinity at low temperatures with minimum particle growth is the hydrothermal treatment. Nütz and Haase [107] synthesized well-crystallized Sb-doped  $\text{SnO}_2$  nanocrystals, with particles in the range of 4–9 nm, using a hydrothermal treatment of colloidal gel. The gel was treated in an autoclave at temperatures in excess of 250 °C. These researchers used a solution of  $\text{SnCl}_4$  and  $\text{SbCl}_3$  or  $\text{SbCl}_5$  in fuming  $\text{HCl}$  as precursors and promoted hydrolysis by increasing the pH (using aqueous ammonium). Goebbert et al. [110] also reported on the synthesis of well-crystallized Sb-doped  $\text{SnO}_2$  using the hydrothermal process. However, they used a solution of  $\text{SnCl}_4$  and  $\text{SbCl}_3$  or  $\text{SbCl}_5$  in ethanol, promoting hydrolysis by raising the pH (using aqueous ammonium). The hydrothermal treatment was carried out at 150 °C using 10 bar of pressure. This synthesis route produced nanocrystals in the range of 5 nm.

Leite [117] recently demonstrated that well-crystallized  $\text{SnO}_2$  nanocrystals could be produced at room temperature with no hydrothermal treatment. This process is based on the hydrolysis of  $\text{SnCl}_2$  in an ethanolic solution, followed by dialysis to remove the  $\text{Cl}^-$  ions. The result of this dialysis is a transparent colloidal suspension, as depicted in Figure 4a. Figure 4b shows an HRTEM image of typical  $\text{SnO}_2$  particles obtained by this process (particles in the range of 2–5 nm).

**Figure 4.** (a) Picture of the  $\text{SnO}_2$  colloidal suspension before and after the dialysis (transparent colloidal suspension); (b) HRTEM image of typical  $\text{SnO}_2$  particles obtained by the hydrolysis of  $\text{SnCl}_2$  in an ethanolic solution (particles in the range of 2–5 nm).

Zinc oxide ( $\text{ZnO}$ ) nanocrystals have also been synthesized at room temperature. The process, developed by Bahnmann et al. [118], consists of hydrolyzing zinc acetate dihydrate dissolved in 2-propanol by the addition of  $\text{NaOH}$  in a 2-propanol solution. A colloidal suspension of crystalline  $\text{ZnO}$  nanoparticles is obtained without hydrothermal treatment. Similar results were obtained by Spanhel and Anderson [119] and by Meulenkamp [112]; however, they dissolved the zinc acetate dihydrate ( $\text{Zn}(\text{Ac})_2 \cdot x\text{H}_2\text{O}$ ) in ethanol and used  $\text{LiOH}$  to promote the  $\text{Zn}^{+2}$  hydrolysis. Particles in the range of 3–6 nm were reportedly obtained by both of these processes.

Rusakova et al. [120] used an interesting approach to control the particle growth of hydrous metal oxide gels. They showed that the growth could be inhibited by replacing the surface hydroxyl group, before the crystallization step, with a functional group that does not condense and that can produce small secondary-phase particles which restrict boundary mobility at high temperatures. These authors reported that fully crystalline  $\text{SnO}_2$ ,  $\text{TiO}_2$ , and  $\text{ZrO}_2$  nanocrystals (ranging in size from 1.5 to 5 nm) can be obtained after heat treating the precipitate gel at 500 °C, by replacing the hydroxyl group with the methyl siloxyl group before firing.

The development of metal oxide nanocrystals by nonhydrolytic synthesis routes results in materials whose surfaces are free of  $\text{OH}^-$  groups and nanocrystals with different properties particularly suitable for catalytic and sensor applications. Several nonhydrolytic processes have been developed to process metal oxides, and the molecular chemistry of these various methods is discussed by Vioux [121].

Based on the strategy used to process II–IV semiconductor nanocrystals, using the rapid decomposition of molecular precursor in the presence of strong coordinating agents, Colvin and co-workers [122] proposed an interesting route to process  $\text{TiO}_2$  nanocrystals, based on the reactions

where X is a halide ion ( $\text{Cl}^-$ ,  $\text{F}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ) and R is an alkyl group. The synthetic route involved injecting the metal alkoxide  $[\text{Ti}(\text{OR})_4]$  into a titanium halide mixed with TOPO and a solvent at high temperature (300 °C). Nanoparticles with a mean particle size of 7.3 nm and anatase phase were obtained.

Alivisatos et al. [123] demonstrated that transition metal oxide nanocrystals ( $\gamma\text{-Fe}_2\text{O}_3$ ,  $\text{Mn}_3\text{O}_4$ ,  $\text{Cu}_2\text{O}$ ) could be prepared using a nonhydrolytic process based on the thermal decomposition of metal Cupferron complexes  $\text{M}_x\text{Cup}_x$  [ $\text{M}$  = metal ion,  $\text{Cup} = \text{C}_6\text{H}_5\text{N}(\text{NO})\text{O}^-$ ] in a hot solvent with surfactant. Their results suggest that a good level of control can be achieved when this approach is used to process metal oxide nanoparticles.

Camargo et al. [124–127] recently developed a new route to synthesize lead-based perovskite nanoparticles, such as PT [124], PZT [125],  $\text{PbZrO}_3$  (PZ) [126], and  $\text{PbHfO}_3$  (PH) [127]. This method, which apparently involves no hydrolytic reaction and is carbon- and halide-free, is called the oxidant-peroxo method (OPM) because it is based on the oxidation–reduction reaction between  $\text{Pb}(\text{II})$  ion and water-soluble

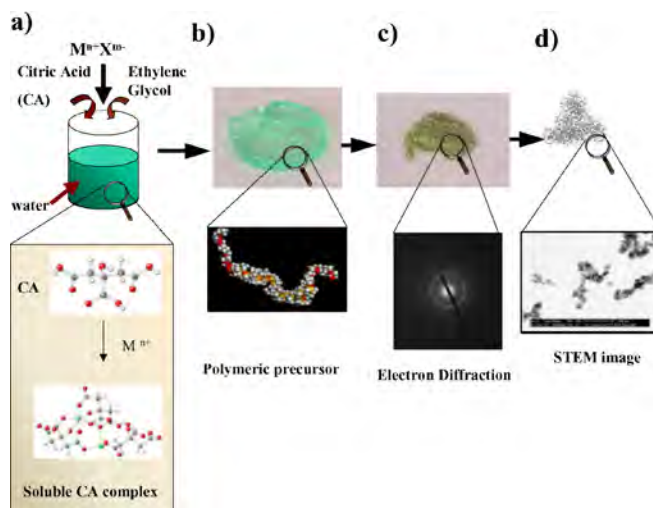

metal–peroxide complexes with high pH. This process results in an inorganic amorphous precursor that requires subsequent thermal treatment to promote crystallization of the desired phase. Figure 5 shows an HRTEM image of a PT nanoparticle obtained by this process. The low crystallization temperatures (400–450 °C for the PT phase) of the amorphous precursor suggest that the OPM method favors the formation of a homogeneous inorganic compound.

An important nonhydrolytic chemical process is the so-called Pechini process [128], or *in-situ* polymerizable complex (IPC) [129]. This process is based on the ability of polycarboxylic acids, particularly citric acid (CA), to form very stable water-soluble chelate complexes. Even cations with a high tendency to become hydrolyzed, such as  $\text{Ti}^{+4}$  and  $\text{Nb}^{+5}$ , can be chelated by CA in a water solution, preventing the hydrolysis and precipitation of hydrous metal oxide. The CA complex thus formed can be immobilized in a solid organic resin through a polyesterification reaction with ethylene glycol (EG). This process leads to the formation of a polymeric precursor with the cations of interest randomly distributed in a three-dimensional solid network, avoiding precipitation or phase segregation during the synthesis of the metal oxide compound [130]. Figure 6 schematically represents the IPC process used in the synthesis of very fine particles.

This method is widely used to process titanates [131–137], niobates [138–140], and other kinds of polycationic or single cationic metal oxides [141, 142]. In the last five years, this method has also proved suitable to process oxide thin films with superior performance [143–148]. Using this process,  $\text{PbTiO}_3$  thin film [148] and nanometric powder [149], for example, can be synthesized at temperatures as low as 450 °C, resulting in a metastable cubic  $\text{PbTiO}_3$  phase. Crystallization was observed at a temperature at which long-range diffusion had to be constrained, and the thermodynamic equilibrium configuration was kinetically suppressed [149]. The ability to form complex metal oxides at low crystallization temperatures and metastable phases is not yet well understood, but it is generally assumed to be associated with the tendency of a polycationic CA complex to develop during the chelation step in water solution [141], and/or the tendency to form an inorganic amorphous phase, with a local

**Figure 5.** HRTEM image of a PT nanoparticle obtained by the OPM.

**Figure 6.** Schematic representation of the IPC process: (a) CA complex formation in water solution; (b) polymerization promoted through a polyesterification reaction between the CA complex and EG; (c) prepolymerization of the polymeric precursor. In this step an inorganic amorphous precursor is obtained (in detail electron diffraction pattern of an amorphous inorganic precursor); (d) crystallization process.

symmetry close to that of the crystalline phase, during the crystallization step [150].

The major problem with this process is maintaining control over the particle size and morphology. During the crystallization process, it is very difficult to keep the nucleation and growth processes separate, resulting in agglomerates made up of nanocrystals. The particle growth process, which was studied in the final stage of the crystallization of nanometric powder processed by the IPC method, showed that growth occurs in two different stages [151]. At heat treatment temperatures of <800 °C, the growth process was associated with the surface diffusion mechanism, with an activation energy in the range of 40–80 kJ/mol. At a temperature of >800 °C, particle growth is controlled by densification of the agglomerate formed by nanometric particles and by the neck-size-controlled growth mechanism [152].

Basically, two methodologies have been used to control the particle size of metal oxides processed by the IPC method. Quinelato et al. [142] demonstrated that the particle size and morphology of  $\text{CeO}_2$ -doped  $\text{ZrO}_2$  could be controlled by controlling the metal/CA ratio. A high concentration of CA leads to smaller particles with a soft agglomeration. Leite et al. [153, 154] showed that the particle size and morphology of  $\text{SnO}_2$  could be controlled by the addition of dopants such as  $\text{Nb}_2\text{O}_5$  and rare earths. The same authors [154] also showed that doped  $\text{SnO}_2$  nanocrystals are highly stable against particle growth, even at high temperatures. The technique used to achieve this high stability was to process supersaturated solid solution between the  $\text{SnO}_2$  and the dopant. Segregation of the dopant on the nanocrystal surface occurs during the heat treatment, decreasing the particle boundary mobility or the surface energy. This approach was originally developed to control the particle growth of metal nanocrystals [5, 155] and was used successfully to control the growth of metal oxide nanocrystals.

### 3.2. Properties

The development of metal oxide nanocrystals can lead to significant improvements of their properties, resulting in materials with superior chemical, electrical, and magnetic performance. An example of how metal oxide-based nanostructured materials can very substantially improve performance is in semiconductor gas sensors. The sensing characteristic of a semiconductor gas sensor using  $\text{SnO}_2$  can be improved by controlling basic parameters relating to the receptor and transducer functions. Stated simply, chemical sensors consist of two functions, that is, a receptor function, which recognizes a chemical substance, and a transducer function, which converts the chemical signal into an output signal.

The transducer function is associated directly with the grain size of the metal oxide and the depth of the surface-charge layer (Debye length) [14]. The semiconductor's sensitivity should improve dramatically when the grain size has the same order of magnitude as the Debye length ( $L_D$ ) (e.g., when the grain size is comparable to  $2L_D$ ). The  $L_D$  for  $\text{SnO}_2$  is  $\sim 3$  nm [156]. The sensitivity can therefore be improved by decreasing the grain size or modifying the  $L_D$  using impure-doped elements [14]. The sensor's response time can also be improved by controlling the particle size. Leite et al. [153, 157] demonstrated that the addition of  $\text{Nb}_2\text{O}_5$  resulted in a smaller  $\text{SnO}_2$  particle size and a shorter response time for the detection of methanol.

The receptor function can be modified by the introduction of dopants on the  $\text{SnO}_2$  surface. Yamazoe [14] showed that the addition of precious metal (Pd and Ag) on  $\text{SnO}_2$  can improve gas sensor performance. Carreño et al. [158] showed that the surface reactivity of doped  $\text{SnO}_2$  nanoparticles, in terms of methanol oxidation, can be modified by controlling the dopant's surface segregation.

Electrochemical devices based on the  $\text{Li}^+$  intercalation process, such as lithium batteries and electrochromic windows, constitute another area in which the development of nanostructured materials based on metal oxide semiconductors can result in high performance devices. Aurbach and co-workers [159] tested  $\text{SnO}$  nanoparticles processed by the sonochemical method for use as anodes in rechargeable Li batteries. The  $\text{SnO}$  nanocrystal was found to be an effective material for electrodes. These electrodes reached almost their theoretical capacity ( $\sim 790$  mAh/g) in electrochemical lithiation–delithiation processes as opposed to a Li counter-electrode in an aqueous Li salt solution.

Felde et al. [160] reported the remarkable electrochromic effect of layers of nanocrystalline  $\text{SnO}_2$  strongly doped with antimony (Sb). The layers were prepared by spin coating of  $\text{SnO}_2\text{:Sb}$  colloids onto conductive substrates. These researchers found that the rate of the color change promoted by the  $\text{Li}^+$  intercalation was determined mainly by the substrate's conductivity. Very fast coloration and decoloration were observed ( $< 10$  ms). Cummins et al. [161] built a dynamic color display based on an electrochromic cell, using two porous metal oxide thin films sandwiched between glass electrodes. The negative electrode was coated with a layer of  $\text{TiO}_2$  nanocrystals with viologen molecules anchored to the nanocrystal surface. Viologen molecules turn blue when injected with charge (e.g.,  $\text{Li}^+$ ). The positive electrode consists of a nanocrystalline  $\text{SnO}_2\text{:Sb}$  film, which is linked to

phenothiazine molecules that turn red when oxidized. The prototype built by Cummins and co-workers showed that the color in the display could be switched on and off in less than 250 milliseconds.

Even in ion-conducting polymer membranes used as electrolytes for lithium batteries, the nanocrystals can play an important role. Scrosati and co-workers [12] showed that ceramic nanoparticles can act as solid plasticizers for polyethylene oxide (PEO), an ion-conducting polymer membrane. They demonstrated  $\text{Li}^+$  ionic conductivities of around  $10^{-4}$   $\text{S cm}^{-1}$  at  $50^\circ\text{C}$  and  $10^{-5}$   $\text{S cm}^{-1}$  at  $30^\circ\text{C}$  in a PEO– $\text{LiClO}_4$  mixture containing  $\text{TiO}_2$  and  $\text{Al}_2\text{O}_3$  powders with 5.8–13 nm particle sizes. This may lead to the development of polymer electrolytes having a true solid-state configuration combined with high conductivity, a high lithium ion transference number, and high interfacial stability with the lithium metal electrode. In fact, the characteristics of the PEO–nanoparticle electrolyte render this material an ideal candidate for use in rechargeable lithium batteries.

In photovoltaic cells (i.e., devices that convert sunlight into electrical power), nanocrystals are responsible for a new and promising generation of devices [8, 162, 163]. The creation of these new devices is based on metal oxide nanocrystals, such as  $\text{TiO}_2$ ,  $\text{SnO}_2$ ,  $\text{ZnO}$ , and others, and on conducting polymers. Generally, the device is composed of a mesoporous oxide film and the pores are filled with a conducting medium (conducting polymers).

## 4. NANOCRYSTALLINE COMPOSITES

Several metal or metal oxide nanocrystal applications or processing steps require high temperature environments. A typical example is materials for heterogeneous catalysis processes, which usually require temperatures of over  $200^\circ\text{C}$  coupled with high pressure [164]. Under such conditions, most nanocrystals are unstable, resulting in particle growth and thus losing their nanoscale dimensions.

As discussed earlier, a good way to improve the thermal stability of nanocrystals and prevent particle growth is to use the supersaturated solid solution process. This process, however, has only been applied for tin oxide [154, 157, 165] and in some restricted metal systems [5, 155].

A satisfactory way of improving thermal stability against particle growth may be the development of nanocomposites (i.e., materials composed of two or more phases with nanometric scale sizes). These nanocomposites must display a special phase distribution, in which the dispersed active phase is isolated from the others, preventing particle growth by coagulation or coalescence at high temperature. This concept is based on the fact that the dispersed solid phase in a solid matrix grows preferentially by coalescence, since a growth process such as Ostwald ripening does not occur due to the low solubility of the dispersed phase in the solid matrix.

Based on this concept, two types of nanocomposite microstructures can be proposed to prevent particle growth: core–shell (CS) nanocomposites and embedded dispersed phase (EDP) nanocomposites. Figure 7 illustrates the two types of nanocomposites proposed. These two types of nanocomposite are now discussed in detail.

**Figure 7.** Nanocomposite microstructures proposed to prevent particle growth: CS nanocomposites and EDP nanocomposites.

#### 4.1. Synthetic Methods

CS nanocomposites composed of an organic shell are basically nanocrystals protected by a surfactant layer that controls particle growth during synthesis and particle coagulation by the steric effect [29, 30]. This process is useful to improve the stability of the nanocrystals in suspension; however, the organic layer is ineffective at high temperature due to its low thermal stability.

CS nanocomposites with inorganic shells can be divided in two subgroups (i.e., crystalline inorganic shells and amorphous inorganic shells). Good reviews about the CS nanocomposite with an inorganic layer are available in the literature [6, 166].

CS nanocomposites with amorphous inorganic shells are composed of metals or metal oxides nanocrystals (core) with an amorphous silica layer (shell) usually synthesized by the sol-gel process [6, 167, 168]. Silica shells have been used on gold nanoparticles to stabilize them and to modulate their optical properties. Liz-Marzán et al. [168] synthesized CS nanocomposites composed of gold nanoparticles and silica shell (these authors introduced the Au@SiO<sub>2</sub> nomenclature to signify gold core and silica shell), using gold nanocrystals prepared by citrate reduction of HAuCl<sub>4</sub>. The silica shell is prepared in two steps. First, the gold particles are coated with (3-aminopropyl)trimethoxysilane (primer layer). The organometallic compound becomes complexed to the gold surface (using the amine groups), replacing the adsorbed citrate ions. This primer layer prevents particle coagulation. The second step consists of adding sodium silicate to form a thin silica layer over the gold particle. The primer layer (formed in the first step) acts as an anchor upon which the silica layer is formed. Further growth of the silica layer can be achieved by transferring the gold-coated particles to an ethanol/water solution with a controlled amount of TEOS. Slow TEOS hydrolysis and a polycondensation reaction cause the silica layer to increase. This technique has been adapted successfully to process several CS nanocomposites such as CdS@SiO<sub>2</sub> [169] and Ag@SiO<sub>2</sub> [170]. Because the silica shell thickness can be controlled, these CS

nanocomposites can be used to process dense thin films with controlled intercore distances [171].

Lu et al. [167] used the sol-gel approach to coat iron oxide nanoparticles with a uniform shell of amorphous silica. The thickness of the silica layer was controlled within the range of 2–100 nm by changing the concentration of the sol-gel solution. In their study, TEOS was used as alkoxide precursor for the silica layer. A primer layer was not necessary to coat the iron oxide.

Oldfield et al. [172] also reported the formation of a tin oxide crystalline layer over gold nanoparticles (Au@SnO<sub>2</sub>) without a primer layer. The crystalline shell was produced through heat treatment and the gold nanocrystals were coated by adding Na<sub>2</sub>SnO<sub>3</sub>·3H<sub>2</sub>O (sodium stannate) to a gold sol with high pH (10.5). Bedja and Kamat [173] successfully prepared a TiO<sub>2</sub> layer on SnO<sub>2</sub> nanocrystals (TiO<sub>2</sub>@SnO<sub>2</sub>) using a sol-gel-like process. They reported on the improved photocatalytic efficiency of the TiO<sub>2</sub>@SnO<sub>2</sub> nanocomposite compared to pure SnO<sub>2</sub> nanocrystals.

As can be seen in Figure 7, the structure of EDP nanocomposites differs from that of CS nanocomposites. In this kind of nanocomposite, the dispersed phase (nanocrystals) is homogeneously distributed in a matrix. In fact, the nanocrystals are embedded in a matrix that can be either porous or dense. Basically, EDP nanocomposites can be divided into two classes: EDP nanocomposites formed by an *in-situ* process and EDP nanocomposites formed by an *ex-situ* process.

With the advent of mesoporous molecular sieves [174, 175], new possibilities for the development of EDP nanocomposites formed by *ex-situ* processing have arisen. These mesoporous sieves present a well-defined pore structure and large surface area, which makes them excellent matrixes for EDP nanocomposites. When these mesoporous materials are used as matrixes for EDP nanocomposites, a second processing step is needed to incorporate the dispersed phase (nanocrystals). This two-step process is called *ex-situ*. The dispersed phase is normally incorporated by liquid infiltration of metal salt solution with subsequent heat treatment in a hydrogen atmosphere, or by vapor phase [176]. The vacuum or electrophoretic method also can be used to fill the channels of mesoporous matrixes with colloidal suspension [177–179].

An alternative way to process EDP nanocomposites is through an *in-situ* process whereby the dispersed phase and the matrix are formed in a single step process. Rolison et al. [180–182] proposed an interesting synthetic route to process EDP nanocomposites by an *in-situ* process. They used silica sol (silica nanoparticles dispersed in a liquid) as a nanoscale glue to prepare composite aerogel by dispersing a nanometric solid together with the silica sol. With the condensation of the silica sol, the second phase was incorporated in a three-dimensional silica network. After gelation, the materials were dried by a supercritical process, keeping their three-dimensional structure and the dispersed phase (metal nanoparticles, carbon black, zeolites, or TiO<sub>2</sub>) embedded in a mesoporous matrix.

Leite et al. [183, 184] recently described a new *in-situ* route for the synthesis of EDP nanocomposites. A mesoporous silica matrix, with a surface area of more than 200 m<sup>2</sup>/g, a narrow pore size distribution, and transition

metal nanocrystals (Ni, Fe, Co, Ag) embedded in the matrix, was obtained in a direct process. Figure 8a shows a bright field (BF) transmission electron microscopy (TEM) image of Ni nanoparticles embedded in an amorphous mesoporous silica matrix processed by this method. A different approach was adopted to process such nanocomposites. This new approach is based on the formation of a hybrid polymer composed of Si, O, C, H, and metal cations arrested in the macromolecule chain and on the control of the pyrolysis step. The CO/CO<sub>2</sub> atmosphere resulting from the pyrolysis of the organic material leads to the reduction of the metallic salt. In this process, CA is used to chelate the Si, resulting in a Si-citric acid complex. EG and the metallic salt are then added to the citrate solution to promote a polyesterification reaction, resulting in a polymeric precursor. The polymeric precursor is then pyrolyzed in an N<sub>2</sub> atmosphere to promote the formation of the EDP nanocomposite. This process leads to the formation of nanocomposites with good catalytic [183, 185] and magnetic properties [186]. The same approach can also be used to process nanocomposites with matrixes other than silica, as illustrated in Figure 8b, which

**Figure 8.** (a) BF TEM image of Ni nanoparticles (dark spots) embedded in an amorphous mesoporous silica matrix; (b) BF-TEM image of a nanocomposite composed of Ni nanocrystals (dark spots) with a mean particle size of 8.8 nm embedded in a matrix composed of amorphous and crystalline (anatase) TiO<sub>2</sub> phase (inset shows a HRTEM image of the nanocomposite, in which can be visualized the anatase, amorphous TiO<sub>2</sub>, and the Ni nanoparticles).

shows a BF-TEM image of a nanocomposite composed of Ni nanocrystals with a mean particle size of 8.8 nm (see inset of Fig. 8b) embedded in a matrix composed of amorphous and crystalline (anatase phase) TiO<sub>2</sub>. In this case, a polymeric precursor composed of Ti, O, C, and H was used.

Chiodini [77] and co-workers reported that they had synthesized SnO<sub>2</sub> nanocrystals embedded in a dense SiO<sub>2</sub> matrix. A modified sol-gel process was used to prepare the nanocomposite. The main step of this process consists of obtaining a starting low-density skeleton from the hydrolysis of organometallic precursors (TEOS as SiO<sub>2</sub> precursor and dibutyl tin diacetate as SnO<sub>2</sub> precursor). With controlled hydrolysis of the precursors and thermal treatment in a controlled atmosphere up to 1050 °C, an EDP nanocomposite is obtained, with SnO<sub>2</sub> nanocrystals (2–8 nm) dispersed in a dense SiO<sub>2</sub> matrix.

## 4.2. Properties

The properties of nanocomposites materials are directly related to the combination of different phases, which potentially result in a material with superior performance. This synergetic effect should, in fact, be considered in the selection of material for nanocomposite processing.

Mulvaney et al. [171] showed that the optical properties of Au nanoparticles can be modulated in a CS nanocomposite, whose shell consists of a silica layer. These authors found that the shell thickness controls the dipole coupling between particles and, hence, the color of the film composed of this CS nanocomposite [171]. The same group found [172] that CS nanocomposites composed of SnO<sub>2</sub> shells and Au cores have more advantageous capacitor properties than the uncoated gold particle. This superior performance derives from the considerable difference between the Fermi level of the core and the shell. This CS nanocomposite is potentially applicable for electron storage and electronic circuit components.

An interesting application for the SiO<sub>2</sub>@Fe<sub>2</sub>O<sub>3</sub> nanocomposite was proposed by Levy and co-authors [187], who used this nanocomposite for targeted diagnostics and therapy. The main purpose of their development was to use the CS material for enhanced contrast magnetic resonance imaging and magnetic-induced cancer therapy.

Nanocomposites also display excellent performance as catalytic material. Leite et al. [183] showed that EDP nanocomposites composed of Ni nanoparticles embedded in a mesoporous silica matrix possess good catalytic properties. This nanocomposite performed well in methanol decomposition and conversion to H<sub>2</sub> and CO. A high methanol conversion was observed (100%), as well as high selectivity for H<sub>2</sub> formation at a temperature of 263 °C, with 53 mg of catalyst mass, a total flow (Ar + CH<sub>3</sub>OH) of 30 cm<sup>2</sup>/min, and a weight hourly space velocity of 34,000 ml/hg. The same nanocomposite showed excellent catalytic performance for β-pinene hydrogenation. This catalytic material displayed high selectivity in relation to the β-pinene hydrogenation, with preferential formation of *cis*-pinane.

The same Ni-SiO<sub>2</sub> EDP nanocomposite showed interesting results as a catalyst for the conversion of methane into synthesis gas [185]. Carreño and co-workers reported that this catalyst presents singular properties to control

the carbon deposition and deactivation of active sites. A comparative study of EDP nanocomposites and conventional catalysts (prepared by impregnation) revealed that impregnated material showed preferential encapsulation and growth of carbon nanotubes on the metal surface. The impregnated catalyst displayed a higher tendency to form carbon nanotubes and whiskers. This tendency was not observed in the EDP nanocomposite.

Rolison et al. [182] have developed a highly active electrocatalytic EPD nanocomposite composed of Pt nanoparticles dispersed in a carbon–silica composite aerogel. They reported electrocatalytic activity for methanol oxidation four orders of magnitude per gram of Pt higher than native Pt-modified carbon powder.

EDP nanocomposites can also be used to process photonic materials for telecommunications. Chiodini et al. [77] developed an EDP nanocomposite with SnO<sub>2</sub> nanoparticles embedded in a dense SiO<sub>2</sub> matrix. The SnO<sub>2</sub> nanoparticles acted as wide-bandgap (>4 eV) quantum dots. In this system, unlike other semiconductor-doped glasses, both the glassy host and the nanophase are oxides of IV-group elements. Due to their thermochemical compatibility, the two phases give stable optical-grade glass ceramics with potential photonic applications.

## 5. CHARACTERIZATION OF NANOCRYSTALS

Because of the finite size of nanocrystals, their surface structure and composition are easily affected, resulting in materials with different chemical and physical properties. Thus the characterization of nanostructured materials is a key step in the development of nanocrystals. This characterization should, basically, answer the following questions: (a) What is the material's particle size and particle size distribution? (b) What is its composition? (c) What is its structure and how does its particle size affect this structure?

The answers to these questions therefore require the use of an arsenal of techniques that allow for characterizations of a morphological, chemical, and structural nature. However, the greatest challenge involves determining the superficial structure of nanocrystals and how the atoms located on their surface change their position (surface reconstruction) to accommodate high surface areas in finite sizes and the interaction of nanocrystals with additives such as surfactants. This section describes characterization techniques that provide answers to the above questions, particularly techniques that can provide information on the surface structure.

The first technique described here is TEM and scanning electron microscopy (SEM). These are quite straightforward techniques to determine the size and shape of nanostructured materials, as well as to obtain chemical and structural information.

TEM uses transmitted and diffracted electrons, which generate a two-dimensional projection of the sample. The principal contrast in this projection (or image) is provided by diffracted electrons. In the so-called bright-field images, the transmitted electrons generate bright regions while the diffracted electrons produce dark regions. In the so-called dark field image, the diffracted electrons preferentially form

the image. In this case, the bright areas in the dark field image represent the regions that produced the diffraction. This technique is useful to build the particle size distribution based on a sample composed of an amorphous phase and crystalline phases, as in EDP nanocomposites. Figure 9a shows a dark field TEM image of an EDP nanocomposite consisting of Ni nanoparticles embedded in an amorphous silica matrix. The bright points represent the Ni nanoparticles. The particle size distribution can be built from the TEM image, using an image analyzing software program that allows one to define the particle area of several particles [several particles (total number of particles >300) are normally necessary to obtain a good statistic] and to determine an equivalent particle size based on these areas. Figure 9b shows an example of particle size distribution of Ni nanoparticles in a Ni–SiO<sub>2</sub> EDP nanocomposite built from dark field TEM images.

In addition to morphological information, TEM provides crystallographic and chemical information. The crystallographic information can be obtained from the diffraction pattern of a selected area, using the so-called select area electron diffraction (SAED) technique. This technique allows for the indexing of crystallographic structures of small or even nanometric regions in the samples. Besides SAED, HRTEM can generate lattice images of the crystalline material, allowing for the direct characterization of a sample's atomic structure. Figures 4b and 5 contain examples of HRTEM images. HRTEM images are particularly sensitive to changes in a phase of the incoming parallel electron wave as it passes through the sample. The atomic structure can also be characterized by scanning transmission electron microscopy (STEM), using a high angle annular dark field detector (HAADF). In fact, the image generated by a HAADF detector, which is sensitive to the atomic number (*Z*), is also known as a *Z*-contrast image [188]. The high-resolution image generated by HAADF detector is sensitive to the chemical composition.

In TEM, the chemical information is provided by the X-rays generated through the interaction of the electronic

**Figure 9.** (a) Dark field TEM image of an EDP nanocomposite consisting of Ni nanoparticles embedded in an amorphous silica matrix. The bright points represent the Ni nanoparticles. (b) Particle size distribution of Ni nanoparticles in a Ni–SiO<sub>2</sub> EDP nanocomposite built from dark field TEM images.

beam with the sample. This technique, known as energy dispersive X-ray spectroscopy (EDS), allows regions as small as 2 nm in a TEM configuration or lower than 0.8 nm to be chemically characterized, using STEM equipment. In addition to EDS analyses, nanostructured materials can also be chemically characterized by electron energy loss spectroscopy (EELS), which allows for a better characterization of light elements, which usually pose a major problem in X-ray spectroscopy-based characterization. Another advantage of EELS spectroscopy is the fact that it is sensitive to the element's chemical environment, allowing information to be obtained on the local structure of the analyzed element. EDS analysis is insensitive to the chemical environment. Detailed information about TEM characterization is given in the book by William and Carter [189].

TEM characterization has been used more recently for *in-situ* studies of materials in the nanoscale range [190, 191]. Using *in-situ* TEM characterization to obtain atom-resolved images of copper nanocrystals on different supports, Hansen and co-workers [190] found that Cu nanocrystals undergo dynamic reversible shape changes in response to changes in the gaseous environment.

SEM is carried out by scanning an electron beam over the sample's surface and detecting the yield of low energy electrons (secondary electrons) and high-energy electrons (backscattered electrons) according to the position of the primary beam. The secondary electrons, which are responsible for the topologic contrast, provide mainly information about the surface morphology. The backscattered electrons, which are responsible for the atomic number contrast (*Z*-contrast), carry information on the sample's composition. Regarding this type of contrast, because the heavy elements (high *Z* value) have the ability to scatter the electrons more efficiently, an image composed of bright areas (consisting of high *Z* elements) and dark ones (consisting of low *Z* elements) is generated. A new generation of SEM has recently emerged as an important tool to characterize nanostructured materials. This state-of-the-art equipment, called a field emission gun (FEG)-SEM, has a FEG that provides the electron beam, and it uses in-lens or semi-in-lens secondary electron detectors to obtain images with a low acceleration voltage and a resolution as high as 1 nm. A STEM detector can be used in the FEG-SEM device, enabling one to obtain the transmitted dark and bright field images of thin specimens or nanoparticles, similar to images obtained with a dedicated STEM. Figure 10 shows images of SnO<sub>2</sub> nanoparticles, with rather good bright and dark field images, which were taken with a FEG-SEM instrument, using a STEM detector.

SEM can provide not only morphological but also chemical information about the sample; however, the spatial resolution is only about 1 μm<sup>3</sup>. This limitation has rendered the chemical characterization of nanostructured materials using SEM practically useless.

The second characterization technique to be analyzed is X-ray diffraction (XRD). XRD is the most popular technique for structural characterization, providing information about the phases present in the material, as well as refined crystallographic parameters and morphological information. XRD consists of the elastic scattering of X-ray photons by

**Figure 10.** STEM images of SnO<sub>2</sub> nanoparticles, which were taken with a FEG-SEM instrument, using a STEM detector. (a) Bright field image; (b) dark field image.

atoms in a periodic lattice. The scattered X-rays (monochromatic) that are in phases provide constructive interference. The lattice space ( $d_{hkl}$ ), or the distance between two lattice planes in a crystal, is described by the Bragg relation

$$2 d_{hkl} \sin \theta = n \lambda \quad (11)$$

where  $\lambda$  is the X-ray wavelength,  $\theta$  is the diffracted angle, and  $n$  is the integer called order of the reflection. A  $d_{hkl}$  set is characteristic of a given compound.

Powder XRD has been used extensively to characterize nanoparticles; however, due to the small particle size, broadening of the diffraction lines occurs at the usual X-ray wavelengths, rendering analyses more complex. These analyses are more difficult if structural parameters are required. In such cases, special X-ray sources like synchrotron radiation and special fit analyses are required to achieve a good structural characterization [192].

X-ray line broadening analysis provides a fast and usually reliable estimate of the particle size [153, 154, 183, 184, 193]. The particle size or, more precisely, the crystallite size ( $\langle D_{hkl} \rangle$ ), can be calculated based on Scherer's equation,

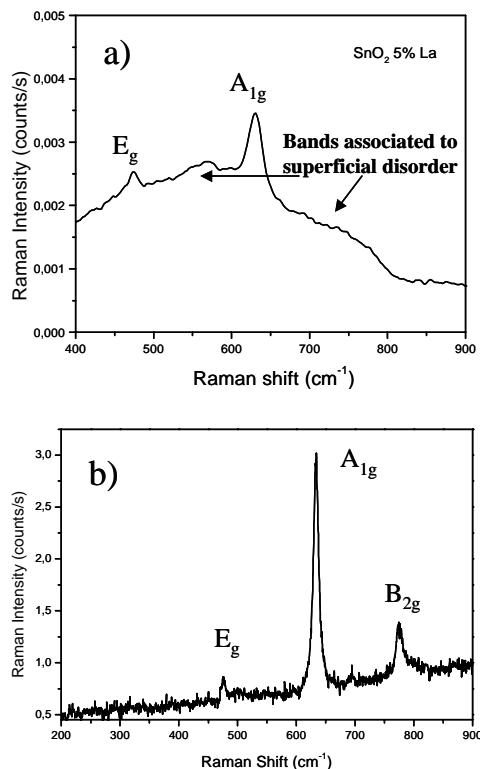

$$\langle D_{hkl} \rangle = K \lambda / \beta \cos \theta \quad (12)$$

where  $K$  is a constant ( $0.9 \leq K \leq 1.0$ ), and  $\beta$  is the corrected full width at half maximum of the diffraction peak. This method of determining the crystallite size takes into account only the X-ray line broadening promoted by the

size effect. Other effects, such as the broadening induced by lattice strain, are not considered. However, considerable discrepancies can occur in metallic nanocrystalline systems [194], even in metal oxide nanoparticles [154]. In such situations, correction of the strain broadening is indispensable for a reliable characterization of the crystallite size. XRD refinement methods, such as the Rietveld method, can be used to correct the strain broadening [195].

Electron microscopy and XRD can provide good morphological, chemical, and structural characterization of nanocrystals; however, these techniques do not provide information about the disordered part of nanocrystals, such as their surfaces. An alternative technique to obtain information about structural disorder in nanocrystals, including surface information of nanocrystals, is X-ray absorption spectroscopy (XAS). This technique is based on the absorption of X-rays and the creation of photoelectrons that are scattered by nearby atoms in a structure. This technique provides information about local structures, such as distance and the number and type of neighbors of the absorbing atom, and can be used to characterize the bulk and surface of solid-state materials, including amorphous materials and catalysts [196, 197]. XAS techniques [X-ray absorption near-edge spectroscopy and extended X-ray absorption fine structure (EXAFS)] have been used to study the size dependence of structural disorder in semiconductors and metal oxide nanocrystals. The results of these techniques have demonstrated that this spectroscopic analysis is sensitive to the structure of the entire nanocrystal, including the surface [198, 199]. By EXAFS analyses of CdS nanoparticles (1.3–12 nm diameter), Rockenberger et al. [200] showed that the stabilization of nanoparticles influences the mean Cd–S distance. Thiol-capped nanoparticles display an expansion of their mean interatomic Cd–S distance, whereas polyphosphate-stabilized particles contract in terms of their CdS bulk. EXAFS has also proved to be highly sensitive in the identification of the surface segregation of foreign cations [201, 202].

Raman spectroscopy can also provide information about the overall nanocrystal structure. Raman spectroscopy is based on the inelastic scattering of photons, which lose energy by exciting vibration in the sample. This technique is very sensitive to the crystal's symmetry and any change can cause modifications in the spectrum, such as shift of the line position, broadening of the line, and new lines. The crystal symmetry of the nanocrystal surface must present differences in relation to the symmetry of the nanocrystal core. Hence, the Raman spectrum of a nanostructured material must be different from the Raman spectrum of the same material with bulk characteristics. In fact, several reports have described the influence of particle size on the Raman spectrum [203–206]. Figure 11a shows Raman spectra of a SnO<sub>2</sub> nanocrystal processed by the IPC process (particle size ~9 nm) compared with a spectrum of a SnO<sub>2</sub> single crystal (Fig. 11b). In addition to the classic modes of the rutile-like structure, the figure clearly shows bands associated with superficial disorder. A detailed discussion of the influence of particle size on the Raman spectrum of SnO<sub>2</sub> is given in the literature [205]. In that work, Dieguez and co-workers proposed a model in which the additional band is due to a

**Figure 11.** Raman spectra of a SnO<sub>2</sub>: (a) nanocrystal processed by the IPC process (particle size ~9 nm); (b) SnO<sub>2</sub> single crystal spectrum.

surface layer of SnO<sub>2</sub> with a dissimilar symmetry. The thickness of this layer was calculated at ~1.1 nm.

Analyses of the Raman line can provide important information about lattice disorder. Such analyses can be performed using the spatial correlation model described by Parayanthal and Pollak [207]. Basically, this model describes the crystal's quality by introducing a parameter called correlation length ( $L$ ), which can be interpreted as the average size of the region of homogeneous materials. According to this model, the Raman line intensity [ $I(\omega)$ ] can be written as

$$I(\omega) = \int_0^1 \exp(-q^2 L^2/4) d^3 q / \{[\omega - \omega(q)]^2 + (\Gamma_0/2)^2\} \quad (13)$$

where  $\omega$  is the frequency,  $q$  is the wave vector,  $\Gamma_0$  is the half-width of the Raman line, and  $\omega(q)$  is the Raman phonon dispersion.

Based on the spatial correlation model, Kosacki et al. [208] demonstrated that the Raman spectra of CeO<sub>2</sub> and Y-doped ZrO<sub>2</sub> thin film are influenced by defects attributed to grain size-controlled nonstoichiometry. Indeed, they proved that Raman spectroscopy could be an effective method to determine the concentration of oxygen vacancies in fluorite-structured oxides.

## 6. SUMMARY

An analysis of the various synthesis routes described above leads to the conclusion that the development of new synthesis routes or the improvement of routes currently under study are necessary to achieve greater control over

the synthesis of nanocrystals, particularly of metal oxide nanocrystals. The advances achieved over the last year in expanding our understanding of the synthesis and control of metal nanocrystals have led to the development of nanoparticles with strictly controlled particle size and particle size distribution, and good control of particle shape. Part of this progress can be attributed to the application of concepts used in the synthesis of semiconductor nanocrystals, such as the thermal decomposition of organometallic compounds and the use of surfactants for the control of particle growth and shape.

The same progress, however, has not been achieved in the synthesis of metal oxide nanocrystals, particularly of metal oxides composed of two or more cations. Part of the reason for this lack of progress is the fact that, during the process of hydrolysis and precipitation, a hydrated amorphous metal oxide phase is formed, requiring heat treatment or a hydrothermal process to promote crystallization of the desired phase. This crystallization step may lead to particle growth, particle shape modification, and particle agglomeration. The use of dopants and surface modifying agents during the synthesis of metal oxide nanoparticles may offer a good alternative to increase the thermal stability of nanocrystals, thus preventing particle growth.

The use of nanocomposites to prevent the growth of nanocrystals, particularly in the case of materials for use at high temperature, appears to be a good strategy. This approach can be combined with the synergism between phases to design nanocomposite materials with superior performance.

There is no doubt that considerable progress has been made in nanocrystal synthesis over the last few years. However, further studies are necessary to achieve improved control over particle size, particle shape, and particle size distribution, as well as to obtain nanoparticles with greater stability against particle growth at high temperatures.

## GLOSSARY

**Nanocomposite** Nanostructured material formed by two or more phases with nanometric scale (1–100 nm).

**Nanocrystal** Crystalline particle with size in the 1–100 nm range.

**Particle growth** Physical–chemical process promoted by the high superficial energy of the particles.

**Self-assembled** Controlled (ordered) particle deposition governed by particle–particle and particle–substrate interaction.

**Sol–gel** Chemical synthesis process in which a sol (often defined as a suspension of small particles or molecules in a liquid phase) undergoes a transition to a gel (a three-dimensional network structure spreading throughout the liquid medium).

## ACKNOWLEDGMENTS

The author thanks many colleagues for stimulating discussions and collaboration, especially Elson Longo, J. A. Varela, Carlos A. Paskocimas, Emersom R. Camargo, Fenelon M. Pontes, N. L. V. Carreño, and Adeilton

P. Maciel. The following Brazilian agencies have provided support for my work: FAPESP, CNPq, and CAPES.

## 1. INTRODUCTION

The interest in nanocrystalline materials comes from the occurrence of a large interface with a surrounding liquid or gaseous medium. A very elementary calculation is helpful here to grasp this importance of size. Any solid matter may be characterized by its molar volume  $M_v$  ( $\text{cm}^3 \text{mol}^{-1}$ ) and its molar surface  $M_s$  ( $\text{cm}^2 \text{mol}^{-1}$ ). For a sphere of radius  $R$ , the number of bulk atoms  $N_v$  should be such that  $N_v \times M_v = N_A (4\pi/3)R^3$ , whereas the number of surface atoms would be given by  $N_s \times M_s = N_A \times 4\pi R^2$  (with  $N_A$  the Avogadro number). Consequently, we may define the atomic surface to volume ratio  $f = N_s/N_v = (3/R) \times (M_v/M_s)$ . As typical values for condensed solid matter would be  $M_v \sim 20 \text{ cm}^3 \text{mol}^{-1}$  and  $M_s \sim 6 \times 10^8 \text{ cm}^2 \text{mol}^{-1}$ , it follows the very simple rule of thumb that  $f \sim 1/R$  (nm). This analysis shows that for  $R = 1$  nm there could exist no core atoms (the nanocrystal is a pure surface as  $f \sim 100\%$ ), while for  $R = 1000$  nm only one atom over 1000 remains accessible. The nanometer range 2–10 nm is thus particularly interesting as in this domain we have enough atoms (at least 50%) into the bulk to insure the existence of some useful mechanical, electrical, optical, magnetic, or chemical property. On the other hand we also have enough atoms (at most 50%) exposed to the outer space, creating an active interface able to deeply modulate the bulk properties. In fact, one may even hope for the appearance of a *new* property. A very nice example is provided by a quite old but very instructive paper

by Gortner concerning the state of water in colloidal and living systems [1]. The author was interested in the difference in mass between a fresh opaque jellyfish (weighting 500 g) and the dried transparent animal (weighting 0.45 g). As the volatile matter at room temperature is water, the conclusion of this simple experience is that the jellyfish was made of 99.9 wt% of water and only 0.1 wt% of solid matter. This solid matter includes all proteins, lipids, carbohydrates, and mineral salts needed to get a living animal. However, just take a glass containing 499.55 g of water and add 0.45 g of a well-dosed amount of organic and inorganic matter. You do not get a living animal, but just an inert more or less stable colloidal solution. Life is here really a *new* property not shared by a glass of water nor by a piece of sugar nor by a drop of oil nor by a chain of amino acids nor by sodium chloride crystals. The key to life apparition in this system is to create a nanosized solid/water interface, where the bulk, the surface, and the solution interact, leading to a system qualitatively different from the sum of its constituents.

This simple example shows that making nanometric sized objects may be quite rewarding. However, in order to remain quite concise we will limit ourselves to the possible mechanisms allowing growing nanocrystalline dispersions and to their stability toward aging and/or aggregation processes. Even if several well-documented reviews already exist covering all these “well-known” aspects, it appears that none take into explicit account the chemical dimension of the problem. This complete absence of chemistry from nucleation, growth, and aggregation equations has the consequence that it is very difficult to establish a causal link between the final equilibrium size of the crystals and the growth conditions. In fact every crystal maker knows that playing with concentration, temperature, pressure, or ionic strength is not enough to fully control crystalline growth. The key to the success of controlled crystal growing lies in the wise use of chemical additives or suitable complexing reagents. It is the aim of this chapter to fully review an often quite old literature and bring to light all the hidden points where chemistry has a role to play. For each important step (nucleation, growth, aging, aggregation) we will put down for the first time a new *analytical* expression, linking the equilibrium final sizes to growth conditions. With these equations in hand crystal

scientists may then understand, on a quantitative basis, why the change in such physical or chemical parameter alters the final equilibrium size.

## 2. NUCLEATION

### 2.1. Physicochemical Parameters

Nanocrystal formation from solutions and gels is ruled by several factors gathered in Figure 1 [2–4]. From the classical nucleation theory (CNT) viewpoint, five parameters are needed to fully characterize the state of the solution. These are the concentration of solute species  $c$  ( $\text{mol l}^{-1}$ ), assumed to bear an electrical charge  $eq$  and moving with diffusion coefficient  $D$ , the dielectric constant of the solvent  $\epsilon$ , and the temperature  $T$ . Recall that for typical molecular solute species we should have a constant value  $D \sim 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ . For the growing solid phase, three parameters may be identified: its solubility  $c_s$  ( $\text{mol l}^{-1}$ ), its density  $\rho$  ( $\text{g cm}^{-3}$ ), or molecular volume  $v = M/\rho N_A$  (with  $M$  molar mass of one structural motif and  $N_A$  the Avogadro number). Notice that another useful way to express the molecular volume is to think to the characteristic molecular size of the structural repeating unit:  $d \sim v^{1/3}$ . For typical binary compounds this value is roughly constant and may be taken approximately equal to  $v \sim d^3 \sim 10^{-28.5} \text{ m}^3$ .

### 2.2. Interfacial Energy

The interfacial energy  $\gamma$  ( $\text{J m}^{-2}$ ) is finally the last critical parameter that remains to be introduced. Its physical meaning is perfectly clear if one refers to the top left diagram of Figure 1. In a growing crystal, two kinds of atoms may be identified. At the bottom, buried inside the core of crystal

are atoms that interact with other similar atoms. The net force acting on these atoms is thus just zero. At the top, exposed to the surface are atoms displaying a clear force unbalance. On one side they are attracted by atoms buried within the bulk of the crystal, but on the other side they are involved in usually much weaker interactions (van der Waals or hydrogen bonds) with solvent molecules. In fact, the highest asymmetric situation is encountered when there is no solvent at all (i.e., crystals are placed under vacuum), leading to a maximum interfacial or surface energy. Consequently, in the presence of a given solvent, this interfacial energy may be strongly reduced. The stronger the interaction with the solvent, the lower the interfacial energy should be. This is just what is expressed by the Gibbs equation:

$$d\gamma = -(\Gamma \times d\mu)_{P,T} \quad (1)$$

Here,  $\Gamma$  stands for the density in adsorption sites (sites  $\text{nm}^{-2}$ ) and  $\mu$  refers to the electrochemical potential of adsorbed species. Table 1 gives some typical values of interfacial energies for aqueous solutions [3, 5–8]. This shows that expected values for this parameter should be in the range  $50 \leq \gamma \leq 400 \text{ mJ m}^{-2}$ . Let us notice that it has been very recently shown that vacuum surface energies may also be derived directly from the knowledge of the crystal structure [9]. In this last study, it was also proved that the surface energy concept remains valid even at a molecular scale.

This last observation is important in a relation with the justified criticism that may be lodged against CNT that assumes constant surface tension for nucleation [10]. The first principles approach in [9] clearly shows that this criticism is not justified. For each crystal, one may define a characteristic vacuum surface energy averaged over a sphere whose value may be fixed (for most simple structures of course) by the relative spatial disposition of less than five atoms!!! Nevertheless, the most serious criticism remains as nucleation is an irreversible process that just cannot be handled by equilibrium thermodynamics. A more correct approach for this review would have then been to use entropy-based nucleation theory [10] instead of CNT. This was, however, not possible as analytical solutions exist only for liquid–vapor interfaces and not for solid–liquid or solid–solid interfaces, the subject of this chapter.

### 2.3. Nucleation Rate $J$

From a macroscopic point of view, the most important quantity governing the final size and number of nanocrystals is the nucleation rate  $J$  (number of nuclei formed per unit volume and per unit time). A detailed analysis of the nucleation phenomenon [6] leads to the following expression for this nucleation rate:

$$J = \frac{D}{v^{5/3}} \times \exp\left(-\frac{\Delta G_N}{kT}\right) \quad (2)$$

In this equation,  $k$  is the Boltzmann constant ( $k \sim 1.38 \times 10^{-23} \text{ JK}^{-1}$ ) and  $\Delta G_N$  is the energetic barrier to nucleation. The value of the pre-exponential factor  $J_0 = J(\Delta G_N = 0) = D/v^{5/3} \sim 10^{32.5} \text{ cm}^{-3} \text{ s}^{-1}$  has a clear physical interpretation. Accordingly, in the absence of any energetic barrier

**Figure 1.** A graphical overview of some factors ruling nucleation, growth, and spinodal decomposition processes. See text for details and explanations.

for incorporation into a crystalline embryo, the limiting step should be the diffusion of the solute species toward the embryo/solution interface. Consequently, the frequency of incorporation  $\nu_{\text{inc}}$  should scale like  $D/d^2$ . This is because the solute species have just to diffuse over an area of size  $d \times d$  to be immediately incorporated (recall that  $v \sim d^3$  and that  $\Delta G_N \sim 0$ ). As the number of structural repeating units per unit volume is just  $1/v \sim 1/d^3$ , the nucleation rate should scale like  $J_0 \sim \nu_{\text{inc}}/v \sim D/d^5 \sim D/v^{5/3}$ , in good agreement with Eq. (2). Obviously,  $J_0 \sim 10^{32.5} \text{ cm}^{-3} \text{ s}^{-1}$  is an incredibly high value and in most cases  $\Delta G_N > 0$ , leading to a strongly reduced value. In fact, from a practical point of view,

nucleation rates can be experimentally measured only when  $1 \leq J \leq 10^{15} \text{ cm}^{-3} \text{ s}^{-1}$ . Consequently, at room temperature, the nucleation barrier  $\Delta G_N$  should be at least  $80 \text{ kJ mol}^{-1}$  and at most  $170 \text{ kJ mol}^{-1}$ .

## 2.4. Thermodynamic Barrier $\Delta G^*$

Two terms are expected to contribute to the nucleation barrier. The first one  $\Delta G^*$  has a thermodynamic origin. It corresponds to the energetic competition existing between reduction of the supersaturation ratio  $S = c/c_s$  when  $S > 1$  and the necessary increase in area  $A$  of the growing solid phase (energetic cost  $\gamma \times A$ ). Identifying activities  $a$  to concentrations  $c$  ( $\mu = kT \times \text{Ln } a \sim kT \times \text{Ln } c$ ), one may write for the transfer of  $n$  moles of solute species from the solution to the crystal

$$\begin{aligned} \Delta G(n_S \rightarrow n_C) &= n \times (\mu_C - \mu_S) + \gamma \times A \\ &\approx \gamma \times A - nkT \times \ln S \end{aligned} \quad (3)$$

The variation of  $\Delta G$  with  $n$  is visualized at the top right corner of Figure 1. If  $\mu_C \sim \mu_S$  (i.e.,  $c \sim c_s$  or  $S \sim 1$ ), the dominant contribution comes from the positive interfacial term (first monotonic curve in Figure 1). On the other hand, when  $S \gg 1$ , the negative chemical contribution insures that a maximum should be reached for a given number  $n^*$  of solute precursors (second curve in Figure 1). According to this analysis, only embryos such that  $n > n^*$  are able to reach a macroscopic size as  $\Delta G < 0$  for the  $n \rightarrow (n + 1)$  addition (growth). For other embryos such as  $n < n^*$  the  $n \rightarrow (n + 1)$  association is characterized by  $\Delta G > 0$ , meaning that such species should dissolve back into the solution. Embryos such that  $n = n^*$  are called critical nuclei, and the corresponding positive  $\Delta G^*$  value defines the first thermodynamic contribution to the nucleation barrier  $\Delta G_N$ . The magnitude of  $\Delta G^*$  may be readily derived under the assumption that embryos undergo no change in shape (only the mean size is changing among similar bodies) during nucleation. Consequently, the ratio  $K = A/V^{2/3}$  should remain invariant, and if the total volume of a given embryo is  $V \sim n \times v$  then the associated area  $A$  may be written  $A = K \times (n \times v)^{2/3}$ . Inserting this value into Eq. (3) and looking for a maximum by setting  $d(\Delta G)/dn = 0$  leads to the following thermodynamic barrier

$$\begin{aligned} \Delta G^* &= \frac{n^*}{2} \times kT \text{Ln } S & n^* &= 2\beta \frac{\gamma^3 v^2}{(kT \text{Ln } S)^3} \\ \beta &= \frac{(A/3)^3}{(V/2)^2} \end{aligned} \quad (4)$$

Table 2 gives the values of the dimensionless shape factor  $\beta$  for some ideal geometries. As evidenced in Eq. (4) the only way to get  $\Delta G^* = 0$  is to have a vanishing interfacial energy. Such a condition ( $\gamma \sim 0$ ) is easily met in polymer chemistry or in metallic alloys, and in this case phase segregation cannot lead to the sharp boundaries characterizing systems with  $\gamma \gg 0$  (bottom left picture in Figure 1). Instead, for this spinodal decomposition scheme, deeply interconnected patterns

**Table 2.** Dimensionless shape factors, for some common regular 3D geometries.

Shape	Area $A$	Volume $V$	$\beta = 4A^3/27V^2$
Sphere	$4\pi a^2$	$\frac{4}{3}\pi a^3$	$\frac{16\phi}{3} = 16.7552$
Regular icosahedron	$5a^2\sqrt{3}$	$\frac{5a^3\phi^2}{6}$	$\frac{16\sqrt{3}}{\phi^4} = 20.2162$
Regular dodecahedron	$\frac{15a^2\sqrt{\phi^3}}{\sqrt{\sqrt{5}}}$	$\frac{a^3\phi^4\sqrt{5}}{2}$	$\frac{80\sqrt{\phi}\sqrt{5}}{\phi^4} = 22.2012$
Regular octahedron	$2a^2\sqrt{3}$	$a^3\frac{\sqrt{2}}{3}$	$16\sqrt{3} = 27.7128$
Cube	$6a^2$	$a^3$	$8 \times 4 = 32$
Parallelepiped $4a \times 2a \times a$	$28a^2$	$8a^3$	$4 \times \left(\frac{7}{3}\right)^3 = 50.8148$
Regular tetrahedron	$a^2\sqrt{3}$	$a^3\frac{\sqrt{2}}{12}$	$32\sqrt{3} = 55.4256$
Rod $10a \times a \times a$	$42a^2$	$10a^3$	$\frac{14^3}{25} = 109.76$
Plate $10a \times 10a \times a$	$240a^2$	$100a^3$	$\frac{4^3}{5} = 204.8$

Note: Shapes are characterized by one size  $a$  and classified by increasing  $\beta$  value. Here  $\phi$  stands for the golden ratio defined as the positive root of the  $x^2 = x + 1$  equation, viz.  $\phi = (1 + \sqrt{5})/2$ .

with rather diffuse boundaries are typically observed (bottom right picture in Figure 1).

## 2.5. Kinetic Barrier $\Delta G'$

As indicated, the thermodynamic barrier  $\Delta G^*$  is not the only contribution to the nucleation barrier  $\Delta G_N$ . Another kinetic barrier  $\Delta G'$  associated with chemical reactions occurring during jumps across the nucleus–solution interface should also be considered. Obviously, for a solid metallic alloy nucleating from a melt one may expect  $\Delta G' \sim 0$  as the system undergoes only a disorder  $\rightarrow$  order phase transition on going from the liquid to the solid state. During this transition local metallic chemical bonds between atoms are not fundamentally changed, explaining the low kinetic cost  $\Delta G' \sim 0$ . Such would not, however, be the case in other systems.

### 2.5.1. Quartz versus Glass

Consider for instance the growth of quartz crystals from a silica melt. Besides the thermodynamic barrier associated with the quartz/fused silica interface and difference in chemical potentials, one has to take into account the fact that the local structure of both phases is very different. In the quartz crystal,  $\text{SiO}_4$  tetrahedra are strongly engaged into spiral chains, whereas in the melt small oligomeric species (which may be chains, cycles, or cages) are encountered. In order to be able to jump across the nucleus/liquid interface and fit inside the crystalline network, oligomeric species must first be reduced to monomeric  $\text{SiO}_4$  tetrahedra. This means that rather strong Si–O–Si bonds have to be broken, and that a corresponding activation energy  $\Delta G' > 0$  has to be provided before nucleation and growth of quartz crystals can occur.

Let us remark that this activation energy  $\Delta G'$  has absolutely nothing to do with thermodynamics as almost the same Si–O–Si bonds are found before (oligomeric species) and after nucleation (spiral chains). This term is a true kinetic barrier inevitably associated with any kind of reconstructive transformation [11]. Accordingly, glass formation is intimately linked to the existence of a large kinetic barrier  $\Delta G'$  which renders the cost of nucleation quite prohibitive just because  $\Delta G_N = \Delta G^* + \Delta G'$ . If  $\Delta G^*$  were the only contribution to nucleation, glasses would never be formed and should not exist.

### 2.5.2. Sodium Chloride: A Case Study

The same kind of kinetic barrier  $\Delta G'$  is expected when crystallization occurs from solutions or gels. First consider the simplest case: nucleation of a crystalline salt (NaCl for instance) from an aqueous solution. In solution we find ionic species such as  $[\text{Na}(\text{OH}_2)_x]^+$  and  $[\text{Cl}(\text{H}_2\text{O})_x]^-$ . The precise value of the coordination number  $x$  does not matter here as it depends on the molar fraction of sodium chloride. Consequently, variation in  $x$  is well reflected by variation of the chemical potential  $\mu_s$  and should influence only the thermodynamic term  $\Delta G^*$ . Our point of interest is rather how such solute species should be transformed in order to allow them to jump across the NaCl/water interface for further incorporation into the NaCl crystalline network. As this crystal is built from a regular stacking of naked  $\text{Na}^+$  and  $\text{Cl}^-$  ions, it is clear that ion pairing should be the very first step:  $[\text{Na}(\text{OH}_2)_x]^+ + [\text{Cl}(\text{H}_2\text{O})_x]^- \rightarrow [\text{NaCl}(\text{OH}_2)_{2x}]$ . Having formed a neutral species, water removal may then occur:  $[\text{NaCl}(\text{OH}_2)_{2x}] \rightarrow [\text{NaCl}]^0 + 2x \text{H}_2\text{O}$ , and only after that incorporation into the network becomes possible. The origin of the kinetic barrier  $\Delta G'$  lies here in the lability of water molecules around cations and anions.

### 2.5.3. Aquo Cations

For the NaCl case, it is obvious that the lability around  $\text{Na}^+$  or  $\text{Cl}^-$  ions is rather high (Fig. 2), meaning that  $\Delta G' \sim 0$ . But this clearly would not be the case for more charged cations, as it is well known that the kinetics of water splitting,  $[\text{M}(\text{OH}_2)_N]^{z+} \rightarrow [\text{M}(\text{OH}_2)_{N-1}]^{z+} + \text{H}_2\text{O}$ , is considerably slowed down if  $z$  increases or if the ionic radius of the metallic element decreases [12]. Also, for some transition metal elements such as  $\text{Cr}^{3+}$ , crystal field stabilization energies may be so high (leading to  $\Delta G' \gg 0$ ) that nucleation of the corresponding hydroxide  $\text{Cr}(\text{OH})_3$  cannot occur anymore. In such a case, gelation (the equivalent for solutions of glass formation from melts) instead of precipitation is usually observed. Figure 2 shows how the kinetic constant  $k_w$  characterizing the removal of aquo ligand from the metal coordination sphere varies for usual ionic species. It was found that, at room temperature, it lies above  $10^{-6} \text{ s}^{-1}$  ( $\text{V}^{2+}$  or  $\text{Cr}^{3+}$  ions) and below  $10^{10} \text{ s}^{-1}$  ( $\text{Ba}^{2+}$  or  $\text{Cs}^+$  cations) [12, 13].

Now, if  $h$  stands for the Planck constant, the activated complex kinetic theory says that the rate constant may be written  $k_w = (kT/h) \times \exp(-\Delta G_0/kT)$  or for  $T = 300 \text{ K}$  ( $\Delta G_0/\text{kJ mol}^{-1} = 73 - 5.71 \times \log(k_w/\text{s}^{-1})$ ). Consequently, assuming that  $\Delta G' \sim G_0$ , the kinetic barrier for nucleation of a metallic salt or hydroxide should be in the range

**Figure 2.** Chemical origin of the kinetic barrier  $\Delta G'$  for oxide, hydroxide, or metallic salt nucleation. Top left: type of ligand expected around a metallic cation  $M^{z+}$  in aqueous solutions as a function of pH. Top right: chemical bonds rearrangements expected for oxy ions or metal alkoxides in the case of oxide nucleation. Bottom: techniques used for measuring lability of water molecules around metallic cations  $M^{z+}$  ( $z \leq 3$ , i.e., hydroxide or metallic salt nucleation).

$15 < \Delta G' < 110 \text{ kJ mol}^{-1}$ , depending on the electronic configuration, ionic radius, or total charge of the metallic cation.

### 2.5.4. Oxo Anions

Obviously this picture can be valid only for metallic cations having a low formal oxidation state (typically  $z \leq 3$ ) allowing them to keep the aquo ligand within their coordination sphere. As shown in Figure 2, cations displaying higher formal oxidation states  $z$  are on the contrary extensively hydrolyzed in aqueous solutions. These cations should then lead to oxide rather hydroxide precipitation [14].

Silicon ( $z = +4$ ) is a good example of this behavior, as it is found under low pH conditions under the silanol form  $\text{Si}(\text{OH})_4$ . As this form does not display any aquo ligand in its coordination sphere, a considerable rearrangement of chemical bonds is necessary (Fig. 2) in order to incorporate it in a network based on corner-sharing  $\text{SiO}_4$  tetrahedra (Si–O–Si bridges). However, as a proton transfer is needed in the transition state to form a good leaving group (water), the kinetics of condensation is expected to depend strongly on the solution pH. Accordingly, experiments [15] shows that the kinetic constants for silanol condensation vary from  $10^{1.8} \text{ M}^{-2} \text{ s}^{-1}$  at  $\text{pH} \sim 7$  up to  $10^{3.4} \text{ M}^{-2} \text{ s}^{-1}$  at  $\text{pH} \sim 10$ . Proceeding as before, this corresponds to a kinetic barrier  $50 \text{ kJ mol}^{-1} < \Delta G' < 70 \text{ kJ mol}^{-1}$ . Another possibility of estimating this kinetic barrier  $\Delta G'$  for nucleation from aqua and oxo ions is to use  $^{18}\text{O}$  exchange studies [16]

### 2.5.5. Metal Alkoxides

The same kinetic barrier is encountered when the nanocrystal nucleates after decomposition of metallo-organic complexes in nonaqueous media. Figure 2 shows that, at least in the case of metallic alkoxides precursors, a considerable rearrangement of chemical bonds should also occur. As before, with hydrolysis of the metal alkoxide requiring a proton transfer, the kinetics depends strongly on the amount of acid or base added with the water. As shown in Table 3 for silicon alkoxides [17–22], the height of the kinetic barrier  $\Delta G'$  is at least  $90 \text{ kJ mol}^{-1}$  explaining the difficulty to nucleate quartz directly from the solution at room temperature. Unfortunately, there is a paucity of kinetic data for other metallic cations. To the best of our knowledge, only a global kinetic constant  $k \sim 30 \text{ s}^{-1}$  is available concerning the nucleation of titanium or aluminum oxides from  $\text{Ti}(\text{OEt})_4$  and  $\text{Al}(\text{O}i\text{Bu})_3$  respectively [23]. This would mean that octahedral species may have significantly lower kinetic barriers ( $\Delta G' \sim 65 \text{ kJ mol}^{-1}$ ) relative to tetrahedral silicate species.

## 2.6. Applications

After this rapid outline of the classical nucleation theory, we may take time to see some typical examples, the relative orders of magnitude of the two kinetic barriers  $\Delta G^*$  and  $\Delta G'$ .

### 2.6.1. Ionic Crystals

Consider first the case of a simple crystalline salt such as KCl for instance ( $M = 74.55 \text{ g mol}^{-1}$ ,  $\rho = 1.984 \text{ g cm}^{-3}$ , i.e.,  $v = 10^{-28.2} \text{ m}^3$ ). Referring to Figure 2, the characteristic residence time of water molecules around the potassium cation is  $\tau < 10^{-10} \text{ s}$ . Consequently we may suppose that  $\Delta G' \leq 16 \text{ kJ mol}^{-1}$ . A look at Table 1 shows that for the KCl/ $\text{H}_2\text{O}$  interface we have  $\gamma \sim 30 \text{ mJ m}^{-2}$ . Consequently, at  $T = 300 \text{ K}$  ( $kT = 4.1 \times 10^{-21} \text{ J}$ , or  $RT = 2.48 \text{ kJ mol}^{-1}$ ), we may write

$$n^* = 0.25 \frac{\beta}{(\log S)^3} \quad \text{and} \quad \Delta G^* = 0.714 \frac{\beta}{(\log S)^2} \text{ kJ mol}^{-1} \quad (5)$$

Owing to its cubic structure one may further assume a cube-shaped nucleus ( $\beta = 32$ ); that is,  $n^* = 8/(\log S)^3$  and

**Table 3.** Measured rate constants and associated kinetic barrier  $\Delta G'$  for the chemical reaction  $(\text{RO})_3\text{Si-OX} + \text{HOY} \rightarrow (\text{RO})_3\text{SiOY} + \text{HOX}$ .

$X(R)$	$Y$	Rate constant	pH	$\Delta G'$ ( $\text{kJ mol}^{-1}$ )	Ref.
$\text{CH}_3$	H	$10^{-5.5} \text{ M}^{-1} \text{ s}^{-1}$	5.5	104	[17]
$\text{C}_2\text{H}_5$	H	$10^{-1.3} \text{ M}^{-1} \text{ s}^{-1} [\text{H}^+]^{-1}$	7–2	120–92	[18]
$\text{C}_4\text{H}_9$	H	$10^{-1.7} \text{ M}^{-1} \text{ s}^{-1} [\text{H}^+]^{-1}$	7–2	123–94	[19]
$\text{C}_6\text{H}_{13}$	H	$10^{-2.1} \text{ M}^{-1} \text{ s}^{-1} [\text{H}^+]^{-1}$	7–2	125–96	[19]
H(Me)	Si	$10^{-4} \text{ M}^{-1} \text{ s}^{-1}$		96	[20]
H(Me)	Si	$10^{-2.1} \text{ M}^{-1} \text{ s}^{-1}$	5.5	85	[17]
$\text{CH}_3$	Si	$10^{-4.8} \text{ M}^{-1} \text{ s}^{-1}$		100	[20]
H(Me)	$\text{Si}_2$	$10^{-4.7} \text{ M}^{-1} \text{ s}^{-1}$	2.8	100	[21]
$\text{CH}_3$	$\text{Si}_2$	$10^{-4.9} \text{ M}^{-1} \text{ s}^{-1}$	2.8	101	[21]
$\text{C}_2\text{H}_5$	H	$10^{-4.2} \text{ M}^{-1} \text{ s}^{-1}$	3.1	97	[22]
H(Et)	Si	$10^{-5.3} \text{ M}^{-1} \text{ s}^{-1}$	3.1	103	[22]

Note:  $Y = \text{Si}_2$  refers to the  $(\text{RO})_3\text{SiOSi}(\text{OH})(\text{OR})_2$  dimer.

$\Delta G^* = (22.8 \text{ kJ mol}^{-1})/(\log S)^2$ . Now for  $S = 2$  (two times the solubility of KCl,  $c_s \sim 34.7 \text{ wt}\%$  at  $20^\circ \text{C}$ ), it transpires that about 300 KCl pairs have to meet together, forming a sphere of radius  $r^* \sim (n^*v)^{1/3} \sim 26 \text{ \AA}$ , in order to nucleate the KCl network. The very low probability of such an event is easily understood by looking at the nucleation rate  $J$ . With  $\Delta G^* = 252 \text{ kJ mol}^{-1}$  and making the conservative choice  $\Delta G' = 16 \text{ kJ mol}^{-1}$ , it comes that  $\Delta G_N = 268 \text{ kJ mol}^{-1}$  leading to  $J = 10^{32} \times \exp(-268/2.48) \sim 10^{-15}$  nuclei per  $\text{cm}^3$  and per second. Another statement of this matter of fact is to say that in order to see one such nucleus appear in  $1 \text{ cm}^3$  of solution, one has to wait about 32 Myr!!! Let us now see what would happen by just doubling the supersaturation ratio  $S$ . Now, with  $S = 4$  the same equations tell us that  $n^* = 37$  (critical nucleus with radius  $\sim 13 \text{ \AA}$ ). If the thermodynamic barrier is still dominant, it has nevertheless been reduced down to  $\Delta G^* = 63 \text{ kJ mol}^{-1}$ . The new barrier to nucleation is thus  $\Delta G_N = 79 \text{ kJ mol}^{-1}$  leading to  $J = 10^{32} \times \exp(-79/2.48) \sim 10^{18} \text{ cm}^{-3} \text{ s}^{-1}$ . Consequently, instead of waiting a virtual eternity to see just one nanocrystal, everything is finished (i.e.,  $c \sim c_s$  corresponding to about  $10^{22}$  nanocrystals with radius  $13 \text{ \AA}$ ) in about 8400 s or less than 3 hours.

### 2.6.2. Critical Supersaturation Ratio $S^*$

This example clearly demonstrates that nucleation is basically a critical phenomenon, as a mere doubling of one parameter  $S$  leads to a variation in  $J$  of about 33 orders of magnitude. These considerations are shown graphically at the bottom of Figure 1 (two middle diagrams). Below a critical value  $S^*$ , nothing can happen, while slightly just above this threshold, the nucleation rate displays a very fast divergence (middle left diagram). The main consequence of this burst of nuclei is that the supersaturation is strongly and rapidly reduced and may instantaneously become smaller than  $S^*$  (middle right diagram). This condition is usually met in moderately dilute solutions leading to just one burst of nuclei. Further removal of the remaining supersaturation would only be removed by growth processes (*vide infra*). This is the classical picture for the formation of monodisperse nanocrystals under homogeneous nucleation conditions [24, 25]. On the contrary, for strongly concentrated solutions, the first birth of nuclei is not able to reduce the supersaturation ratio below  $S^*$ , meaning that  $J > 0$  during all the precipitation process. Under such circumstances, a polydispersed system is usually obtained and aggregation phenomena may become competitive for determining the final particle size or shape. From a practical viewpoint, the critical supersaturation ratio  $S^*$  may be defined as the value of  $S$  leading to  $J = 1$  or  $\log J = 0$  [26]

$$\text{Ln } S^* = \sqrt{\frac{\beta\gamma^3 v^2}{(kT)^3 \text{Ln}[(Dv^{-5/3}g_N)/1]}} \quad (6)$$

### 2.6.3. Silica

This example also illustrates the crucial role played by the kinetic barrier  $\Delta G'$ . It is just because the thermodynamic term is dominant and the kinetic one negligible that it is so difficult to keep control over the nucleation

rate. To see that, let us consider the nucleation of silica  $\text{SiO}_2 \cdot 2\text{H}_2\text{O}$  ( $M = 78.08 \text{ g mol}^{-1}$ ,  $\rho = 2.2 \text{ g cm}^{-3}$ , i.e.,  $v = 10^{-28.2} \text{ m}^3$  and  $\gamma \sim 45 \text{ mJ m}^{-2}$ ) [8, 27]. For nuclei displaying spherical shapes, we may write  $n^* = 14/(\log S)^3$  and  $\Delta G^* = (40 \text{ kJ mol}^{-1})/(\log S)^2$ . Now, let us choose  $\Delta G' \sim 100 \text{ kJ mol}^{-1}$  as a typical value characterizing the interfacial oxolation reaction (see Table 3):  $\text{Si-OH} + \text{HO-Si} \rightarrow \text{Si-O-Si} + \text{H}_2\text{O}$ . This choice then leads to  $\Delta G_N \sim 540 \text{ kJ mol}^{-1}$  for  $S = 2$  and  $\Delta G_N \sim 210 \text{ kJ mol}^{-1}$  for  $S = 4$ . Converting these values into nucleation rates according to  $J(\text{cm}^{-3} \text{ s}^{-1}) = 10^{32} \times \exp[-\Delta G_N(\text{kJ mol}^{-1})/2.48]$  leads to  $J \sim 3 \times 10^{-63} \text{ cm}^{-3} \text{ s}^{-1}$  ( $S = 2$ ) and for  $S = 4$ , to only  $J \sim 2 \times 10^{-5} \text{ cm}^{-3} \text{ s}^{-1}$ . Consequently, doubling the supersaturation ratio as before has here no practical consequences, as the nucleation rate remains quite negligible (about 1 nucleus per  $\text{cm}^3$  after one day). Notice that even for  $S = 10$  (10 times the solubility of amorphous silica, or  $c[\text{Si}(\text{OH})_4] \sim 10^{-2} \text{ M}$ ) the nucleation rate is only  $J \sim 3 \times 10^7 \text{ cm}^{-3} \text{ s}^{-1}$ , a perfectly measurable value. The presence of a reasonable kinetic barrier then provides an efficient healing mechanism against the otherwise pathological behavior of the nucleation rate versus supersaturation variation. For oxide or hydroxide precipitation, the kinetic term is provided by the inertness of the metallic cation toward water substitution. It is thus possible to control the nucleation process under dilute conditions through thermal hydrolysis for instance [28].

### 2.6.4. Metallic Salts

For metallic salts (such as carbonates, sulfates, or phosphates for instance) the kinetic barrier should be provided by the slow decomposition of a suitable preformed metallic complex [29]. Only in this case do we get a chance to keep some control over the nucleation process. Among the numerous chemical methods available to control the nucleation stage for sparingly soluble substances, we may cite [29–34]:

- (i) Variation of pH induced by temperature elevation (thermal solvolysis) is a method well suited for acidic media. In order to generate basic conditions a suitable organic reagent able to decompose into ammonia (urea, hexamethylene tetramine) upon heating should be added.
- (ii) Some anions such as  $[\text{CO}_3]^{2-}$ ,  $[\text{C}_2\text{O}_4]^{2-}$ ,  $[\text{SO}_4]^{2-}$ ,  $[\text{PO}_4]^{3-}$  or  $\text{S}^{2-}$  may also be generated *in-situ* after decomposition of various esters or amides.
- (iii) Metallic cations may be masked by formation of a suitable complex that may be carefully destroyed through pH changes or through exchange with another complex.
- (iv) The use of mixed solvents with one volatile component is another useful strategy. Upon aging or heating the volatile species will be evaporated inducing controlled precipitation.
- (v) For transition metals displaying several oxidation states, one may add a reducing reagent for high-valency forms or an oxidizing one for low-valency forms.
- (vi) Finally, if the temperature of the medium cannot be changed, the possibility remains to use a light sensitive molecule that should release one of the

nucleating species upon irradiation with ultraviolet-visible light or even  $\gamma$ -rays.

## 2.7. Heterogeneous Nucleation

It is a well known experimental fact that nucleation from a vapor, melt, or solution is affected considerably by traces of impurities in the system. Indeed, some authors even say that true examples of homogeneous nucleation in the condensed state should be indeed very rare [26]. One may then wonder about the practical utility of this treatment. In fact, it has been shown [35] that if  $R$  is the radius of the foreign nucleating particle and if  $\theta$  stands for the contact angle with the foreign surface, then  $\Delta G^*$  (hetero) =  $\Delta G^*$  (homo)  $\times \Phi(\cos \theta, R/r^*)$  with  $\Phi \sim 1$  when  $R < 10$  nm or when  $\theta = 180^\circ$ . Above 100 nm  $\Phi$  becomes independent of  $R$  (with  $\Phi < 1$ ) leading to [26]

$$R \rightarrow \infty \implies \Delta G_H^* = \Delta G^* \times \left( \frac{2 - 3\cos\theta + \cos^3\theta}{4} \right) \quad (7)$$

$$r^* = \frac{2\gamma v}{kT \ln S} \sin \frac{\theta}{2}$$

The important point is that due to the existence of a kinetic barrier  $\Delta G'$ , homogeneous nucleation is already governed by a sticking probability  $g_N = \exp(-\Delta G'/kT)$

$$J \sim Dv^{-5/3} g_N \times \exp(-\Delta G^*/kT) \quad (8)$$

Now as we know that  $0 \leq \Phi \leq 1$  we may rewrite (7) as  $\Delta G^*$  (hetero) =  $\delta G^*$  (homo) -  $E(\cos \theta, R/r^*)$ , with  $E$  the energetic correction that should be applied and such that  $E = 0$  if  $R = 0$  or  $\theta = 180^\circ$ . As far as the nucleation rate is concerned, we then just have to define a modified sticking probability  $g_H = \exp[(E - \Delta G')/kT]$  showing that only the pre-exponential term is affected. These two terms  $g_N$  and  $g_H$  could then help to understand the considerable spreading of the measured kinetic constant  $J_0 = J(\Delta G^* = 0)$  observed in literature ( $10 \leq J_0 \leq 10^{32} \text{ cm}^{-3} \text{ s}^{-1}$ ) [26]. Obviously, this spreading is no more surprising in view of the earlier analysis but just reflects the importance of the competition between the kinetic barrier  $\Delta G'$  and the heterogeneous activation  $E$ . For this chapter, we will still use (8) as the correct expression for the nucleation rate. However, the  $g_N$  term should be interpreted as a nucleation probability whose value depends on at least three physicochemical parameters:  $\Delta G'$ ,  $\cos \theta$ , and  $R$ . With this new interpretation of the kinetic constant  $J_0$ , the exact nature of the nucleating event (either homogeneous or heterogeneous) becomes immaterial as soon as  $g_N$  reflects the exact physicochemical state of the solution.

## 3. CRYSTALLINE GROWTH

### 3.1. Competitive Growth

Ideally, it is desirable that the nucleation stage should be the whole story of nanocrystal formation from solutions and gels. From a practical point of view, one has then to ensure that other stages such as growth, Ostwald ripening, or aggregation should be avoided. In the following, we will try to understand how this should be possible by studying the

various mechanisms of these competing processes. Kinetically speaking, the dominant process just after nucleation has occurred should be crystal growth. Accordingly, Ostwald ripening is ruled by the Ostwald-Freundlich equation for two spheres with radii ( $a_1, a_2$ ) characterized by their solubility ( $c_1$  and  $c_2$  respectively) [36]

$$kT \times \ln \frac{c_1}{c_2} = 2v\gamma \left( \frac{1}{a_1} - \frac{1}{a_2} \right) \quad (9)$$

It is then expected to become important only when  $a_2 \gg a_1$  in order to have  $c_1 \gg c_2$  (disappearance of small crystals and growth of larger ones). On the other hand, aggregation implies that nuclei have to move through diffusion in order to meet together. According to the Einstein equation  $D = kT/(6\pi\eta a)$ ,  $D$  should be, for a given solution viscosity  $\eta$ , smaller for a nuclei displaying a size  $a$  much larger than that of active solute species for crystal growth. In the following, we consider a solution containing  $N$  nanocrystals per unit volume, all built from incorporation of  $n(t)$  solute species. As  $n$  is changing with time, this means that some characteristic linear size  $r(t)$  increases with time according to a given growth law  $dr(t)/dt = f(c, r)$ . Writing the volume  $V$  of each nanocrystal as  $V = \omega \times r^3$ , where  $\omega$  is a shape factor ( $\omega = 4\pi/3$  for spheres,  $\omega = 8$  for cubes, etc.) means that  $n(t) = \omega \times [r(t)]^3/v$ . According to literature [3, 5], four main mechanisms may be recognized for crystalline growth (see Fig. 1).

### 3.2. Diffusion Controlled Growth

In this first mechanism, each partner is characterized by a linear size [ $r_m$  for solute species and  $r(t)$  for nanocrystals] and a diffusion coefficient ( $D$  for solute species and  $D_r$  for nanocrystals). If the solute species can be incorporated into the crystalline network immediately after sticking to a crystal, the limiting step should be diffusion of solute species toward the solid/liquid interface.

#### 3.2.1. Growth Law

Let  $d\Omega$  be the solid angle spanning the direction in which a sticking event has been observed. The rate for mass increase of the nanocrystals may be written  $d^2n/dt d\Omega = k \times (c - c_s)$  with  $k$  a kinetic constant which may be approximated by  $k \sim (D_r + D)(r + r_m)$ . As  $D_r \ll D$  and  $r \gg r_m$ , it comes  $k \sim D \times r$ , or after integration over all the possible sticking directions:  $dn/dt = 4\pi D(c - c_s)r$ . But as  $n(t) = (\omega \times r^3/v)$ , we should also have  $dn/dt = (3\omega \times r^2/v) \times (dr/dt)$ . The final growth law for pure diffusion may thus be written

$$\frac{dr}{dt} = \left( \frac{4\pi}{3\omega} \right) \frac{Dv(c - c_s)}{r} \iff \frac{dr^2}{dt} = \left( \frac{4\pi}{3\omega} \right) Dv(c - c_s) \quad (10)$$

An interesting point is that irrespective of the original size  $r_0$  at nucleation time ( $t = 0$ ) and provided that  $c \sim c_0$ , then the square of the radius of all particles increases at the same rate [37]. Consequently, calling the absolute width of the distribution  $\Delta r$  for radius  $r$  and  $\Delta r_0$  for radius  $r_0$ , we have  $r \times \Delta r \sim r_0 \times \Delta r_0$ . This means that the absolute width of the distribution becomes narrower with time ( $\Delta r \sim [r_0/r] \times \Delta r_0$ ) while the relative width will decrease even faster ( $\Delta r/r \sim [r_0/r]^2 \times [\Delta r_0/r_0]$ ).

### 3.2.2. Chronomals

From a practical point of view, one way to decide if such a rate law applies is to measure how the concentration in solute species  $c(t)$  changes with time. Knowing  $c(t)$  and the initial concentration  $c_0$ , one may write for spherical shapes ( $\omega = 4\pi/3$ )  $c(t) = c_0 - N \times (4\pi r^3/3v)$  and compute the following quantity

$$x_D = \frac{c_0 - c_t}{c_0 - c_s} \iff r = r_e \sqrt[3]{x_D} \quad (11)$$

Here  $r_e$  is the equilibrium size of the nanocrystals given by  $c_s = c_0 - N \times (4\pi r_e^3/3v)$ . Inserting (11) into (10) then leads to the characteristic  $t = K_D I_D$  law [5] with  $K_D = r_e^2/[3Dv(c_0 - c_s)]$  and

$$I_D = \int_0^{x_D} \frac{dx}{(1-x)\sqrt[3]{x}} = \frac{1}{2} \text{Ln} \frac{1-x_D}{(1-\sqrt[3]{x_D})^3} - \sqrt{3} \tan^{-1} \frac{\sqrt{3}}{2+x_D^{-1/3}} \quad (12)$$

A decisive test (named chronomal analysis) for validating this mechanism would be to observe a straight line for an  $I_D = f(t)$  plot leading to a diffusion coefficient  $D$  (computed from the observed slope  $K_D$ ) close to  $10^{-5} \text{ cm}^2 \text{ s}^{-1}$ . Also notice that for crystals large enough the growth rate through diffusion may be increased by convection according to

$$\frac{dr}{dt} = F \frac{Dv(c - c_s)}{r} \quad (13)$$

Here  $F$  is a complex hydrodynamic factor function of the solution viscosity [3].

### 3.2.3. Characteristic Time

Besides knowing the growth law, one may also be interested in relating the final equilibrium size  $r_e$  to initial concentration in solution  $c_0$ . Let  $t_D$  be the characteristic time below which the condition  $S > S^*$  remains satisfied. In this time domain  $J > 0$  and if the initial concentration is high enough, we are allowed to write  $J(c) \sim J(c_0)$ . When the condition  $S < S^*$  is reached due to solute species consumption during nucleation and growth ( $t > t_D$ ), one should expect that  $J$  drops suddenly from  $J(c_0)$  down to zero. Further matter consumption should then be attributed to crystalline growth only. Now, from the growth law, we know that a nanocrystal nucleated at time  $\tau$  has reached, at time  $t$ , a size

$$r(\tau, t) = \int_{\tau}^t f(c_\theta, r_\theta) \times d\theta \quad (\tau \leq \theta \leq t) \quad (14)$$

Consequently, the concentration in solute species at time  $t$  should be given by

$$c_t = c_0 - \frac{\omega}{v} \int_0^t J(c_\tau) [r(\tau, t)]^3 d\tau \\ \implies v(c_0 - c_t) \approx \omega \int_0^t J(c_0) [r(\tau, t)]^3 d\tau \quad (15)$$

For diffusion growth, the magnitude of  $t_D$  may be evaluated from (10) and (14) by setting  $c_\theta \sim c_0$ , leading to

$$r(\tau, t) = \sqrt{\frac{8\pi Dv c_0}{3\omega}} (t - \tau)^{1/2} \\ \implies v(c_0 - c_t) \approx \left[ \frac{2\omega J(c_0)}{5} \right] \times \left( \frac{8\pi Dv c_0}{3\omega} \right)^{3/2} \times t^{5/2} \quad (16)$$

This shows that concentration of solute species decreases with time according  $c_t = c_0 [1 - (t/t_D)^{5/2}]$  with  $t_D$  given by

$$t_D \approx \left[ \left( \frac{3}{8\pi} \right)^3 \times \left( \frac{5}{2} \right)^2 \right]^{1/5} \left( \frac{\omega}{v c_0} \right)^{1/5} \times \frac{1}{J(c_0)^{2/5} D^{3/5}} \\ \approx \frac{2}{5} \left( \frac{\omega}{v c_0} \right)^{1/5} \times \frac{1}{J_0^{2/5} D^{3/5}} \quad (17)$$

### 3.2.4. Equilibrium Size

The next problem is now to compute the total number of particles  $N \approx \int_0^{t_D} J \times dt$  formed during time  $t_D$ . To do this, one may notice that from (8) and (4) that if  $n^*$  changes slowly with time

$$\frac{\partial \text{Ln } J}{\partial \text{Ln } c} = 2\beta \frac{\gamma^3 v^2}{(kT \text{Ln } S)^3} = n^* \implies J \approx J(c_0) \left( \frac{c}{c_0} \right)^{n^*} \quad (18)$$

Thus, for the particular case of diffusion growth

$$c = c_0 \left[ 1 - \left( \frac{t}{t_D} \right)^{5/2} \right] \implies N \approx J(c_0) t_D f(n^*)$$

$$f(n^*) = \int_0^1 (1 - x^{5/2})^{n^*} dx = \prod_{k=1}^{n^*} \left[ \frac{k}{(k + 2/5)} \right] \quad (19)$$

Then, from the mass conservation law  $N\omega \langle r_e \rangle^3 = (c_0 - c_s)v \sim c_0 v$ , it becomes possible to get an analytical expression linking the average equilibrium size  $\langle r_e \rangle$  of the nanocrystals to the solid phase and solution properties

$$\langle r_e \rangle^3 \approx \frac{v c_0}{\omega N} = \left[ \frac{1}{\omega f(n^*)} \right] \left( \frac{94}{\omega} \right)^{1/5} v^{11/5} c_0^{6/5} g_N^{-3/5} \\ \times \exp \left( \frac{3\beta \gamma^3 v^2}{5(kT)^3 (\text{Ln } S_0)^2} \right) \quad (20)$$

Figure 3 shows the typical variation of  $\langle r_e \rangle$  with concentration in solute species  $c$  for several values of the dimensionless nucleation constant  $\sigma_N = \beta \gamma^3 v^2 / (kT \text{Ln } 10)^3$ . This fundamental curve shows that when  $\sigma_N$  is low,  $\langle r_e \rangle$  remains roughly constant above  $S = 10$ , with typical sizes close to 1 nm. On the other hand, when  $\sigma_N$  is high, nanocrystals with typical sizes close to 10 nm can be formed from concentrated solutions. In all cases, there is a critical concentration domain where average size suddenly drops from the millimetric range down to the nanoscopic one. One may also notice that for given physical conditions (sursaturation ratio  $S$  and nucleation constant  $\sigma_N$  kept constant), chemistry can still play a determinant role on particle size through the sticking probability term (or kinetic barrier)  $g_N$ . As seen in (20), decreasing the sticking probability (i.e., increasing the kinetic barrier) should lead to larger nanocrystals.

**Figure 3.** Crystalline growth controlled by diffusion. Boxed curve shows the shape of the chronomal function  $I_D$  given by Eq. (9). Other decreasing curves were plotted according to Eq. (20) assuming a spherical shape ( $\omega = 4\pi/3, \beta = 4\omega$ ) with  $\langle f(n^*) \rangle = 1/3$  for six typical values of the nucleation constant  $\sigma_N = \beta\gamma^3 v^2 / (kT \text{Ln } 10)^3$  leading to  $\log r_c = (1/3) \log(18v^{11/5}/4\pi) + (6/15) \log c - (1/5) \log g_N + \sigma_N / [5(\log c/c_s)^2]$ . Other parameters were  $v = 10^{-28.5} \text{ m}^{-3}$ ,  $c_s = 10^{22} \text{ m}^{-3}$ , and  $g = \exp(-\Delta G'/kT) = 10^{-5}$ . The key point is the final nanometer size of the crystal when precipitation occurs in concentrated solutions.

### 3.3. Interface-Limited Growth

One has to remember that (20) applies only when diffusion in solution is the rate limiting step for crystalline growth. Physically, this means that if a sticking probability exists for nucleation ( $g_N \ll 1$ ), the corresponding growth sticking probability  $g_C$  should be close to unity. Obviously, systems satisfying simultaneously these two conditions are not very common, and in most experimental situations if  $g_N \ll 1$ , then  $g_C \ll 1$  too. Consequently, we must look for a possible generalization of (20) in order to be able to cover the widest range of chemical systems.

#### 3.3.1. Surface Nucleation Rate

In this mechanism it is supposed that in order to form a new layer, solute species have to be adsorbed onto the crystal surface and make, through surface diffusion, a critical two-dimensional nucleus. As some chemical reactions must occur to lead to this new 2D nucleus, bulk diffusion in the solution cannot be the rate-determining step. As before, one may define a surface nucleation rate  $J' \sim Dv^{-4/3} \times \exp(-\Delta G_c/kT)$  with  $\Delta G_c = \Delta G'^* + \Delta G''$ . Here, the pre-exponential factor has been written by taking into account that for  $\Delta G_c \sim 0$ , the surface nucleation rate may be approximated by  $J' \sim (1/d^2) \times v_{\text{inc}} = Dv^{-4/3} \sim 10^{25} \text{ cm}^{-2} \text{ s}^{-1}$ . Concerning the thermodynamic barrier  $\Delta G'^*$ , the prime symbol is a reminder for the fact that we are now treating a two-dimensional (2D) problem instead of a 3D one. Similarly, the double prime symbol refers to the kinetic barrier associated with all chemical reactions needed to transfer a structural motif from the surface into the crystalline lattice.

#### 3.3.2. Thermodynamic $\Delta G'^*$ and Kinetic Barrier $\Delta G''$

At first sight, one may think that as the solute species responsible for crystalline growth are the same as those responsible for bulk nucleation, one should have  $\Delta G'' \sim \Delta G'$ . In fact, this cannot be true. For bulk nucleation a crystal/solution interface first has to be created in order to initiate crystalline growth. For interface-limited growth, the solid interface is already there and by its mere presence may catalyze or inhibit the incorporation of the solute species inside the crystalline network. Consequently, in the most general case  $\Delta G'' \neq \Delta G'$ , the equality being realized only in the case of a completely neutral crystalline interface. As before, we should define  $g_C = \exp(-\Delta G''/kT)$  as the growth sticking probability. Concerning the associated thermodynamic barrier to surface nucleation, it should depend on a frontier energy  $\gamma' = (\partial G/\partial L)_{p,T}$  ( $\text{mJ m}^{-1}$ ) similar to the surface energy concept  $\gamma = (\partial G/\partial A)_{p,T}$  ( $\text{mJ m}^{-2}$ ). In order to simplify the problem we will assume that  $\gamma' \sim \gamma d = \gamma v^{1/3}$ . With this simplification the free energy variation for incorporation of  $m$  moles of surface species inside the crystal may be written

$$\begin{aligned} \Delta G_S(m_S \rightarrow m_C) &= m \times (\mu_C - \mu_S) + \gamma' \times L \\ &\approx \gamma' \times L - mkT \times \text{Ln } S \end{aligned} \quad (21)$$

As for 3D nucleation, the magnitude of  $\Delta G'^*$  may be readily derived under the assumption that surface embryos undergo no change in shape (only the mean size is changing among similar bodies) during surface nucleation. Consequently, the ratio  $K' = L/A^{1/2}$  should remain invariant, and if the total area of a given embryo is  $A \sim m \times a$  then its frontier  $L$  may be written  $L = K' \times (m)^{1/2} \times v^{1/3}$ . Inserting this value into Eq. (21) and looking for a maximum by setting  $d(\Delta G_S)/dm = 0$  leads to the following thermodynamic barrier

$$\Delta G'^* = m^* \times kT \text{Ln } S \quad m^* = \beta' \frac{\gamma^2 v^{4/3}}{(kT \text{Ln } S)^2} \quad \beta' = \frac{L^2}{4A} \quad (22)$$

Table 4 gives the values of the dimensionless shape factor  $\beta'$  for some ideal 2D geometries.

**Table 4.** Dimensionless shape factors, for some common regular 2D geometries.

Shape	Length $L$	Area $A$	$\beta' = L^2/4A$
Circle	$2\pi a$	$\pi a^2$	$\pi = 3.1416$
Regular hexagon	$6a$	$\frac{3a^2\sqrt{3}}{2}$	$2\sqrt{3} = 3.4641$
Square	$4a$	$a^2$	4.0000
Rectangle $2a \times a$	$6a$	$2a^2$	$9/2 = 4.5000$
Equilateral triangle	$3a$	$\frac{a^2\sqrt{3}}{4}$	$3\sqrt{3} = 5.1962$
Rectangle $10a \times a$	$22a$	$10a^2$	$121/10 = 12.1000$

Note: Shapes are characterized by one size  $a$  and classified by increasing  $\beta'$  value.

### 3.3.3. Timing Events

Having a suitable expression for the rate of surface nucleation  $J' \sim Dv^{-4/3}g_c \times \exp(-\Delta G^*/kT)$ , two characteristic times have to be considered:

- (i) The time  $\tau_N = (J'A_i)^{-1}$  needed to nucleate a new layer on a perfectly planar interface displaying area  $A_i$ .
- (ii) The time  $\tau_C = a_i/k'$  needed to get a full coverage of the area  $A_i$  just after surface nucleation. Here  $a_i$  stands for the largest linear size found on surface  $A_i$  and  $k' = da/dt$  is the linear growth rate of surface nuclei. This rate should be proportional to the frequency of arrival of solute species at any edge of the surface times a sticking probability ( $v' \sim D \times g_c/d$ ) and should also depend on their average number at the interface [ $n' \sim (c - c_s)v$ ]. Consequently, with  $d \sim v^{1/3}$ , we should have  $k' \sim n' \times v' \sim Dg_c v^{2/3}(c - c_s)$ . Now, depending on the relative values of  $\tau_N$  and  $\tau_C$  two limiting cases may be encountered.

### 3.3.4. Mononuclear Growth Law

For mononuclear crystalline growth, the rate limiting step is the apparition of a new 2D nucleus on the surface ( $\tau_N \gg \tau_C$ ). In this case, the linear growth rate  $dr/dt$  may be written

$$\begin{aligned} \frac{dr}{dt} &= \frac{d}{\tau_N} \sim J'\omega'r^2v^{1/3} \\ &= \omega'Dg_cv^{-1} \exp\left(\frac{\Delta G^*}{kT}\right)r^2 = k_m \times r^2 \end{aligned} \quad (23)$$

Here  $\omega'$  stands for the shape factor of the surface nucleus. It should be obvious that such a mechanism cannot be the whole story as if one starts with a size  $r_0$ , then at time  $t$  one would have  $k_m \int_0^t dt = \int_{r_0}^{r_t} dr/r^2$ ; that is,  $r_t = [r_0/(1 - k_m t r_0)]$ . It thus appears that  $r_t \rightarrow +\infty$  for a finite time  $t \rightarrow 1/(k_m r_0)$ . Such a divergence being unacceptable from a physical standpoint, this means that this mechanism should be valid only for very small sizes.

### 3.3.5. Polynuclear Growth Law

Accordingly, when the exposed surface becomes large enough, the probability to observe several nucleation events on the same area  $A_i$  cannot be neglected and one has to switch to the polynuclear growth. In this alternative mechanism, the rate limiting step is the coverage of a surface by all its surface nuclei ( $\tau_N \ll \tau_C$ ). If the whole area is covered at time  $t = \tau_C$ , then  $dr/dt = d/\tau_C$  for the linear growth rate. In order to find a reasonable value for this time one should consider that at any time  $0 \leq \theta \leq \tau_C$ , a certain amount of surface nuclei  $dn_\theta = (\tau_N)^{-1}d\theta = (J'A_i)d\theta$  have appeared. First assume an independent growth for each germ so that if  $da/dt = k'$  then  $a = \int_0^\theta da = k' \int_0^{\tau_C} dt = k'(\tau - \theta)$ . The total area covered by germs that have appeared at  $t = \theta$  may then be written

$$\begin{aligned} dA_\theta &= \omega'a^2 dn_\theta = \omega'J'A_i k'^2 (\tau - \theta)^2 \\ \implies A_i &= \int_0^{\tau_C} dA_\theta = \frac{\omega'}{3} J'A_i k'^2 \tau_C^3 \end{aligned} \quad (24)$$

Taking into account that in fact germs may overlap during growth we may write  $\tau_C = (\omega'\varphi J'k'^2/3)^{-1/3}$ , where  $\varphi$  is the numerical geometric correction describing the geometric details of the various overlaps. For disk-shaped 2D germs it may be shown that  $\varphi \sim 0.6$  [5]. This gives our final polynuclear growth law

$$\begin{aligned} \frac{dr}{dt} &= \frac{d}{\tau_C} = (\omega'\varphi v/3)^{1/3} Dg_c (c - c_s)^{2/3} \exp\left(-\frac{\Delta G^*}{3kT}\right) \\ &= vk_p c^p \quad p = \frac{m^* + 2}{3} \end{aligned} \quad (25)$$

The expression in the right hand side of (25) comes from an alternative evaluation of  $J'$  based on the observation that from (22):  $\partial(\ln J')/\partial(\ln S) = m^* \Leftrightarrow J' \sim k_c c^{m^*}$ .

It is interesting to compare relations (10) and (25). In both cases, the growth rate depends on the diffusion coefficient  $D$ , and on the difference  $(c - c_s)$ . The differences are that we have a power law for the concentration dependence with a growth rate independent of crystal size in the case of polynuclear growth. According to this last mechanism this means that the absolute width of the size distribution should be constant ( $\Delta r \sim \Delta r_0$ ) at all times and that only the relative width may decrease with time ( $\Delta r/r \sim [r_0/r] \times [\Delta r_0/r_0]$ ).

### 3.3.6. Chronomals and Equilibrium Size

As for the diffusion law, one may introduce a chronomal analysis in order to find the order  $p$  for crystalline growth. Setting  $c = c_0(1 - x_p)$  and  $r = r_e x_p^{1/3}$  then leads to  $t = K_p I_p$ , with

$$K_p = \frac{r_e}{3vc_0^p k_p} \quad \text{and} \quad I_p = \int_0^{x_p} x^{-2/3}(1-x)^{-p} dx \quad (26)$$

Figure 4 shows the variation of  $I_p$  with  $x_p$  for increasing values of  $p$ . Concerning the integrated form of the polynuclear growth law, let  $t_p$  be the characteristic time below which the condition  $S > S^*$  remains satisfied. From (14) and (15) it comes that  $c_t = c_0[1 - (t/t_p)^4]$  with  $t_p$  given by

$$t_p = \left(\frac{12}{\omega\omega'\varphi}\right)^{1/4} J(c_0)^{-1/4} D^{-3/4} g_c^{-3/4} c_0^{-1/4} \exp\left(\frac{\Delta G^*}{4kT}\right) \quad (27)$$

As done, this induction time may be used to evaluate the number of nanocrystals  $N$  formed per unit volume

$$\begin{aligned} c &= c_0 \left[1 - \left(\frac{t}{t_p}\right)^4\right] \implies N \approx J(c_0)t_p F(n^*) \\ F(n^*) &= \int_0^1 (1-x^4)^{n^*} dx = \prod_{k=1}^{n^*} \left[\frac{k}{(k+1/4)}\right] \end{aligned} \quad (28)$$

This in turn leads to an analytical expression linking the average equilibrium size  $\langle r_e \rangle$  of the nanocrystals to the solid phase and solution properties

$$\begin{aligned} \langle r_e \rangle^3 &= \left[\frac{1}{\omega F(n^*)}\right] \left(\frac{\omega\omega'\varphi}{12}\right)^{1/4} v^{9/4} c_0^{5/4} \left(\frac{g_c}{g_N}\right)^{3/4} \\ &\times \exp\left(\frac{3\beta\gamma^3 v^2}{4(kT)^3 (\ln S_0)^2} - \frac{\beta'\gamma^2 v^{4/3}}{4(kT)^2 \ln S_0}\right) \end{aligned} \quad (29)$$

**Figure 4.** Crystalline growth controlled by the interface. Boxed curve shows the shape of the chronomal functions  $I_p$  given by Eq. (24). Other decreasing curves were plotted according to Eq. (29) assuming a spherical shape ( $\omega = 4\pi/3$ ,  $\beta = 4\omega$ ) for 3D nuclei and a disk shape ( $\omega' = \beta' = \pi$ ,  $\varphi = 0.6$ ) with  $\langle F(n^*) \rangle = 3/8$  for five typical values of the growth constant  $\sigma_C = \beta' \gamma^2 v^{4/3} / (kT \text{Ln } 10)^2$ . For these particular shapes we have  $\sigma_N \sim 3(\sigma_C)^{3/2}$  leading to  $\log r_e = (1/3) \log(6v^{9/4}/4\pi) + (5/12) \log c + (1/4) \log(g_C/g_N) + \sigma_C [9\sqrt{\sigma_C} - \log(c/c_s)] / [12(\log c/c_s)^2]$ . Other parameters were  $v = 10^{-28.5} \text{ m}^{-3}$ ,  $c_s = 10^{22} \text{ m}^{-3}$ , and  $g_C/g_N = 10^{-6}$ . As for diffusion controlled growth, nanometer sized nanocrystals are formed when precipitation occurs in concentrated solutions.

Figure 4 shows the typical variation of  $\langle r_e \rangle$  with concentration in solute species  $c$  for several values of the dimensionless growth constant  $\sigma_C = \beta' \gamma^2 v^{4/3} / (kT \text{Ln } 10)^2$ . One may notice that as  $\sigma_N = \beta \gamma^3 v^2 / kT \text{PLn } 10^3$ , the link  $\sigma_N = \beta(\sigma_C/\beta') \sqrt{(\sigma_C/\beta')}$  exists between growth and nucleation constants. As in the case of diffusion, these curves show that when  $\sigma_N$  is low,  $\langle r_e \rangle$  remains roughly constant above  $S = 10$ , with typical sizes close to 100 nm. On the other hand, when  $\sigma_N$  is high, nanocrystals with typical sizes close to 1  $\mu\text{m}$  can be formed from concentrated solutions. Again, in all cases, there is a critical concentration domain where average size suddenly drops from the millimetric range down to the nanoscopic one. One may also see that nucleation and growth terms have antagonist effects on the equilibrium size. Concerning the role of chemistry at the interface larger crystals are expected when  $g' > g$  (i.e., when  $\Delta G'' < \Delta G'$ ).

### 3.4. Dislocation Controlled Growth

When the supersaturation ratio  $S$  is smaller than about 2, the rate of surface nucleation may become so slow that the crystal growth rate becomes practically nil. In fact there are numerous examples in literature where crystalline growth is easily observed even when  $S = 1.01$ . In such cases, it has been shown [2] that growth may be initiated on crystalline defaults (dislocations or stacking faults). Among the possible defaults, it appears that the most efficient ones are screw dislocations leading to the formation of typical Archimedean spirals on the surface [2, 3].

### 3.4.1. Growth Law

In this mechanism, we have to estimate the normal velocity of advancement  $u$  for the leading step of the growing spiral. For a spiral of radius  $R$ , this rate should be proportional to the frequency of arrival of solute species at the leading edge times a sticking probability ( $v' \sim D \times g_C/d$ ) and should also depend on their average number at the interface [ $n' \sim (c - c_R)v$ ]. Consequently, with  $d \sim v^{1/3}$ , we should have  $u \sim n' \times v' \sim Dc g_C v^{2/3} (1 - c_R/c)$ . Now, from (22) with  $\beta' = \pi$ , it is possible to relate the concentration just outside the crystal surface  $c$  to a critical germ radius  $r'^*$  according to  $\pi(r'^*)^2 = m^* \times v^{2/3}$ ; that is,  $r'^* = \gamma v / (kT \text{Ln } S)$ . Moreover, applying (9) with  $r_2 \rightarrow +\infty$  (i.e.,  $c_2 \rightarrow c_s$ ) and  $r_1 = R$  or  $r'^*$  allows one to express the ratio  $c_R/c$  as

$$\frac{c_R}{c} = \exp\left[\frac{\gamma v}{kT} \left(\frac{1}{R} - \frac{1}{r'^*}\right)\right] \approx 1 + \frac{\gamma v}{kT} \left(\frac{1}{R} - \frac{1}{r'^*}\right)$$

$$\Rightarrow \lim_{R \rightarrow +\infty} u = \frac{D\gamma v^{5/3} c}{kT r'^*} g_C \quad (30)$$

Assuming a spiral displaying a stationary shape and rotating with a constant angular velocity  $\omega_S$  (rad  $\text{s}^{-1}$ ), it may be shown that  $\omega_S = u_\infty / (\pi r'^*)$  [38]. Consequently, each spiral turn should deposit a layer of thickness  $d \sim v^{1/3}$  leading to the following linear rate of growth

$$\frac{dr}{dt} \sim \left(\frac{\omega_S}{2\pi}\right) \times v^{1/3} = g_C \frac{DkTc}{2\pi^2 \gamma} (\text{Ln } S)^2 \quad (31)$$

### 3.4.2. Two Limit Cases

Two important limiting cases may be discussed. When  $c \sim c_s$  (i.e.,  $S = 1 + \varepsilon$ ), then  $\text{Ln } S = \text{Ln}(c/c_s) \sim (c - c_s)/c_s$ , and we get a nonvanishing growth rate  $dr/dt = [g_C DkT / (2\pi^2 \gamma c_s)] \times (c - c_s)^2$ . This explains the possibility of growing large single crystals from solutions even when  $S \sim 1$ . On the other hand, when  $c \gg c_s$  the growth rate may become quite large, but very soon the diffusion of solute species toward the spiral leading edge will become rate determining. As both rate laws are known, it is possible to see for which value of  $S$  both processes should contribute equally to the crystalline growth

$$g_C \frac{DkTc}{2\pi^2 \gamma} (\text{Ln } S)^2 \approx \frac{Dv(1 - S^{-1})}{r}$$

$$\Rightarrow \frac{S(\text{Ln } S)^2}{S - 1} \approx \frac{2\pi^2}{g_C} \left(\frac{\gamma v}{kTr}\right) \quad (32)$$

Using  $\gamma \sim 0.1 \text{ J m}^{-2}$ ,  $v \sim 10^{-28.5} \text{ m}^3$ , and  $T = 300 \text{ K}$  as typical values leads to the following condition:  $[g_C r(\text{nm})] \times S(\text{Ln } S)^2 \approx 15.2(S - 1)$ . Setting  $g_C \sim 1$  and  $r = 1 \text{ nm}$  as reasonable limits leads to  $S = 47.338$ . Under these conditions, diffusion should become the rate limiting step as soon as  $S > 50$ . However, if one considers a millimeter-sized single crystal ( $r \sim 10^6 \text{ nm}$ ) with rather low kinetic barrier ( $g_C \sim 1$  for purely ionic crystals such as NaCl or KCl) well developed spirals should be evidenced only if  $S \approx 1 + 15.2/(g_C r) < 1.00001$ . However, if  $g_C \sim 10^{-7}$  (i.e.,  $\Delta G'' \sim 40 \text{ kJ mol}^{-1}$ ), then for the same single crystal size diffusion toward the interface will be rate determining only when  $S \approx \exp[\sqrt{15.2/(g_C r)}] > 10^5$ . A direct consequence of this fact is that nanocrystal formation ( $r \sim 10 \text{ nm}$ ) should never be under diffusion control, unless  $g_C > 0.1$ .

### 3.4.3. Chronomals

Interestingly enough, when spiral growth is the rate limiting step, the chronomal analysis shows that it would be rather difficult to distinguish between the spiral and the polynuclear growth. Proceeding as before by setting  $c = c_0(1 - x_S)$  and  $r = r_e x_S^{1/3}$  leads to  $t = K_S^p I_p$ , where  $I_p$  is the polynuclear chronomal limited to values of  $p = 1$  or  $2$  and  $K_S^p$  stands for two time constants given by

$$K_S^p = \frac{r_e}{3g_C} \times \frac{2\pi^2\gamma}{DkTf_p(c_0)} \quad \text{with}$$

$$I_p = \int_0^{x_S} x^{-2/3}(1-x)^{-p} dx \quad p = 1 \text{ or } 2 \quad (33)$$

The two  $p$ -values correspond to the two previously described limiting cases. When  $c \gg c_s$ , then  $c \sim c - c_s$  and  $\text{Ln } S \sim \text{Ln}(c_0/c_s)$  leading to  $t = K_S^2 I_1$  with  $f_1(c_0) = c_0[\text{Ln}(c_0/c_s)]^2$ . For the other limiting case  $c \sim c_s$ , we have  $t = K_S^2 I_2$  with  $f_2(c_0) = c_s/(c_0 - c_s)^2$ . On the other hand, if diffusion is the rate limiting step, then one should follow the  $I_D$  chronomal given by (12). This analysis shows that observing a crystalline growth law following  $I_D$ ,  $I_1$ , or  $I_2$  chronomals does not rule out the spiral mechanism. In fact the only clear evidence for the occurrence of the polynuclear mechanism would be to follow chronomals  $I_p$  characterized by  $p > 2$ . To the best of our knowledge such a situation has been scarcely reported in literature as most precipitation processes follow either  $I_D$  or  $I_1$  chronomals.

This result may just be a direct consequence of the very high efficiency of the spiral growth for nanocrystals which bypassing the bottleneck of surface nucleation run directly into the one of diffusion toward the interface. If this is true, then all nanocrystals grown using concentrated solutions should in fact be formed from numerous interpenetrating nanospirals and not from overlapping surface nuclei.

### 3.4.4. Equilibrium Sizes

At last, we may consider the integrated form of the spiral growth law, characterized by a time  $t_S$  below which the condition  $S > S^*$  remains satisfied. From (14) and (15) it comes that  $c_t = c_0[1 - (t/t_S)^4]$  with  $t_S$  given by

$$t_S = \left(\frac{4}{\omega}\right)^{1/4} \left[\frac{v}{c_0^2 J(c_0)}\right]^{1/4} \left[\frac{2\pi^2\gamma}{g_C DkT(\text{Ln } S_0)^2}\right]^{3/4} \quad (34)$$

As the power dependence of concentration with time is similar than that observed for polynuclear growth, (28) holds with  $t_p$  replaced by  $t_S$ , leading to

$$\langle r_e \rangle^3 = \left[\frac{1}{\omega F(n^*)}\right] \left(\frac{\omega}{4}\right)^{1/4} v^2 c_0^{3/2} \left(\frac{g_C}{g_N}\right)^{3/4} \left[\frac{kT(\text{Ln } S_0)^2}{2\pi^2\gamma}\right]^{3/4} \\ \times \exp\left(\frac{3\beta\gamma^3 v^2}{4(kT)^3(\text{Ln } S_0)^2}\right) \quad (35)$$

## 3.5. Discussion

At this stage a comparison between Figures 3, 4, and 5 may be useful. All curves display the same characteristic L-shaped aspect, the decreasing left part coming from an exponential term and the increasing right part from a power

**Figure 5.** Spiral crystal growth controlled by screw dislocations. Boxed curve shows the shape of the two chronomal functions  $I_1$  and  $I_2$  given by Eq. (26). Other decreasing curves were plotted according to Eq. (35) assuming a spherical shape ( $\omega = 4\pi/3, \beta = 4\omega$ ) for 3D nuclei with  $\langle F(n^*) \rangle = 1/2$  for five typical values of the nucleation constant  $\sigma_N = \beta\gamma^3 v^2 / (kT \text{Ln } 10)^3$  leading to  $\log r_e = (1/3) \log(6v^2/4\pi) + (1/2) \log c + (1/4) \log(g_C/g_N) + (1/4) \log[kT(\text{Ln } S_0)^2/2\pi^2\gamma] + \sigma_N/[4(\log c/c_s)^2]$ . Other parameters were  $T = 300$  K,  $v = 10^{-28.5}$  m<sup>3</sup>,  $\gamma = 0.1$  J m<sup>-2</sup>,  $c_s = 10^{22}$  m<sup>-3</sup>, and  $g_C/g_N = 10^5$ . As for other growth mechanisms, nanometer sized nanocrystals are formed when precipitation occurs in concentrated solutions.

of the total concentration  $c_0$ . In these drawings the two sticking probabilities  $g_N$  and  $g_C$  (linked to the occurrence of kinetic barriers  $\Delta G'$  and  $\Delta G''$  for nucleation and growth) have been adjusted in order to have  $r_e > 0.1$  nm in all the investigated concentration range. In the case of diffusion controlled growth, one should have  $g_C \sim 1$  and the size of the nanocrystals will be fixed by the relative values of  $\sigma_N$  and  $g_N$ . This is no more the case for the two other mechanisms, where the two competing terms are  $\sigma_N$  and the  $(g_C/g_N)$  ratio. However, a clear difference exists between polynuclear and spiral growth as one must set  $(g_C/g_N) = 10^{-6}$  for the first mechanism and  $(g_C/g_N) = 10^{+5}$  for the second one in order to get reasonable sizes. The chemical interpretation of this phenomenon is straightforward. Polynuclear (or mononuclear at low  $S$ -values) growth should be suspected as soon as  $g_C < g_N$ , that is, when solute species are more easily incorporated when the nanocrystal has not yet appeared (embryo stage). Chemically speaking, we are in a situation where crystal growth is poisoned by the decomposition products of the solute precursors. In this case, it seems obvious that the highly reactive leading edge of a growing spiral will be much more affected by the poisonous material than a less reactive flat layer. Owing to the presence of the poison, the surface nucleation bottleneck is unavoidable and the polynuclear picture dominates crystalline growth.

In the reverse situation,  $g_C > g_N$ , the decomposition products of solute precursors are expected to show no affinity for the crystal/solution interface. In this case, solute species absorption should occur at the most reactive sites, and one may expect a crossover between polynuclear and spiral growth. It then appears that Eqs. (20), (29), and (35) should cover both qualitatively and quantitatively all the pertinent physical and chemical aspects of nucleation and crystalline growth from solutions.

## 4. LIMITED AND SECONDARY GROWTH

It should be noticed that the previous equations have been reached without any explicit description of the structure of the solution/crystal interface. One should then expect that some other important aspects remain yet hidden, particularly in the interfacial energy  $\gamma$ . In the previous treatment, it was tacitly assumed that the interfacial energy  $\gamma$  was a constant characterizing the solution/crystal interface. In this section, we will consider what should happen to the final equilibrium size of a nanocrystalline dispersion when  $\gamma$  may change owing to variations in pH or ionic strength. To do this we must dispose of a faithful model of the crystal/solution interface. In the following, we will consider mainly oxide/water interfaces that are by far the most commonly encountered experimental cases. Generalizations for nonaqueous or nonoxide interfaces will not be discussed in this chapter.

### 4.1. Solute–Solvent Interface

The best way to understand what the structure of an oxide water interface should be is to start from the molecular scale (Frank and Wen model [39]). Accordingly, X-ray or neutron diffraction studies of aqueous solutions [13, 40] have shown that the molecular environment around a given solute is not a random medium. At less than 0.3 nm, a first shell of frozen solvent molecules is very often found in close contact with the solute species. After this coordination shell, other more or less immobilized shells may be found. The spatial extension of this zone is typically between 0.3 and 0.5 nm. In this critical zone, it may be observed that the local order characterizing the solvent in a pure state may either be broken or strengthened. This comes from the fact that on one side solvent molecules are under the influence of the more or less rigid coordination shell around the solute. On the other side, they are under the influence of the random motions of their congeners that are far from any solute (this holds for sufficiently diluted solutions). When the solute coordination shell is highly structured and rigid, this orderliness tends to be propagated at longer distances. One then speaks of a *structure-forming* solute. Conversely, if the coordination shell is highly labile and disordered, the disorder will also be more or less transmitted to the neighboring shells breaking the original structure of the pure solvent. In this case, one may speak of *structure-breaking* species.

### 4.2. Oxide–Water Interface

This classical picture of the solvent–solute interaction may serve as a faithful basis for a realistic model of the solid/liquid interface. As explained in previous sections, nucleation is an irreversible phenomenon by which several solute precursors meet together in a limited volume (thermodynamic barrier  $\Delta G^*$ ). Within this confined state, they may further expel partly or fully their coordination shell (kinetic barrier  $\Delta G'$ ) in order to build a new solid phase. Chemically speaking, the solid phase may be viewed as the result of a giant polymerization process of solute species. On this basis, one may expect that their respective coordination shells should also merge together defining the solid/liquid

interface. This merging process should, however, also apply to secondary coordination shells leading to a more or less compact layer, tightly bonded to the interface (called hereafter the “Stern” layer). Finally, just outside this more or less immobilized Stern layer a slipping plane for solvent molecules should exist, that may be identified as the “outer Helmholtz plane” (OHP).

Adopting this “natural” model for the solid/liquid interface allows us to zoom more deeply into the crystalline growth process. For instance, the quite vague statement of “diffusion toward the solid/liquid interface” may then acquire an accurate formulation. Accordingly, diffusing solute species may be identified as any kind of fully solvated chemical entity not able to go beyond the OHP. One must realize that the last statement is not an assumption, but a logical consequence of the chosen model. Accordingly, assume that some kind of solute species has been able to jump over the OHP landing inside the Stern layer. The chemical consequence of this hopping should be that some spatial reorganization of the surrounding solvating shell was possible in order to fit the local structure of the Stern layer. If the energetic cost of this reorganization were too expensive, the jumping would have been a very unlikely process. Consequently, the solute species would show no tendency to cross the OHP, preferring to diffuse quietly far away from this unfriendly disturbing spatial zone.

Conversely, it may happen that some otherwise quietly diffusing solute species may experience a very high structural affinity for the Stern layer. Such a species is then expected to cross the OHP ending up right inside the Stern layer. As a result of this jump, a quite new solvating shell more adapted to the local structure of the Stern layer should be adopted, leaving with no regret the older one more adapted to the structure of the bulk solvent. The automatic consequence of fact is the existence of a second kind of molecular plane, named the “inner Helmholtz plane” (IHP). By its very definition this plane lies somewhere outside the solid surface and well below the OHP. From a chemical standpoint, it is formed by the locus of all strongly adsorbed species that are not allowed to diffuse freely into the solution due to their particular affinity for the Stern layer. At last, chemical entities already localized within the Stern layer may exist and could display rather high chemical affinity for the crystalline surface. For such species, full reorganization of their coordination shell needed for a “perfect” sticking to the surface is not a problem. They are thus not expected to stay localized close to the IHP but may undergo a last final jump right inside the crystalline lattice. The immediate result of this ultimate sacrifice is an increase of the spatial extension of the interface by one step, another way of saying that crystalline growth has occurred.

### 4.3. Surface Charge

The next step is now to see how the surface charges may develop. As shown in Figure 6 (top left) metallic cations exposed at the surface are found to be hydroxylated owing to water chemisorption. Consequently, like soluble aquo, hydroxo, or oxo complexes they may acquire or lose protons according to the polarizing power of the metallic cation

**Figure 6.** A natural model for the oxide/water interface. Top left shows the H-bonded structure of the Stern layer in close contact with the oxide surface. Top right illustrates the Frank and Wen model (scale <math>< 1\text{ nm}</math>) for a solute  $S$  far away from the interface. Black region corresponds to the naked solute. At a distance less than  $0.3\text{ nm}$  from the solute, one finds the coordination shell indicated is dark gray. Between  $0.3$  and  $0.5\text{ nm}$ , one finds more or less perturbed secondary shells (light gray). Above  $0.5\text{ nm}$ , water recovers its characteristic flickering structure. Top middle shows the direct vicinity of the oxide/water interface with the Stern and diffuse layers of counterions (scale <math>< 10\text{ nm}</math>). Bottom left shows the effect of chemisorption at the surface on chemical potentials and interfacial energy. Bottom right is the effect on the equilibrium size of nanocrystals with the domain of thermodynamic instability (Ostwald ripening).

This allows one to define the net surface charge  $\sigma_0 = (F/A)([\text{MOH}_2^{\oplus}] - [\text{MO}^{\ominus}])$ , where  $F$  stands for the Faraday constant ( $F = 96,500\text{ C mol}^{-1}$ ) and  $A$  stands for the exposed surface area ( $\text{m}^2\text{ l}^{-1}$ ). The quantities in brackets are the concentration ( $\text{mol l}^{-1}$ ) in charged surface sites.

#### 4.3.1. Acidity Constants

To a given surface charge distribution, one may associate an electrostatic potential  $\psi_0$  at the interface. Assuming Maxwell-Boltzmann statistics, the surface concentration  $[\text{H}_3^+]$  of protons should be related to the concentration in solution  $[\text{H}^+]$  by  $[\text{H}_3^+] = [\text{H}^+] \times \exp(-F\psi_0/RT)$ . Consequently, these two equilibria may be shifted toward the left or the right by changing the solution pH. To take into account this fact, surface equilibrium constants  $K_0^+$  and  $K_0^-$  may be introduced

$$\begin{aligned} K_0^+ &= \frac{[-\text{MOH}][\text{H}_3^+]}{[-\text{MOH}_2^+]} = K^+ \exp\left(-\frac{F\psi_0}{RT}\right) \\ K_0^- &= \frac{[-\text{MO}^-][\text{H}_3^+]}{[-\text{MOH}]} = K^- \exp\left(-\frac{F\psi_0}{RT}\right) \end{aligned} \quad (36)$$

In this relation,  $K^+$  and  $K^-$  are two affinity ratios characterizing MOH surface group acidity at nil surface potential ( $\psi_0 = 0$ ). These intrinsic constants may change according to the number of bonds (usually one, two, or three) between the hydroxo moiety and the metallic cation. Structural models have been developed in the literature to model this surface acidity as a function of crystallographic structure [41].

#### 4.3.2. Point of Zero Charge

It may be shown that the two constants  $K^+$  and  $K^-$  fully characterize the surface behavior toward pH variations. Accordingly, by looking at their average, one may define the point of zero charge of the interface,  $\text{PZC} = \frac{1}{2}(pK^+ + pK^-) = \frac{1}{2}(pK_0^+ + pK_0^-)$ . Chemically speaking, this corresponds to the pH value at which concentrations of positive  $[\text{MOH}_2^{\oplus}]$  and negative  $[\text{MO}^{\ominus}]$  surface sites are the same, leading to a nil surface charge ( $\sigma_0 = 0$ ). Similarly, their difference,  $\Delta pK = (pK^- - pK^+)$ , helps one to visualize the concentration of charged sites  $N' = [\text{MOH}_2^{\oplus}] = [\text{MO}^{\ominus}]$  at the PZC. This may be easily understood by writing the total number of surface group as  $N = [\text{MOH}_2^{\oplus}] + [\text{MO}^{\ominus}] + [\text{MOH}] = 2N' + [\text{MOH}]$ . Introducing the fraction  $\theta = N'/N$  of charged sites at the PZC, leads to  $\Delta pK = 2 \log[(1 - 2\theta)/\theta]$ . When  $\Delta pK$  is high ( $\Delta pK > 4$ ),  $[\text{MOH}] \gg [\text{MOH}_2^{\oplus}] = [\text{MO}^{\ominus}]$  at the PZC, and the interface may really be viewed as a surface displaying only neutral unionized sites. Conversely, when  $\Delta pK$  is small or even negative, the number of charged groups  $[\text{MOH}_2^{\oplus}]$ ,  $[\text{MO}^{\ominus}]$  is large and the interface behaves like a protein. In this case, its PZC is better interpreted as an isoelectric point in order to reflect a  $\theta \rightarrow \frac{1}{2}$  situation.

#### 4.3.3. Charge-Potential Relationship

One may also be interested in the surface equation of state far from the PZC. Considering a total number of surface groups per unit area  $N_s = ([\text{MOH}_2^{\oplus}] + [\text{MO}^{\ominus}] + [\text{MOH}])/A$ , we may write

$$\sigma_0 = FN_s \frac{[\text{MOH}_2^+]}{[\text{MOH}_2^+] + [\text{MO}^-] + [\text{MOH}]} \quad (37)$$

Using (36) to express  $[\text{MOH}_2^{\oplus}]$  and  $[\text{MO}^{\ominus}]$  as a function of  $[\text{MOH}]$  concentration leads to the relationship linking the net surface charge density  $\sigma_0$  to the surface potential  $\psi_0$ . Concerning the relationship between surface potential and solution pH, one may start from the definition of  $\text{PZC} = \frac{1}{2}(pK_0^+ + pK_0^-)$  and eliminates the  $[-\text{MOH}]$  term using (36) with  $[\text{H}_3^+] = [\text{H}^+] \times \exp(-F\psi_0/RT)$

$$\psi_0 = \frac{RT \text{Ln } 10}{F} (\text{PZC} - \text{pH}) - \frac{RT}{2F} \text{Ln} \frac{[\text{MOH}_2^+]}{[\text{MO}^-]} \quad (38)$$

This shows that interfaces characterized by small or negative  $\Delta pK$  ( $[\text{MOH}_2^{\oplus}] \sim [\text{MO}^{\ominus}]$ ) tend to follow the well-known Nernst law.

#### 4.4. Diffuse Layer

The apparition of a superficial charge at the oxide/water interface also has the consequence of creating at any distance  $x$  from the interface a concentration gradient of ionic solute species  $i$  bearing an electrical charge  $z_i$ . Assuming as before Maxwell-Boltzmann statistics for these ions leads to  $c_i(x) = c_i(\infty) \times \exp[-z_i F\psi(x)/RT]$ , where  $c_i(\infty)$  stands for the concentration of species  $i$  far away from the charged interface. These counterions subjected to both the surface potential and thermal agitation are then distributed in a diffuse layer whose charge  $\sigma_d$  at the OHP compensates for the surface charge  $\sigma_0$ . In the case of specific adsorption

within the Stern layer, this compensation may also include the charge  $\sigma_\beta$  coming from all charges localized at the IHP ( $-\sigma_d = \sigma_0 + \sigma_\beta$ ).

The potential behavior within this diffuse layer may be derived by solving the Poisson equation  $\Delta\psi = -\rho/\varepsilon\varepsilon_0$ , relating density of charges  $\rho$  to potential  $\psi$  through the relative dielectric constant  $\varepsilon$  of the solution and vacuum permittivity  $\varepsilon_0$ . An approximate solution to this problem may be easily found by considering a planar interface (1D problem) submitted to the boundary conditions:  $\psi(x) = \psi_d$  when  $x = d$ , the thickness of the Stern layer, and  $\psi(x) = d\psi(x)/dx = 0$  when  $x \rightarrow \infty$ . For a symmetric  $\pm ze$  electrolyte with solution conditions such that  $zF\psi(x) \ll RT$ , the ionic concentrations at distance  $x$  may be approximated as  $c_\pm(x) \sim c(\infty) \times [1 \mp zF\psi(x)/RT]$ . Consequently, the associated charge density should be  $\rho(x) = zF[c_+(x) - c_-(x)] \sim (-2c_\infty z^2 F/RT)\psi(x)$ . The solution of the Poisson equation should then be  $\psi(x) = \psi_d \times \exp[-\kappa(x - d)]$  and  $\sigma_d = -\varepsilon\varepsilon_0\kappa\psi_d$  with

$$\kappa = \sqrt{\frac{2z^2 F^2 c_\infty}{\varepsilon\varepsilon_0 RT}} = \sqrt{\frac{2000 F^2 I}{\varepsilon\varepsilon_0 RT}} \quad I(\text{mol l}^{-1}) = \frac{1}{2} \sum_{i=1}^n c_i z_i^2 \quad (39)$$

The parameter  $\kappa$  having the dimension of the reciprocal of length, its inverse  $\kappa^{-1}$  is then a measure of the thickness of the diffuse layer. In water at 25 °C ( $\varepsilon = 78.5$ ) it has the value  $\kappa(\text{nm}^{-1}) = 3.29\sqrt{I(\text{mol l}^{-1})}$ , showing its high sensitivity to the concentration and charge of ionic solute species (the diffuse layer is compressed when the ionic strength  $I$  increases). A more correct treatment of the Poisson equation for a symmetric  $z : z$  electrolyte in water at  $T = 25$  °C would have led to [42]:

$$\sigma = \frac{4zFc}{\kappa} \sinh\left(\frac{zF\psi}{2RT}\right) \\ \implies \sigma_d(C \cdot \text{m}^{-2}) = -0.1174\sqrt{c(\text{mol l}^{-1})} \\ \times \sinh[19.46z\psi_d(V)] \quad (40)$$

## 4.5. Thermodynamic Limited Growth

We are now in position to treat the oxide/water interface as a thermodynamic system able to undergo chemical changes occurring through adsorption of charged chemical species. These are not only solvated  $\text{H}^\oplus$  and  $\text{OH}^\ominus$  ions, but also any cationic  $\text{X}^\oplus$  and anionic  $\text{Y}^\ominus$  species coming from a dissolved XY electrolyte.

### 4.5.1. Adsorption Model

As we are dealing with a charged interface, Gibbs relation (1) applies using electrochemical potentials  $\mu = \mu_c + zF\psi$ . Here the  $\mu_c$  component is assumed to carry the concentration dependence (chemical term) while the  $zF\psi$  component takes care of any changes in the total electrical charge (potential term). Let us apply (1) to the oxide/water interface in the presence of an acid HY and an electrolyte XY fixing the ionic strength. Assuming a constant ionic strength

$I$  ( $c_{\text{XY}} \gg c_{\text{HY}}$ ) leads to  $d\mu_{\text{XY}} = 0$ ,  $d\mu_{\text{HY}} = d\mu_{\text{H}} + d\mu_{\text{Y}} \sim d\mu_{\text{H}}$ , and a lowering of the interfacial energy given by [44]

$$d\gamma = -(\Gamma_{[\text{MOH}_2^+]} - \Gamma_{[\text{MO}^-]}) \times d\mu_{\text{HY}} \\ - (\Gamma_{\text{X}^+} - \Gamma_{\text{Y}^-}) \times d\mu_{\text{XY}} \sim -\frac{\sigma}{F} d\mu_{\text{H}} \quad (41)$$

The middle curve at the bottom left part of Figure 6 illustrates Eq. (41). Let us develop the electrochemical potential of the solvated proton as  $d\mu_{\text{H}} = d\mu_{\text{H}}^c + Fd\psi_0$ , where  $\psi_0$  stands for the value of the potential at the charged interface displaying a superficial charge density  $\sigma$ . As we are describing adsorption of a charged species, the Langmuir isotherm (formation of a monolayer) is well suited for describing the  $d\mu_{\text{H}}^c$  chemical contribution, leading to  $d\mu_{\text{H}}^c = RTd[\text{Ln}(\theta/(1-\theta))]$  where  $\theta$  is the fraction of charged sites at the PZC (*vide supra*). Taking into account the fact that the density of adsorption sites is limited by the underlying oxide crystal structure, one may write  $\theta = (\sigma_{\text{max}} + \sigma)/2\sigma_{\text{max}}$  with  $\sigma_{\text{max}} = 2F\Gamma_{\text{max}}$  (top curve at the bottom left part of Fig. 6). This allows us to write the chemical contribution to  $d\gamma$  as

$$d\mu_{\text{H}}^c = RT d \ln \frac{\theta}{1-\theta} = RT d \ln \frac{\sigma_{\text{max}} + \sigma}{\sigma_{\text{max}} - \sigma} = \frac{2RT\sigma_{\text{max}}}{\sigma_{\text{max}}^2 - \sigma^2} d\sigma \quad (42)$$

### 4.5.2. Interfacial Energy Lowering

Now the Gouy–Chapman theory through Eq. (40) with  $z = 1$  (i.e.,  $I = c$ ) allows us to relate the density of charge  $\sigma$  to the potential  $\psi$ , leading by integration of (41) to

$$\Delta\gamma = \int_{\gamma_0}^{\gamma} d\gamma = \gamma - \gamma_0 - \frac{4FI}{\kappa} \int_0^{\psi_0} \sinh\left(\frac{F\psi}{2RT}\right) d\psi \\ - \frac{RT}{F} \sigma_{\text{max}} \int_0^{\sigma_0} \frac{2\sigma d\sigma}{\sigma_{\text{max}}^2 - \sigma^2} \quad (43)$$

Evaluation of the integrals being quite straightforward we may readily evaluate the decrease of the interfacial energy coming from the adsorption of charges at the interface:

$$\gamma = \gamma_0 - \frac{8RTI}{\kappa} \left[ \cosh\left(\frac{F\psi_0}{2RT}\right) - 1 \right] \\ + \frac{RT}{F} \sigma_{\text{max}} \ln\left(1 - \frac{\sigma^2}{\sigma_{\text{max}}^2}\right) \quad (44)$$

Consequently, we note that both the electrical and chemical terms contribute to the lowering of  $\gamma_0$ , the value of the interfacial energy at the PZC (lower diagram at the bottom left of Fig. 6). However, one may notice that if the electrical term remains finite, a divergence of the chemical term is observed when we approach full coverage of available adsorption sites ( $\sigma \rightarrow \pm\sigma_{\text{max}}$ ). As a negative interfacial energy means that surface creation is now a thermodynamically favorable process, more adsorption sites should be created by reducing the equilibrium size  $r_e$  of the crystals. Consequently, if crystalline growth occurs under full saturation of the interface ( $\sigma \sim \pm\sigma_{\text{max}}$ ), then the final equilibrium size will not be fixed by Eqs. (20), (29), and (35), but rather by the concentration in potential determining ions (PDIs) in the solution.

### 4.5.3. Point of Zero Interfacial Energy

In the case of oxide materials PDIs are protons and consequently, there should exist a critical  $\text{pH}^*$  at which full coverage of the interface will occur. This critical point corresponding to a nil interfacial energy [ $\text{pH}^* = \text{point of zero interfacial energy (PZIE)}$ ] may be readily evaluated from (44) if one uses the Gouy–Chapman theory and assumes that the interface obeys the Nernst law given by Eq. (38). Thus, with  $F\psi_0/RT \sim (\ln 10)(\text{PZC} - \text{pH}^*) = (\ln 10)\Delta\text{pH}^*$  and recalling that for large  $x$   $\text{sh}^{-1}(x) = \ln(x + \sqrt{x^2 + 1}) \approx \ln(2x)$ , it comes from the condition  $\sigma \sim \pm\sigma_{\max}$  that

$$\frac{4000FI}{\kappa} \text{sh} \left[ \frac{(\ln 10) \Delta\text{pH}^*}{2} \right] \approx \pm\sigma_{\max}$$

$$\implies |\Delta\text{pH}^*| \approx -\log(2000\varepsilon\varepsilon_0RT) - \log I - 2\log \sigma_{\max} \quad (45)$$

This relation holds for the ionic strength  $I$  expressed in  $\text{mol l}^{-1}$ , the surface charge in  $\text{C m}^{-2}$ , and other constants in SI units. Consequently, for water at  $T = 25^\circ\text{C}$  we may write

$$\text{pH}^* = \text{PZIE} \sim \text{PZC} \pm (\log I - 2\log \sigma_{\max} - 2.5) \quad (46)$$

For instance, an oxide material such that  $\text{PZC} = 5$  and  $\sigma_{\max} = 1 \text{ C m}^{-2}$  placed in a solution containing a one molar 1 : 1 electrolyte would have two PZIE at  $\text{pH}^* = 2.5$  (acid side) and  $\text{pH}^* = 7.5$  (basic side). Consequently, if crystalline growth occurs below  $\text{pH} = 2.5$  or above  $\text{pH} = 7.5$  the interface will be saturated and the final size will be ruled by the exact  $\text{pH}$  value. Under such conditions, the resulting nanocrystal dispersion will be thermodynamically stable with an equilibrium size readily computed from a materials balance [40].

### 4.5.4. Equilibrium Size

Consider a dispersion of  $N$  monodispersed spherical oxide particles (radius  $r$ ) per unit volume formed by precipitation from a solution containing a concentration  $c_0$  of solute precursors. As  $N = 3N_Avc_0/(4\pi r^3)$ , the total area exposed per unit volume is  $A/V = N \times 4\pi r^2 = 3N_Avc_0/r$  and the amount of adsorbed proton per unit volume should be given by  $\sigma A/VF = 3\sigma N_Avc_0/(er)$ . If  $c_H$  is the total acid concentration in solution, we should have  $c_H = \sigma A/VF + c'_H$  where  $c'_H$  is the excess acid concentration not adsorbed by the interface. At the PZIE ( $r = r_e$ ) we know that  $\sigma \sim \sigma_{\max}$  and  $c'_H = c_H^*$ , leading to

$$c_H - c_H^* = \frac{3vc_0}{er_e} \sigma_{\max}$$

$$\iff r_e = \frac{3v\sigma_{\max}}{e} \times \frac{c_0}{c_H - c_H^*} \quad (47)$$

For this example ( $\sigma_{\max} = 1 \text{ C m}^{-2}$ ), with  $\text{PZIE} = 2.5$  ( $c_H^* = 10^{-2.5} \text{ M}$ ), assuming  $v \sim 10^{-28.5} \text{ m}^{-3}$  and  $c_0 = 1 \text{ M}$  would mean that at  $\text{pH} \sim 0$  particles cannot be larger than 0.6 nm. This is a typical size for polycationic species. Consequently, formation of stable polycations before oxide precipitation fits nicely into this treatment. Increasing the  $\text{pH}$  around 1 would allow the formation of a stable 6.2 nm nanocrystalline dispersion, while at  $\text{pH} \sim 2$  the equilibrium size will be much larger with  $r_e \sim 88 \text{ nm}$ . Finally, close to  $\text{pH} \sim 2.5$  (and

above), the thermodynamically allowed equilibrium size is infinite and Eqs. (20), (29), and (35) may be applied. Obviously, owing to the symmetry of our treatment, the same phenomenon may be observed in the presence of a base as shown in the bottom right part of Figure 6. This last diagram thus provides a very nice thermodynamic explanation of the existence of quite stable polyanions and polycations far from the PZC of an insoluble oxide or hydroxide phase. It also explains the possibility of converting an oxide right down to monomeric aquo, hydroxo, or oxo complexes.

## 4.6. Ostwald Ripening

In all the previous treatments we have always considered formation of a monodispersed system in order to relate equilibrium sizes to solution conditions. In fact this should be the case only for thermodynamically, stable dispersions [43].

### 4.6.1. Physical Origin

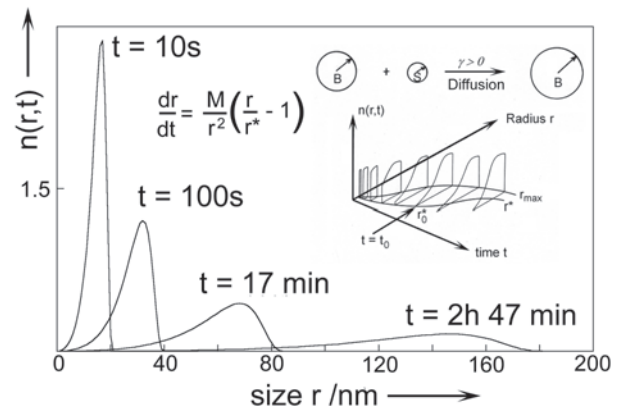

When crystal growth occurs far from the PZIE (and thus around the PZC), a polydisperse system has to be expected. This may be understood by looking at the top left part of Figure 7 showing the time evolution of the function  $n(r, t)$  giving the number of crystals displaying sizes between  $r$  and  $r + dr$  at time  $t$ . This function may be related to the cumulative  $N(r, t)$  function giving the total number of crystals present at time  $t$  when  $r = 0$ :

$$N(r, t) = \int_r^\infty n(r, t) dr$$

$$\iff -\frac{\partial N(r, t)}{\partial r} = n(r, t)$$

$$\iff -\frac{\partial^2 N(r, t)}{\partial r \partial t} = \frac{\partial n(r, t)}{\partial t} \quad (48)$$

At the beginning of the precipitation, the rate of nucleation will be at its maximum value. Owing to continuous nucleation and growth, the supersaturation ratio declines with time and beyond  $S = S^*$ , its decrease is solely the result of crystal growth. Consequently, the first born nuclei should form the leading edge of the size distribution curve  $n(r, t)$  giving rise to the most numerous and largest crystals. On the other

**Figure 7.** Evolution with time through Ostwald ripening of the size distribution  $n(r, t)$  of a nanocrystalline dispersion.

hand, the trailing edge of the distribution gives the number of nuclei born at any time  $t$ . The size of these nuclei is  $r^*$  (the size of the critical nucleus) which should increase with time owing to the decrease in  $S$ . This should easily be understood by applying Eq. (4) to spherical nuclei ( $\beta = 16\pi/3$ ) leading to

$$\frac{4}{3}\pi r(r^*)^3 = n^* \times v \implies r^* = \frac{2\gamma v}{kT \ln S} \quad (49)$$

When the critical supersaturation  $S^*$  is reached, the ordinate of the trailing edge becomes nil (arrow in the diagram) and as  $S$  continues to decline (crystal growth)  $r^*$  continues to increase. The Ostwald ripening may occur as soon as the magnitude of  $r^*$  overtakes the size of the smallest crystals. Consequently, the smallest crystals should redissolve leading to a spreading of the size distribution. Notice that at all times the condition  $r^* < r_{\max}$  (size of the largest crystals) should hold (otherwise the whole precipitate would redissolve). As explained if such a redissolution is thermodynamically allowed, it requires conditions of growth far from the PZC that are not fulfilled here.

#### 4.6.2. General Continuity Equation

The effect of this Ostwald ripening on the size distribution  $n(r, t)$  may be obtained by solving a general continuity equation. This equation may be easily derived by noticing that large crystals will never dissolve. This implies that for large  $r$ , the function  $N(r, t)$  cannot change with time. Accordingly, using the condition  $dN(r, t) = 0$  in conjunction with (48) leads to

$$\begin{aligned} dN(r, t) &= \left[ \frac{\partial N(r, t)}{\partial t} \right] dt + \left[ \frac{\partial N(r, t)}{\partial r} \right] dr = 0 \\ \implies \frac{\partial N(r, t)}{\partial t} - n(r, t) \frac{dr}{dt} &= 0 \end{aligned} \quad (50)$$

Now, taking the partial derivative of (50) relative to size  $r$  leads to the following differential equation for the size distribution  $n(r, t)$ :

$$\frac{\partial n(r, t)}{\partial t} + \frac{\partial}{\partial r} \left[ n(r, t) \frac{dr}{dt} \right] = 0 \quad (51)$$

Integration of (51) is possible analytically only when the system has reached a quasi-steady state after a long time period controlled by diffusion in the solution.

#### 4.6.3. Time Dependence

Let us approximate each crystal by a sphere with radius  $r$  lying in a spherical diffusion field of solute species. The solubility  $c_r$  of the small crystals may be computed from (9) with  $r_2 \rightarrow +\infty$  (i.e.,  $c_2 \rightarrow c_s$ ) and  $r_1 = r$ . A similar relationship also applies to the concentration  $c$  in the bulk that is in metastable equilibrium with the nuclei of size  $r^*$  (now with  $r_1 = r^*$ ). Expanding exponential terms up to second order then leads to the following linear growth rate:

$$\begin{aligned} c &= c_s \exp\left(\frac{2\gamma v}{kTr^*}\right) \quad \text{and} \quad c_r = c_s \exp\left(\frac{2\gamma v}{kTr}\right) \\ \implies \frac{dr}{dt} &= \frac{vD(c - c_r)}{r} \approx \frac{2\gamma v^2 Dc_s}{kTr} \left( \frac{1}{r^*} - \frac{1}{r} \right) \end{aligned} \quad (52)$$

In this diffusion controlled regime all crystals larger than  $r^*$  are growing at the expense of all crystals smaller than  $r^*$ . Consequently, the rate at which the smallest crystals disappear is also the rate at which the total number of crystals  $N(0, t)$  diminishes. Then, using Eqs. (50) and (52) it follows that as  $dN(0, t)/dt$  is always finite and not zero,  $n(r, t)$  should scale like  $r^2$ . Using a dimensionless relative size  $\rho = r/r^*$ , a possible solution may then be written  $n(r, t) = g(t) \times h(\rho) \times \rho^2$ . The differential equation ruling the evolution in time  $g(t)$  may be easily found by applying (48) to  $dN(r \rightarrow 0, t)/dt$  and by insertion of (52) into (50) taking the same limit for the left hand side [44]. Assuming with no loss of generality that  $h(\rho) \rightarrow 1$  when  $r \rightarrow 0$  then leads to

$$\begin{aligned} M &= \frac{2\gamma v^2 Dc_s}{kT} \implies \lim_{r \rightarrow 0} \frac{dr}{dt} = -\frac{M}{(\rho r^*)^2} \\ &\implies \frac{d \ln[g(t)r^*]}{dt} = -\frac{M}{\alpha(r^*)^3} \\ \alpha &= \int_0^\infty \rho^2 h(\rho) d\rho \end{aligned} \quad (53)$$

This may be easily integrated if the total volume of crystalline precipitate  $\phi(t)$  is conserved during the ripening process:

$$\begin{aligned} \phi(t) &= \omega \int_0^\infty n(r, t) r^3 dr \\ \implies g(t)r^* &= \frac{1}{K} \left[ \frac{1}{(r^*)^3} \right] \quad K = \frac{\omega}{\phi} \int_0^\infty \rho^5 h(\rho) d\rho \end{aligned} \quad (54)$$

Accordingly, reporting (54) into (53) and assuming  $dK/dt \sim 0$  leads to  $3(r^*)^2 dr^* = (M/\alpha)dt$ . Then, if Ostwald ripening starts at  $t = t_0$  with a critical size  $r_0^*$ , then at time  $t > t_0$ , one should have

$$\frac{r^*}{r_0^*} = \left[ 1 + \frac{M(t - t_0)}{\alpha(r_0^*)^3} \right]^{1/3} \implies g(t) = g(t_0) \left( \frac{r_0^*}{r^*} \right)^4 \quad (55)$$

#### 4.6.4. Size Distribution

As the time variation of  $r^*$  and  $g(t)$  is known, we may notice that

$$\begin{aligned} \frac{dg(t)}{dt} &= -\frac{4Mg(t)}{3\alpha(r^*)^3} \quad \frac{dr^*}{dt} = \frac{M}{3\alpha(r^*)^2} \\ \implies \left( \frac{\partial \rho}{\partial t} \right)_r &= -\frac{M\rho}{3\alpha(r^*)^3} \end{aligned} \quad (56)$$

In order to get the size dependence  $h(\rho)$  of  $n(r, t)$  one may insert the growth rate given by (52) into (51) leading, after transformation of variable  $r = \rho \times r^*$  and some tedious algebra involving relations (56), to the following differential equation:

$$\begin{aligned} \left[ 6\rho^2 h(\rho) + \rho^3 \frac{dh(\rho)}{d\rho} \right] &= (3\alpha) \left[ (\rho - 1) \frac{dh(\rho)}{d\rho} + h(\rho) \right] \\ \implies \frac{d \ln h(\rho)}{d\rho} &= \frac{3 - (6\rho^2/\alpha)}{\rho^3/\alpha - 3\rho + 3} \end{aligned} \quad (57)$$

At this stage, as from (53)  $\alpha$  is a number depending on the integral of the yet unknown  $h$  function, the solution may seem not obvious. However, we may notice that the denominator in (57) has the simple form  $x^3 = ax + b$  with  $a = -b = 3\alpha$ . A possible solution to this cubic equation is thus  $x = [(b/2) + \Delta^{1/2}]^{1/3} + [(b/2) - \Delta^{1/2}]^{1/3}$ , with  $\Delta = (b/2)^2 - (a/3)^3$  (Cardan formula). Consequently, setting  $\alpha = 9/4$  would lead to  $\Delta = 0$  (i.e., to the most simple root  $x = -3$ ), allowing one to factorize the denominator as  $(\rho + 3)(\rho - 3/2)^2$ . Remembering that with  $h(0) = 1$ , integration of (57) is straightforward:

$$\alpha = \frac{9}{4} \implies h(\rho) = \left(\frac{3}{3+\rho}\right)^{7/3} \left(\frac{3/2}{3/2-\rho}\right)^{11/3} \times \exp\left(-\frac{\rho}{3/2-\rho}\right) \quad (58)$$

Figure 7 illustrates the previous considerations for some typical values of the solid phase and solution parameters, assuming a monodispersed and nanosized dispersion of particles ( $r_0^* = 10$  nm) at the beginning of the Ostwald ripening. It is worth noticing the considerable spreading of the size distribution at long time and its typical asymmetric shape. This characteristic shape emerges from the fact that small particles are disappearing from the solution, allowing the bigger crystals to become still bigger. Concerning the time scale of the ripening, it was mainly ruled by the selection of a diffusion-limited growth mechanism for describing the dissolution–reprecipitation events. Obviously, this should hold only for largely ionic crystals, and for other materials, one may expect an interface-limited ripening. In this case, a numerical solution to the ripening equations (51) and (54) may be the best way of handling the problem [41].

## 5. AGGREGATION

It is now time to remove the assumption that nanocrystals may nucleate and grow independently of each other [i.e., that the  $N(r, t)$  function should be more or less constant during the whole precipitation process].

### 5.1. Position of the Problem

As explained, this assumption was crucial for deriving relations (20), (29), (35), (47), or (54) relating sizes to solution conditions and solid phase properties. Accordingly, even if nanocrystals have their diffusion coefficient 2 or 3 orders of magnitude less than solute species they may nevertheless, from time to time, undergo some collisions between each other. If the sticking probability is high during a collision, aggregates may be formed decreasing by two units the value of  $N(r, t)$ . Obviously, if all possible processes influencing the mean size  $r$  of nanocrystalline dispersions (nucleation, growth, ripening, and aggregation) were occurring with the same rate, the situation would be hopeless. Fortunately, owing to the physics involved in each kind of phenomenon not all these processes are expected to occur simultaneously. For instance, for any kind of reaction to occur, reactants (either complexes or particles) first have to diffuse toward each other. According to the Stokes–Einstein equation

$D = kT/(6\pi\eta a)$ , the diffusion coefficient  $D$  in a solution displaying viscosity  $\eta$  at temperature  $T$  is expected to be the highest for species displaying the lowest size  $a$ . This means that aggregation, like Ostwald ripening, should be important only at long time. However, if ripening is concerned by the behavior of  $N(r, t)$  when  $r \rightarrow 0$  and  $t \rightarrow \infty$ , aggregation focuses on the behavior of this same function when both  $r$  and  $t$  become large.

### 5.2. Fuchs Integral

Consequently, we now assume that after a rather long lapse of time during which the function  $N(r, t)$  has assumed an almost constant value hereafter noted  $N_0$ , this number may change owing to binary collisions between the crystals. Let  $V_T(R)$  be the potential function covering all possible physical or chemical interactions that may occur during the collision. If  $C(R)$  is the concentration of crystals at distance  $R$ , the flux of particles (number of crystals per unit area and per unit time)  $j(t)$  is given by the modified Fick law:

$$j(t) = -D_{\text{rel}} \frac{dC(R)}{dR} - \frac{C(R)}{kT} \times \frac{dV_T}{dR} = -D_{\text{rel}} \exp\left(-\frac{V_T}{kT}\right) \frac{d[C(R) \exp(V_T/kT)]}{dR} \quad (59)$$

In this relationship, the first term arises from the free Brownian motion of the particles. As some external forces  $F_T = -dV_T(R)/dR$  may act on the moving particles, the second term takes care of the additional flux  $C(R) \times v$ , proportional to the speed  $v$  of the particles. As usual, speeds may be related to forces through a friction factor  $f$  ( $v = F_T/f$ ) derived from the Einstein relationship  $D = kT/f$ . Notice that as we are considering a binary collision between two moving particles, the Fick law uses a relative diffusion coefficient  $D_{\text{rel}}$ . The link between  $D_{\text{rel}}$  and  $D_1$  or  $D_2$ , diffusion coefficients of one single particle, may be easily derived by reference to the fundamental law of Brownian motion:  $\langle r_i^2 \rangle = 2D_i t$ . Consequently for a collision between two particles at a relative distance  $(\vec{r}_1 - \vec{r}_2)$  we should have

$$\langle |\vec{r}_1 - \vec{r}_2|^2 \rangle = \langle \vec{r}_1^2 \rangle + \langle \vec{r}_2^2 \rangle - 2\langle \vec{r}_1 \cdot \vec{r}_2 \rangle = 2D_1 t + 2D_2 t = 2D_{\text{rel}} t \implies D_{\text{rel}} = D_1 + D_2 \quad (60)$$

Let us now apply (59) to compute the flux of identical particles across a sphere of radius  $R$ . From (60)  $D_{\text{rel}} = 2D$  and considering the spherical symmetry of the problem, we may write  $J(t) = 4\pi R^2 \times j(t)$  leading after integration to

$$C(R) \exp\left(\frac{V_T}{kT}\right) = -\frac{J}{8\pi D} \int_R^{+\infty} \exp\left(\frac{V_T}{kT}\right) \frac{dR}{R^2} + A \implies J_t \int_{2a}^{+\infty} \exp\left(\frac{V_T}{kT}\right) \frac{dR}{R^2} = 8\pi D C_{\infty} \quad (61)$$

Boundary conditions  $V_T \rightarrow 0$  and  $C(R) \rightarrow C_{\infty} \sim N_0/V$  when  $R \rightarrow +\infty$  and  $C(2a) = 0$  have been applied to get the integration constant  $A$ .

### 5.3. Hard Spheres Model

Let us apply (61) to the most simple case of noninteracting particles characterized by  $V_T \sim 0$  (i.e., by  $J_i^\circ = 16\pi DaC$ ). Now, for a given flux  $J_i$ , half particles are expected to move in a direction allowing a close encounter at  $R = 2a$ , while the other half are moving in the right opposite direction. As all encounters lead to an irreversible sticking of both partners, the rate of disappearance of the crystals through coagulation should be

$$-\frac{dC}{dt} = \frac{1}{2} J_i^\circ C = 8\pi DaC^2$$

$$\Rightarrow C(t) = \frac{C_0}{(1 + 8\pi DaC_0 t)} \quad k_f = 8\pi Da = \frac{4kT}{3\eta} \quad (62)$$

Here  $C_0 = N_0/V$  is the total concentration at time  $t = 0$  that governs the characteristic lifetime  $t_{1/2}$  [such that  $C(t_{1/2}) = C_0/2$ ] of the dispersion. As shown in (62), this time is given by  $t_{1/2} = (k_f C_0)^{-1} = (3\eta/4kTC_0)$ . For water at  $T = 298$  K, we have  $t_{1/2}(s) = 2 \times 10^{11}/C_0(\text{cm}^{-3})$ , showing that the lifetime of dispersions characterized by  $V_T \sim 0$  is quite short (a few milliseconds when  $C_0 \sim 10^{14} \text{ cm}^{-3}$ ).

### 5.4. Attractive Forces

In fact the solution given by (62) is a little bit unrealistic as the situation  $V_T \sim 0$  is never encountered in reality and because the equation applies only to doublets formed by the association of two single particles. For instance, due to the universality of the London dispersion interaction, an attracting potential should always be expected at any distance. Accordingly, quantum mechanical considerations have shown that the potential energy of attraction between two atoms A and B, separated by a distance  $r$ , is given by  $V_A = -L/r^6$  (London force) [45]. The constant  $L$ , characterizing the two interacting atoms, has been roughly estimated by London from the atomic polarizabilities  $\alpha$  and first ionization energies  $I$  as  $L = (3/2) \times [\alpha_A \alpha_B / (4\pi \epsilon_0)^2] \times (I_A^{-1} + I_B^{-1})^{-1}$  [46].

#### 5.4.1. Hamaker Constant $A$

This quantum mechanical expression for the dispersion interaction may readily be used for computing attractive forces between surfaces [42]. For instance, the interaction between an atom and a crown of matter (as always characterized by its molecular volume  $v$ ) of radius  $a$ , width  $da$ , and thickness  $dx$ , is just  $d^2V = -(L/v)(2\pi adadx)r^{-6}$ . If  $R$  is the distance separating the atom from the surface, we may write using Pythagoras's theorem  $r^2 = [(R+x)^2 + a^2]$ , leading after integration (from zero to infinity) against  $x$  and  $a$  to  $V_A = -(\pi L/6v)/R^3$ . Considering that the previous atom belongs in fact to a plate of thickness  $dz$  situated at a distance  $(R+x)$  from the other surface leads to an energy of attraction per unit area  $dv_A = -(\pi L/6v^2)dz/(R+z)^3$ . A last integration against  $z$  from zero to infinity leads to the well-known formula giving the van der Waals interaction between two infinitely large flat plates separated by a distance  $H$ :  $V_A = -A/(12\pi R^2)$ . The parameter  $A = \pi^2(L/v^2)$  characterizing the macroscopic interaction is called the Hamaker constant after the man

who first did this analysis [44]. This is a characteristic value for any condensed substance (whether solid or liquid) as shown in Table 5 [47]. As detailed previously for similar substances one would expect  $L \propto \alpha^2 \times I$  [i.e.,  $A \propto (\alpha^2 \times I)/v^2$ ]. Materials displaying high Hamaker constants are then those with large polarizability  $\alpha$ , high first ionization potential  $I$ , and high atomic density ( $1/v$ ). This explains the extreme position of ice and diamond in Table 5. Obviously, Table 5 should be applicable only for vacuum interactions. When two particles of substance A (Hamaker constant  $A_1$ ) and B (Hamaker constant  $A_2$ ) are immersed in substance C (Hamaker constant  $A_3$ ), one may show [48] that the resulting interaction  $A_{123}$  may be characterized by

$$A_{123} = (\sqrt{A_1} - \sqrt{A_3})(\sqrt{A_2} - \sqrt{A_3})$$

$$= (\sqrt{A_1} - \sqrt{A_3})^2 \quad \text{if } A_1 = A_2 \quad (63)$$

The use of square roots in (63) comes from the fact that  $A \propto (\alpha/v)^2$  while polarizabilities  $\alpha$  are additive quantities. According to this relationship, one may expect for water/oxide interfaces Hamaker constants that are ranging from 0.2 up to 0.5 eV.

As far as nanocrystals are concerned the relationship  $V_A = -A/(12\pi R^2)$  cannot be very useful as it applies to two infinite planar interfaces. Performing the previous integration with spheres displaying radii  $a_1$  and  $a_2$ , with a center to center separation  $S$ , leads to [44]

$$V_A(S) = -\frac{A}{6} \left\{ \frac{2a_1 a_2}{S^2 - (a_1 + a_2)^2} + \frac{2a_1 a_2}{S^2 - (a_1 - a_2)^2} + \ln \frac{S^2 - (a_1 + a_2)^2}{S^2 - (a_1 - a_2)^2} \right\} \quad (64)$$

**Table 5.** Some Hamaker constants  $A$  for condensed matter characterizing the intensity of van der Waals interactions between microscopic objects.

Matter	$A$ (eV)
Hexagonal ice	0.19
Liquid water H <sub>2</sub> O	0.23

Diamond	2.81

### 5.4.2. Application

In order to see the effect of such a potential on the rate constant  $k_f$ , we may simplify (64) by writing  $S = R + a_1 + a_2$  and assuming a very small distance  $R \ll (a_1 + a_2)$  between the two spheres. In such a case the first term of (64) is the leading one and  $V_A(R) \sim -(A/6R)[1/a_1 + 1/a_2]^{-1} = -Aa/12R$  for two spheres of equal sizes ( $a_1 = a_2$ ). Replacement of  $V_T$  by  $V_A(R)$  in (61) then leads after integration and expansion of the exponential term up to second order to  $J_i = 16\pi DaC(1 + A/[48kT])$ . As  $A$  is at most a few tens of  $kT$ , the kinetic constant  $k_f$  should be at most multiplied by a factor 2, relative to its value at  $V_T \sim 0$ . Even if this correction appears to be negligible relative to the  $10^{11} \text{ cm}^{-3}$  term, it nevertheless shows that aggregation is accelerated (particularly at low temperature and for materials displaying high Hamaker constant) relative to pure diffusion. Consequently, if the dispersion has to be stabilized against irreversible aggregation, one must play with experimental factors leading to a  $V_T$  curve that must display some maximum positive value  $V_{\max}$  at a given distance  $R > 2a$ . Accordingly, the previous analysis has shown that the additional destabilization factor coming from the region where the potential displays strongly negative values was at most two. Such a modest contribution is then expected to be negligible even in the presence of a small maximum. This observation simplifies integration of Eq. (61) and allows one to write  $J_i = J_i^0/W$ , where  $W$  is the so-called stability ratio  $W \sim \exp(V_{\max}/kT)$ . The higher  $V_{\max}$ , the higher  $W$  and the longer the lifetime of the dispersion as  $k_f \sim 8\pi Da/W$  and  $t_{1/2} = (k_f C_0)^{-1} \propto W$ . For instance, the stabilization for about one year of a dispersion displaying about  $10^{14}$  particles per cubic centimeter would require a stability ratio of about  $10^{10.5}$ . This corresponds to a potential maximum of about  $24 \text{ kT}$  ( $\sim 60 \text{ kJ mol}^{-1}$  or  $0.6 \text{ eV}$  at  $T = 298 \text{ K}$ ).

## 5.5. Repulsive Electrical Forces

The first method widely used to stabilize colloidal dispersion is to work with charged surfaces. For oxide materials, this is done by changing the pH or the ionic strength  $I$ . Owing to the rapid diffusion of protons in aqueous solutions, any pH variation instantaneously affects the surface potential  $\psi_0$  as evidenced by Eq. (38). By playing with the ionic strength, the spatial extensions of the double layers around colloidal particles are deeply affected. Consequently, let us evaluate the time duration  $\tau_B$  of a collision between two charged particles. During this collision, each particle must then diffuse over a length scale of the order of the Debye–Hückel length  $\kappa^{-1}$  given by Eq. (39). If  $D_p$  is the diffusion coefficient of the colliding partners (fixed by radius  $a$  and solution viscosity  $\eta$ ), then  $\tau_B = \kappa^{-2}/2D_p = 3\pi\eta a/(\kappa^2 kT)$ . For water at room temperature ( $T = 298 \text{ K}$ ,  $\eta \sim 10^{-3} \text{ Pas}$ ), we should have  $\tau_B(\text{ns}) = 0.2 \times [a(\text{nm})/I(\text{mol l}^{-1})]$ . For nanosized particles ( $1 \leq a \leq 100 \text{ nm}$ ) with typical ionic strength ( $10^{-3} \leq I \leq 1 \text{ M}$ ), a Brownian collision cannot be shorter than  $100 \text{ ps}$  (small particles or high ionic strength). On the other hand, for larger size or lower ionic strength it cannot be longer than  $0.1 \text{ ms}$ . Due to the geometric changes involved by the collision, several relaxation processes have to occur in order to restore complete equilibrium.

### 5.5.1. Diffuse Layer Relaxation

The first one is the Debye–Hückel relaxation by which counterions located in the diffuse layer move with a diffusion coefficient  $D_i$  in order to adjust the structure of the double layer to the new conditions. The characteristic relaxation time  $\tau_{DH}$  associated with this process is equal to the average time needed for displacement of ions across the double layer:  $\tau_{DH} = \kappa^{-2}/2D_i$ . For aqueous solutions at room temperature  $D_i \sim 10^{-9} \text{ m}^2 \text{ s}^{-1}$  leading to  $\tau_{DH}(\text{ps}) \sim 46/[I(\text{mol l}^{-1})]$ . Consequently, one may safely assume that double layers are always at equilibrium during collision, as even for  $a = 1 \text{ nm}$  we still have  $\tau_B \sim 4\tau_{DH}$ .

### 5.5.2. Stern Layer Relaxation

The second mechanism relies on the adsorption or desorption of all the PDIs involved in the double layer equilibrium. This includes charged species located at the surface as well as those located at the IHP within the Stern layer. Here the rate of charge adjustment is ruled by the value of the exchange current density  $i_0$  between the surface and the Stern layer. For a given charge density ( $\sigma_0 + \sigma_\beta$ ) the characteristic relaxation time may be evaluated as  $\tau_{AD} = (\sigma_0 + \sigma_\beta)/i_0$ . If the exact value of  $i_0$  is highly dependent on the detailed structure of the interface,  $1 \text{ A cm}^{-2}$  is surely a very high value and  $10^{-10} \text{ A cm}^{-2}$  is a very low one [49]. With  $1 \mu\text{C cm}^{-2} \leq (\sigma_0 + \sigma_\beta) \leq 100 \mu\text{C cm}^{-2}$ , it follows that PDI relaxation should take at least  $1 \mu\text{s}$  and may in the worst cases (high surface charge and low mobility of the charges) be as long as several days.

### 5.5.3. Interactions at Constant Charge or Potential

It follows from the last analysis that two limiting cases will be encountered during a Brownian collision between two charged particles:

- (i) For large nanocrystals displaying a low surface charge with high mobility of the PDI and placed under low ionic strength conditions, one may safely assume that  $\tau_B > \tau_{AD}$ . In such a case, the interface, as a whole, is completely relaxed during the collision. This means that at all times the potential remains constant.
- (ii) In all other cases, one may expect that  $\tau_B \ll \tau_{AD}$ , and in this case, only the diffuse part of the double layer is completely relaxed. As  $\sigma = -\epsilon\epsilon_0 d\psi/dx$ , this means that at all times the slope at the surface of the  $\psi = f(x)$  curve cannot change leading to an increase of the surface potential  $\psi_0$ . A consequence of this fact is that the distance of closest approach should not be  $S = 2a$ , but  $S = 2 \times (a + \delta)$ , where  $\delta$  is thickness of the Stern layer holding some of the PDI ions [49]. Obviously, this nonequilibrium situation holds only during a time  $\tau_B$ . If particles remain stuck together after the collision, a discharge current will appear allowing a reduction of the potential toward its equilibrium value. This relaxation allows a still closest approach between the two cores of the particles, until  $S = 2a$  at equilibrium. In this fully relaxed state particles are irreversibly bonded through the van der Waals interaction and cannot be separated anymore.

This constant charge mechanism helps to explain the reptization phenomenon by which a flocculated system may be dispersed again by changing the composition of the medium without stirring [49].

### 5.5.4. Osmotic Pressure and Repulsive Potential

From a physical point of view, the origin of the repulsion between two overlapping double layers comes from the existence of an osmotic pressure  $p_R$ , which develops due to the accumulation of ions between the two surfaces. At sufficiently long distances, the two interacting particles may be viewed as almost planar interfaces. The actual force per unit area exerted on the plates is given by the difference in the osmotic pressure between the solution in the midplane  $\psi_m$  and that in the bulk (concentration  $c_0$ ). With  $c_+$  and  $c_-$  the concentrations at the middle plane, we may write  $p_R = RT(c_+ + c_- - 2c_0)$ . Assuming that  $c_{\pm} = c_0 \exp(\mp zF\psi_m/RT)$  and developing the exponential terms up to second order ( $\frac{1}{2}[e^x + e^{-x}] \sim 1 + x^2/2$  when  $x$  is small) allows one to express this osmotic pressure as  $p_R = \frac{1}{2}\kappa^2\epsilon\epsilon_0\psi_m^2$ . In the case of small overlap between the two plates, potentials are expected to be additive leading to  $\psi_m = 2\psi(x = R/2) \sim 2\psi_d \exp(-\kappa R/2)$ . The resulting repulsion potential is thus obtained after integration over  $R$  leading to

$$\begin{aligned} V_R &= \int_R^\infty p_R dR = \frac{4\kappa^2\epsilon\epsilon_0}{2}\psi_d^2 \int_R^\infty \exp(-\kappa R) dR \\ &= 2\kappa\epsilon\epsilon_0\psi_d^2 \exp(-\kappa R) \end{aligned} \quad (65)$$

Equation (65) is useful as it shows that a high value of  $\psi_d$  is to be associated with a strong repulsive potential. It is, however, not very realistic, as it suggests that high ionic strength (i.e., high  $\kappa$  values) also favors strong repulsion. Keeping the low potential approximation, but considering spheres of radii  $a_1$  and  $a_2$  instead of infinite plates, leads to a more satisfying result when  $|\psi_d| < 60$  mV and  $\kappa a \gg 1$  [50]:

$$\begin{aligned} V_R^\psi &= \frac{\pi\epsilon\epsilon_0 a_1 a_2 (\psi_{d1}^2 + \psi_{d2}^2)}{(a_1 + a_2)} \\ &\times \left[ \frac{2\psi_{d1}\psi_{d2}}{(\psi_{d1}^2 + \psi_{d2}^2)} \ln\left(\frac{1 + \exp[-\kappa R]}{1 - \exp[-\kappa R]}\right) \right. \\ &\quad \left. + \ln(1 + \exp[-2\kappa R]) \right] \end{aligned} \quad (66)$$

When  $a_1 = a_2 = a$  and  $\psi_{d1} = \psi_{d2} = \psi_d$ , (66) reduces to a much simpler expression,  $V_R^\psi = 2\pi\epsilon\epsilon_0 a \psi_d^2 \ln[1 + \exp(-\kappa R)]$ , that does not show the previously noted  $\kappa$  dependence. The  $\psi$  superscript in the previous relationships refers to an overlap between double layers occurring at constant potential. For the other case (constant charge), an additional term has to be subtracted [51]:

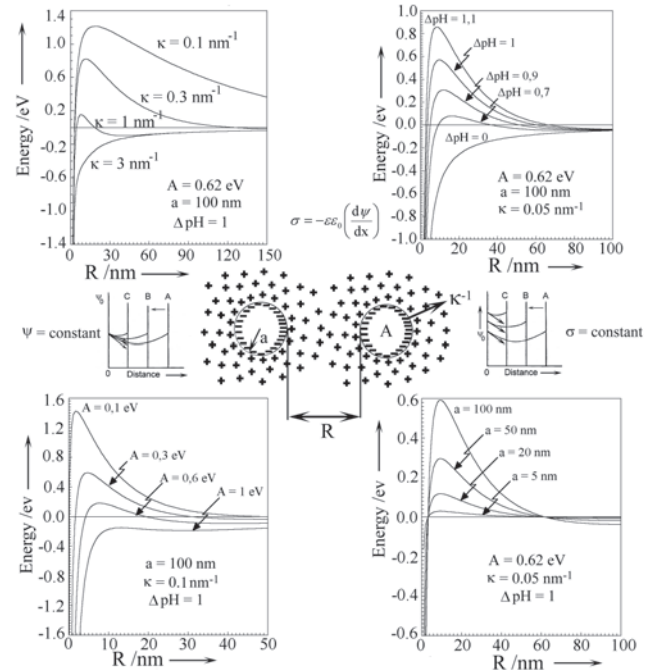

$$V_R^\sigma = V_R^\psi - \frac{2\pi\epsilon\epsilon_0 a_1 a_2 (\psi_{d1}^2 + \psi_{d2}^2)}{(a_1 + a_2)} [\ln(1 + \exp[-2\kappa R])] \quad (67)$$

Again, when  $a_1 = a_2 = a$  and  $\psi_{d1} = \psi_{d2} = \psi_d$ , (67) reduces to a much simpler expression,  $V_R^\sigma = -2\pi\epsilon\epsilon_0 a \psi_d^2 \ln[1 - \exp(-\kappa R)]$ . For large distances ( $\kappa R \gg 1$ ) both equations

reduce to an expression similar to (65):  $V_R^\psi = V_R^\sigma = 2\pi\epsilon\epsilon_0 a \psi_d^2 \exp(-\kappa R)$ . Other expressions are available in the literature for situations where the approximations  $|\psi_d| < 60$  mV and  $\kappa a \gg 1$  are not valid [49, 52–55].

### 5.5.5. DLVO Theory

Figure 8 shows the resulting potential curves  $V_T = V_A + V_R^\psi$  obtained when the Hamaker attraction given by (64) is added to the repulsive contribution  $V_R^\psi$  coming from the overlap of double layers given by (66). As shown, four parameters have a deep influence on the occurrence of a maximum. The curve at the top left part of Figure 8 shows the effect of changing the ionic strength for a constant Hamaker constant, size, and surface potential. At high ionic strength or  $\kappa$  there is no maximum and the dispersion should flocculate. This is not true at low ionic strength where the interaction is largely repulsive at all distances  $R > \kappa^{-1}$ . It is a well-known experimental fact (Schulze–Hardy rule) that the critical coagulation concentration (c.c.c.) displays a strong dependence on the valency  $z$  of the coagulating ion (c.c.c.  $\propto 1/z^6$ ). This c.c.c. should correspond to the point at which the maximum in the total potential energy curve just touches the horizontal axis ( $V_T = dV_T/dR = 0$ ). As coagulation implies a low potential and a rather small separation  $R$ , we may use  $V_R^\psi = V_R^\sigma = 2\pi\epsilon\epsilon_0 a \psi_d^2 \exp(-\kappa R)$  and  $V_A(R) = -Aa/12R$  for the repulsive and attractive parts respectively. Applying

**Figure 8.** DLVO (Deryaguin, Landau, Verwey, and Overbeek) theory for the stabilization of colloidal particles with radius  $a$  against van der Waals attraction (Hamaker constant  $A$ ). The four curves were computed using a potential fixed by the PZC of the particles:  $\psi_0$  (mV) =  $25.7 \times (\text{PZC} - \text{pH}) = 25.7\Delta\text{pH}$ . These curves are the result of adding an attractive contribution,  $V_A(R) = -Aa/12R$ , to a repulsive one,  $V_R$  (eV) =  $0.018 \times a$  (nm)  $\Delta\text{pH}^2 \exp(-\kappa R)$  coming from the osmotic pressure induced by the compression of the diffuse layers characterized by their thickness  $\kappa^{-1}$ .

the conditions  $V_T = V_A(R) + V_R(R) = dV_T/dR = 0$  to this particular form leads to

$$\begin{aligned} \kappa R = 1 &\implies \kappa = \frac{24\pi\epsilon\epsilon_0\psi_d^2}{Ae} = \sqrt{\frac{2z^2 F \text{c.c.c.}}{RT\epsilon\epsilon_0}} \\ &\implies \text{c.c.c.} = \left(\frac{288\pi^2}{e^2 F^2}\right) \left[\frac{RT(\epsilon\epsilon_0)^3}{A^2}\right] \left(\frac{\psi_d^4}{z^2}\right) \quad (68) \end{aligned}$$

This interesting formula shows that the sensibility of a given dispersion to an increase in ionic strength is governed by two main factors. The first factor depends mainly on the physicochemical state of the solvent (temperature, dielectric constant  $\epsilon$ ) and on the chemical nature of the dispersed solid phase (Hamaker constant  $A$ ). Typically a high sensitivity (low c.c.c. value) is expected for materials displaying large polarizability and high density (high Hamaker constant) dispersed in apolar solvents (low dielectric constant) at low temperature. The second factor involves the valency  $z$  of the added ions and the electrokinetic potential  $\zeta \sim \psi_d$ . Here, high sensitivity means low electrokinetic potential and large valency. Recalling that from the Poisson–Boltzmann equation we have  $\sigma_d = -\epsilon\epsilon_0\kappa\psi_d$  with  $\kappa \propto z$ , we may expect that  $\psi_d \propto z^{-1}$ , providing a nice explanation for the empirical Schulze–Hardy rule.

The top right curve in Figure 8 shows the effect of changing the surface potential  $\psi_0 = (RT/F \ln 10)(\text{PZC} - \text{pH})$  at constant Hamaker constant, size, and ionic strength. At the PZC, the attractive term dominates while for  $\Delta\text{pH} \geq 1$  a high maximum always exists. The bottom left curve illustrates the effect of changing the Hamaker constant at constant ionic strength, size, and surface potential. It shows that materials such that  $A > 1$  eV are not good candidates for making stable dispersions. A very high surface charge or low ionic strength is mandatory in this case. At last, the bottom right curve shows the effect of the nanocrystal size at constant ionic strength, surface potential, and Hamaker constant. The interesting point is the absence of maximum for small particles. A direct consequence of this fact is that during a precipitation experiment involving aggregation, the smallest crystals should be selectively removed from the solution, while the largest ones would remain unaffected. This means that starting from a highly polydisperse system, a narrowing of the size distribution is to be expected. This explains the possibility of getting, for any kind of material, dispersions displaying very narrow size distributions as exemplified by the beautiful work of Matijevic [25]. Here, through a fine-tuning of experimental conditions it should be possible to heal by aggregation the inescapable polydispersity generated by nucleation and growth or Ostwald ripening processes.

## 5.6. Entropic Forces

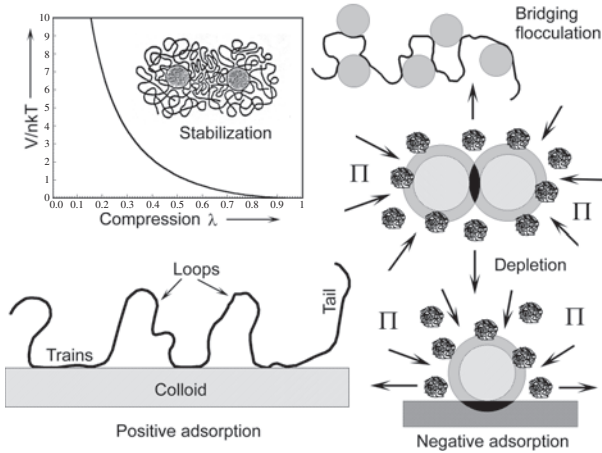

We have so far discussed only enthalpic stabilization. Another possible stabilization mechanism would be to play with entropy instead of enthalpy. In fact, steric stabilization through the adsorption of polymeric species is of widespread use. Accordingly, a polymer can adsorb on the surface of a colloidal particle because of various interactions (charge–charge, dipole–dipole, hydrogen bonding, or van der Waals) acting alone or in combination.

### 5.6.1. Depletion Interaction

When a surface exerts no net attraction on the polymer, a net attractive force may nevertheless exist between the two colloids coming from the unsymmetrical repartition of the osmotic pressure between the overlapping and nonoverlapping zones. Assuming a perfect gas behavior, this osmotic pressure  $\pi = \rho(r)kT$  should be proportional to temperature  $T$  and to the local density  $\rho(r)$  in solute species (here polymers) at distance  $r$  from the surface. Let us further assume that the local density  $\rho(r)$  is close to the bulk density of solute  $\rho_S$ , and that the distance  $d$  is smaller than the sum of the diameters of colloidal  $\sigma_C$  and polymeric species  $\sigma_S$  ( $d < \sigma_C + \sigma_S$ ). Then it is clear that solute species considered as hard spheres should be excluded from the central volume  $V_c$ , leading to a nil osmotic pressure in this central zone. To this depletion phenomenon [56] is associated an attractive potential between the two surfaces given by  $V_{\text{dep}} = -\pi V_c = -kT\rho_S V_c$ . It should be realized that this depletion force is not always attractive. If one looks the interaction at a larger distance ( $\sigma_C + \sigma_S < d < (\sigma_C + 2\sigma_S)$ ), then one finds a repulsive potential. Accordingly, as there is now enough room between the two surfaces, a polymer approaching a surface is pushed against it (negative adsorption) by the osmotic pressure unbalance existing between the surface zone (no polymers) and the bulk solution (density  $\rho_S$ ). Consequently, the local density in polymers in the middle zone should be higher than in the two opposite directions, leading to a neat repulsive force. For a still larger distance ( $(\sigma_C + 2\sigma_S) < d < (\sigma_C + 3\sigma_S)$ ), the potential is again attractive because we have now a system of two coated surfaces displaying again an excluded volume for other polymers in the middle zone. In fact, one may understand that the effective potential for a system of large hard spheres (colloids) in contact with a large amount of smaller hard spheres (polymers) is not a regular one. It always displays a strong attractive component at very small distance (naked surfaces) and displays regular oscillations (period ruled by  $\sigma_S$ ) at longer distances. The higher the volume fraction occupied by the small spheres, the more visible the oscillations and the longer the interaction range.

### 5.6.2. Positive Adsorption

The depletion phenomenon (negative adsorption) will always exist when a polymer solution is near an inert surface. However, if the attractive forces are strong enough, the enthalpy gained overcomes the entropy lost, leading to the model at the bottom of Figure 9 [56]. In this model [57], the links in contact with the surface are called trains. These are adsorbed on the surface, by physical forces invoked above. The loops may be defined as parts of the polymer connecting two trains but displaying no contact with the surface. Finally, the tails are all the nonadsorbed chain ends pointing outside the particle. Using this model, one may define the bound fraction as that fraction of chains forming trains. At very low polymer concentrations, a “pancake” conformation having a relatively large bound fraction may be formed. In this conformation, as there is plenty of room at the surface, the chains in contact with the surface tend to spread out. At higher solution concentrations, severe competition for the available space may occur, leading to shorter

**Figure 9.** Colloidal interactions between solids and polymeric chains. For inert interfaces only depletion and negative adsorption may occur (existence of an excluded volume shown in black leading to osmotic pressure unbalance  $\Pi$ ). Positive adsorption and steric stabilization require some affinity between the surface and the chains. Bridging flocculation is very often observed with small nanocrystals.

trains. In this case, long tails and loops stick out into the solution leading to a “brush” conformation. At last another possibility is that when two particles are brought together it may occur for the loops and tails of one polymer to attach them to bare patches on the other approaching particles (top right drawing in Fig. 9). Obviously, this bridging process is favored if the adsorption density of the polymer is not too high and should be most successful for half-surface coverage and small colloid size.

### 5.6.3. Relaxation Time

Let us now have a closer look at the dynamic aspect of the collision between particles coated with polymeric chains. Relaxation time involved in the adjustment of the conformation of an adsorbed chain or loop has been estimated to be  $2 \times 10^{-4}$  s for polystyrene ( $M = 50,000$ ) in a liquid with viscosity 0.2 Pa s [49]. On the other hand, adjustment of the loop size distribution is a much slower process requiring several minutes. For these systems, the time involved in a Brownian encounter should be defined as the time needed to travel over a distance equal to the thickness of the adsorbed polymeric layer  $\delta$ :  $\tau_B \sim \delta^2/2D_p = 3\pi\eta\delta^2 a/kT$ . For a viscosity  $\eta = 1$  Pa s at  $T = 298$  K,  $\tau_B(\mu\text{s}) = 2.3 \times [a(\text{nm}) \times \delta(\text{nm})^2]$ . With  $1 \leq a \leq 100$  nm and  $1 \leq \delta \leq 10$  nm, we find that the conformation adjustment can follow the collision process. This is not the case for loop size redistribution.

### 5.6.4. Steric Stabilization

With the help of this model, it is easy to track the entropic origin of the steric stabilization. Let  $W$  be the total number of conformations available to the system. Then the corresponding entropy  $S$  should be given by the Boltzmann definition  $S = k \ln(W)$ . Let  $n$  be the number of loops or tails, let  $N_0$  be the number of allowed conformations, and let  $\langle r^2 \rangle$  be the mean square end-to-end distance for each loop or tail.

Provided that a loop or a tail does not approach full extension, the probability that it extends randomly from an arbitrary point  $(x, y, z)$  to another point  $(x + dx, y + dy, z + dz)$  should be given by a simple Gaussian distribution, leading to

$$W = \prod_{i=1}^n W_i$$

$$W_i = N_0 \left( \frac{3}{2\pi\langle r^2 \rangle} \right)^{3/2} \exp\left( -\frac{3}{2} \left[ \frac{\Delta x_i^2 + \Delta y_i^2 + \Delta z_i^2}{\langle r^2 \rangle} \right] \right) \quad (69)$$

In this expression we may replace each  $\Delta x_i^2$ ,  $\Delta y_i^2$ , and  $\Delta z_i^2$  by the mean-square average for the assembly:  $\sum_{i=1}^n \Delta u_i^2 = \langle \Delta u^2 \rangle$  ( $u = x, y, z$ ). The resulting conformation entropy  $S_C$  may then readily be expressed as

$$S_C = k \ln W = nk \ln N_0 \left( \frac{3}{2\pi\langle r^2 \rangle} \right)^{3/2} - \frac{3nk}{2\langle r^2 \rangle} (\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle + \langle \Delta z^2 \rangle) \quad (70)$$

Let us now consider that the loops are deformed along the  $x$  direction at constant volume. Relation (70) still holds, but the mean-square averages are now  $\Delta x_d = \lambda_x \Delta x$ ,  $\Delta y_d = \lambda_y \Delta y$ ,  $\Delta z_d = \lambda_z \Delta z$ , with  $\lambda_x \lambda_y \lambda_z = 1$ ,  $\lambda_y^2 = \lambda_z^2 = 1/\lambda_x = 1/\lambda$ . For an isotropic medium all directions are equally probable, so that on the average  $\langle \Delta x^2 \rangle = \langle \Delta y^2 \rangle = \langle \Delta z^2 \rangle = \langle r^2 \rangle/3$  leading to

$$S(\lambda) = S_C - \frac{nk}{2} \left( \lambda^2 + \frac{2}{\lambda} - 3 \right) \quad (71)$$

Consequently, any deformation of the loops or tails occurring during a Brownian collision has an unfavorable entropic cost  $V = -2T[S(\lambda) - S(\lambda = 1)] = nkT(\lambda^2 + 2/\lambda - 3)$ . The curve at the top of Figure 9 shows the steep increase in energy provided by the compression of the polymeric chains occurring when the distance between two coated particles is reduced. Obviously, this repulsive potential could play the same role as the repulsive  $V(R)$  term of the DLVO theory. When added to the attractive  $V_A(R)$  term, it should also lead to a maximum at some distance  $R$ . Let us also notice that when the chains belonging to two particles start to overlap, this amounts to a local increase of the concentration. Consequently, besides the repulsive force coming from the volume restriction, another repulsive contribution coming from the apparition of an osmotic pressure is also present (depletion).

## 5.7. Kinetics of Aggregation

We are now in a position to treat the full problem of irreversible aggregation by looking at the time evolution of the aggregate size distribution.

### 5.7.1. Von Smoluchowski Equations

The kinetic equations that must be used had been derived as early as 1916 by Max Von Smoluchowski through the use of aggregation kernels  $K_{ij}$  associated with the following irreversible reaction:  $[i] + [j] \rightarrow [i + j]$ . Here the notation  $[i]$  refers to the ensemble of aggregates containing  $i$  particles

while the  $K_{ij}$  carry all the physical and chemical aspects of the collision. The equations may be written by noticing that  $[k]$  species may appear in solution as a result of the reaction between  $[i]$  and  $[j]$  species such that  $i + j = k$ . But the same  $[k]$  species may also disappear after reaction with any  $[i]$  species. Consequently, if  $c_k$  stands for the number of aggregates of size  $k$  per unit volume, the time evolution of this concentration should be given by

$$\frac{dc_k}{dt} = \frac{1}{2} \sum_{i+j=k} K_{ij} c_i c_j - \sum_i K_{ik} c_i c_k \quad (72)$$

The  $\frac{1}{2}$  factor is there to avoid double counting in the first sum describing the creation of species  $[k]$ . As all the physical and chemical aspects are encapsulated in the  $K_{ij}$  kinetic constants, all the problems lie in getting a meaningful  $i, j$  dependence of these kernels and in the resolution of an infinite system of coupled equations. As for the nucleation and growth steps, it may be useful to consider two limiting cases: diffusion-limited and interface-limited aggregation.

### 5.7.2. Pure Diffusion Kernel

If there is no chemistry involved in the sticking of two aggregates, we may use diffusion equations to get a kernel  $K_{ij}$ . Here, we are interested by the probability  $P_{ij}$  that a cluster with radius  $R_i$  shall be hit in the time interval  $dt$  by another cluster of radius  $R_j$  having the concentration  $c_j$ . This probability should be equal to the diffusion flux  $\varphi_{ij}$  into a sphere of radius  $R_{ij} = (R_i + R_j)$ . From Fick's first ( $j = -D \times \text{grad } c$ ) and second laws ( $dc/dt = D\nabla^2 c$ ) the concentration  $c(\rho, t)$  of species  $[j]$  at a distance  $\rho$  from the center of the sphere of radius  $R_{ij}$  may be written

$$c(\rho, t) = c_j \left\{ 1 - \frac{R_{ij}}{\rho} \left( 1 - \text{erf} \left[ \frac{\rho - R_{ij}}{\sqrt{2Dt}} \right] \right) \right\}$$

$$\Rightarrow \varphi_{ij} = \lim_{t \rightarrow \infty} \left( \frac{dc}{d\rho} \right)_{\rho=R_{ij}} = \frac{c_j}{R_{ij}} \quad (73)$$

As both clusters are undergoing Brownian motion, their relative diffusion coefficient should be  $D_{\text{rel}} = (D_i + D_j)$ . With this diffusion flux of matter, the sticking probability may easily be evaluated as

$$P_{ij} dt = 4\pi R_{ij}^2 D_{\text{rel}} \varphi_{ij} dt \Rightarrow K_{ij} = (D_i + D_j)(R_i + R_j) \quad (74)$$

Now, the Stokes–Einstein equation  $D = kT/6\pi\eta R$  and the fact that for compact objects  $R_k = R_1 \times k^{1/3}$  lead to

$$K_{ij} = \frac{kT}{6\pi\eta} (i^{1/3} + j^{1/3})(i^{-1/3} + j^{-1/3}) \quad (75)$$

### 5.7.3. Getting an Analytical Solution

Consequently, even for the simplest situation, the problem has no analytic solution. However, one may notice that there is no  $i, j$  dependence when  $i = j$  as  $K_{ii} = 4kT/6\pi\eta = K$ . This suggests that one look at what the solution will be if  $K_{ij} = K$  for all clusters (even those for which  $i \neq j$ ). This is obviously a considerable simplification of the problem,

allowing one to find an analytical solution. Inserting  $K_{ij} = K$  into (72) allows one to perform the following factorizations:

$$C = \sum_{k=1}^{\infty} c_k \Rightarrow \frac{dc_k}{dt} = \frac{K}{2} \sum_{i=1}^{k-1} c_i c_{k-i} - Kc_k C$$

$$\Rightarrow \sum_{k=1}^{\infty} \frac{dc_k}{dt} = \frac{dC}{dt} = \frac{KC^2}{2} - KC^2$$

$$= -\frac{KC^2}{2} \quad (76)$$

If we start from an initially monodispersed system (i.e., at  $t = 0$  we have  $c_1 = c_0$  and  $c_k = 0$  for  $k > 1$ ), then the variations with time of the total concentration in clusters  $C(t)$  or in single particles  $c_1(t)$  are obtained after integration of (76):

$$C(t) = \frac{c_0}{[1 + (Kc_0/2)t]} \Rightarrow c_1(t) = \frac{c_0}{[1 + (Kc_0/2)t]^2} \quad (77)$$

$c_1(t), c_2(t)$  may be obtained from (76) by making  $k = 2$  leading to  $dc_2/dt = \alpha[c_0(1 + \alpha t)^{-3} - 2c_2(t)(1 + \alpha t)^{-1}]$  where we have set  $\alpha = (Kc_0/2)$ . A solution to this equation may be easily found by setting  $c_2(t) = g(t)c_0(1 + \alpha t)^{-3}$  with  $g(t)$  satisfying the differential equation  $dg/(1 + g) = \alpha dt/(1 + \alpha t)$  [i.e.,  $g(t) = \alpha t$ ]. These two particular solutions for  $k = 1$  and  $k = 2$  may be put under the following general form:

$$c_k(t) = c_0 \frac{(Kc_0 t/2)^{k-1}}{[1 + (Kc_0 t/2)]^{k+1}}$$

$$\Rightarrow k^2 c_k(t) = \frac{4}{K^2 c_0} \left( \frac{k}{t} \right)^2 \left[ \frac{1}{1 + 2/(Kc_0 t)} \right]^{(k+1)} \quad (78)$$

It is easy to show that (78) is a general solution to (76) leading to

$$\frac{dc_k(t)}{dt} = 0 \Rightarrow t = \frac{(k-1)}{Kc_0}$$

$$\Rightarrow c_k^{\text{max}} = 4c_0 \frac{(k-1)^{(k-1)}}{(k+1)^{(k+1)}} \quad (79)$$

### 5.7.4. Discussion

Consequently, for a given  $k > 1$ ,  $c_k$  goes through a maximum and tends to zero as  $t^{-2}$  for very large times. In this last case (i.e., when  $t \gg 2/Kc_0$ ), the power term in (78) may be developed as

$$\left[ \frac{1}{1 + 2/(Kc_0 t)} \right]^{(k+1)} \approx [1 - 2/(Kc_0 t)]^k$$

$$= \exp(k \ln[1 - 2/(Kc_0 t)])$$

$$\approx \exp\left(-\frac{2k}{Kc_0 t}\right) \quad (80)$$

This shows that for a given time, the size distribution has the shape of a decreasing exponential whose decreasing rate becomes smaller as time increases. It also means that the

size distribution function may be written under an interesting scaling form

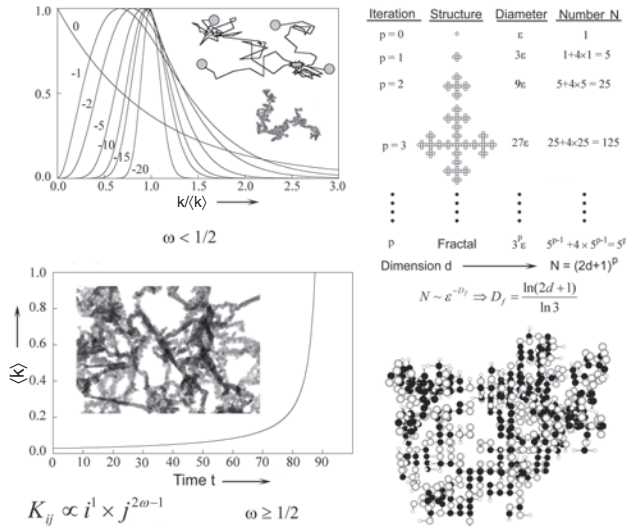

$$\langle k \rangle = \frac{\sum_{k=1}^{\infty} k c_k}{\sum_{k=1}^{\infty} c_k} = \frac{c_0}{C(t)} = 1 + \left( \frac{K c_0}{2} \right) t$$

$$\Rightarrow c_k(t \rightarrow \infty) = \langle k \rangle^{-2} \exp\left(-\frac{k}{\langle k \rangle}\right) \quad (81)$$

The important point in this relation is that the  $k$  and  $t$  dependence of  $c_k(t)$  is given through an universal function of a single variable  $k/\langle k(t) \rangle \propto k/t^\gamma$  that does not depend on the initial distribution. For the present case the scaling exponents were  $\tau = 2$  and  $\gamma = 1$ .

## 5.8. Fractal Geometry

Obviously, the case of constant kernel  $K_{ij} = K$  is interesting by its analytical solution but not very realistic and one may seek a more general solution. To do that we may notice that according to (75)  $K_{ij}$  kernels are invariant under any scaling  $\lambda$  as  $K(\lambda i, \lambda j) = K(i, j)$ . In fact it may be shown that it is this very particular scaling relation that is responsible for the asymptotic scaling of the solutions  $c_k \sim \langle k \rangle^{-2} \exp(-k/\langle k \rangle)$ . Let us recall that (74) and (75) were derived under the assumptions of dense aggregates undergoing Brownian motion. A direct observation of these aggregates by transmission electron microscopy has in reality shown that their structures were highly ramified and tortuous exhibiting a scale invariance [59].

**Figure 10.** Aggregation and fractal aggregates. Top left shows the fractal ( $\omega < 1/2$ ) and limited aggregation ( $\omega < 0$ ) regimes. Bottom left illustrates the case ( $\omega \geq 1/2$ ) leading to a divergence of the mean cluster size (gelation regime). Top right diagram shows how a fractal object may be generated through iteration of simple rules. Bottom right is a 3D-percolation cluster characterized by the fractal exponents  $\delta = 2.53$ ,  $\sigma = 1.84$ ,  $\chi = 1.30$ ,  $\mu = 1.87$ ,  $\beta = 1.143$ ,  $\nu = 3.89$ ,  $\eta = 2.548$  and  $\lambda = 1.374$ . Black spheres correspond to the backbone ( $\mu = 1.87$ ), large gray spheres to the red contacts ( $\beta = 1.143$ ), and small white spheres to dangling ends.

### 5.8.1. Fractal Dimension $\delta$

A direct measure of this scale invariance is provided by the associated fractal dimension  $\delta$  [60]. Figure 10 (top right) shows how a bidimensional ( $d = 2$ ) fractal object may be generated by sticking together identical spherical particles of diameter  $\epsilon$ . First, a seed sphere is centered at the origin. In a second step, four other spheres are added at the left, right, top, and bottom of the seed. In a third step, the ensemble of five spheres is considered a unique object, on which four similar objects may be added using the same rule as before. After a large number of iterations, it is easy to see that the resulting highly ramified object has a diameter  $L = 3^p \epsilon$  and contains  $N = 5^p$  spheres. Now a fractal object characterized by a fractal dimension  $\delta$  may be defined by the property that the minimal number of spheres  $N$  of diameter  $\epsilon$  needed to cover its matter scales like  $N \sim \epsilon^{-\delta}$ . In the present case we have

$$L = 3^p \epsilon \quad N = 5^p$$

$$\Rightarrow p = \frac{\ln(L/\epsilon)}{\ln 3} = \frac{\ln N}{\ln 5}$$

$$\Rightarrow N = \left(\frac{L}{\epsilon}\right)^\delta \quad \delta = \frac{\ln 5}{\ln 3} \approx 1.47 \quad (82)$$

The fact that  $\delta < d = 2$  is here the geometric expression that the object displays holes at any scale.

The same model could be used to derive a fractal dimension when  $d = 3$ . At each step, we have to add two similar objects above and below the plane. For the same diameter, the number of spheres is just  $N = 7^{p-1} + 6 \times 7^{p-1} = 7^p$ , leading to  $\delta = \ln 7 / \ln 3 = 1.77 < d = 3$ . Table 6 gives the fractal dimensions observed for some physical processes leading to highly ramified structure. As can be seen the ideal value of  $\delta = 1.77$  is found to be very close to that found for Brownian cluster-cluster aggregation. This should not be very surprising, as fractal dimensions are universal exponents that do not characterize uniquely the geometry of ramified objects. They just inform us about the kind of growth mechanism that has been used in order to generate the aggregates. Consequently, all objects grown using a hierarchical cluster-cluster mechanism should share the same fractal dimension close to 1.8, even if their local structure may appear quite different.

**Table 6.** Some fractal dimensions  $D_f$  for physical processes leading to ramified structures (compiled from [59]).

Structure	$D_f$
Solvated linear polymer	1.66
Brownian cluster-cluster aggregation	1.77
Ballistic cluster-cluster aggregation	1.91
Ideal linear polymer	2.0
Solvated branched polymer	2.0
Chemical cluster-cluster aggregation	2.04
Ideal branched polymer	2.16
Diffusion limited aggregation	2.50
Percolation cluster	2.49
Ballistic limited aggregation	2.8–3.0
Dense particle	3.0

A direct consequence of this matter of fact is that fractal dimension gives only information on the total mass  $M(R) \sim R^\delta$  found in a sphere of radius  $R$ . In particular, it does not give any details concerning the connectivity properties (the way masses are connected in space). In order to describe these connectivity properties, several other scaling exponents have to be used [59, 60].

### 5.8.2. Bond Dimension $\lambda$

The *bond* dimension  $\lambda$  (or *tortuosity*) gives the minimal distance  $L = R^\lambda$  that must be covered by a walk entirely contained in the object in order to go from two points separated by a Pythagorean distance  $R$ . A high  $\lambda$  value means that very tortuous circumvolutions are present between one point in space to another. However, since the minimum path in the cluster should not be shorter than the Pythagorean distance  $d$  nor longer than a complete random walk, we should have  $1 \leq \lambda \leq 2$ . Usually this exponent is evaluated through the use of numerical simulations. For instance, it has been found that diffusion-limited aggregates ( $\lambda = 1.02$ ) are much less tortuous than cluster–cluster aggregates ( $\lambda = 1.25$ ) [61]. The most tortuous structures are found with 3D-percolation clusters ( $\lambda = 1.374$ ) [62] or branched polymers ( $\lambda = 1.36$ ) [63]. One may notice that both  $\delta$  and  $\lambda$  are *extrinsic* dimensions as they link a fractal property of the object (mass  $M$  or minimal walk  $L$ ) to a Pythagorean distance  $R$  measured in an Euclidian space.

### 5.8.3. Topological Dimension $\sigma$

The *topological* (also *graph* or *chemical*) dimension  $\sigma$  gives the total mass  $M(L) \sim L^\sigma$  visited along a walk of distance  $L$  entirely contained in the object. It may be noticed that this last exponent is not independent of the two others  $\delta$  and  $\sigma$ . Accordingly, as  $L \sim R^\lambda$ ,  $M \sim L^\sigma \sim R^\delta$ , it comes that  $\delta = \lambda\sigma$ . For determinist fractals one usually have either  $\sigma = \delta$  (e.g., the Sierpinski gasket displaying no tortuosity but only lacunarity) or  $\sigma = 1$  (e.g., the Koch curve that has no lacunarity but is tortuous at all length scales). In contrast, with the fractal or bond dimensions,  $\sigma$  is an *intrinsic* dimension as it links two properties (mass  $M$  to the minimal length  $L$ ) of a given fractal object. This fact is also expressed by the relation  $\sigma = \delta/\lambda$  showing that the ratio of two extrinsic dimensions should be another intrinsic one.

### 5.8.4. Spectral Dimension $\chi$

The *spectral* dimension  $\chi$  affects all properties depending not only on space (static dimensions) but also on time (dynamical dimensions). This exponent is linked to the number  $S \sim M \sim t^{\chi/2}$  of distinct sites visited by a random walk (the de Gennes “ant” [64]) after  $t$ -steps, or to the probability  $P_0 \sim t^{-\chi/2}$  that the ant ends up at time  $t$  on its starting point. As  $\chi$  is clearly an intrinsic property independent of the embedding space, it should also be expressed as the ratio of two other extrinsic dimensions. For example a random walk in ordinary homogeneous space is such that the mean square distance varies proportionally to the time  $\langle R^2 \rangle \sim t$ , the proportionality factor  $\langle R^2 \rangle/t$  being the diffusion coefficient. Consequently, for a random walk occurring on a fractal structure one may expect that the mean

square displacement will scale like  $\langle R^2 \rangle \sim t^{2/\nu}$ , the extrinsic exponent  $\nu > 2$  characterizing the fractal walk. Writing that  $M \sim (\langle R^2 \rangle)^{\delta/2} \sim t^{\delta/\nu} \sim t^{\chi/2}$  shows that we have  $\chi = 2\delta/\nu$ . The intrinsic exponent  $\chi$  ratio of two extrinsic dimensions affects all transport properties in a fractal medium. For example, the diffusion coefficient is no more a constant but must depend on the distance  $R$  as  $R^{2-\nu}$ . A similar relation holds for electrical conductivity that becomes size dependent. Concerning the low-energy behavior of the phonon density of states it becomes  $n(E) = E^{\chi/2-1}$ , leading to a density of states per unit frequency  $\rho(\omega) = \omega^{\chi-1}$  (fractons) [65]. A consequence is that the specific heat at low temperature  $T$  scales like  $T^\chi$ .

One of the big advantages of the spectral dimension is that it can be either measured on real objects (mainly through light or neutron scattering) or computed from simulations by at least three independent ways. Strangely enough, very close  $\chi$  values were found from two very different fractal models (percolation cluster with  $\chi = 1.30$  [66] and diffusion-limited aggregates with  $\chi = 1.35$  [61, 67]). This has led to the conjecture that some fundamental link should exist between static and dynamic exponents. For instance, following conjecture  $\nu = 3\delta/2$  (or  $\chi = 4/3 \sim 1.33$ ) [65] may help to explain these data. However, this conjecture does not hold for lattice animals that are characterized by  $\chi = 1.19$  [63] and for screened growth aggregates characterized by  $\chi$  values ranging from 1.10 to 1.22 [68]. However, it may be demonstrated that for any fractal for which loops are irrelevant one should have  $\chi = 2\sigma/(\sigma + 1)$  [68]. This shows that a relation between static and dynamical exponents may occur but only on structures displaying no loops. According to this last relationship, if cluster–cluster aggregation ( $\sigma = 1.42$ ) leads to fractals with no loops, their spectral dimension should be  $\chi = 1.18$ .

### 5.8.5. Backbone Dimension $\mu$

Another exponent has to be introduced for dealing with mechanical properties of fractal aggregates. This is *backbone* dimension  $\mu$  that is always less than the fractal dimension  $\delta$ . It allows one to differentiate between domains connected by at least two contacts and dangling ends that are connected to the backbone only once and hence have no effect on mechanical properties. The backbone dimension is thus the fractal dimension of the object generated by removing all dangling ends to a given fractal. Going one step further one may differentiate between *red* contacts and *blobs*. Red contacts are those parts of the backbone whose removal cuts the object into two independent pieces (particles with coordination number equal to 2). The isolated clusters remaining after this operation and made of all particles having a coordination number of at least 3 are the blobs. The new object made by all the blobs has its own *blob* dimension  $\beta$  that should again be less than the backbone dimension. The backbone and blob dimensions are currently known only from numerical simulation (for a 3D-percolation cluster  $\delta = 2.53 > \mu = 1.87 > \beta = 1.143$ ) [69].

### 5.8.6. Hull Dimension $\eta$

Another important exponent for fractal interfaces is the *hull* dimension  $\eta$  [69]. This exponent relates the external perimeter or surface of the aggregates to the Euclidean distance

between two points. The hull consists of all cluster sites that are connected to infinity through an uninterrupted chain or plane of empty sites. In other words, it is the negative imprint of the aggregates onto the embedding space. Like the backbone and blob dimensions it is currently known only from numerical simulation (for a 3D-percolation cluster  $\eta = 2.548$ ).

## 5.9. General Solution

The previous section has shown that the properties of a fractal object cannot be obtained by rewriting formulae valid on 3D-Euclidean space and simply replacing 3 by  $\delta$ . In fact, one may rigorously define a 3D-Euclidean object by the fact that  $\delta = \sigma = \chi = \mu = \beta = 3$ ,  $\nu = \eta = 2$ , and  $\lambda = 1$ . This degeneracy no longer holds for a fractal such as a 3D-percolation cluster where  $\delta = 2.53$ ,  $\sigma = 1.84$ ,  $\chi = 1.30$ ,  $\mu = 1.87$ ,  $\beta = 1.143$ ,  $\nu = 3.89$ ,  $\eta = 2.548$ , and  $\lambda = 1.374$  [69]. Obviously, it would be hopeless to find an analytical model able to explain all these values from a given set of kernels  $K_{ij}$ . For such situations, numerical simulations are obviously of considerable help. Also, it would have been a very naïve attitude to take the kernel (75) and simply write  $K_{ij} = (kT/6\pi\eta)(i^{1/\delta} + j^{1/\delta})(i^{-1/\delta} + j^{-1/\delta})$  with the hope that everything will run fine. Even if such expression may be found in a large number of papers or textbooks, it is definitely not correct to use the consequence of a growth process (a fractal object characterized by various exponents  $\delta, \sigma, \chi, \mu, \beta, \nu, \eta, \lambda$ ) as the ultimate cause of its appearance. A more correct approach is to guess some general properties for the aggregation kernel  $K_{ij}$  from physical principles. Then one may seek either an analytical or a numerical solution to see if the resulting fractal matches some experimental structure.

### 5.9.1. Realistic and Simple Kernel

The really fundamental point in (75) lies in the scale invariance of the aggregation kernels  $K(\lambda i, \lambda j) = \lambda^0 K(i, j)$ . In this last expression, we have emphasized the null power of the scale parameter  $\lambda$  because one may expect that in the more general case we should have  $K(\lambda i, \lambda j) = \lambda^{2\omega} K(i, j)$ . However, we have to restrict the values of  $\omega$  to the range  $\omega < 1$ , since the averaged active sites in an aggregate cannot grow faster than its size  $i$  or  $j$  [70]. Another physically acceptable assumption is that the largest cluster (say cluster  $[i]$ ) that has the slowest diffusion rate would be explored for a possible reaction among its  $i$  accessible sites by the smallest one  $[j]$  that has the largest diffusion coefficient. As far as seeking the simplest model able to handle the largest number of experimental cases, there is no loss of generality to consider the homogeneous kernel:  $K_{ij} = (kT/6\pi\eta)[i^1 \times j^{2\omega-1}]$ .

The advantage of this quite simple formulation is that all the complex interfacial physics and chemistry are contained in the single  $\omega$ -exponent characterizing the most active aggregate. The restriction comes from the unit power affecting the  $i$ -cluster. This choice reflects the possibility for species  $[j]$  to have full time to explore all exposed sites on cluster  $[i]$ . Consequently, we are limiting ourselves to the case of interface-limited aggregation. The case of diffusion-limited aggregation and derived models will thus not be

covered. However, as it corresponds to an unphysical mechanism for nanocrystal aggregation in solution, we are safe. Another important physical aspect contained in our kernel is the existence of a critical  $\omega$ -value  $\omega^* = \frac{1}{2}$  for which the kernel becomes independent of  $j$ . At this critical point, any  $[j]$  species, whatever its size, is able to stick to any  $i$  site. This is a very clear signal for gelation to occur and one may understand that two qualitatively different regimes may be anticipated.

### 5.9.2. Gelation Regime

Gelling kernels are characterized by  $\omega > \frac{1}{2}$  (Fig. 10). In this regime it may be shown [71] that there exists a finite time  $t_g$  such that

$$t_g = \frac{2\omega - 1}{2\kappa c_0} \implies c_k(t < t_g) = \frac{c_0}{\langle k \rangle^\tau} \psi\left(\frac{k}{\langle k \rangle}\right) \quad \text{with } \langle k \rangle \propto (t_g - t)^{2/(1-2\omega)} \quad (83)$$

In this equation  $\kappa \propto (kT/\eta)$  is a kinetic constant function of temperature and solution viscosity and  $\psi$  is a universal scaling function such that  $\psi(x) \sim Bx^{-\tau}$ . The exponent  $\tau$  should be such that  $\tau = (2\omega + 3)/2 > 2$  ensuring that the mass flux of finite particles (sol) to the infinite cluster (gel) remains bounded for any time  $t > t_g$ . As  $\omega > \frac{1}{2}$  (83) shows that the mean cluster size  $\langle k \rangle$  diverges when  $t \rightarrow t_g$ . In the postgel stage ( $t > t_g$ ) the size distribution is qualitatively different and takes the form  $c_k(t) \sim B(t)k^{-\tau}$  with again  $\tau = (2\omega + 3)/2$ . For this regime,  $\omega > \frac{1}{2}$ , to occur the key point is that we should have a size selectivity mechanism favoring aggregation of large species over smaller ones. This is well evidenced by the power law  $c_k(t) \propto k^{-\tau}$  (with  $\tau > 2$ ) or by the positive contribution in our  $K_{ij}$  kernel of the power of  $[j]$  ( $2\omega - 1 > 0 \Leftrightarrow \omega > \frac{1}{2}$ ). As soon as  $\omega < \frac{1}{2}$ , the power reactivity of  $[j]$  species becomes negative explaining the crossover toward a regime where the size selectivity mechanism favors small clusters over larger ones. Therefore, the probability of finding an infinite cluster occupying the whole solution volume becomes zero in which case only precipitates or size-limited aggregates should be formed (Fig. 10).

### 5.9.3. Fractal Regime

One of the amazing things in this  $\omega < \frac{1}{2}$  regime is that the scaling invariance  $K(\lambda i, \lambda j) = \lambda^{2\omega} K(i, j)$  is sufficient to determine the asymptotic shape  $c_k(t) \sim \langle k \rangle^{-2} \psi(k/\langle k \rangle)$  of the solutions to the Smoluchowski kinetic equations [70, 71]. In this case, the average cluster size  $\langle k \rangle \sim t^\gamma$  carries all the time dependence, whereas the universal function  $\psi$  governs the shape of the size distribution. As this function is universal, it does not depend on the complex details of the aggregation kernels and can be determined by just looking at the most probable configuration coming out of a multinomial distribution [70]

$$\begin{aligned} N_c &= \sum_k n_k & N &= \sum_k k n_k \\ \implies n_k &= \frac{(1-2\omega)^{1-2\omega}}{\Gamma(1-2\omega)} \frac{N_c^2}{N - N_c} \left(\frac{N - N_c}{k N_c}\right)^{2\omega} \\ &\quad \times \left(1 - \frac{k}{N - N_c}\right)^{(1-2\omega)N_c} \end{aligned} \quad (84)$$

In this equation,  $n_k = c_k \times V$ , where  $V$  is the total volume of the solution and  $\Gamma$  is the gamma function. This expression may be further simplified by introducing the reduced variable  $x = k/\langle k \rangle = N_c k/N$  and taking the limit  $N_c \rightarrow 0$  leading to

$$\begin{aligned} n_k &= \frac{N}{\langle k \rangle^2} \psi(x) \\ \implies \psi(x) &= \frac{(1-2\omega)^{1-2\omega}}{\Gamma(1-2\omega)} x^{-2\omega} \exp[-(1-2\omega)x] \\ &\quad \left( \omega < \frac{1}{2} \right) \end{aligned} \quad (85)$$

As explained, the mean cluster size  $\langle k \rangle$  carries all the time dependence that may be expressed as [71]

$$\begin{aligned} \langle k \rangle &= \frac{N}{N_c} \sim [1 + \kappa c_0 (1-2\omega)t]^{1/(2\omega-1)} \sim t^{-\gamma} \\ &\quad \text{with } \gamma = \frac{1}{1-2\omega} \end{aligned} \quad (86)$$

Figure 10 shows the behavior of the normalized size distribution  $\psi(x)$  for several values of the  $\omega$  exponent. It is seen that when  $0 \leq \omega < \frac{1}{2}$ , the size distribution displays a monotonic exponential decreasing behavior. Interestingly enough, when  $\omega = 0$ , we recover exactly the analytical solution of the Von Smoluchowski equation at constant kernel  $K_{ij} = K$ .

#### 5.9.4. Limited Aggregation Regime

When  $\omega < 0$ , another qualitative change of the size distribution occurs. Instead of a monotonic decrease, we have now a bell-shaped curve leading to a narrowing of size distribution as  $\omega$  decreases. This crossover between a highly polydisperse size distribution ( $\omega > 0$ ) and a more monodispersed limited aggregation ( $\omega < 0$ ) is again well modeled by the  $K_{ij} \propto [i^1 \times j^{2\omega-1}]$  kernel. Accordingly, when  $\omega = 0$ , we get the most symmetric kernel  $K_{ij} = i/j$  meaning that no clear distinction exists between the explored cluster and the exploring one. This is no more the case when  $\omega > 0$  modeling a situation where the most probable events are the sticking of the any  $[j]$  species onto the dangling ends of the slowly moving  $[i]$  clusters. One may then understand that the result of this site selectivity (dangling ends more reactive than the backbone) would be a polydisperse collection of objects displaying holes at any scale.

The situation is also unsymmetrical when  $\omega < 0$ . In this regime, we may say that dangling ends are poisoned becoming inactive toward sticking. By consequence, the largest  $[j]$  species, being able to explore only the outer tips of the larger  $[i]$  clusters, cannot participate in the growth process anymore. In this case, the better the poisoning, the lower  $\omega$  and the better the selectivity both in size (only the smallest species are allowed) and in site (backbone free of poison becomes more reactive than dangling ends). This explains the crossover from a fractal regime toward a more compact regime characterized by a bell-shaped size distribution (larger clusters just “eat” the smallest ones without being eaten by their congeners). A high compactness may be expected for large negative values of  $\omega$ , as only very small aggregates are allowed to explore the whole backbone in

order to fill any hole. The larger ones are still there but they are staying quietly outside waiting their turn to fill the holes. Because of this hierarchical mechanism based on a full osmosis between size and site selectivity, one may also expect a strong narrowing of the size distribution as evidenced in Figure 10.

## 6. CONCLUSION

We are now at the very end of the description of all the physical and chemical processes that may cooperate to make nanocrystals appear from initially homogeneous solutions. We have taken care to cover the whole size range, from molecular solute species displaying sizes less 0.5 nm up to macroscopic crystals or gels having size higher than 1 cm. Besides size, one may notice that we have also covered the whole time range starting from nucleation ( $t = 0$ ) and ending with ripened crystals or aggregates ( $t \rightarrow \infty$ ). At each step, analytical expressions have been derived, because this is the only way to be able to fully understand the underlying physics or chemistry involved in experimental or simulation results. At this stage, we want to stress that all the derived equations are in fact very new, even if they share the same analytical shape with already published ones. The novelty comes from the fact that they are all clearly interpreted on a molecular basis, leading to deep conceptual modifications in quite old theories. Moreover, as we have for the first time a full coverage of precipitation from solutions, it is worthwhile to emphasize where fundamental changes have occurred. This will also help us to point to the directions where considerable work remains to be done to get a fully quantitative picture.

Concerning nucleation theories, the deep change was the explicit introduction of a kinetic barrier  $\Delta G'$  linked to the complex underlying chemistry involved in embryo formation. This chemistry has been reviewed and orders of magnitude have been given. The presence of this additional contribution has led to the appearance of a sticking probability  $g_N = \exp(-\Delta G'/kT)$  in the pre-exponential factor  $J_0$  of the nucleation rate. It was the neglect of this fundamental factor in older theories that explains the differences often observed with experimental measurements [10]. It also allows one to close definitively the controversial discussion relative to homogeneous versus heterogeneous nucleation. Accordingly, for homogeneous nucleation, it was shown that  $g_N$  carries purely chemical structural information. In all the cases where nucleation is really induced by impurities or defaults,  $g_N$  carries additional information about the size of the heterogeneous host and about its chemical nature through a contact angle. In fact, with the introduction of this sticking probability, we have reached the ultimate correct formulation of equilibrium nucleation theory resolving most discrepancies with experiments. Going one step beyond would require one to use nonequilibrium thermodynamics based on entropic fluxes avoiding the use of thermodynamic potentials (Gibbs function) that just cannot be defined for irreversible processes such as nucleation.

By symmetry, the same conceptual change has been introduced in interface-limited crystalline growth, through another kinetic barrier  $\Delta G''$  and through the associated growth sticking probability  $g_C = \exp(-\Delta G''/kT)$ . Another

quite novel aspect was the derivation of Eq. (35) for spiral growth that has never been published before. Here also a deep conceptual change has occurred. In older theories, the accepted paradigm was

This widely accepted view has several conceptual difficulties. First, diffusion should be the rate limiting step only for  $g_C \sim 1$ , a very rare case. Second, the most efficient mechanism (spiral growth) plays a minor role in crystalline growth literature and is usually treated separately from diffusion-limited or interface-limited growth. A much more logical scheme emerges by taking into account the existence of a growth sticking probability:

Here, just after nucleation, the created interface may act either as a catalyst or as an inhibitor for solute species incorporation. In the first case ( $g_C > g_N$ ), we invoke the most efficient mechanism avoiding the bottleneck of surface nucleation. However, owing to its very high efficiency, it very soon ends up either in the bottleneck of diffusion ( $g_C \gg g_N$ ) or switching to the polynuclear mechanism if several spirals compete (high supersaturation ratios) for the same limited crystal volume. The essential point is that as the final morphology is always governed by the slowest growth mechanism, the only chance to see well-developed spirals is to use the supersaturation ratio very close to unity. The second case ( $g_C \ll g_N$ ) means that for some chemical reason, the most reactive growth sites are poisoned. The spiral growth relying on the presence of these active sites is then killed. The only way to proceed is to make somewhere in a flat zone a 2D nucleus that will first grow independently from other nuclei (mononuclear mechanism) and then start to overlap (polynuclear mechanism) at some stage. Future work along these lines would be to reinterpret already published data and design new experimental settings and experiences to validate definitively this simple and logical picture.

Few novelties have been brought in the section devoted to the role of the interface on the growth process. This is because the most important conceptual change (existence of a point of zero interfacial energy or PZIE) has been treated elsewhere [41]. Nevertheless, some new features have been added in order to get a deeper coherence. First, we have pointed to a useful link between the Frank and Wen model of solute–water interface and the double layer model (Stern and diffuse layers) for oxide–water interfaces. Then explicit expressions for the PZIE, Eq. (46), and equilibrium sizes, Eq. (47), have been derived. Finally, a more logical derivation from the Cardan formula of the  $\alpha = 9/4$  value allowing one to solve ripening equations has been proposed. Future work should obviously be oriented toward the elaboration of simple models for nonoxide and nonaqueous solid–liquid

interfaces. New solutions for the ripening equations covering interface-limited growth also have to be derived.

The last section dealing with aggregation processes is surely the most critical one. This is just because, due to their small sizes, individual nanocrystals cannot remain isolated from their congeners. For the same reasons that molecular species may be assembled through weak bonds into supramolecular species, nanocrystals should be used as building blocks for making supracrystalline aggregates. In fact, it may be realized that all major applications involving nanocrystals should handle a more or less ordered array of such objects and not a disordered set. Consequently, if the control of the final size distribution of an assembly of nanocrystals is of the utmost importance, the control of the corresponding mesoscopic or macroscopic texture is yet another scientific challenge. This is the reason we have tried to introduce the very confusing literature devoted to aggregation processes in the most logical and synthetic way. First, we have attempted to make a clear distinction between enthalpy and entropic effects. Furthermore, if we have presented the quite old and criticized DLVO theory, it is just because no other simple theory is yet available. Consequently, if quantum electrodynamics is known to heal some obvious defaults of DLVO theory [72], it is of little practical use, being useful only in some pathological cases. Another highly confusing area concerns the geometric description of fractal objects coming out from aggregation processes. Here most published papers are concerned with the determination or measure of the fractal dimension  $\delta$  of the aggregates. One must realize that reducing such complex objects to a single real number is a considerable loss of valuable information. Moreover, fractal dimension being an extrinsic parameter, it just points to the kind of mechanism that has been used to generate the aggregate in our three-dimensional Euclidian space. In particular, it can say nothing about the internal architecture or detailed topology of the aggregate. To get this kind of crucial information for all practical applications, one has to rely on an intrinsic dimension such as the topological dimension  $\sigma$  or the spectral dimension  $\chi$ . Being the ratio of two extrinsic dimensions (one of them being always the fractal dimension  $\delta$ ), these intrinsic parameters helps us to understand the chemical or physical properties of the associated fractal object. Unfortunately, accurate determination of these very interesting exponents is rather rare and currently limited to ideal mathematical objects coming from numerical simulations. Future work should then be oriented toward the collection of a wealth of experimental data concerning these intrinsic fractal dimensions.

Concerning the kinetics of formation of aggregates, a major conceptual change has been introduced through the  $K_{ij} = (kT/6\pi\eta)[i^1 \times j^{2\omega-1}]$  kernel. The simplicity of this kernel relative to other awkward expressions found in the literature is noteworthy. First, it allows one to understand the existence of three qualitatively different aggregation regimes: gelation (apparition of an infinite cluster if  $\omega \geq \frac{1}{2}$ ), fractal growth (exponential distribution when  $0 \leq \omega < \frac{1}{2}$ ), and limited aggregation (bell-shaped distribution when  $\omega < 0$ ). Second, it avoids the widespread practice of putting at the origin (kernel  $K_{ij}$ ) the result (fractal dimension  $\delta$ ) of the growth process. Obviously, what is still lacking is an analytical link between the exponent  $\omega$  and the molecular

chemistry occurring at the solid–liquid interface. This should be a major challenge for the coming years.

## GLOSSARY

**Aggregate** Large particle formed after irreversible sticking of several small colloidal particles.

**Aggregation** Irreversible sticking of particles undergoing Brownian motion.

**Aggregation kernel** Kinetic constant describing the process by which two aggregates containing  $i$  and  $j$  particles respectively leads to a new aggregate formed of  $(i + j)$  particles.

**Agging** Change of structure, morphology, or porosity with time.

**Aquo cations** Soluble cationic hydrated species  $[M(H_2O)_N]^{z+}$  displaying low electrical charge ( $z < 3$ ) and stable at low pH.

**Backbone dimension** Fractal dimension of an object generated by removing all dangling ends to a given fractal object.

**Blob dimension** Fractal dimension of an object generated by removing all red contacts to a given fractal object.

**Bond dimension** See tortuosity.

**Chemical dimension** See topological dimension.

**Chronomal** Mathematical integral equation  $I(x)$  describing the time evolution  $t = K \times I(x)$  of a phase separation process in terms of a dimensionless reaction coordinate  $x$  and a kinetic constant  $K$ , see Eqs. (12), (26), and (33).

**Classical nucleation theory (CNT)** Theory for nucleation based on equilibrium thermodynamics and mean field approximations.

**Cluster** See aggregate.

**Coagulation** Precipitation of a colloidal solution after addition of an electrolyte.

**Colloidal solution or sol** Dispersion of solid particles (diameter 1–100 nm) in a liquid.

**Critical coagulation concentration (c.c.c.)** Minimal electrolyte concentration allowing spontaneous coagulation of a colloidal dispersion.

**Critical nucleus** Unstable concentration fluctuations that either redissolve or undergo further growth.

**Crystal** Solid matter characterized by a well ordered atomic structure allowing X-ray diffraction.

**Crystal field stabilization energy (CFSE)** Stabilization energy associated to a non-spherical charge distribution of electrons around the atomic nucleus of a transition metal element.

**Debye–Hückel length** Thickness of the double layer function of the solution ionic strength, see Eq. (39).

**Depletion interaction** Net attractive or repulsive force between two colloidal particles induced by the presence of a polymer in the dispersion medium.

**Diffuse layer** Layer of counter-ions around a colloidal particle compensating at the OHP the sum of the surface charges and of the charges located at the IHP. The thickness

of this layer is mainly function of the ionic strength of the solution.

**Diffusion controlled growth** Growth during which the rate-limiting step is the diffusion of solute species towards the solid/liquid interface.

**Diffusion-limited aggregation** Aggregation process during which the rate-limiting step is the diffusion of colloidal particles in the dispersing medium.

**Dislocation controlled growth** Growth initiated on screw dislocations and bypassing the formation of a surface nucleus.

**DLVO theory** Mathematical law giving the interaction energy of two overlapping diffuse layer as a function of their separation derived by first by Derjaguin, Landau, Verwey and Overbeek, see Eqs. (65–67).

**Electrokinetic potential** In a colloidal dispersion, the difference in potential between the immovable layer attached to the surface of the dispersed phase and the dispersion medium (usually approximated by the potential at the OHP).

**Embryos** Unstable concentration fluctuations that are doomed to redissolve at equilibrium.

**Extrinsic dimension** Scaling exponent linking a property of a given fractal object to a Pythagorean distance measured in an Euclidian space.

**Fick's laws** Two mathematical expressions relating through the diffusion coefficient (i) the flux of matter to a gradient concentration and (ii) the variation of concentration with time to its laplacian.

**Fractal** Mathematical object displaying holes at any scale. Corresponding physical objects are porous solids displaying porosity over several order of magnitude of scale length.

**Fractal dimension** Scaling exponent  $\delta$  giving for an aggregate the total mass found in a sphere of radius  $R$ :  $M(R) \sim R^\delta$ .

**Frank and Wen model** Assumption of the existence of at least three structured domains for a solvent around a given solute ( $A$  = solvent in direct contact,  $C$  = bulk solvent and  $B = A/C$  interface).

**Frontier energy** Energy needed for increasing the length of a given surface perimeter by one length unit.

**Fuchs integral** Total flux of particles towards a given colloidal particle corrected for their possible interaction energy.

**Gel** Dispersion of liquid droplets (diameter 1–100 nm) in a solid.

**Gibbs equation** Relationship linking the decrease in interfacial energy to the concentration of adsorbed species (see Eq. (1)).

**Glass** Solid matter displaying no crystalline order showing only X-ray diffusion.

**Gouy–Chapman theory** Mathematical law linking the diffuse layer charge density to its associated potential at the OHP, see Eq. (40).

**Graph dimension** See topological dimension.

**Growth constant** Dimensionless constant incorporating shape factor, frontier energy, molecular volume, temperature, and ruling the change of the growth thermodynamic barrier with the supersaturation.

**Growth rate** Rate of matter addition to an already existing particle and characterized by the rate of change of a characteristic length with time.

**Hamaker constant** Energy parameter measuring attractive forces between surfaces, see Table 5.

**Hull dimension** Scaling exponent relating the external perimeter or surface of a fractal object to the Euclidian distance between two points.

**Inner Helmholtz plane (IHP)** Mean plane defined by all ionic species adsorbed into the Stern layer and not in direct contact with the surface of the colloidal particle.

**Interface limited aggregation** Aggregation process during which the rate-limiting step is the irreversible sticking of two colloidal particles.

**Interface limited growth** Crystalline growth during which the rate-limiting step is the formation of a surface nucleus.

**Interfacial energy or surface energy** Energy needed for increasing the area of a given interface by one surface unit.

**Intrinsic dimension** Scaling exponent linking two properties of a given fractal object.

**Isoelectric point (IEP)** Solution conditions for which there is an equal number of positive and negative adsorbed species.

**Kinetic barrier** Energetic contribution to the nucleation activation energy associated to the crossing of the solid/liquid interface.

**Langmuir isotherm** Mathematical law describing the adsorption at a given interface of a single layer of ions, see Eq. (42).

**Lattice animals** Connected subsets of the square lattice tiling of the plane used for modeling the theta transition displayed by branched polymers in a solvent.

**Loops** Parts of a polymer connecting two trains.

**Metal alkoxides** Organometallic complexes of general formula  $M(OR)_z$  ( $R = C_nH_{2n+1}$ ) leading after hydrolysis and condensation to metallic oxides  $MO_{z/2}$ :  $M(OR)_z + z/2 H_2O \rightarrow MO_{z/2} + z ROH$ .

**Mononuclear growth** Growth process occurring at very low supersaturation and during which a single surface nucleus is able to cover a whole crystalline face.

**Nucleation** Formation of thermodynamically stable particles (solid or liquid) from an initially homogeneous medium (solid, liquid, or gas). It may occur either in the bulk (homogeneous nucleation) or at an interface (heterogeneous nucleation).

**Nucleation constant** Dimensionless constant incorporating shape factor, interfacial energy, molecular volume, temperature, and ruling the change of the nucleation thermodynamic barrier with the supersaturation.

**Nucleation rate** Number of nuclei formed per unit volume and per unit time.

**Nuclei** Stable concentration fluctuations allowed undergoing further growth leading to ultimately to phase separation.

**Ostwald–Freundlich equation** Relationship relating solubility to particle size, see Eq. (9).

**Ostwald ripening** Change upon aging of the size distribution of a collection of particles owing to the occurrence of redissolution/precipitation phenomena.

**Outer Helmholtz plane (OHP)** Slipping plane for solvent molecule defining the thickness of the Stern layer.

**Oxo anions** Soluble anionic species  $[MO_N]^{(2N-z)-}$  displaying high electrical charge ( $z > 4$ ) and stable at high pH.

**Percolation** A simple model in which sites on a lattice are randomly chosen and occupied and where nearest-neighbor particles are then considered to be connected, resulting in clusters of varying sizes and geometries.

**Percolation cluster** Fractal aggregate percolating through an entire lattice network and whose formation is accompanied by the divergence of the mean cluster size and the range of connectivity.

**Point of zero charge (PZC)** Solution conditions for which the surface of a colloidal particle is completely free of ionic species.

**Point of zero interfacial energy (PZIE)** Solution conditions for which full covering of a surface by ionic species occur.

**Poisson–Boltzmann equation** Mathematical law relating the laplacian of the potential to the charge density in volume and to the dielectric constant of the medium.

**Polyanions** Small oligomeric species formed after adding an acid to oxo-anions.

**Polycations** Small oligomeric species formed after adding a base to aquo-cations.

**Polynuclear growth** Growth process during which several surface nuclei compete to cover the same crystalline face.

**Potential determining ions (PDI)** Ions adsorbed on the surface of a colloidal particle or adsorbed into the Stern layer.

**Red contact** Parts of the backbone of a fractal object whose removal cuts this object into two independent pieces.

**Schulze–Hardy rule** Empirical law stating that the c.c.c. of a colloidal dispersion should vary as in the sixth inverse power of the electrolyte valency.

**Screw dislocation** Crystalline defect arising from the occurrence of atomic stacking faults and moving perpendicular to the line joining the two points of an open circuit surrounding the dislocation (Burger's vector).

**Shape factor** Dimensionless quantity linking the volume or the surface of a particle to the cube or the square of its characteristic length (see Tables 2 and 4).

**Sol** See colloidal solution.

**Spectral dimension** Scaling exponent  $\chi$  giving for an aggregate the number of distinct vacant sites  $S$  visited by a random walk involving  $t$ -steps  $S \sim t^{\chi/2}$ .

**Spiral growth** Growth process following a screw dislocation.

**Stability ratio** Dimensionless parameter ruling the life time of a colloidal dispersion.

**Steric stabilization** Stabilization of a colloidal dispersion by entropic forces (usually through polymer adsorption).

**Stern layer** Compact shell of solvent molecules moving with a colloidal particle.

**Sticking probability** Probability of incorporation of solute species according to Maxwell–Boltzmann statistics.

**Stokes–Einstein equation** Relationship linking diffusion coefficient of a particle to its radius and to medium viscosity.

**Surface charge** Density of adsorbed ionic species in direct contact with the surface of the colloidal particle.

**Surface energy** See interfacial energy.

**Sursaturation** Ratio between the concentration in solution at time  $t$  and the concentration at equilibrium (solubility) when  $t \rightarrow +\infty$ .

**Tails** Non-adsorbed chain ends of a polymer pointing towards the solution.

**Thermodynamic barrier** Energetic contribution to the nucleation activation energy associated to concentration fluctuations.

**Topological dimension** Scaling exponent  $\sigma$  giving for an aggregate the total mass  $M$  visited along a walk of distance  $L$  entirely contained in the object:  $M(L) \sim L^\sigma$ .

**Tortuosity** Scaling exponent  $\lambda$  giving for an aggregate the minimal distance  $L$  that must be covered in order to go from two points separated by a pythagorean distance  $R$ :  $L(R) \sim R^\lambda$ .

**Trains** Bonds of a polymer in direct contact with the surface of a colloidal particle.

**Von Smoluchowsky equations** Infinite system of coupled differential equations describing the kinetic of aggregation of a colloidal dispersion.

## 1. INTRODUCTION

Since their discovery about two decades ago, the research devoted to colloidal semiconductor nanocrystals grows exponentially as judged from the increasing number of publications and conferences related to the chemistry, physics, and materials science of these nano-objects. This makes any attempt to provide an exhaustive review of the domain difficult and therefore the selection the data presented in this chapter is purely subjective and reflects the research interests of the authors. Special emphasis is put on the aspects of nanocrystal science which are most closely related to their expected technological and industrial applications. The organization of this chapter is as follows:

The first part of the chapter reviews progress in the synthesis of monodisperse semiconductor nanocrystals and gives a basic introduction to their specific physical properties. In conformity with the literature, the term “monodisperse” is used here to describe colloidal samples in which the standard deviation of the particle diameter does not

exceed 5%. Throughout the text we will restrict ourselves to the description of A(II)B(VI) semiconductor nanocrystals with A being an element of the triad zinc, cadmium, mercury and B an element of the chalcogene group. These systems exhibit optical properties which can be varied in the visible part of the spectrum, near ultraviolet (UV) or near infrared (IR), by changing the nanocrystal size. Monodispersity of the samples is of crucial importance for several reasons. First, size induced tuning of the physical properties of nanocrystals is only possible for their fractions with narrow size dispersions. Second, an appropriate functionalization of monodisperse nanocrystals may lead to well-defined individual objects on the molecular scale with specifically designed properties. Third, assembly of monodisperse nano-objects frequently results in close-packed, highly ordered structures such as “colloidal crystals” and superlattices, opening up routes to novel materials with unusual properties.

At the center of our interest are A(II)B(VI) systems with A = Cd and B = S, Se, or Te, for which the largest number of gram-scale preparation methods have been developed. In spite of the increasing interest in A(III)B(V) semiconductor nanocrystals (A = Ga, In; B = N, P, As), to date the research concerning their synthesis is still less advanced as compared to that carried out on A(II)B(VI) systems.

The second part of the chapter is dedicated to organic/inorganic materials formed by conjugated polymers and nanocrystals. Their use in optoelectronic devices such as light emitting diodes or photovoltaic cells is—besides biological labelling—the most promising application of nanocrystals which has emerged to date.

A number of excellent reviews deal with the synthesis and physical properties of nanocrystals [1–3], whereas less work exists on their organic/inorganic composites [4, 5]. The present chapter gives an overview of the aforementioned research fields with special focus on the latest results and developments including our own work.

## 2. BASIC PHYSICAL PROPERTIES OF A(II)B(VI) SEMICONDUCTOR NANOCRYSTALS

### 2.1. Description

A(II)B(VI) semiconductor nanocrystals are crystalline particles with diameters ranging typically from 1 to 10 nm, comprising some tens to thousands of metal and chalcogene atoms. In the case of colloidal dispersions of nanocrystals the inorganic core consisting of the semiconductor material is capped by a shell of molecules, which provide sufficient repulsion between the crystals to prevent them from agglomeration. In the nanometer size regime many physical properties of the semiconductor particles change with respect to the bulk material. Examples of this behavior are melting points and charging energies of nanocrystals, which are, to first order, proportional to the reciprocal value of their radii. At the origin of the great interest for nanocrystals was yet another observation, namely the possibility to change the semiconductor bandgap—that, is the energy difference between the electron-filled valence band and the empty conduction band—by varying the particle size. In a bulk semiconductor an electron  $e^-$  can be excited from the valence to the conduction band by absorption of a photon with an appropriate energy, leaving a hole  $h^+$  in the valence band. Feeling each other's charge, the electron and hole do not move independently of each other because of Coulomb attraction. The formed  $e^-h^+$  bound pair is called an exciton and has its lowest energy state slightly below the lower edge of the conduction band. At the same time its wave function is extended over a large region (several lattice spacings); that is, the exciton radius is large, since the effective masses of the charge carriers are small and the dielectric constant is high [6]. To give examples, the Bohr exciton radii in bulk CdS and CdSe are approximately 3 and 5 nm. In Table 1 the bandgaps of A(II)B(VI) semiconductors are listed.

Reduction of the particle size to a few nanometers produces the unusual situation that the exciton size can exceed the crystal dimensions. To “fit” into the nanocrystal, the charge carriers have to assume higher kinetic energies leading to an increasing bandgap and quantization of the energy levels to discrete values. This phenomenon is commonly called the “quantum confinement effect” [8], and its theoretical treatment is usually based on the quantum mechanical particle-in-a-box model [9]. With decreasing particle size, the energetic structure of the nanocrystals (often also

referred to as *quantum dots*) changes from a bandlike one to discrete levels. Therefore, in some cases a description by means of molecular orbital theory may be more appropriate, applying the terms highest occupied molecular orbital and lowest unoccupied molecular orbital instead of conduction band and valence band. This ambiguity in terminology reflects the fact that the properties of semiconductor nanocrystals lie between those of the corresponding bulk material and molecular compounds.

Another class of substances characterized by the quantum-confined state is chalcogene bridged transition metal clusters. Here individual, identical molecules in the nanometer or subnanometer range are assembled periodically in single crystals. Although it has not yet been possible for the majority of A(II)B(VI) semiconductors to isolate clusters in the nanometer size range, the impact of cluster science on nanocrystal research is of great importance. Single crystal X-ray diffraction is a powerful tool to obtain crystal structures from clusters and to elucidate their coordination chemistry [10–12]. In view of the lack of a comparable characterization technique for nanocrystals, this information is very worthy for the understanding of their structural properties, since clusters can be considered as model compounds or building blocks for nanocrystals. Furthermore, it has been observed in a large number of examples that, during nanocrystal growth, stable intermediates, often called “magic-sized clusters,” are formed [13, 14]. Quantum chemical calculations on cluster systems can reveal the structures of such thermodynamically stable species as well as their absorption spectra and thus contribute to a more detailed comprehension of the growth process [15, 16]. Finally, established preparation methods for cluster compounds are a helpful guideline for the choice of precursors, solvents, and reaction conditions, especially in the case of organometallic and related synthesis routes for nanocrystals (Sections 3.3 and 3.4).

### 2.2. Optical Properties of A(II)B(VI) Semiconductor Nanocrystals

#### 2.2.1. Absorption

As has already been stated (see Section 2.1), absorption of a photon by the nanocrystal occurs if its energy exceeds the bandgap. Due to quantum confinement, decreasing the particle size results in a hypsochromic (blue)shift of the absorption onset [17, 18]. A relatively sharp absorption feature near the absorption onset corresponds to the excitonic peak, that is, the lowest excited state exhibiting an important oscillator strength (cf. Fig. 1). While its position depends on the bandgap and, consequently, on the particle size, its form and width are strongly influenced by the distribution in size, as well as the form and stoichiometry of the nanocrystals. Therefore polydisperse samples typically exhibit only a shoulder in the absorption spectrum at the position of the excitonic transition. Less pronounced absorption features in the lower wavelength range correspond to excited states of higher energy [19]. As a rule of thumb, it can be asserted that the larger the number of such spectral features and the more distinctly they are resolved in the absorption spectrum, the smaller the size dispersion of

**Table 1.** Energy bandgaps at 300 K of A(II)B(VI) semiconductors [7].

the sample. In Figure 1 the absorption and photoluminescence spectra of a series of CdSe nanocrystals differing in size are depicted.

### 2.2.2. Photoluminescence

After absorption of photons by nanocrystals, resulting in the formation of excitons, the system may return to the ground state via radiative electron–hole recombination. The emitted photons have an energy corresponding to the bandgap of the nanocrystals and for this reason the emission color can be tuned by changing the particle size [17, 18]. It should be noted here that efficient room temperature band-edge emission is only observed for nanocrystals with proper surface passivation because otherwise charge carriers are very likely to be trapped in surface states, enhancing nonradiative recombination. Due to spectral diffusion and the size distribution of nanocrystals, the room temperature luminescence linewidths of ensembles lie for the best samples in the range of 20–25 nm [full width at half maximum (FWHM)]. As can be seen in Figure 1, the maxima of the emission peak are redshifted by ca. 10–20 nm as compared to the excitonic peak in the absorption spectra. This phenomenon is usually referred to as *Stokes shift* and has its origin in the particular structure of the exciton energy levels inside the nanocrystal. Models using the effective mass approximation show that in bulk wurtzite CdSe the exciton state ( $1S_{3/2}1S_e$ ) is eightfold degenerate [21]. In CdSe nanocrystals, this degeneracy is partially lifted and the band-edge state is split into five states, due to the influence of the internal crystal field, effects arising from the nonspherical particle shape, and the

**Figure 1.** Absorption and normalized photoluminescence spectra of CdSe nanocrystals (P. Reiss and J. Bleuse, unpublished data). The diameters have been determined on the basis of data published by Mikulec et al. [20].

electron–hole exchange interaction (see Fig. 2). The latter term is strongly enhanced by quantum confinement [22].

Two states, one singlet state and one doublet state, are optically inactive for symmetry reasons. The energetic order of the three remaining states depends on the size and form of the nanocrystal. In the case of weak excitation of a given state, absorption depends exclusively on its oscillator strength. As the oscillator strength of the second and third excited (“bright”) states is significantly higher than that of the first (“dark”) one, excitation by photon absorption occurs to the bright states. In contrast, photoluminescence depends on the product of oscillator strength and population of the concerned state. Relaxation via acoustic phonon emission from bright states to the dark band-edge state causes strong population of the latter and enables radiative recombination (see Fig. 2). This model is corroborated by the experimental room temperature values of the *Stokes shift*, which are consistent with the energy differences between the related bright and dark states.

### 2.2.3. Emission of Single Nanocrystals, Blinking Phenomenon

Spectroscopic investigation of single semiconductor nanocrystals revealed that their emission under continuous excitation turns on and off intermittently. This blinking is a common feature also for other nanostructured materials, involving porous Si [23] and epitaxially grown InP quantum dots [24], as well as chromophores at the single molecule level such as polymer segments [25], organic dye molecules [26], and green fluorescent protein [27]. However, the origin of the intermittence is completely different for nanocrystals and single dye molecules: in the latter resonant excitation into a single absorbing state takes place. Due to spectral shifting events the excitation is no longer in resonance and a dark period begins. Nanocrystals, on the other hand, are excited nonresonantly into a large density of states above the band edge. While their emission statistics and its modelling are the issue of a large number of publications [28–32], a detailed understanding of the blinking phenomenon has not yet been achieved. As a consequence, experimental efforts to overcome it have not been successful so far. Its resolution would be of great benefit in applications associated with the use of nanocrystals as biological labels, in particular on the single molecule level.

The sequence of “on” and “off” periods resembles a random telegraph signal on a time scale varying over several orders of magnitude up to minutes and follows a temporal statistics described by an inverse power law [30]. Transition from an “on” to an “off” state of the nanocrystal seems to

**Figure 2.** Schematic representation of the exciton states of CdSe nanocrystals involved in absorption and emission processes.

occur by photoionization, which implies the trapping of a charge carrier in the surrounding matrix (dangling bonds on the surface, solvent, etc.). A single delocalized electron or hole rests in the nanocrystal core. Upon further excitation this gives rise to fast (nanosecond order) nonradiative relaxation through Auger processes (i.e., energy transfer from the created exciton to the delocalized charge carrier) [33]. Mechanisms for a return to the “on” state are the recapture of the localized charge carrier into the core or the capture of an opposite charge carrier from traps in the proximity. Both pathways can be accompanied by a reorganization of the charge distribution around the nanocrystals. As a consequence the local electric field changes leading to a Stark shift of the photoluminescence peak [31, 32].

#### 2.2.4. Efficiency of the Emission: Fluorescence Quantum Yield

The emission efficiency of an ensemble of nanocrystals is expressed in terms of the fluorescence quantum yield (QY), that is, the ratio between the number of absorbed photons and the number of emitted photons. As a consequence of the blinking phenomenon (vide supra) the theoretical value of 1 is not observed because a certain number of nanocrystals are in “off” states. Furthermore the QY may be additionally reduced as a result of quenching caused by surface trap states. As both of these limiting factors are closely related to the quality of the nanocrystal surface, they can be considerably diminished by its improved passivation. This can be achieved by changing the nature of the organic ligands, capping the nanocrystals after their synthesis. To give an example, after substitution of the trioctylphosphine oxide (TOPO) cap on CdSe nanocrystals by hexadecylamine or allylamine, an increase of the QY from about 10% to values of 40–50% has been reported [34]. In this case better surface passivation probably results from an increased capping density of the sterically less hindered amines as compared to TOPO. On the other hand, in view of further nanocrystal functionalization, it is desirable to provide a surface passivation which is less sensitive to subsequent ligand exchanges. A suitable method consists of the growth of an inorganic shell on the (core) nanocrystals, resulting in core/shell systems as depicted schematically in Figure 3. In order to confine both electrons and holes in the core, a wider bandgap semiconductor with an appropriate band alignment (type I or normal configuration; see Fig. 3) is chosen as the shell material.

Further attention has to be paid to the lattice mismatch parameter between the core and shell lattices. Significant

**Figure 3.** Scheme of a CdSe/ZnSe core/shell nanocrystal (left) and of its energy levels (right; CB = conduction band, VB = valence band).

constraints at the core/shell interface lead to the creation of new trapping sites for the charge carriers, which quench the fluorescence. This is clearly visible in the case of the most studied system, CdSe nanocrystals. In terms of bandgap and band alignment ZnS is an excellent candidate as a shell material, which has led to its widespread use. However, due to the large lattice mismatch parameter of 10.6% between CdSe and ZnS, the reported values of QY do not exceed 50–60%. Moreover, only relatively thin shells give rise to an increase of the QY. If a certain shell thickness is exceeded, the QY diminishes, clearly pointing out the formation of structural defects. On the other hand, ZnSe is a shell material which provides less efficient charge carrier confinement with respect to ZnS, due to its lower bandgap. This is especially true for the holes as can be seen from the small conduction band offset in Figure 2 [35]. Nevertheless, as a result of the better crystal lattice matching in CdSe/ZnSe as compared to CdSe/ZnS, higher values for the fluorescence QY are reported in the former case. Table 2 summarizes the properties of different core/shell systems with CdSe as the core material.

### 2.3. Electronic Properties of Nanocrystals

As discussed in Section 2.2, the effects of quantum confinement give rise to a strong size dependence of the optical properties of nanocrystals. However, in such nano-objects essentially all physical properties exhibit size dependence in a more or less pronounced way, including their electronic properties. If one considers a nanocrystal as a spherical capacitor, its capacitance  $C$  is a function of its radius  $r$  [40],

$$C(r) = 4\pi\epsilon_0\epsilon r \quad (1)$$

where  $\epsilon_0$  and  $\epsilon$  are the dielectric constants of the vacuum and of the surrounding medium of the nanocrystal, respectively. Adding a simple charge to the nanocrystal requires the charging energy  $E_c$ ,

$$E_c = e^2/2C(r) \quad (2)$$

At temperatures where  $kT < E_c$ , tunneling of single charges onto nanocrystals can occur, which can be revealed by scanning tunneling microscopy measurements [41–45]. The current–voltage curves obtained in these experiments exhibit a barrier to current flow, arising from  $E_c$ , which is called a Coulomb blockade.

**Table 2.** Shell materials for the overcoating of CdSe nanocrystals: bandgaps (CdSe: 1.76 eV), lattice mismatch parameters  $a$  with respect to CdSe, and reported room temperature QYs of the core/shell systems.

Shell material	Gap (eV)	$a$ (%)	QY (%)	Ref.

### 3. SOLUTION PHASE SYNTHESIS OF A(II)B(VI) SEMICONDUCTOR NANOCRYSTALS

#### 3.1. Historical Review of the Synthesis Methods

Solution phase (or wet chemical) methods for the synthesis A(II)B(VI) semiconductor nanocrystals can be roughly divided into two general categories:

1. room temperature procedures consisting of nanocrystal precipitation in aqueous media, either in the presence of stabilizers (method 1.1) or within inverse micelles (method 1.2)
2. high temperature reactions in nonaqueous media based on temporal separation of nanocrystal nucleation and growth, applying either organometallic precursors (method 2.1) or inorganic precursors, such as oxides or salts (method 2.2)

Table 3 gives a nonexhaustive overview of reported applications of the aforementioned preparation methods for the fabrication of A(II)B(VI) nanocrystals.

Initially developed procedures comprise nanocrystal formation in homogenous aqueous solutions containing appropriate reagents and surfactant-type or polymer-type stabilizers [53, 61]. The latter bind to the nanocrystal surface and stabilize the particles by steric hindrance and/or electrostatic repulsion in the case of charged stabilizers. In parallel to this monophasic synthesis, a biphasic technique has been developed which is based on the arrested precipitation of nanocrystals within inverse micelles [54, 55, 62, 63]. Here nanometer-sized water droplets (dispersed phase) are stabilized in an oil (continuous phase) by an amphiphilic surfactant. They serve as microreactors for the nanocrystal growth and prevent at the same time particle agglomeration. Both methods provide relatively simple experimental approaches using standard reagents as well as room temperature reactions and were of great importance for the development of nanocrystal synthesis. On the other hand, the samples prepared by these synthetic routes usually exhibit size dispersions exceeding 15% and therefore material consuming

procedures of nanocrystal separation into “sharp” fractions have to be applied in order to obtain monodisperse samples.

The introduction of high temperature preparation methods in 1993 [50] constituted an important step toward the fabrication of CdS, CdSe, and CdTe nanocrystals exhibiting much lower size dispersions as compared to samples prepared in aqueous media. As demonstrated in classical studies by La Mer and Dinegar [64], the synthesis of monodisperse colloids requires a temporal separation of nucleation and growth of the seeds. This can be achieved by rapid injection of the reagents into the hot solvent which raises the precursor concentration in the reaction flask above the nucleation threshold. A nucleation burst takes place which lowers immediately the supersaturation and afterward no new seeds are formed. In an ideal case all crystallization nuclei are created at the same time and undergo identical growth until the precursors (sometimes also called “monomers”) in the solution are consumed. At this stage of the reaction it is possible to carry out subsequent injections of precursors in order to increase the mean particle size without deterioration of the narrow size distribution as long as the concentration of the nucleation threshold is not exceeded. Crystal growth from solution is in many cases followed by a second distinct growth process, which is referred to as Ostwald ripening [65, 66]. It consists of the dissolution of the smallest particles because of their high surface energy and subsequent redeposition of the dissolved matter onto the bigger ones. Thereby the total number of nanocrystals decreases, whereas their mean size increases. If diffusion is assumed to be the rate limiting step, the size dependent growth rate can be expressed by means of the *Gibbs–Thomson equation* [67]:

$$S(r) = S_{\text{bulk}} \exp(2\sigma V_m / rRT) \quad (3)$$

$S(r)$  and  $S_{\text{bulk}}$  are the solubilities of a nanocrystal with radius  $r$  and of the bulk solid, respectively.  $\sigma$  is the specific surface energy,  $V_m$  is the molar volume of the solid,  $R$  is the gas constant, and  $T$  is the temperature. As shown by Reiss [68], Ostwald ripening can lead to smaller size dispersions in the case of micrometer-sized colloids. For nanometer-sized particles, validity of Eq. (3) and focusing of size distributions during the diffusion-controlled nanocrystal growth have been confirmed [69, 70]. Within the framework of the organometallic preparation method, samples with 8–10% standard deviation from the mean size can typically be obtained.

One of the main disadvantages of this preparation method lies in the fact that pyrophoric organometallic precursors such as dimethylcadmium or diethylzinc are applied. Their use requires special experimental precautions and their extremely high reactivity restricts the batches to laboratory scale quantities. As a result, in recent years the development of nanocrystal high temperature synthesis was focused on the replacement of these organometallic precursors by easy to handle standard reagents. To give an example, in the preparation of CdB(VI) nanocrystals, dimethylcadmium can be substituted by cadmium oxide or cadmium salts of weak acids ( $\text{CdAc}_2$ ,  $\text{CdCO}_3$ ) after complexation with long chain phosphonic or carboxylic acids [51, 52]. In the subsequent text this and related procedures will be termed “mixed

**Table 3.** Synthesis methods for A(II)B(VI) nanocrystals.

inorganic/organometallic” methods. A further modification of the high temperature methods consists of the appropriate selection of coordinating and noncoordinating solvents, with the goal to determine their influence on the nucleation and growth of the nanocrystals and to reduce their size distributions below 5% [34]. It is very likely that in the near future similar methods for the synthesis of ZnB(VI) and HgB(VI) nanocrystals will be developed.

At the end of this brief historical review, it should be pointed out that essentially all discussed preparation methods have one important point in common: slight variations in the experimental conditions can lead to significant differences in the result. The interested reader who desires to reproduce nanocrystal syntheses in his own laboratory should therefore follow exactly the directions given in the original literature.

## 3.2. Synthesis in Aqueous Media

### 3.2.1. Precipitation in Presence of Stabilizers

Well established preparation methods for CdS and CdTe nanocrystals comprise their precipitation from an aqueous solution containing cadmium ions and appropriate stabilizers such as thioglycerol or thioglycolic acid [71]. If the precipitation is carried out with the use of H<sub>2</sub>S or H<sub>2</sub>Te the pH value is a crucial parameter in the control of the particle size and its dispersion. Alkaline pH values are necessary to shift the equilibrium of the H<sub>2</sub>S (or H<sub>2</sub>Te) dissociation enabling the formation of CdS (or CdTe) seeds:

During the reaction the pH drops to acidic values due to the release of protons and the particles grow either from solution or by Ostwald ripening while no new seeds are formed. The growth can be stopped by increasing the pH to alkaline values once again. An inherent feature of the nanocrystals synthesized by this method is their surface charge, which makes them dispersible in water. Their stabilities as well as their fluorescence efficiencies depend strongly on the nature of the stabilizing agent.

### 3.2.2. Precipitation in Inverse Micelles

Surfactant molecules can be classified into cationic (e.g., amines), anionic (e.g., carboxylic or sulfonic acids), and nonionic (e.g., polyethers) ones. They have an amphiphilic character, which means that they contain both hydrophilic and hydrophobic moieties, and for thermodynamic reasons they self-assemble in aqueous solutions to form aggregates, called micelles. In a biphasic system consisting of water and oil (hydrocarbon), the creation of different shaped micelles is possible such as spherical, cylindrical, or lamellar ones, depending on the relative concentrations of the constituents of the ternary system [72]. A high volume fraction of the oil phase leads to the formation of inverse micelles (i.e., water droplets in oil with the hydrophobic parts of the surfactant molecules sticking out of the droplet). These can be used as compartments for the arrested precipitation of nanocrystals. In this case no stabilizers are necessary to prevent from

particle agglomeration (compare Section 3.2.1), because the individual nanocrystals are shielded by the surfactant and the continuous phase. The most popular system in this context comprises sodium bis(2-ethylhexyl)sulfosuccinate, also known as aerosol OT or Na(AOT), as the surfactant in a water/isooctane or water/heptane mixture [54–56]. In this case the diameter  $d$  of the inverse micelles can be controlled by the water content  $w$  [73]:

$$w = [\text{H}_2\text{O}]/[\text{AOT}] \quad (5)$$

$$d \text{ (nm)} \cong 0.3 w \quad (6)$$

Equation (6) is valid for values of  $w$  superior to 15, whereas it underestimates the micellar size for lower values of this parameter. The synthesis of nanocrystals inside inverse micelles can be carried out in two different ways: either by mixing two micellar solutions, one containing metal ions and the other containing chalcogenide ions in the water droplets, or by bubbling the metal ions containing solution with gaseous hydrogen chalcogenide. In addition to the important size distribution, a drawback of the micellar method is the fact that the maximum size, which can be obtained for semiconductor nanocrystals, is limited to ca. 4 nm [72]. On the other hand, it is very versatile synthesis technique that allows the preparation of a large number of different semiconductor, metal, alloy, and oxide nanoparticles (see [72, 74] and references therein).

## 3.3. Organometallic Synthesis

The organometallic nanocrystal synthesis consists of the reaction between an organometallic metal precursor and an appropriate chalcogene precursor carried out in a coordinating solvent at high temperature. The originally reported preparation method [50] typically yields nanocrystals with size dispersions of 8–10% in the case of CdSe and of 10–15% in the case of CdS and CdTe nanocrystals. The procedure can be divided into three steps:

- (i) Nucleation of the seeds: Nucleation of the seeds is achieved by swift injection of the organometallic precursors into the reaction flask which contains the coordinating solvent vigorously stirred at high temperature (300–350 °C). As mentioned in Section 3.1, such quick addition provokes a transient supersaturation necessary for the nucleation process. Besides, the injection of the cold (ca. 25 °C) precursors results in a significant temperature drop inside the flask.
- (ii) Particle growth: During particle growth, which follows the nucleation step, temperature is maintained between 250 and 300 °C. The growth process can be monitored by the evolution of the absorption spectra of small aliquots taken periodically from the reaction mixture or *in-situ* using a fiber optics probe.
- (iii) Growth termination: When the desired particle size is reached, temperature is dropped below 100 °C to stop crystal growth. Nanocrystals are then isolated by precipitation and purified by washing with adequate solvents in order to remove by-products and excess coordinating solvent.

Although originally developed for the CdB(VI) series, a similar approach has been adapted for the synthesis of ZnB(VI) and HgB(VI) semiconductor nanocrystals (see Table 3). Organometallic metal precursors generally comprise metal alkyls or aryls (dimethylcadmium, diethylzinc, dibenzylmercury) whereas S, Se, or Te sources are mostly chosen from trialkylphosphine chalcogenides ( $R_3PSe$ ,  $R_3PTe$  with  $R = \text{octyl or butyl}$ ) or bistrimethylsilylchalcogenides such as  $(Me_3Si)_2S$ . The trialkylphosphine chalcogenides can easily be prepared by dissolution of the chalcogenide powder in the phosphine. In the case of sulfur, the silylated compound is preferred over the trialkylphosphine sulfide because the latter exhibits too low reactivity in the temperature range used for the synthesis.

The choice of the coordinating solvent is of crucial importance because it influences the reactivity of the precursors as well as the kinetics of the growth process. Furthermore, being the capping agent, it determines the “solubility” of the nanocrystals and the stability of their colloidal dispersions. Usually applied are mixtures of alkylphosphines  $R_3P$ , alkylphosphine oxides  $R_3PO$  [ $R = H(CH_2)_n$  with  $n \geq 4$ ], long-chain alkylamines, etc. Prerequisites for the selection are that the solvent system does not show any decomposition at the high reaction temperatures and that the boiling points of all components are sufficiently high. Further attention has to be paid to the basic strength of the solvent which has to be adapted according to the type of semiconductor nanocrystal to be synthesized. To give an example, the most widely used coordinating solvent for the preparation of CdB(VI) nanocrystals is a mixture of trioctylphosphine oxide/trioctylphosphine or trioctylphosphine oxide/tributylphosphine. For the synthesis of ZnB(VI) analogs of the CdB(VI) family, the previously described solvent mixtures cannot be applied because the interactions between TOPO and the zinc precursor ( $ZnEt_2$ ) are too strong. As a result, the reaction between the metal source and the chalcogenide source is impeded and the nucleation and/or growth process does not occur. This problem can be overcome by the replacement of TOPO with hexadecylamine (HDA) which is a weaker base. The HDA/TOP mixed solvent provides sufficient reactivity between the precursors and enables the growth of ZnB(VI) nanocrystals [47].

A large variety of precursor/coordinating solvent systems, whose mutual interactions can be tuned as to obtain the optimum synthesis conditions for nanocrystals of a given semiconductor, makes the organometallic route a very versatile preparation method. However, the pyrophoric character of organometallic reagents, which implies special experimental precautions, and their high price motivated researchers to develop alternative procedures in recent years. Some of them yield nanocrystals of equal or even superior quality as compared to those prepared by organometallic synthesis (see Section 3.4).

### 3.4. Mixed Inorganic/Organometallic Synthesis

As has been stated, the temporal separation of nucleation and growth is very likely to be of crucial importance for the synthesis of monodisperse nanocrystals. In the framework

of the organometallic preparation route this is achieved by the use of highly reactive metal precursors which decompose readily after their injection into the hot solvent. Nevertheless this reaction type is not limited to organometallic, pyrophoric reagents and a number of inorganic compounds such as oxides or salts can be applied in the same way. The first example reported was the use of cadmium oxide, complexed with alkylphosphonic acids, as a Cd source in the synthesis of CdB(VI) nanocrystals [51]. The resulting cadmium phosphonates are sufficiently reactive toward Se or Te solutions in trioctylphosphine and yield nearly monodisperse CdSe and CdTe nanocrystals in the size range of ca. 2.5–5 nm. In the same manner as in the case of the organometallic synthesis route (Section 3.3) [34], the size distribution can be further lowered to values below 5%, if a mixed solvent of TOPO/HDA is used instead of TOPO alone [39]. Larger sized nanocrystals can be prepared by applying cadmium carboxylates as a Cd source, with the crystal growth rate being inversely proportional to the chain length of the carboxylic acid [52]. By proper choice of the cadmium source and solvent, this method allows the synthesis of CdSe nanocrystals with diameters up to 25 nm, while for the organometallic approach maximum values of ca. 11 nm have been reported [50].

Moreover, this scheme can easily be extended to the synthesis of nanocrystals of shapes different from spherical and in particular to the preparation of “nanorods” (i.e., elongated crystals with a high aspect ratio) [75]. In order to promote and control such a one-dimensional (1D) growth, it is desirable to have less reactive cadmium sources than dialkylcadmium compounds, for example certain cadmium phosphonates. The experimental results show that, as in a number of other examples [10, 13, 14, 76], in the early stages of the reaction a relatively stable, “magic-sized” cluster of ca. 10–20 cadmium atoms is formed. Furthermore the same cluster seems to be at the origin of all different shaped nanocrystals (rod-shaped, rice-shaped, or branched). Thus, for a given temperature, the shape can be controlled by the monomer concentration in the solution, which in all cases of anisotropic growth has to be high compared to the growth of spherical particles.

The latest studies in the framework of the mixed inorganic/organometallic synthesis reveal a further similarity with cluster chemistry. For a long time the use of coordinating solvents such as TOPO or HDA was believed to be indispensable for a controlled nanocrystal growth. Now, like in cluster synthesis, the use of high boiling noncoordinating solvents (e.g., alkanes such as octadecene), in association with a controlled amount of ligands (phosphine oxides, phosphines, amines, carboxylic or phosphonic acids, etc.), provides a much wider approach to nanocrystal synthesis [77]. The latter allows not only the fine-tuning of nanocrystals sizes, size distributions, and shapes but also the transfer of the synthesis scheme to other types of semiconductors, such as InP, InAs [78], or PbSe [79, 80]. The listed advantages make the mixed inorganic/organometallic preparation method a very powerful tool for the design of new materials on the nanometer scale.

### 3.5. Synthesis of Core/Shell Systems

Among all core/shell systems CdSe/ZnS is the most studied case. The large bandgap of ZnS in combination with a favorable band alignment of CdSe and ZnS (see Section 2.2.4) yields core/shell nanocrystals with a significantly improved fluorescence QY with respect to the “bare” core crystals. The procedure for the shell growth is very similar to the organometallic nanocrystal preparation method (Section 3.3), with the use of diethylzinc and bistrimethylsilyl sulfide [37, 38]. Important differences are, however, the slow injection of these precursors in combination with relatively low reaction temperatures (150–210 °C). These measures are necessary in order to promote an epitaxial-type deposition of the shell material on the core crystals and to prevent nucleation of separate ZnS seeds. Furthermore, at higher temperatures Ostwald ripening of the core particles may occur, deteriorating their size distribution.

After the successful introduction of the mixed inorganic/organometallic preparation method to the synthesis of CdB(VI) core nanocrystals, it is a logic step to replace the pyrophoric dialkylzinc precursors, routinely used for the shell preparation, by safer reagents. However, the use of zinc phosphonates, in analogy to the inorganic/organometallic core synthesis, does not result in a successful ZnS shell growth because they exhibit too low reactivity toward the chalcogenide source in the cited temperature range. On the contrary, zinc stearate is an excellent zinc source in this context [39]. This easy to manipulate and commercially available compound reacts readily with both sulfur and selenium precursors to form CdSe/ZnS and CdSe/ZnSe core/shell nanocrystals or CdSe/ZnSe/ZnS core/double shell systems [81].

### 3.6. Size Sorting Procedures

With few exceptions, nanocrystal preparation techniques usually yield samples with a polydispersity significantly exceeding 5% (i.e., the level required for many specific applications of these nano-objects). In such cases postpreparative size-sorting procedures have to be used with the goal to isolate fractions of low polydispersity. The most prominent techniques are based on similar principles as widely applied in polymer technology, size-selective precipitation [50] or size exclusion chromatography [82]. The former method implies the destabilization of the colloidal nanocrystal dispersion by adding a nonsolvent, miscible with the original solvent. Thereby the repulsive force between the nanocrystals due to their capping groups is reduced and the largest ones tend to aggregate because they exhibit the strongest attractive *van der Waals* interactions. They can be separated by centrifugation or filtration from the smaller-size nanocrystals, which do not agglomerate and remain dispersed in the solvent/nonsolvent medium. Subsequent cycles of redispersion in an adapted solvent and partial flocculation of the largest nanocrystals provide quasi-monodisperse samples. The major disadvantage of this technique is its low yield: less than 30% of nanocrystals with a size dispersion of 5% are obtained from an initial sample with a size dispersion of 10% [3].

In the case of size exclusion chromatography (SEC) [82], the nanocrystal dispersion (mobile phase) flows through a column loaded with porous hydrophobic microgels, such as

cross-linked polystyrene (stationary phase). As the smaller crystals penetrate deeper into the pores than the larger ones, their retention time in the column is longer. More precisely, the elution time  $t_e$  of nanocrystals is in direct relationship with their radius  $r$  [83]:

$$t_e = k_1 + k_2 \lg r \quad (7)$$

Additionally, after calibration SEC can be used to determine the mean size and size dispersions of samples containing spherical particles. The technique is limited to nanocrystals, which are well passivated by a cap of nonpolar organic ligands because otherwise they risk being adsorbed permanently inside the column due to strong interactions with the microgel.

On the contrary, gel electrophoresis, another size sorting technique which has been used with the goal to lower the polydispersity of nanocrystals [84], requires charged particles and is well adapted for aqueous solutions. The nanocrystals move through a column filled with a polymer gel such as weakly cross-linked acrylamide, driven by an electrical field between both ends of the column. Particles with a high surface charge and small diameter move most quickly through the gel. After sufficient separation, the gel is cut into thin slices and the nanocrystal fractions in each slice are redissolved while gel residues are filtered off.

## 4. FUNCTIONALIZATION OF NANOCRYSTALS

Nanocrystals possess a very high surface/volume ratio, which increases strongly with decreasing radius. Individual crystals are prevented from agglomeration by means of an organic ligand cap on their surface. At the same time, these ligand molecules complete the coordination sphere of the nanocrystal surface atoms and thus reduce the number of dangling bonds, which cause fluorescence quenching. A large number of potential applications of nanocrystals require nonetheless a modification of this organic ligand cap, with the goal to make the colloids dispersible in various solvents and/or to graft them to other molecules of biological or electronic interest, to solid substrates, etc. By consequence, in recent years different approaches have been developed to perform nanocrystal surface chemistry. A widely applied method consists of the exchange of the organic molecules at the surface by bifunctional ligands X–S–Y [85–87]. Such ligands contain, on the one hand, a functional group X, which provides strong interaction with the metal ions on the nanocrystal surface and on the other hand a second chemical moiety Y, which allows the subsequent binding to molecules or substrates. Typical examples for X are thiol or phosphonic acid groups, whereas carboxyl, amine, or alcohol functions are representative for Y, to name a few. The selection of Y is of crucial importance, not only in view of nanocrystals grafting to given objects, but also for their dispersion in polar solvents and in particular in water, indispensable for biological applications. X and Y are usually separated by a spacer, S, of alkyl or aryl type.

Bifunctional ligands X–S–Y, in which Y is an ionizable group, can also facilitate the formation of a more or less ordered aggregation of nanocrystals with oppositely charged macromolecules via electrostatic interactions. A typical

example is the electrostatic self-assembly of carboxylic acid coated and thus negatively charged nanocrystals and a synthetically engineered, positively charged protein [88]. Since this protein enables the conjugation of biological molecules such as antibodies, highly stable and specific conjugates for immunoassays can be created using this method.

The main problem of the described functionalization methods is the fact that, in the majority of cases, the exchange of the original ligands results in a significant decrease of the fluorescence QY. This problem can be overcome by the use of a so-called “nanocrystal encapsulation method.” Hereby the initial optical properties of the nanocrystals can be essentially maintained, since it does not involve the exchange of the passivating ligands. The procedure will be described here for hydrophobic nanocrystals with TOPO and/or HDA ligands on their surface. The encapsulation is carried out in a three-component system consisting of water, oil, and an appropriate surfactant of amphiphilic nature. The surfactant molecules, being at the interface of the water continuous phase and the droplets of the oil, stabilize the formation of a microemulsion. If hydrophobic nanocrystals are introduced into this microemulsion, micellar-type system, they are placed in the hydrophobic environment (i.e., within the oil microdroplets). After the evaporation of both solvents, alkyl chains of the surfactant molecules “interdigitate” with the alkyl groups of the nanocrystal ligands, encapsulating in such a manner the nanocrystal, while the polar groups of the surfactant are directed on the outside of the encapsulated particle. An example of the successful application of this technique is the nanocrystal encapsulation by phospholipid micelles, enabling *in vivo* imaging experiments [89].

## 5. CONJUGATED POLYMER/NANOCRYSTAL COMPOSITE SYSTEMS

### 5.1. Introduction

Conjugated polymers (i.e., polymers with a spatially extended  $\pi$ -bonding system), although known for many years, did not draw significant research attention because they were intractable and, in many cases, unstable in ambient conditions. However, in the past two decades extensive and systematic research has been devoted to various aspects of the chemistry and physics of this previously underestimated family of macromolecular systems. It resulted in the preparation of stable, processible conjugated polymers offering unique physical properties which cannot be obtained for conventional polymers [90]. Both in their undoped (semiconducting) and doped (conducting) states, conjugated polymers can be used as components of so-called “plastic electronics.” In 2000 A. J. Heeger, A. G. MacDiarmid, and H. Shirakawa—the founders of “conjugated polymer science”—were granted the Nobel Prize in chemistry (Nobel Lectures, [91–93]).

Conjugated polymers in their neutral (undoped) state are materials, which combine electronic properties of intrinsic semiconductors with mechanical properties and solution processibility of macromolecular systems. Moreover they

frequently dissolve in the same solvents as the ones that are used to disperse A(II)B(VI) nanocrystals. Thus conjugated polymer/nanocrystal composite films can relatively easily be prepared by casting from a common solvent. Why are such composite materials of technological interest? First, the electronic properties of the two semiconductor constituents can be tuned individually and adapted to each other. In the case of the nanocrystal component of the composite, this can be done by size control (*vide supra*). The bandgap of the polymeric component can, in turn, controllably be altered by changing the chemical constitution of the conjugated backbone via copolymerization (random or block) and/or by appropriate functionalization with lateral groups exhibiting electron donating or electron withdrawing properties. Second, the interface area between the polymer phase and the nanocrystal one is very large due to the very high surface/volume ratio of the nanocrystals. This enables efficient electronic transport between these two components. Third, the conductivity of the polymeric phase can be varied via oxidative or acid–base doping. For this reason doped conjugated polymers are sometimes used in light emitting diodes as hole or electron transporting layers. They facilitate the charge injection into the emitting layer consisting of an undoped polymer and nanocrystals. Finally, the polymeric phase of the composite assures better mechanical properties of the system as compared to pure inorganic semiconductor materials.

For all aforementioned reasons composites of conjugated polymers and nanocrystals have been used in recent years as components of various electronic, optoelectronic, and sensing devices such as light emitting diodes, photovoltaic cells, electrochemical sensors, to name a few [94, 95].

Although conjugated polymer/nanocrystal composites should exhibit significant advantages over both all-organic materials and inorganic semiconductors, still considerable research efforts have to precede their industrial applications. The main difficulty is caused by the fact that several important properties of the composite, such as charge carrier mobility, electroluminescence, etc., are strongly dependent on even small changes in the polymer supramolecular structure and on the distribution of the nanocrystals within the polymer matrix, which are not easy to control.

In the method outlined previously for the preparation of composite materials, both constituents are synthesized individually and then mixed together using a solvent, which easily dissolves the polymer and disperses the colloidal nanocrystals. Alternatively one can synthesize nanocrystals within an already formed polymer matrix, for example by doping the polymer with nanocrystal precursors. However, the control of the nanocrystal size distribution is, in this case, extremely difficult. Thus, this method is used only for those applications in which monodispersity is not crucial, for example in the preparation of polymer supported heterogeneous catalysts.

### 5.2. Selected Properties of Conjugated Polymer/Nanocrystal Composites

Doped conjugated polymers frequently combine metallic-type conductivity with film forming properties of macromolecular systems. Some of them, like polyaniline

protonated with selected sulfonic acids, are solution processible [96, 97]. Thus doped polymers can provide simple electrical contacts to nanocrystals, which are easy to fabricate in a large variety of configurations.

The same arguments apply to the preparation of composites comprising undoped (semiconducting) conjugated polymers and A(II)B(VI) nanocrystals. It should be, however, noted here that in such composites two semiconductor phases of different properties coexist. At the polymer/nanocrystal interface the former acts as an electron donor and the latter as an electron acceptor due to its higher electron affinity (see Table 4). Thus in a typical conjugated polymer/A(II)B(VI) nanocrystal composite the polymer phase serves as the hole transporting medium and the nanocrystals as the electron transporting one. This property is very important in view of applications of polymer/nanocrystal composites for the fabrication of solar cells (see Section 5.3).

The polymer phase is usually continuous whereas the nanocrystals are dispersed, although some of them may form aggregates of different sizes. Such a picture implies that, if the electron transport is governed by the nanocrystal phase, it must be described in terms of percolation. In the simplest approach the percolation threshold is defined as the lowest volume fraction of the nanocrystal phase which assures an interconnected network of particles and by consequence the transport of the charge carriers on a macroscopic scale. This percolation threshold is strongly dependent on the so-called "aspect ratio" (i.e., the ratio of the longest dimension of the nanoparticle to the dimension perpendicular to it). With an increase of the aspect ratio, the value of the percolation threshold decreases. Thus, it is higher for globular-shaped nanocrystals (aspect ratio = 1) than for rod-shaped nanocrystals (aspect ratio  $\gg 1$ ). Finally, it should be stressed that nanocrystals are incorporated in the polymer matrix not as "bare" objects but together with a layer of (organic) capping ligands on their surface. This ligand layer impedes direct interconnectivity of the nanocrystals and can act as a barrier for the charge carrier transport between adjacent nanocrystals as well as for the charge separation at the polymer/nanocrystal interface. Therefore electrical transport

phenomena in the composite material must involve hopping between individual nanocrystals. In this perspective the chemical nature of the capping ligands is of crucial importance. The exchange of "classical" ligands such as TOPO or HDA, containing aliphatic substituents which act as isolating barriers, for "tailor made" ligands with functional groups facilitating charge transport is a challenging area of nanocrystal and polymer chemistry.

### 5.3. Conjugated Polymer/Nanocrystal Composites as New Materials for the Fabrication of Organic-Inorganic Solar Cells

At the beginning of this section it is instructive to briefly discuss the operation principle of photovoltaic cells and in particular of polymeric solar cells. Photovoltaic cells are devices which transform radiation energy originating from solar light into electricity. A polymeric solar cell, in its simplest version, consists of a layer of a semiconducting conjugated polymer, sandwiched between two electrodes of different work functions. One of them must be transparent and consists usually of ITO (indium tin oxide). Radiation induces the formation of excitons, which then undergo dissociation followed by the migration of the created positive and negative charges to the electrodes. However, in such a simple device the photoinduced charge generation, required for the operation of the cell, is extremely inefficient [101]. Semiconducting conjugated polymers are, in their large majority, good electron donors upon photoexcitation. If an electron-accepting molecule is available in close vicinity, the photoinduced charge generation is facilitated. First electron acceptors used together with conjugated polymers in "plastic" solar cells were fullerene ( $C_{60}$ ) molecules. One can imagine that a fullerene layer is introduced between the anode and the semiconducting polymer layer. This results in an increase of the efficiency of photoinduced charge generation at the polymer layer/fullerene layer interface [102]. Even further improvement of the conversion efficiency is achieved when the previously described bilayered heterostructure is replaced by a single composite layer consisting of  $C_{60}$  dispersed in a conjugated polymer matrix [103]. In this case the large interface area promotes the photoinduced charge generation. The formed charge carriers are then transported to the electrodes via the polymer phase (holes) or the fullerene phase (electrons), which percolates.

The same principle applies to solar cells in which, instead of fullerenes, A(II)B(VI) semiconductor nanocrystals are used as composite components, facilitating the dissociation of excitons [104]. This type of solar cell is schematically depicted in Figure 4.

As in "pure polymeric" solar cells, ITO is used as a transparent cathode, and aluminum, deposited by vacuum evaporation, as the anode. Additionally a hole transporting layer separates the ITO electrode and the polymer/nanocrystals composite with the goal to facilitate the transport of the charge carriers to the cathode. This additional layer consists of a molecular blend of poly(ethylene dioxythiophene) with poly(styrene sulfonic acid) (abbreviated as PEDOT:PSS), the latter serving as the dopant increasing electrical conductivity of PEDOT.

**Table 4.** Electron affinities and energy gaps of selected conjugated polymers and nanocrystals (see Appendix) [98–100].

Material	Electron affinity (eV)	Gap (eV)
Indium tin oxide	−4.7	0.0
CdS (2 nm)	−3.8	3.1
CdS (6 nm)	−4.5	2.6
CdSe (2 nm)	−4.0	2.6
CdSe (5 nm)	−4.7	2.0
MEH-PPV	−3.0	2.4
MDMO-PPV	−3.0	2.3
PANI-EB	−4.0	1.4
PANI-PB	−4.2	2.0

PVK	−2.2	3.6
PPV	−2.6	2.5
PTPTB	−3.5	1.8
PEDOT-EHI-ITN	−4.0	0.5
PCBM	−4.1	0.0
Al	−4.3	0.0

**Figure 4.** Schematic representation of a polymeric/nanocrystal solar cell.

The composite material used in [104] consists of 90 wt% CdSe nanorods (7 nm by 60 nm) in poly(3-hexylthiophene). The authors claim that (1D) nanorods are preferable to spherical (0D) nanocrystals as they exhibit improved electrical transport due to directed particle stacking as a result of the elevated aspect ratio. Very high mass fractions of nanorods in the composite material are necessary to facilitate the transport of electrons, which at low contents of nanorods occurs via inefficient hopping. As shown in earlier studies [98], the capping ligand TOPO, forming a 1.1 nm thick layer at the surface of CdSe nanocrystals, causes a significant decrease in the device efficiency, as it acts as a charge barrier. This problem can be overcome by using a pyridine/chloroform solvent mixture for the preparation of the polymer/nanocrystal composite [104]. Pyridine is known to easily displace TOPO molecules at the nanocrystal surface, acting itself as a weakly bound ligand subsequently.

The extent of photoluminescence quenching in the composite material characterizes the efficiency of the charge separation via exciton dissociation. Many literature examples report a weak remaining photoluminescence of the polymer and/or the nanocrystals, which may originate from a lowering of the polymer/nanocrystal interface area caused by the presence of isolated nanocrystal aggregates and zones significantly enriched in polymer. In this context two types of materials can be distinguished: first, composites in which the conjugated polymer absorbs solar light and excitons can be created in both the nanocrystals and in the polymer matrix; second, composites in which the conjugated polymer does not absorb in the visible spectrum and photoexcitation exclusively takes place in the nanocrystals. In the former, which is the more common case, different photophysical processes are possible [98]:

- (i) absorption and exciton formation in the polymer, followed by electron transfer onto the nanocrystal
- (ii) absorption and exciton formation in the polymer, followed by exciton transfer onto the nanocrystal and subsequent hole transfer onto the polymer
- (iii) absorption and exciton formation in the nanocrystal, followed by hole transfer onto the polymer
- (iv) absorption and exciton formation in the nanocrystal, followed by exciton transfer onto the polymer and subsequent electron transfer onto the nanocrystal

For a given composite material process (ii) excludes process (iv) and vice versa because such *Förster*-type exciton transfer occurs solely from the larger to the lower bandgap component. Further insight into the photophysical properties of a device can be provided by photoconductivity measurements revealing the spectral response of the photocurrent. Hereby the short-circuit current is measured as a function of the

wavelength of the incident light. Obviously the spectral response depends strongly on the absorption spectrum of the composite material. To a first approximation, such a spectrum consists of the sum of the absorption spectra of the conjugated polymer and of the nanocrystals. For the former, the position of the absorption bands depends strongly on the chemical structure, whereas for the latter the absorption threshold depends on size (see Section 2.2.1). Therefore the spectral response can be improved by using CdSe nanocrystals with large diameters, since they absorb the largest part of the visible spectrum. Further improvement toward absorption of solar light in the near infrared region can be achieved by applying either smaller bandgap semiconductor nanocrystals or polymers which absorb in this area. An important parameter is the short-circuit quantum efficiency which represents the numbers of electrons generated per photon. It can be used to determine the optimum content of nanocrystals for a given polymer/nanocrystal couple and solar cell configuration. Although in the majority of cases the charge separation is very efficient, the overall efficiency values may be significantly lower than unity because of problems with charge transport to the electrodes. More precisely, electrons are trapped within the (imperfect) nanocrystal network, in so-called “dead ends,” from which they cannot reach the electrode and recombine instead with holes in the surrounding polymer. This mechanism is consistent with an observed linear dependence of the photocurrent at low intensities. Transmission electron microscopy studies of the composite thin films reveal polymer rich zones separated from nanocrystals [98, 104]. In general, structural and morphological properties of the composites are strongly influenced by the type of the conjugated polymer, nanocrystal form, size, content, type of surface ligands, solvents used, and last but not least the film preparation conditions. As a consequence, it is very difficult to optimize a system and at present the control of the composite morphology is the most important drawback for conjugated polymer/nanocrystal composite devices.

From a technological point of view, conjugated polymer/nanocrystal composite systems offer rather facile processing steps for the fabrication of solar cells, which are in addition not very energy consuming. However, the values of the energy conversion efficiency of these devices are still significantly lower, not only with respect to those reported for crystalline silicon based solar cells, but also in comparison to cells fabricated from amorphous silicon [105]. Given the large number of different parameters which characterize the performance of photovoltaic cells, it is sometimes difficult to compare literature values. To eliminate this problem, all data given in the following represent energy conversion efficiencies under air mass (AM) 1.5 conditions (typical solar spectrum, 100 mW/cm<sup>2</sup>) according to the relationships [4]

$$\text{energy conversion efficiency} \quad \eta = I_{SC} U_{OC} FF / P \quad (8)$$

$$\text{fill factor} \quad FF = I_M U_M / (I_{SC} U_{OC}) \quad (9)$$

where  $I_{SC}$  is the short circuit current and  $U_{OC}$  the open circuit voltage of the cell.  $I_M$ ,  $U_M$  are the current and voltage, which provide maximum power output of the cell and  $P$  stands for the integral radiation power per device surface area.

In Table 5 the energy conversion efficiencies of devices based on conjugated polymer/nanocrystal composites are compared to a number of “all-inorganic” and “all-organic” solar cells. This list is nonexhaustive and serves rather as an illustration of technological trends in solar cell technology. Thermodynamic calculations show that, if one assumes an ideal behavior, there exist a “limit” energy conversion efficiency of ca. 30% and an optimum value for the energy gap of the light absorbing material. The latter accounts for ca. 1.5 eV, a value for which the maximum of energy can be transferred from the incident sunlight to excitons [106]. As can be clearly seen from the data in Table 5, “classical” silicon based devices possess the highest performances approaching the limit value. Furthermore they exhibit an excellent long-term stability versus aging processes such as photocorrosion. The latter parameter is of crucial importance for large-scale terrestrial applications. Nevertheless the high production costs of large-size crystalline silicon devices makes research on substitute materials indispensable.

Recent progress on photovoltaic devices based on conjugated polymer/nanocrystal composites [104] resulted in the fabrication of solar cells with conversion efficiencies reaching the same range as reported for “plastic” solar cells with fullerene admixtures, such as MEH-PPV/C<sub>60</sub> [103].

Taking into account the relatively short time since their discovery and their easy fabrication as compared to crystalline silicon based devices, this research direction seems very promising. Still significant effort must be put into improving their efficiency and long term stability.

#### 5.4. Light Emitting Diodes Made of Conjugated Polymers and Nanocrystals

A light emitting diode (LED) is an electronic device which exploits the phenomenon of electroluminescence. In an elementary manner, electroluminescence can be defined as light generation caused by electrical excitation. In this

**Table 5.** Energy conversion efficiencies reported for photovoltaic devices of various types.

Material	$\eta$ (AM 1.5)	Ref.
Crystalline silicon	24.4% (12–16%)	[107]
Polycrystalline silicon	18% (9–12%)	[108]
Amorphous silicon	13% (4–8%)	[105]
Dye-sensitized mesoporous TiO <sub>2</sub> /redox couple in liquid electrolyte	10–11%	[109]
Dye-sensitized mesoporous TiO <sub>2</sub> /OMeTAD (solid state)	2.6%	[110]
MEH-PPV/C <sub>60</sub>	1.4%	[103]
MDMO-PPV/PCBM	2.5%	[111]
MEH-PPV/CdSe nanocrystals	0.2%	[98]
P3HT/CdSe nanorods	1.7%	[104]

*Note:* In addition to the highest reported value, the numbers in brackets indicate typical values observed for the corresponding device type (see the Appendix).

respect LEDs can be considered as inverse to photovoltaic cells. The simplest version of a LED consists of a single layer of a semiconducting electroluminescent material, sandwiched between two electrodes. Similar to the case of photovoltaic cells, one of the electrodes must be transparent to transmit the light created through electroluminescence. Such a one-layer/two-electrode device is called an electroluminescent diode because it shows  $I$ – $V$  characteristics typical of diodes. This means that up to a given voltage no current flows and, above this onset voltage, the current quickly increases with increasing voltage. If the quantum efficiency for electroluminescence is constant, the luminance–voltage characteristics follow the current–voltage characteristics. The operation of a single-layer device can be described as follows. Opposite charge carriers (holes and electrons) are injected into the semiconductor layer from the anode and cathode, respectively. The injected charges may form either singlet or triplet excitons, while only the former decay radiatively to give out light. In more advanced structures, additional layers, which lower the barriers for hole and electron injection are used, the so-called “hole transporting layer” and “electron transporting layer.” In the past 12 years impressive progress has been achieved in the fabrication of conjugated polymer LEDs, with lifetimes exceeding several thousands of hours and external efficiencies  $\eta_{\text{ext}}$  as high as 20% [112, 113].

An alternative way to fabricate LEDs is the use of an emissive layer made of nanocrystals. However, to date the reported efficiencies of such devices are far below those of presently developed polymeric LEDs, with the highest value being  $\eta_{\text{ext}} = 0.52\%$  [114]. So why is it still interesting to perform research on conjugated polymer/nanocrystal LEDs? The principal reason is that semiconductor nanocrystals of low polydispersity show emissive properties unmatched by any class of polymeric chromophores. Typical electroluminescence linewidths of nanocrystals are as low as ca. 30 nm (FWHM) whereas emissive lines of conjugated polymers are much broader and frequently perturbed by the vibrational structure [113]. One may expect that conjugated polymer/nanocrystal composites may combine the efficiencies of polymeric LEDs with the color purity of semiconductor nanocrystals. In reality this is only possible when an efficient energy transfer from the polymer host to the nanocrystal occurs, resulting in electroluminescence essentially from the nanocrystals. However, the optimization of a LED with an emissive layer consisting of a conjugated polymer/nanocrystal composite is a difficult task. First, an appropriate core/shell system has to be selected, which efficiently shields the created excitons localized in the core from non-radiative relaxation induced by interactions with the polymer host. Simultaneously the energy transfer from the polymer host to the nanocrystals must be possible either through charge transfer or through neutral-excitation energy transfer via Förster or Dexter mechanisms [115]. An advantage of conjugated polymer/nanocrystal LEDs is the precise tunability of their emission color. This can be done throughout the whole visible range of the spectrum in the case of CdSe core nanocrystals. By using a semiconductor with a different bandgap, the flexibility can even be further extended to other spectral regions, for which no appropriate polymeric emitters exist. To give an example, when

InAs/ZnSe core/shell nanocrystals are applied, a conjugated polymer/nanocrystal LED emitting in the near infrared can be realized [116]. Moreover, by mixing polymers with fractions of nanocrystals differing in size one can produce LEDs emitting white light.

Similar to the case of photovoltaic cells [102, 103], two device architectures are possible:

- (i) The nanocrystals and the conjugated polymer form a bilayer structure.
- (ii) The nanocrystals are dispersed in the conjugated polymer.

The latter facilitates energy transfer between the polymer and the nanocrystals; however, it also increases the possibility of different nonradiative relaxation pathways (vide supra).

Composites of semiconductor nanocrystals with conventional polymers, which do not show semiconducting properties, have been used in the fabrication of tuneable “nanocrystal–polymer down-conversion LEDs” [117]. The principle of these devices, based on CdSe/ZnS core/shell nanocrystals, can be outlined as follows. Due to their absorption threshold in the visible part of the spectrum, different sized nanocrystals can be excited simultaneously by a single, shorter wavelength light source. Therefore, if the light of a blue emitting diode passes through a nanocrystal–transparent polymer composite, it is absorbed and re-emitted in a color depending on the size of the nanocrystals (see Fig. 5). By controlling the ratio of different sized nanocrystals one can precisely tune the color of the re-emission.

Of course, the polymer matrix must fulfill several conditions. First, nanocrystals dispersed in the polymer should retain their original emission efficiency to the largest possible extent. Second, the matrix must be amorphous to assure optical transparency. Third, nanocrystals should be homogeneously dispersed in the matrix since their aggregation not only lowers the transparency of the composite but also results in some luminescence quenching. Poly(alkyl methacrylates) with long and branched alkyl substituents, for example poly(lauryl methacrylates), respond to these requirements. The composite can be obtained by radical polymerization of the corresponding monomer (lauryl methacrylate) in the presence of ethyleneglycol dimethacrylate as the cross-linking agent and CdSe/ZnS core/shell nanocrystals [117]. Thereby composites exhibiting good optical quality and low luminescence quenching can be fabricated.

**Figure 5.** Scheme of a nanocrystal/polymer down-conversion LED.

## 6. HYBRID ORGANIC/INORGANIC SYSTEMS

The composite materials described in Section 5 are sometimes referred to as “hybrid systems” in the literature, despite the fact that they are simple physical mixtures of conjugated polymers and nanocrystals of different degrees of dispersion. Thus, from a chemist’s standpoint this is not totally correct since the term “hybrid system” or “hybrid molecule” is reserved to a chemical species consisting of at least two entities of different origin (for example, inorganic and organic), which are linked together by chemical bonds. One can easily imagine several types of true polyconjugated molecules/nanocrystal hybrid systems. This is an emerging area of research and to the best of our knowledge the only true hybrid system reported to date is penta(alkylthiophene) phosphonic acid, grafted on CdSe nanocrystals [118].

The synthesis of this hybrid material, consisting of conjugated oligomer/nanocrystal adducts, is very promising, since phase separation phenomena are less pronounced in this case as compared to the physical mixture of both constituents. Moreover, even relatively short conjugated oligomers usually well mimic the majority of physical properties of their corresponding polymers. If for the grafting reaction linear oligomers with two reactive functional groups were used, a three-dimensional network of nanocrystals linked by conjugated spacers could be created.

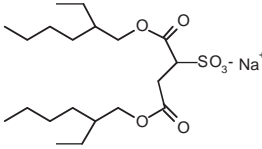

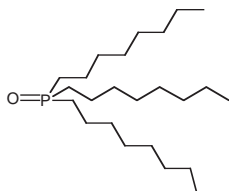

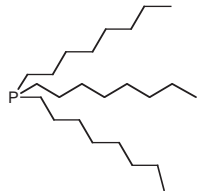

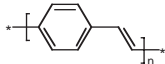

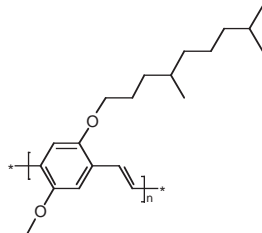

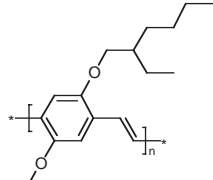

Among other potential approaches leading to conjugated macromolecule/nanocrystal hybrid compounds of different topology, one seems especially interesting. It involves the synthesis of comb-shaped polymers in which the pending groups, attached to the conjugated backbone, bind to nanocrystals. This idea is closely related to the fabrication of so-called “double-cable polymers,” which has recently been developed in connection with the fabrication of polymeric photovoltaic cells of the newest generation [111]. In a double-cable system side groups being good electron acceptors are attached to a conjugated polymer, which is in turn a good electron donor. This can be exemplified by grafting functionalized fullerenes such as PCBM to conjugated polymers [111]. The term “double cable” points out the ability of this true hybrid system to transport simultaneously electrons and holes to the corresponding electrodes. In principle, double-cable polymers containing nanocrystals as pending groups are very promising candidates for the fabrication of photovoltaic cells, especially in view of the fact that even simple physical mixtures of nanocrystals and conjugated polymers yield devices with remarkable efficiencies (see Section 5.3).

Although the research on true conjugated polymer/nanocrystal hybrids is just in the beginning stages, several advantages of these systems with respect to the corresponding composite materials can already be pointed out. First, the separation of charge is facilitated in this case, since both the electron donor and the electron acceptor are inherent parts of the same chemical entity and for this reason no interface, in the classical sense of the term, exists between them. Furthermore, the chemical bonding between the organic and inorganic components eliminates or

at least strongly impedes phase segregation in solid films of hybrid materials. The latter is the principal problem of polymer/nanocrystal composites, showing frequently the coexistence of polymer rich and nanocrystal rich zones. As a result, in true hybrid materials, electron transport to the electrode can occur in a more efficient way, as “dead ends” in the nanocrystal network are suppressed. Generally conjugated polymer/nanocrystal hybrids provide better control of the

material morphology with the possibility to build up really interpenetrating organic/inorganic networks. Finally, from a synthetic point of view, hybrid systems facilitate the preparation of high-quality thin films by casting from solution. This is an advantage over composite materials because for the latter it is sometimes difficult to find a cosolvent, which enables the simultaneous dissolution of the polymer and the colloidal dispersion of the nanocrystals.

## 1. INTRODUCTION

### 1.1. History of Writing

*Direct deposition* is one of the oldest methods to create patterns on solid surfaces. The early Egyptians, Romans, Greeks, and Hebrews utilized *pens* to write on *papyrus and parchment paper*. One of the oldest pieces of writing on papyrus known to us today is the Egyptian “Prisse Papyrus” which dates back to 2000 B.C. The Romans used reed pens to write documents on paper [1]. Then quill pens appeared at about 700 A.D., and it became the main writing tool until 1800 A.D. Quill pens are made of birds’ feathers. When the ink-coated pen is in contact with paper, liquid ink flow is driven onto paper via *capillary flow*. After the development of advanced metallurgy during the industrial revolution, feathers were replaced by metallic nibs. However, the basic strategy of utilizing capillary flow has not changed.

One important event in the history of pens may be the invention of fountain pens. Working fountain pens were first invented by Lewis Edson Waterman in 1884 [2]. Before the invention of fountain pens, one had to dip the pen in the ink well frequently to write long documents. Waterman attached a small ink well as a part of the pen and modified the shape of the nib to achieve stable ink flow. It should be noted that the fountain pen was realized only after proper scientific understanding about liquid flow and technological advances to build small capillary tubes and ink wells.

The development of electronics and mechanics has automated modern *pen writing*. Current ink jet printers, with the help of microelectromechanical system technology, can now

deposit a picoliter volume of liquid ink with  $\sim 20 \mu\text{m}$  spatial resolution. However, modern automated pens still share remarkable similarities with their predecessors: *liquid ink* and *capillary flow*. In all conventional pen writing, *solid ink materials* are first mixed with *solvent* to prepare *liquid ink*, then liquid ink is deposited onto the surface via *capillary flow* or *small driving pressure on it*. After writing, the solvent molecules are vaporized leaving only solid ink patterns on the surface.

Another direct deposition strategy is the *stamping* method in which solid templates with built-in structures are utilized to deposit ink onto the substrate via direct contact. Stamping also has very long history. The “Phaistos disk” found on the island of Crete was produced by pressing relief-carved symbols into the soft clay in 1500 B.C. In 450 A.D., seals were printed with true ink, which was the first instance of actual printing with an incised stamp upon paper. The basic mechanism of the stamping method is quite different from that of pen writing. Unlike pen writing that relies on the *capillary flow* of liquid ink for deposition, the stamping is based on *direct contact between ink and paper*. Since the stamping method patterns the entire surface simultaneously in a parallel manner, it is inherently a faster method than pen writing. However, once the template is made, it is very difficult to change its pattern shape. For these reasons, stamping is suitable for producing multiple copies of identical patterns, while pen writing has been extensively utilized to generate a small amount of arbitrary shape patterns very quickly.

### 1.2. Microfabrication

One of the key technologies that enable modern microelectronics and information technology is the micrometer scale photographic patterning method, *photolithography*. Figure 1 shows the basic steps of the photolithography technique. In this process, solid surfaces are first coated with a polymer resist layer, and then a specific region on the resist layer is exposed to the ultraviolet light through a photographic mask. The exposure of light breaks (or strengthens) the molecular bonding in the polymer resist layer. The exposed (or unexposed) resist layer is specifically removed by immersing the substrate into certain solvents, and the

**Figure 1.** Schematic diagram depicting the basic steps of photolithography.

polymer resist patterns were left on the specific area of the substrate. The polymer resist pattern can be used as a resist of subsequent etching or other processing steps. By repeating these processes, many complicated microelectronic components can be created on a single substrate, which enables integrated computer chips and, eventually, modern information technology.

During the last four decades, the semiconductor industry has been extensively working on improving the resolution of photolithography method so that more components can be integrated in a single chip. This size reduction and higher degree of integration are crucial to improve the performance and power efficiency of the integrated circuits, which can effectively reduce the manufacturing cost. Currently, microelectronic chips with feature sizes as small as 90 nm are commercially available.

There are two major parameters determining the ultimate resolution of the photolithography method: (1) wavelength of light and (2) thickness of the resist layer. The resolution of the photolithography method is subject to the limitation set by optical diffraction according to the Rayleigh equation [3],

$$R = k_1 \lambda / NA$$

where  $\lambda$  is the wavelength of the light used,  $NA$  is the numerical aperture of the lens system, and  $k_1$  is a constant

that depends on the photoresist. It is usually believed that resolution of the photolithography is approximately  $\lambda/2$ . Extensive efforts have been given to use shorter wavelength light to improve the resolution. Ultraviolet light with a wavelength of  $\sim 160$  nm has been employed to fabricate  $\sim 90$  nm commercial chips. However, it is increasingly difficult to find a proper optics component for shorter wavelength light.

On the other hand, the minimum feature size is also affected by the thickness of the resist layer. It is due to the unpredictable *slope* at the edge of the photoresist patterns as shown in Figure 1. High-resolution lithography resist layers are usually thinner than 100 nm.

Considering these two parameters, the resolution limit of the photolithography technique is believed to be around  $\sim 100$  nm. Extensive efforts have been given to develop a next generation lithographic technique that can overcome the resolution limit of photolithography and continue to decrease the size of electronic chips. Possible candidates include X-ray lithography, e-beam projectors, scanning probe-based lithography, and soft lithography [4]. These methods demonstrated lithography resolution down to 10 nm. However, it is not yet clear which method will eventually replace the photolithography technique. Modern nanodeposition methods such as dip-pen nanolithography or microcontact printing also have been extensively developed as a possible candidate to replace photolithography. Since the direct deposition strategy does not rely on light, the resolution is not limited by the wavelength of the light.

### 1.3. Hybrid Devices

On the other hand, we can find another important motivation for the development of nanodeposition methods in soft material-patterning applications. Recent dramatic development of nanotechnology and biological science provide us *new nanometer scale building blocks* for functional devices (Fig. 2). By combining these new materials with conventional solid-state devices, one should be able to build

Nanostructures	Diagram	Possible Applications
<b>Protein Motors</b>		Nano-mechanical System
<b>DNA</b>		Information Storage, Highly Selective Molecular Glue
<b>Nanotube</b>		Nanowires, Chemical Sensor
<b>Clusters</b>		Quantum dots
<b>Conjugated Molecules</b>		Nanowires
<b>D-σ-A</b>		Diode

**Figure 2.** New nanostructures and their possible applications.

a generation of new functional devices. These include biological sensors [85–89] to detect harmful viruses and protein motor-based nanomechanical systems [90]. These new generation devices can be termed as *hybrid devices* because they are comprised of *organic materials* as well as *solid-state nanostructures*. These hybrid devices are expected to flourish for the next few decades because there is a huge demand for new functional devices, especially for medical and biological applications.

One significant difference between hybrid devices and conventional solid-state electronics is the mode of fabrication. Since with hybrid devices most of the molecular functional units are first synthesized under *solution* or *vapor* conditions, additional *nanometer scale assembly steps* are required to fabricate such structures. In contrast, the functional components (e.g., transistors, resist) of conventional solid-state devices are directly fabricated by modifying the solid substrate. Conventional microfabrication techniques such as photolithography cannot be used for fabricating molecule-based structures because of the complex chemical reactivity of most of the molecular units.

The nanoscale direct deposition strategy seems to be an ideal method because it can deposit general organic materials directly onto solid surfaces without any complicated processing steps. Nanodeposition methods have been extensively utilized to pattern chemical and biological molecules on solid substrates in a nanometer scale resolution.

#### 1.4. Modern Nanodeposition

As a possible solution to solve the *resolution* problem in the semiconductor industry and the *compatibility* issue in soft materials-based applications, two new direct deposition methods have been drawing attention: (1) dip-pen nanolithography (DPN) and (2) microcontact printing. DPN utilizes an atomic force microscopy (AFM) tip as a nanoscale pen to deposit organic molecular substances onto solid substrates, and its basic idea is similar to that of its macroscale counterpart—the quill pen. The microcontact printing method utilizes micro- and submicrometer scale stamps to print general organic molecules on solid surfaces. Despite their similarities with conventional direct deposition methods, these state-of-the-art nano-deposition methods differentiate themselves from macroscale deposition methods in several aspects: (1) nanoscale resolution and (2) generality in chemical and biological molecular ink.

In the following sections, we will provide a comparative overview of these two nanoscale direct deposition methods. Furthermore, we will try to answer several in-depth questions regarding nanodeposition processes: (1) What are the key scientific aspects which enable the *nanoscale resolution deposition* of general organic molecules? (2) What are the possible future impacts of this new lithographic technology in everyday human life?

## 2. DIP-PEN NANOLITHOGRAPHY

### 2.1. Key Strategy

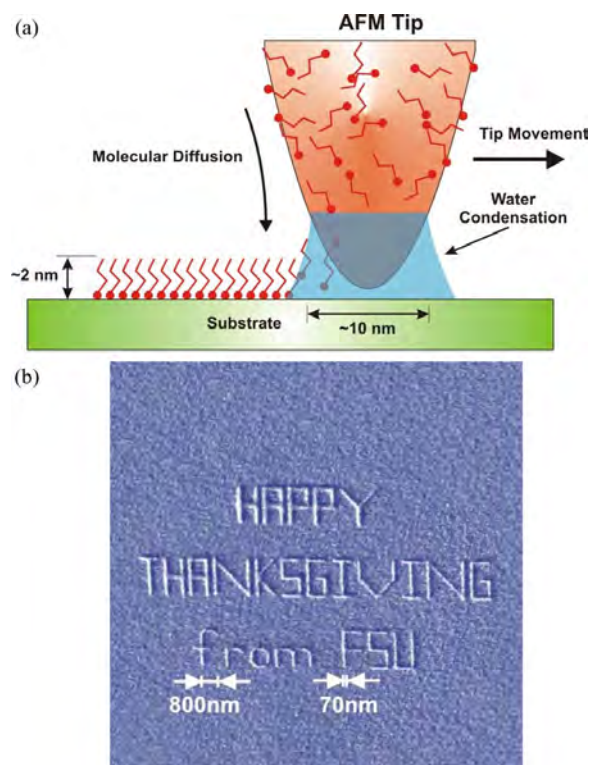

The DPN process is a new direct deposition technique that was first developed in Mirkin's lab at Northwestern University in 1998 [6–10]. It utilizes an (AFM) tip as a *nanoscale*

*pen*, molecular substances as ink, and solid substrates as *paper*. Figure 3(a) shows the basic mechanism of DPN as well as approximate dimensions of commonly used pen and ink molecules. When the molecule-coated tip is in contact with the substrate, molecules *diffuse* out onto the substrate, *chemically anchor* to the surface, and form well-ordered *self-assembled monolayer* (SAM) patterns. Under ambient conditions, water condenses at the AFM tip/substrate junction and affects the molecular diffusion. Like macroscale quill pens, the molecular ink coating on the tip surface works as an ink reservoir. A number of variables including relative humidity, temperature, and the tip movement speed can be adjusted to control the ink transport rate, feature size, and linewidth.

Figure 3(b) shows an example patterns generated via DPN. With the help of automated lithography software, one can directly print out organic molecular patterns from the PC onto solid substrates like ink-jet printers print graphics on paper.

Even though the DPN technique shares remarkable similarities with ancient quill pens, they also have significant qualitative and quantitative differences.

First of all, the dimensions involved in the DPN process including *the size of the pen* and the *thickness of the generated patterns* are in the nanometer scale regime (Figure 3a), which is crucial in achieving nanoscale patterning resolution. In this case, one can say, “size does matter.” Even with its short history, the DPN method demonstrated unprecedented  $\sim 10$  nm patterning resolution [6]. Considering the resolution of current commercial ink-jet printers,  $\sim 20$   $\mu\text{m}$ ,

**Figure 3.** (a) Schematic diagram depicting dip-pen nanolithography. (b) Nanoscale “greetings” written via dip-pen nanolithography. The letters are written with 16-mercaptohexadecanoic acid on amorphous Au surface.

the resolution of DPN is revolutionary. This revolutionary resolution can be attributed to several core scientific developments in nanotechnology including the nanofabrication technique for AFM tip preparation, the self-assembled monolayer for a new type of molecular ink, and nanoscale precision control system for nanoscale AFM tip movements.

Second, unlike conventional pens, bulk ink coating on the pen (the AFM tip) usually remains *solid* throughout the DPN process because DPN writing is usually performed below the melting temperature of molecular ink. [However, readers should be cautioned. At this stage, the exact phase *at the tip/substrate junction* is not yet clearly understood. Because of the water meniscus and nanoscale dimension of the junction, the phase of molecules at the junction might be quite different from that on the tip surface (Fig. 3a).] Thus, the behavior of molecular ink in the DPN process can be described by individual *molecular diffusion* rather than *capillary flow* of liquid ink. In case of a macroscale pen that is based on the capillary flow of liquid ink, the ultimate resolution of pen writing is determined by the properties of ink solvent. It is often very difficult to control the liquid flow in nanoscale resolution due to several unpredictable behaviors of liquid such as viscosity change, ink meniscus, etc. However, in most DPN processes, ink molecules behave like a noninteracting two-dimensional gas whose behavior can be described by the Fickian diffusion model [11]. Molecular diffusion based on *random walk* is usually easier to predict and control than the capillary flow of liquid. The nanometer scale precision of DPN can be partly attributed to this different phase of molecular ink and writing mechanism.

It is also worth mentioning several other important characteristics of DPN.

One aspect of practical importance is a *stable ink deposition rate*. When the DPN process is stabilized, the deposition rate of molecules from the tip to the substrate remains almost constant. The stable writing speed can be attributed to the small contact point between the AFM tip and the substrate. As a result, the amount of ink molecules deposited through the contact point is relatively small compared with the amount of molecular ink (ink reservoir) on the AFM tip surface. This is the same reason macroscale quill pens and fountain pens have a stable ink deposition rate.

Second, unlike other scanning probe-based nanolithography methods, DPN is relying on *molecular diffusion* for writing, and it usually does not require *external forces*. With the same environmental conditions, the amount of deposited molecules simply depends on the contact time between the tip and the substrate. However, additional forces such as the electric field can be utilized to achieve better control of the process.

Third, since DPN is based on diffusion of individual molecules, its behavior depends on several environmental conditions including *temperature* and *humidity*. For example, the temperature change can change the *diffusion constant of molecules* on the surface. The change of humidity should alter the amount of water condensation at the tip/substrate junction as well as that on the surface, and it will change the behavior of diffusing molecules. However, it should be noted that DPN is now able to deposit quite a broad range of molecular species with quite different chemical and physical properties [12–20]. Thus, one should be cautious when

understanding this dependence because the results for each molecular ink may be different depending on the properties of individual molecular species such as hydrophobicity and melting temperature.

## 2.2. Experimental Procedure

### 2.2.1. Molecular Ink

Various types of organic molecules have been used for DPN experiments. Most commonly used organic molecules form SAMs on substrates (Fig. 4A). These molecules are comprised of three different parts: (1) a chemisorbing group, (2) an end group, and (3) a spacer (inert part). When these molecules are deposited onto a proper substrate, they chemically anchor to the substrate and form a well-ordered stable crystalline monolayer film with a thickness ranging from 1 to 10 nm. Molecules that form SAMs on various substrates are listed in Table 1. Specific binding groups can be chosen depending on the substrate. By depositing these molecules, one can completely change the chemical properties of the surface to that of end groups. Various end groups can be used for specific applications. For example, one can even use specific sequence DNA or proteins as end groups.

The best characterized systems of SAMs are alkanethiols  $R(\text{CH}_2)_n\text{SH}$  adsorbed on a gold surface (Fig. 4B). Alkanethiols are chemisorbed spontaneously on a gold surface and form alkanethiolates. This process is assumed to occur with the loss of dihydrogen by the cleavage of the S–H bond. Sulfur atoms bonded to the gold surface bring the alkyl chains into close contact: these contacts freeze out configurational entropy and lead to an ordered structure. For alkyl chains of up to approximately 20 carbon atoms, the

degree of interaction in a SAM increases with the density of molecules on the surface and the length of the alkyl backbones. This assembly is a very quick process that may occur in a couple of seconds. This ability to form ordered structures rapidly might be one of the factors that ultimately determine the success of nanodeposition techniques.

The structures and properties of SAMs of alkanethiolate binding on a gold surface have been extensively investigated using a number of techniques such as contact angle measurement [50], ellipsometry [51], infrared [52], Raman [53], electrochemistry [54], X-ray photoelectron spectroscopy [55], scanning tunneling microscopy (STM) [56], and AFM [57]. As a result, it is generally accepted that sulfur atoms form an overlayer in SAMs. Recent STM studies show that these systems are heterogeneous and structurally complex: The alkyl chains may form a “superlattice” at the surface of the monolayer, that is, a lattice with a symmetry and dimension different from that of the underlying hexagonal lattice formed by sulfur atoms [58].

Significantly, when these molecules are deposited via DPN, they also form high quality crystalline SAMs like those SAMs resulting from bulk solution immersion or vapor deposition methods. For example, when 1-octadecanethiol molecules are deposited onto the atomically flat Au (111) surface via DPN, the molecular patterns show hexagonal crystalline structures (Fig. 5). This implies that DPN is based on a natural molecular diffusion and self-assembly process, and the molecule-coated AFM tip simply directs the formation of the self-assembled monolayers in the desired regions.

Thin self-assembled monolayer formation is an important factor that enables patterning of very large substrate areas via DPN. DPN relies on thin molecular coating on the AFM tip as an ink reservoir. Considering the total size of commercial AFM tips ( $\sim 5 \mu\text{m}$ ), the volume of molecular coating on the AFM tip is  $\sim 1 \mu\text{m}^3$  (Fig. 6), which is very small. However, the thickness of DPN-generated patterns is just a single molecular layer,  $\sim 2 \text{nm}$ , implying that a single molecular coating on the AFM tip is enough to cover a surface area as large as  $500 \mu\text{m}^2$ .

Even though a self-assembled monolayer with chemical surface binding helps reliable DPN writing, the covalent surface binding of molecules to the substrate is not a necessary condition for DPN writing. There are several reports utilizing molecules without covalent binding on the surface. Usually, it is possible to deposit molecules via DPN if the molecules have a *large diffusion constant* and the *affinity to substrate*. Various molecular species that have been utilized in the DPN process are listed in Table 2.

### 2.2.2. Nanoscale Pen

AFM tips with various shapes and chemical surfaces have been utilized as nanopens for the DPN process. Figure 6 shows the scanning electron microscope (SEM) image of a typical AFM tip made of Si<sub>3</sub>N<sub>4</sub>. The shape of the AFM tip is determined by the fabrication step. Most common materials for the AFM tips are Si<sub>3</sub>N<sub>4</sub> and Si. Si<sub>3</sub>N<sub>4</sub> tips usually have a pyramid shape, while Si tips are conical [62]. The heights of usual AFM tips are about 3–10  $\mu\text{m}$ . The diameter of the

tip can be as small as  $\sim 10$  nm. The sharpness of the tip is one of the major factors determining the resolution of the DPN process. Utilizing commercial silicon nitride AFM tips, Hong et al. demonstrated patterning of  $\sim 10$  nm size molecular nanostructures via DPN [10]. Further improvement of the resolution can be expected if special tips are utilized. Possible higher resolution tips are carbon nanotube tips [63] and electrodeposited carbon tips [64].

Since DPN relies on molecular ink coating on the tip surface as an ink supply, ink loading on the AFM tip surface is critical for reliable DPN writing. For reliable ink loading, one should consider the surface chemistry of AFM tips. When the AFM tip is coated from the solution of molecular ink, the amount of loaded ink is determined by the adhesion properties of *solvent molecules*. Even though clean  $\text{Si}_3\text{N}_4$  and Si surfaces are *hydrophilic*, the AFM surfaces become *hydrophobic* after a couple of days of air exposure because of carbon contamination. In the case of nonpolar solvent, one can use commercial AFM tips without special treatment. However, many biomolecules can be dissolved only in polar

**Figure 6.** Atomic force microscope tip (nanopen for DPN) made of  $\text{Si}_3\text{N}_4$ .

solvent like water. For stable ink loading of those molecules, surface treatment is required.

One common method for the surface treatment is cleaning AFM tips with the oxygen plasma cleaner. Oxygen plasma treatment creates  $-\text{OH}$  group on the AFM tip surface and makes the surface hydrophilic. However, the effect lasts only for a short time period ranging from a few minutes to a few hours because of the contamination from the air. To achieve the desired functionality on the AFM tip for a relatively long time period, a self-assembled monolayer (e.g.,  $\text{Cl}_3\text{SiR-X}$ ) can be formed on the plasma treated AFM tip surface [65].

An alternative method is thin solid film coating. For example, evaporation of an  $\sim 10$  nm thin titanium coating can make the AFM tip more hydrophilic. However, one should be careful when depositing a metallic film on the AFM tip because solid coating may deform the AFM cantilever significantly. Usually, a solid coating with thickness less than  $\sim 10$  nm can change the surface properties without significant deformation of AFM cantilevers.

One trick that can be utilized for general molecular species is coating the tip surface with the same solid materials as substrates and then coating the tip surface with ink molecules. For example, if one wants to deposit certain thiol molecules on an Au substrate, the AFM tip can be coated with Au followed by the thiol molecules. Thiol molecules can form a monolayer easily on the Au coating on the AFM tip and thus make the tip *compatible* with solvent molecules which will be utilized to prepare molecular solution.

### 2.2.3. Molecular Coating

Molecular coating can be achieved via solution or vapor coating methods. Solution coating is similar to dipping macroscale pens in ink solution. In this method, the solution of a desired molecular species is first prepared utilizing

proper solvents. Then, the AFM tip is dipped into the solution for a short time period (e.g.,  $\sim 30$  sec), and excess molecular ink is *blown dry* by clean nitrogen gas. This process leaves a thin *solid* molecular coating on the AFM tip. In case of 16-mercaptohexadecanoic acid, the AFM tip is usually dipped in the 1 mM solution in acetonitrile for  $\sim 30$  seconds. Reliable coating of organic molecules on the AFM tip is one of the keys for successful DPN writing.

Molecules with a high vapor pressure can be coated via the vapor coating method. In this method, the AFM tip and molecules are placed together in a small closed reaction vessel and the vessel is heated to vaporize the molecular species. When the vessel is cooled down, the vaporized molecules are adsorbed on the AFM tip surface and a thin molecular layer is formed. In case of 1-octadecanethiol (ODT), 200 mg ODT and AFM tips are placed in a small closed tin can ( $\sim 15$  ml) and the tin can is heated up to  $60^\circ\text{C}$  for 20 min. When the tin can is cooled down to room temperature, the vaporized molecules are adsorbed on the AFM tip surface and leave a thin molecular coating. However, the vapor coating method is usually limited for volatile molecular species.

Even though both coating methods leave a *solid* molecular coating on the AFM tip, the properties of the coatings on the AFM tip via two different methods may be quite different. A vapor coated molecular coating is usually pure and contains less impurities. In case of the solution coating method, the molecular coating on an AFM tip contains a significant amount of *solvent molecules* for a time period as long as a couple of hours. During the time period, solvent molecules significantly enhance the diffusion of organic molecules and thus enhance the DPN writing speed. For example, 16-mercaptohexadecanoic acid (MHA) molecules coated from 1 mM acetonitrile solution will contain a significant amount of solvent and will have a fast writing speed for a couple of hours. Also, the residual solvent molecules may alter the behavior of DPN writing under different temperature and humidity conditions.

#### 2.2.4. DPN Writing

Once the tip coating is completed, one can create complicated soft nanostructure patterns on the solid surfaces by putting the AFM tip in direct contact with the substrate. Since DPN writing is driven by natural thermal diffusion of molecules, and it does not rely on the contact force, the contact force does not affect the deposition rate of molecular inks much. In this case, a *smaller contact force* is preferred to avoid any accidental damage on the substrate due to excessive force. In actual DPN writing, the AFM tip is operated in a *contact* mode with a contact force  $\sim 1$  nN and the tip is moved along the substrate to direct the deposition of molecular species onto the desired region.

However, some researchers have demonstrated DPN writing in *tapping* mode. In tapping mode, the AFM tip oscillates and gently taps the substrate. As a result, the AFM tip periodically makes contact with the substrate only in a short time period. In this case, the deposition rate (amount of deposited molecules in a unit time) depends on the AFM set point because the effective contact time changes depending on the set point. The advantage of tapping mode writing is

that the interaction between the AFM tip and the substrate is much weaker than that in contact mode. DPN writing via noncontact mode may be more suitable for extremely soft nanostructures such as weakly bound proteins [66]. The patterned surface can be imaged and tested with the molecule-coated AFM tip. Since the molecular coating on the AFM tip is very thin, one can still image surface patterns with the molecule-coated AFM tip. The most common method for imaging thin organic molecular patterns is *lateral force microscopy* (LFM) in contact mode or *phase imaging* in non-contact mode. Lateral force microscopy measures the tip bending due to the frictional force, while phase imaging measures phase shift of the tip oscillation caused by the attractive force between the AFM tip and the molecular patterns. Since the frictional force also originates from the attractive force, both techniques are, in fact, utilizing the *attractive force map* to characterize the molecular patterns. In the air, the attractive force is usually determined by capillary force due to water meniscus at the tip/substrate junction. The capillary force is larger than any other attractive forces at least by an order of magnitude. Since the magnitude of the capillary force depends on the hydrophobicity of the tip and the surface, LFM or phase images under ambient conditions simply measure the *hydrophobicity* of the molecular patterns.

In the DPN process, complicated patterns can be generated by the combination of two basic patterns: (1) dots and (2) lines. A dot pattern can be generated by holding the molecule-coated AFM tip at a fixed position on the substrate so that molecules diffuse out in a radial direction to form a circular “dot” pattern (Fig. 7A). The size of the dot pattern is determined by the *contact time* between the AFM tip and the substrates. Line patterns can be generated by

**Figure 7.** (A) Typical DPN-generated “dot” patterns. Each dot is generated by holding the AFM tip coated with 16-mercaptohexadecanoic acid at a fixed point on the Au substrate. If the deposition rate is constant,  $R \sim t^{0.5}$ . (B)  $R$  vs  $t$  graph showing a constant deposition rate of the DPN writing.

moving the AFM tip with a constant speed while in contact with the substrate. Here, the linewidth is determined by the moving *speed* of the AFM tip.

To apply the DPN process for practical lithography applications, one should be able to predict the final shapes of molecular patterns. It is especially crucial to precisely predict the sizes of two basic patterns, “dots” and “lines.” If deposited molecules form SAMs with a uniform density, the *total number of deposited molecules* is proportional to the *area of the molecular patterns*. Utilizing the assumption of “constant deposition rate” which has been experimentally proved in many cases, a simple empirical equation can be utilized to characterize the DPN generated patterns,

$$(\text{Area}) = C \times (\text{Contact time})$$

where  $C$  is the deposition rate. From a practical point of view, this equation implies that if the deposition constant  $C$  is measured once, one can precisely predict the pattern size with known contact time. For example, for *dot* patterns,  $(\text{Area}) = \pi R^2 = Ct$ , which results in the equation for the radius,

$$R = \sqrt{Ct/\pi}$$

For line patterns,  $(\text{Area}) = WL = Ct$  where  $W$  and  $L$  are the width and length of the line, respectively.

$$W = C/(L/t) = C/(\text{speed}).$$

$C$  can be easily measured by a simple test experiment before actual DPN patterning. Once  $C$  is measured, one can generate desired size “dot” and “line” patterns by controlling the *contact time* and *tip sweeping speed*. Eventually, one can get more complicated patterns with a high precision.

In the scanning probe-based lithography processes which rely on a contact force or electric current as a mean of writing, it is very difficult to precisely predict the shape and size of final patterns. However, in the DPN process, once one finds out the diffusion constant  $C$  by a simple test experiment, one can precisely control the pattern size for the rest of the experiments. This *predictability* is one of the most critical advantages of the DPN process as a practical lithographic method.

## 2.3. Lithographic Capability

### 2.3.1. Resolution Limit

Hong et al. demonstrated  $\sim 10$  nm resolution of DPN writing [6]. The ultimate resolution of DPN should depend on various parameters such as the tip diameter, substrate roughness, and the properties of molecules. Figure 8 shows example patterns of MHA on Au (111) and amorphous gold surfaces. On the atomically flat Au (111) surface, molecular dots as small as 25 nm show *isotropic* circular shape (Fig. 8A), while the larger dots on the amorphous Au surface are distorted significantly due to the surface roughness (Fig. 8B). These pictures show a routine resolution which can be easily achieved via DPN under ambient conditions without any special preparation. It should be noted that considering the lattice structures of SAMs, a single 25 nm diameter dot is comprised of only 4500 molecules.

**Figure 8.** (A) Sub-50 nm dot patterns on atomically flat Au (111). Each dot is comprised of 16-mercaptohexadecanoic acid molecules. (B) Molecular dots on an amorphous Au surface showing the effect of surface roughness.

Since DPN relies on direct deposition of molecules utilizing the AFM tip as a pen, its resolution is not limited by the wavelength of light. Sharper tips can be used to achieve better resolution. Current resolution of DPN could be improved if special tips such as carbon nanotube tips are used for DPN writing.

The high resolution of DPN can be attributed partly to the properties of ink molecules. Unlike conventional direct deposition methods, DPN utilizes *solid* ink in most cases, and it relies on molecular diffusion. In case of conventional pens, the ultimate resolution is limited by the ink properties such as capillary size of liquid ink at the pen/surface junction. Since DPN utilizes solid ink, individual molecules diffuse by a random walk, and it is easier to control the molecular flow in the nanometer scale precision. The formation of high quality self-assembled monolayers is another important factor for the high resolution of DPN. It allows one to generate uniform nanoscale patterns reliably via the DPN method.

Moreover, DPN has two major advantages over traditional nanolithographic techniques: *ultrahigh registration* and *multiple-ink patterning* [6]. Because DPN allows one to image nanostructures with the same tool used to form them, one can use DPN to generate and align nanostructures with pre-existing patterns on the substrate with ultrahigh registration (Fig. 9). With the help of the dip-pen nanolithography software, one can generate multicomponent patterns using alignment marks, a strategy analogous to that used to register e-beam lithography patterns. A distinct advantage of this approach over e-beam methods is that it utilizes the scanning probe for generating and locating alignment marks. This is very important because it is less destructive than e-beam methodology for finding alignment marks (i.e., it is compatible with soft materials), and it is an inherently higher resolution imaging technique than optical or electron beam methods.

### 2.3.2. Multiple Pen Writing

DPN writing is based on the thermal diffusion process and does not rely on the *contact force*. As a result, slight variation of the contact force does not affect the deposition rate in the DPN process.

**Figure 9.** Left: Diagram depicting the method for generating aligned soft nanostructures. Right: SAMs in the shapes of polygons drawn by DPN with 16-mercaptohexadecanoic acid on an Au surface. An ODT SAM has been *overwritten* around the polygons. Adapted with permission from [6], S. Hong et al., *Science* 286, 523 (1999). © 1999, American Association for the Advancement of Science.

One major problem in serial writing processes is patterning speed. Since one has to generate complicated patterns with a *single* pen, it usually takes much longer time than parallel patterning methods such as photolithography. One strategy to overcome this limitation is writing with *multiple* pens simultaneously. In most other scanning probe lithography methods, the writing speed depends on the contact force or applied electric field between the AFM tip and substrate. Since these parameters depend on the surface conditions, complicated feedback circuits are required to precisely maintain identical contact forces or electric field on each tip. In this case, to achieve the identical pattern size, one has to build a separate feedback circuit for each AFM tip, which dramatically increases the instrumentation cost.

In the case of DPN with multiple pens, even with different contact forces on each AFM tip, each tip should generate the same patterns. Figure 10 shows a schematic diagram depicting the multiple-pen writing strategy. In this scheme, the laser feedback is applied on the AFM tip with the largest separation from the surface to ensure that all other AFM tips are in contact with the substrate. Although

**Figure 10.** Schematic diagram depicting multiple dip-pen writing utilizing a single force feedback system.

the force between the tip and surface may be different, it still results in the same deposition rate. Hong and Mirkin demonstrated that DPN writing with eight pens and a single feedback gives identical nanoscale patterns (Fig. 11) [8]. The possible maximum force variation on the contact point depends on the mechanical strength of SAMs and substrates. Under ambient conditions, there is a report of applying up to 100 nN contact forces on alkanethiol SAMs without significant structural damage [58].

Extensive efforts are currently given to increase the density of tips. Zhang et al. demonstrated high density 32-pen parallel writing (Fig. 12) [67].

## 2.4. Applications

The soft materials patterning capabilities of DPN opens up new possibilities in many practical applications.

### 2.4.1. Etching

Self-assembled monolayer patterns generated via DPN have been utilized to fabricate solid nanostructures (Fig. 13). In this process, the monolayer patterns are used as an *etching resist* layer. Weinberger et al. demonstrated etching of Au utilizing 1-octadecanethiol as an etching resist layer [9]. Then, the etched Au patterns are used as an etching resist for the silicon etching process (Fig. 14).

**Figure 11.** Lateral force microscope images of eight identical patterns generated with one imaging tip and eight writing tips coated with 1-octadecanethiol molecules. **Figure 13.** Schematic diagram depicting solid nanostructure fabrication via DPN

**Figure 14.** Nanoscale silicon structures utilizing DPN-generated SAM patterns as an etching resist layer. Adapted with permission from [9], D. A. Weinberger et al., *Adv. Mater.* 12, 1601 (2000). © 2000, Wiley-VCH.

Significantly, since the thickness of the SAM is  $\sim 2$  nm, it can be an ideal etching resist layer. Also, the resolution of DPN is not limited by optical wavelength. One disadvantage for practical applications might be its speed because DPN is a serial process. Zhang et al. demonstrated fabrication of multiple solid nanostructures via a multiple pen writing strategy [67]. Considering recent active works in multiple pen systems such as Millipede from IBM, further improvement of its speed can be expected. Table 3 shows possible SAM resist layers with corresponding etchants.

#### 2.4.2. Surface-Templated Assembly

Nature uses molecular recognition between complex macromolecules to form sophisticated meso- and macroscopic architectures. Proteins, DNA, and other biomolecular structures all have been programmed to form specific structures based upon relatively simple precursor molecules such as nucleotides or peptides. Recently, significant efforts have been given to construct functional materials utilizing the molecular recognition mechanism.

Specific assembly steps inspired by DPN-generated molecular patterns can be utilized to place nanoscale functional elements at the specific position. In the process as depicted in Figure 15, the desired nanometer scale region on the surface is first functionalized with specific organic molecules via dip-pen nanolithography. The molecules contain specific functional groups which have a strong affinity to desired nanostructures. For example, MHA binds on the Au surface with thiol group and exposes carboxylic acid group on the SAM surface. The  $\text{Fe}_3\text{O}_4$  magnetic nanoparticles have a specific affinity to the carboxylic acid groups. After surface functionalization the remaining surface area should be passivated via the SAM with inert functional groups to avoid nonspecific binding of nanostructures. Methyl ( $-\text{CH}_3$ ) terminated molecules such as 1-octadecanethiol are often used for passivation. Then, the sample is placed in the solution containing desired nanostructures so that nanostructures can assemble onto the desired area via molecular recognition mechanism. Figure 15 shows magnetic nanoparticle patterns assembled onto the SAM surface covered with carboxylic acid groups ( $-\text{COOH}$ ). In this process, nanoscale dot patterns comprised of 16-mercaptohexadecanoic acid are prepared via DPN and the remaining surface is passivated via methyl terminated ODT molecules.

Various interactions can be utilized to specifically assemble nanostructures onto a desired surface area. These include covalent bonding, electrostatic interactions, and

**Table 3.** Possible combination of SAMs and etchants.

SAM	Surface	Etchant	Example molecules	Ref.
Thiol	Au	KCN/ $\text{O}_2$	$\text{HS}(\text{CH}_2)_{15}\text{SH}$ , $\text{HS}(\text{CH}_2)_{18}\text{SH}$	[9, 68–70]
	Ag	KCN/ $\text{O}_2$	$\text{CH}_3(\text{CH}_2)_{15}\text{SH}$	[71, 76]
	Cu	$\text{FeCl}_3/\text{HCl}$	$\text{CH}_3(\text{CH}_2)_{15}\text{SH}$	[69, 72]
	GaAs	$\text{HCl}/\text{HNO}_3$	$\text{CH}_3(\text{CH}_2)_{15}\text{SH}$	[69, 77]
$\text{RPO}_3^-$	Al	$\text{HCl}/\text{HNO}_3$	$\text{C}_{18}\text{PO}(\text{OH})_2$	[74]
$\text{RSiO}_{3/2}$	Si/ $\text{SiO}_2$	$\text{HF}/\text{NH}_4\text{F}$	$\text{HSC}_{15}\text{H}_{30}\text{COOH}$	[78]
$\text{RSiO}_{3/2}$	Glass	$\text{HF}/\text{NH}_4\text{F}$	$\text{HSC}_{15}\text{H}_{30}\text{COOH}$	[78]

**Figure 15.** Surface-templated assembly process for nanoparticles. An array of iron oxide dots prepared by the surface-templated assembly process. Adapted with permission from [91], X. Liu et al., *Adv. Mater.* 14, 231 (2002). © 2002, Wiley-VCH.

biomolecular interactions. Biomolecular interaction is especially intriguing because of its variety and specificity. Unlike most other molecular recognition mechanisms where possible choices are limited (e.g., thiol to Au, carboxylic acid to aluminum, etc.), biomolecular recognition provides a virtually infinite number of combinations. For example, Demers et al. demonstrated surface functionalization with single strand DNA (ssDNA) molecules [16]. When the functionalized substrate is immersed in the solution of DNA-functionalized nanoparticles, only nanoparticles with a specific *complementary* sequence of ssDNAs can assemble to the desired surface area. Suppose one uses ssDNA with  $n$  base pairs. Since each base pair of ssDNA can have 4 different sequences (A, T, G, or C),  $4^n$  different combinations are possible.

### 2.4.3. Patterning of Biomolecules

Biomolecular patterning via DPN is of huge practical importance. DPN allows one to directly deposit general biological molecules onto solid surfaces with a nanometer scale resolution. This new capability allows one to envision new biomolecular functional devices such as ultrahigh density gene chips or nanoscale biosensors.

Usually, additional consideration is usually required for DPN patterning of biomolecules. First of all, most biomolecules are relatively large compared with other self-assembled monolayer molecules. As a result, the interaction between AFM tip and biomolecules can be very large. Contact mode writing with a small contact force or tapping mode writing is often necessary for stable DPN patterning of large biomolecules [6]. Second, most biomolecules prefer water as solvent. So the AFM tip should be treated to make it hydrophilic. Finally, some biological molecules lose their functionality and are destroyed when dried. Those sensitive molecules could be patterned via a surface-templated assembly process instead of a direct deposition method. In

this method, the surface is first coated with specific functional groups and the assembly of biomolecules is directed via specific assembly.

Wilson et al. demonstrated direct patterning of  $\sim 100$  nm size thiol-modified *collagen* molecules on a Au surface [20]. In this experiment, thiol groups bind to the Au surface and form stable structures. However, they also observed that the contact mode writing is not suitable for patterning large biomolecules because direct contact of the AFM tip to the molecules can destroy the biomolecular structures on the surface. Tapping mode patterning is first applied to generate the organic molecular patterns on the surface. In the tapping mode, the AFM tip gently taps the surface without a direct contact, which can minimize the interaction between AFM tip and the surface nanostructures. It allows one to create stable biomolecular structures with less damage. By this method, Wilson et al. created a collagen patterns with 30 nm linewidth [20].

Demers et al. demonstrated direct deposition of thiol-modified DNA molecules (Fig. 16) [93]. To enhance the ink loading on the AFM tip, the surface of the AFM tip is first modified by 3'-aminopropyltrimethoxysilane, which promotes reliable adhesion of the DNA ink to the tip surface. Demers et al. also demonstrated the direct deposition of DNA onto the SiO<sub>2</sub> surface. Before the DPN writing, the surface of the thermally oxidized Si wafer was activated with 3'-mercaptopropyltrimethoxysilane. Then, DNA molecules with acrylamide groups are deposited via DPN, and they form stable nanostructures on the surface. The final patterns are characterized by nanoparticle assembly and optical methods.

On the other hand, some proteins lose their functionality when dried for DPN experiments. One example might be motor proteins such as actomyosin. In this case, the surface is first patterned via other chemical molecules and the assembly of proteins in the protein buffer solution is directed via electrostatic interaction. This method allows one to pattern sensitive biological molecules while maintaining their functionality. Demers and Mirkin demonstrated patterning of DNA molecules via *indirect surface-templated assembly process* [16].

**Figure 16.** Direct patterning of multiple-DNA inks by DPN. Demers et al., *Science* 296, 1836 (2002). © 2002, American Association for the Advancement of Science.

## 2.5. DPN Theory

### 2.5.1. Diffusion Model

Jang et al. presented a theoretical model explaining DPN as a three-step process (Fig. 17) [11]: (1) *constant rate molecular deposition*, (2) *lateral diffusion on a monolayer of molecules*, and (3) *termination of diffusion by chemical binding to a substrate*.

In many previous experimental results, DPN writing demonstrated almost *constant deposition rate* (Fig. 7). It is mainly because the amount of deposited molecules is much smaller than the volume of organic molecules on the AFM tip. On the substrate, molecules can diffuse via random walk until they meet the bare Au surface. Whenever the molecules meet the bare substrate, molecules are irreversibly bound onto the surface.

For a tip fixed in a position, the ink diffusion is isotropic, giving (filled) circles on the surfaces. Assuming cylindrical symmetry of diffusion and treating the position of ink molecules as continuous variable, a simple analytical theory for the growth of circles can be derived based on diffusion equations and boundary conditions

$$\frac{\partial C}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left( rD \frac{\partial C}{\partial r} \right)$$

In this picture, molecules cannot move on the bare surface but can diffuse through the region already covered by other molecules. However, the boundary of a circle with radius  $R(t)$  varying in time has been known as a *moving boundary problem*, specifically, for a given boundary,  $R(t)$ , the diffusion equation for the number density within ( $r < R$ ) and outside the boundary with different diffusion constant  $D$  (finite) and  $D' (- > 0)$ , respectively. At the boundary,  $r = R$ , the number density is taken to be the monolayer density  $\rho$ , and the density flux must be continuous,

$$C(R, t) = C'(R, t) = \rho$$

$$D \frac{\partial C}{\partial r} = D' \frac{\partial C'}{\partial r}$$

where  $C(r, t)$  and  $C'(r, t)$  are the densities within and outside the boundary, respectively.

This kind of boundary growth has been solved for various geometries of boundary including spheres, cylinders, and ellipsoids. The derivation of solution is well described in [79].

Figure 17. DPN process with strong surface binding.

In order for the first boundary condition to be met for all  $t$ ,  $R(t)$  must take the form

$$R(t)^2 = \lambda^2 4Dt$$

The number densities inside and outside the boundary are given by

$$C(r, t) = \rho - \frac{n}{4\pi D} \left[ Ei\left(\frac{-r^2}{4Dt}\right) - Ei(-\lambda^2) \right]$$

$$C'(r, t) = 0$$

where  $\lambda^2$  satisfies the equation

$$e^{-\lambda^2} = \frac{4D}{(n/\pi\rho)} \lambda^2$$

This analytical result assumed *perfectly circular patterns*. This assumption can be tested via *random walk simulation*. In case of random walk simulation, the results do not have perfect cylindrical symmetry assumed in the analytical theory. Thus the boundary of the circular patterns may fluctuate from a perfect circle. This fuzziness of the circle boundary pertains to the quality of circles generated via DPN and thus is of practical importance. The first step quantifying the noncircular deviation is calculating *circularity*. Moreover, for an  $N$ -side polygon whose peripheral points are uniformly distributed, it has been found that

$$N \cong 1.3869(\mu_R/\sigma_R)^{0.4721}$$

where  $\mu$  and  $\sigma$  are the average and standard deviation of the distance of the peripheral points. The random walk simulation shows that the circularity is independent of the deposition rate and increases as the pattern size increases. This implies that even the very large patterns should have a smooth edge, which is also a very good indication for future DPN patterning applications.

### 2.5.2. Deposition

Jang et al. successfully explained the pattern formation on substrate [11]. However, the theory simply assumed a constant deposition rate and does not provide any explanation about the *deposition* step. Several researchers presented different models.

Sheehan and Whitman adapted a different assumption to describe the DPN process based on the diffusion model [80]. Instead of the constant deposition rate, *the density of molecules below the contact point is assumed to be identical to that on the AFM tip and remains constant through the DPN process*. This assumption provides a solution different from that of Jang et al. The analytical approximation is

$$C(r, t) = C_0 \frac{E_i(r^2/4Dt)}{\ln(4Dt/a^2 e^{2\gamma})}$$

where  $E_i$  is the exponential integral and  $\gamma$  is Euler's gamma ( $\cong 0.577$ ). However, this solution provides only a *decreasing* flux (deposition rate), and it cannot explain the DPN writing cases with a *constant* or *slightly increasing* flux. Considering the complicated geometry of the tip/surface junction

and possible water condensation under ambient conditions, the *constant density* assumption might be too much simplification. This contradiction implies that it is necessary to consider more complicated aspects of tip/substrate junction such as water meniscus to provide the proper description of the DPN process.

Weeks et al. showed a model including the water meniscus at the junction between the AFM tip and substrate [81], where the deposition of organic molecules is explained by *dissolution kinetics* of organic molecules in the water meniscus at the tip/substrate junction. In the model, the total number of molecules  $N$  transferred to the substrate will be given by the integral of the transfer rate  $dN/dt$  over the total tip-surface contact time  $\tau$ . Two terms contribute to  $dN/dt$ : First molecules dissolve from the tip through thermally activated detachment at a rate

$$\left(\frac{dN}{dt}\right)_+ = \frac{A}{\pi a^2} \beta_+ = \frac{A}{\pi a^2} \nu e^{-E_D/kT}$$

where  $A$  is the contact area between the tip and the meniscus,  $\pi a^2$  is the average area per thiol ink molecule,  $E_D$  is the activation energy of ink detachment,  $k$  is Boltzmann's constant,  $T$  is the temperature, and  $\nu$  is an attempt frequency.

Second, molecules return to the tip simply due to improvement and attachment at a rate given by

$$\left(\frac{dN}{dt}\right)_- = A\beta_- C_0 \approx A\left(\frac{kT}{2\pi m}\right)^{1/2} \nu e^{-E_D/kT} C_0$$

where  $m$  is the mass of a thiol,  $E$  is the activation energy for attachment, and  $C_0$  is the concentration of thiols in solution adjacent to the tip. The dot radius is related to  $N$  through  $\pi R^2 = N\pi a^2$ .

Combining these relationships gives

$$R^2 = A\left[\beta_+\tau - \pi a^2\beta_- \int_0^r C_0(r) dt\right]$$

The results show transition to the *diffusive regime* with a slow diffusion rate after a long time. In the model, the density of molecules on the substrate below the AFM tip is assumed to depend on the dissolution kinetics of thiol molecules and surface diffusion.

As described in Section 2.5, the DPN process is based on nanoscale molecular diffusion on solid substrates. Since DPN allows one to deposit organic molecules in a nanometer scale resolution and image the result directly without complication, it can be an ideal tool to study the nanoscale surface diffusion process. In addition to practical applications, the development of DPN brought up many scientific questions: What is the phase of diffusion molecules in nanoscale direct deposition processes? What is the effect of environmental conditions? Is there any interaction between diffusing molecules? These are the questions we have to answer in the future.

## 2.6. Variation from Conventional DPN

The conventional DPN process is based on *thermal diffusion* of organic molecules and it usually utilizes self-assembled monolayer molecules which chemically anchor to the substrate. However, one can also apply additional driving forces to provide the better control of the deposition process. Also, it is possible to deposit molecules without covalent bond to the substrate.

### 2.6.1. Electrochemical DPN

Li et al. utilized an electric current to induce electrochemical reactions during the DPN writing process. In the electrochemical DPN, precursor molecules are utilized to create metallic structures on solid surface. For example Li et al. coated the AFM tip surface with  $H_2PtCl_6$  and applied a current inducing chemical reaction [13]

Here, the water meniscus between the AFM tip and surface works as a small reaction vessel. The writing leaves Pt nanostructures on the silicon surface. Li et al. successfully demonstrated the deposition of Au, Ge, Ag, Cu, and Pd via this strategy [13, 82].

These results demonstrate that DPN can be utilized to generate metallic nanostructures on solid surfaces. Metallic nanostructures are of particular interest in the semiconductor industry because they allow one to modify electronic circuits in nanometer scale resolution without any complicated processing steps.

### 2.6.2. Nanodeposition via Electrostatic Interaction

Conducting polymers are of great interest these days due to their possible applications in organic display and flexible electronic circuits. They form well-ordered crystalline structures on insulating surfaces such as on  $SiO_2$ . However, conducting polymers usually do not have strong chemical bindings to the substrate. Since their electronic properties are determined by the crystalline structures, any chemical modification can significantly change their electronic structures. Lim and Mirkin utilized electrostatic interaction between conducting polymers and substrate to create polymer nanostructures on the surface [61].

In the experiment, self-doped sulfonated polyaniline (SPAN) and doped polypyrrole (PPY) conducting polymers dissolved in water are used for writing. SPAN and PPY have negatively or positively charged backbones, respectively. The  $SiO_2$  surface is positively charged by coating the surface with trimethoxysilylpropyldiethylenetriamine (DETA) and negatively by piranha solution. Negatively charged SPAN can be deposited only onto the positively charged DETA coated surface, while positively charged PPY molecules can be assembled onto the piranha solution cleaned surface. This experiment first proves that it is possible to generate stable nanostructures utilizing electrostatic interactions. The *constant deposition rate* is also confirmed in the conducting polymer writing process.

### 2.6.3. Nanografting

In most DPN method, molecules are directly deposited onto bare surface. If molecules are deposited on top of other molecular layers, the *exchange* reaction may occur depending on their binding energies and detailed kinetics. The exchange can be enhanced by a strong contact force during the DPN writing. Xu et al. coated the AFM tip with molecules and wrote patterns on top of other molecular layers [83]. The strong contact force induced the exchange reaction and the molecules from the AFM tip can replace the molecular layer on the surface.

## 3. MICROCONTACT PRINTING

### 3.1. Key Strategy

The microcontact printing method was first developed by Kumar and Whitesides at Harvard University in 1993 [68]. In this method, soft micrometer scale stamps made of poly(dimethylsiloxane) (PDMS) are utilized to deposit organic molecules onto solid substrates via direct contact like macroscale printing techniques (Fig. 18A). Since microcontact stamping is a parallel printing method, it can pattern a large surface area very quickly (Fig. 18B). Stamping methods have demonstrated  $\sim 35$  nm resolution with thiol molecules on a Au surface [69]. However, since the stamps are made of soft polymer materials, the bending of stamps due to swelling of solvent molecules or external pressure is one of the major factors limiting its resolution. In typical applications, the microcontact printing method has been utilized to pattern large surface areas very quickly with a micro- or submicrometer scale resolution.

Dip-pen nanolithography and microcontact printing can be good complimentary methods for general organic materials patterning. Microcontact stamping is a parallel printing

**Figure 18.** (A) Stamping procedure. (B) 1-Octadecanethiol patterns on Au surface generated via microcontact printing.

method which is inherently faster than dip-pen nanolithography utilizing a single pen. However, once stamps are made, it is difficult to modify the design, while DPN allows one to modify and directly print out new patterns from the computer without any intermediate steps. Since the stamping method relies on *direct contact* for molecular deposition, it can be used to deposit quite large molecules or nanostructures such as a few micrometer long carbon nanotubes. The maximum size of molecules that can be deposited via DPN is usually limited by the size of the AFM tips. On the other hand, the DPN process can have additional driving forces for deposition of various materials including metals. By applying electric current at the AFM tip during the DPN process, Li et al. could deposit metallic nanowires onto solid surfaces, while it is extremely difficult, if not impossible, to apply current during the stamping experiment. Overall, microcontact printing is suitable for patterning large surface areas with submicrometer resolution, while DPN is suitable for rapid prototyping of various nanoscale organic structures.

A more comprehensive review about the microcontact printing technique can be found in [4]. Here, we will describe the basic concepts of the microcontact printing method and compare it with the dip-pen nanolithography method.

### 3.2. Procedures to Make Stamp

Figure 19 shows the basic procedure for stamp fabrication. The first step is preparation of a template. The template can be virtually anything with structures. These include TEM grids and photoresist patterns on  $\text{SiO}_2$  surfaces. Then, PDMS elastomer mixed with a curing agent is poured onto the template and is heated up to  $60^\circ\text{C}$  until the PDMS becomes solid. Once the PDMS is cured, it is separated and can be utilized to deposit organic molecules onto substrates.

One key condition to make a good stamp is that the template should not have *undercut* structures. If there are undercut structures as depicted in Figure 19B, it is difficult to separate stamps from the template after the curing process. For example, developed photoresist layer patterns can be a good template because they do not have undercut structures, while etched  $\text{SiO}_2$  substrates are not a good template because wet etching often results in significant undercut structures.

**Figure 19.** Stamp fabrication procedure with (A) a good template and (B) a bad template.

A fabricated stamp surface can be coated with molecules from the solution. For reliable stamping, good adhesion of ink molecules on the surface is very important. In the air, the stamp surface usually remains hydrophobic making it suitable for molecular ink based on nonpolar solvent. Additional treatment is required for stamping of water-based molecular solution. A common method for stamp surface modification is plasma cleaning followed by SAM assembly. Plasma cleaning created hydroxyl ( $-\text{OH}$ ) group on the surface, and desired functionality can be achieved by attaching molecules with silyl chloride group.

Once the good molecular coating is achieved, one can generate submicrometer scale patterns simply by applying the coated stamp to the solid surface (Fig. 18).

### 3.3. Mechanism

The detailed mechanism is well described in [84]. The major deposition mechanism for microcontact printing is direct contact [(a) in Fig. 20]. However, other deposition routes were also observed: (b) diffusion and (c) vaporization.

Direct contact is the major deposition mechanism in the stamping process. The key for successful direct contact is uniform coating of molecules on the stamp surface. In most cases, molecular ink is coated from solution. It is desirable to make the stamp surface favorable to the “solvent.” Another key parameter of stamping is the *fast reaction* of organic molecules with the surface. The reaction speed of self-assembled monolayer varies depending on molecules and environment. For air sensitive molecules, it is required to do the stamping under a controlled environment such as a nitrogen-filled glove box.

Another deposition path is the *diffusion* of molecules on the substrate. Unlike DPN experiments where the diffusion is the major deposition mechanism, the surface diffusion is not a favorable phenomenon in the stamping method because it increases the pattern size and often results in unpredictable pattern shapes. The equation to describe the diffusion results in the stamping method is also quite different from the DPN experiment. For lines with a fixed length  $L$ , the linewidth  $W$  of the stamped patterns is proportional to  $\log t$ , where  $t$  is the contact time. This implies that the deposition rate of molecules in the stamping is proportional to  $1/t$ . In the DPN method, the linewidth is proportional to the total contact time  $t$  since the deposition rate of molecules remains almost constant. This difference comes from different boundary conditions, especially the different shapes of the deposition region in each process. DPN is relying on a *point contact* between the AFM tip and the substrate as a deposition region of molecules. As a result, the amount of deposited molecules is much smaller than the molecules on the AFM tip (ink reservoir) and it does not

**Figure 20.** Deposition routes of stamps: (a) direct contact, (b) diffusion, and (c) vaporization.

affect the deposition rate in time. However, the deposition region of the stamping method is the *long linear edge* of the stamp and the amount of deposited molecules via the diffusion process is comparable to the total amount of ink in the ink reservoir.

Another deposition path is *vapor deposition*. Some volatile molecules can be vaporized and directly deposited onto the substrate. This is another undesirable phenomenon in both stamping and DPN writing. A small amount of vapor deposited molecules usually forms submonolayer films on substrates. To avoid unwanted vapor deposition, molecular ink with low vapor pressure is preferred in both stamping and DPN methods.

### 3.4. Applications

Since the development of microcontact printing [68], the stamping method has been extensively utilized in many applications. There are three major strategies in stamp-based applications. First of all, various materials have been *directly deposited* on the surface in a parallel manner. These include most of the SAM molecules in Table 1, various biomolecules, and very large nanostructures such as nanoparticles or carbon nanotubes.

Second, the molecular patterns can be utilized as an *etching resist* for semiconductor fabrication. Various devices have been demonstrated via the stamping method including silicon transistors and GaAs devices (Fig. 21). Table 3 shows possible etchants for various SAM molecules.

Third, the patterned surface can be utilized for the surface-templated assembly process to capture additional materials. In this process, the substrates are first patterned with a self-assembled monolayer and then the substrate is

**Figure 21.** Micrographs of FETs with various gate lengths  $L$  and gate widths  $Z$  fabricated by soft lithography. (a)  $L = 26 \mu\text{m}$  and  $Z = 16 \mu\text{m}$ ; (b)  $L = 34 \mu\text{m}$  and  $Z = 30 \mu\text{m}$ ; (c)  $L = 44 \mu\text{m}$  and  $Z = 32 \mu\text{m}$ ; (d)  $L = 52 \mu\text{m}$  and  $Z = 47 \mu\text{m}$ . **Figure 22.** Actin proteins assembled onto stamp-generated imidazole SAM patterns.

immersed in the solution which contains desired nanostructures. The desired nanostructures are captured onto the surface via a molecular recognition mechanism. Figure 22 shows actin motor proteins assembled onto stamp-generated imidazole molecular patterns.

#### 4. CONCLUSIONS

DPN and microcontact printing are two complementary methods which allow one to pattern general soft nanostructures on solid substrates. DPN is suitable for nanoscale high resolution patterning with a precision alignment. Since DPN can directly *print out* nanoscale soft material patterns without intermediate processing steps, the time required from pattern design to realization can be extremely short. It is an ideal tool for *rapid prototyping of nanoscale devices*.

On the other hand, the preparation of microcontact stamps takes a long time. However, once stamps are made, they can be utilized to pattern very large surface areas in a parallel fashion quickly. Microcontact printing is an ideal choice to pattern large surface areas with a sub-microscale resolution.

The development of nanodeposition methods can be a historic triggering event that opens up the door to new generation devices. Since one can now combine chemical or biological molecules with conventional solid state devices, it is possible to envision new hybrid devices. These include nanoscale biological sensors which can detect a single biomolecular unit [85–89]. Many researchers are now working on new nanoscale mechanical systems driven by the power of biological motor proteins [90].

As predicted by many pioneering researchers, now is the dawn of the new age when people first begin to understand and manipulate individual molecular functionalities. It is the time when mankind first touches the secret of life at the molecular level. For the next few decades, new functional devices assembled by the newly developed nanodeposition methods could flourish and eventually change the face of everyday human life.

#### GLOSSARY

**Atomic force microscopy (AFM)** One of the most common scanning probe microscopy modes. It operates by measuring attractive or repulsive forces between the tip and the sample and provides information on the topography of the surface. AFM probes the surfaces of the sample with a sharp tip a couple of micrometers long and often less than 100 Å in diameter. Depending on the interaction between the AFM tip and surface, there exist various AFM modes such as contact AFM, noncontact AFM, intermittent contact AFM etc.

**Dip-pen nanolithography (DPN)** A recently developed technique which is very useful in the field of nanofabrication and nanometer sized surface modification. It uses the SPM tip as a pen and the target chemical compound as ink to “write” on the sample surface just like a pen writing on paper. This method can produce nanometer sized patterns, which is critical for the nanofabrication of molecular devices and complicated nanostructures.

**Hybrid nanodevices** A generation of new nanometer sized functional devices that are built by combining soft materials with conventional solid-state devices. These include biological/chemical sensors to detect harmful viruses/environments and protein motor-based nanomechanical systems.

**Microcontact printing** A recently developed high resolution printing method which utilizes micro- or submicrometer scale polymer stamps to “print” general organic molecules onto solid surfaces. It has a principle similar to conventional printing techniques, but unlike conventional printing, it utilizes solid substrates (e.g., gold, silicon, etc.) such as paper and soft materials such as ink. The printed feature size is usually in the micrometer scale, but it can be as small as a few tens of nanometers some considerations.

**Molecular recognition** The ability of molecular components to “recognize” other molecular components based on specific interaction forces (e.g., chemical bond, biomolecular interaction, electrostatic interaction, etc.).

**Nanofabrication** Nanometer-scale precision fabrication technology appeared with the development of nanotechnology. This technique can be used to design and produce nanometer sized devices that have distinct advantages such as ultrasmall size, multifunctionalities, and high sensitivity compared to conventional devices.

**Scanning probe microscopy** A widely used instrument in the field of surface/interface research which can provide atomic scale and real-time/real space topography information of the scanned surface. It works by scanning the nanometer sized tip on the substrate surface (or sample surface scanning under the tip) and measuring various interactions (e.g., attractive or repulsive forces, tunneling current, frictional force, etc.) between the tip and the substrate surface, providing the topographic information of the substrate surface. It includes STM, AFM, magnetic force microscopy, LFM, etc.

**Self-assembled monolayer (SAM)** When certain molecules are in contact with a certain solid surface, the molecules will form a highly packed, naturally uniform monolayer on the solid surface via chemical reactions between the function groups of the molecules and the active atoms of the solid surface. It is now widely used

in the field of corrosion inhibition, surface modification, nanofabrication, etc.

**Soft materials** Materials like classical fluids, liquid crystals, polymers, colloids, and emulsions are representative of what are now identified as “soft” as opposed to “hard” materials. They are materials that flow or distort easily in response to shear and other external forces. When deposited or put on the solid surface, some soft materials can form a chemically stable and highly oriented thin film or even monolayers, which can be used in the fields of nanofabrication and surface modification.

**Surface-templated assembly** A new assembly method based on the interaction force existing between the molecules on the solid surface and the target molecules. In this method, the desired region on the solid substrate is first coated with organic molecules with specific chemical functional groups, and then the substrate is placed in the solution of target molecules (or nanostructures). Due to the specific attractive force between the chemical functional groups on the surface and molecules in the solution, the assembly of molecules (or nanostructures) from the solution is directed only onto the functionalized region of the surface. Especially useful in mass production of some nanometer sized devices.

## ACKNOWLEDGMENTS

We acknowledge the AFOSR for support of our DPN works and the DARPA for supporting our protein motor research. We also thank P. Bryant Chase at Florida State University for supplying protein motors. Pradeep Manandhar is acknowledged for his help in preparing some figures.

## 1. INTRODUCTION

At neutral pH, DNA is a charged molecule. As such, it responds directly to an electric field, the phenomenon of *electrophoresis*. In contrast, the phenomenon of *dielectrophoresis* occurs when there is a dc or an ac electric field *gradient*. In that case, the development of nonuniform electric fields causes a force on any polarizable object, charged or neutral. The term dielectrophoresis was coined by Pohl in 1951 [1], and the general principles are outlined in his 1978 book of the same title [2]. Since then, the use of microfabricated electrodes has been employed for separating micron-sized objects such as cells, and this technology is currently being integrated with lab-on-a-chip systems. This review article discusses recent progress at extending the practice of dielectrophoresis to the nanoscale, for applications in nanomanufacturing, nanobiotechnology, and molecular electronics. Compared to the use of dielectrophoresis for the manipulation of cells, the use of electric fields at the nanoscale to assemble nanocircuits is still in its infancy.

## 1.1. Other Reviews

The main reference for the fundamentals of dielectrophoresis is Pohl's 1978 book [2]. The physics of the dielectric properties of biological molecules in solution are covered in a 1979 book by Pethig [3] and a 1978 book by Grant et al. [4]. Pethig [5, 6] has a good review of applications of dielectrophoresis in biotechnology. Another review article covering the manipulation of cells with electric fields is in Führ's 1996 book chapter [7, 8]. The topic of dielectrophoresis is covered in Madou's textbook on microfabrication [9]. A review by Hughes [10] discusses some applications of dielectrophoresis in nanotechnology. This review will also be concerned primarily with the applications of dielectrophoresis in nanotechnology: "nanodielectrophoresis."

## 2. OVERVIEW OF DIELECTROPHORESIS

The discovery of dielectrophoresis (DEP) goes all the way back to at least 600 B.C., when Thales of Miletus in Turkey observed that rubbed amber attracted small particles of fluff [2]. In retrospect the amber, being charged up from the rubbing, generated an electric field which polarized the fluff particles. The induced dipole in the fluff particles was acted on by the (nonuniform) electric fields, attracting it to the charged amber. Today we would call this effect (dc) positive dielectrophoresis.

In Figure 1, the principle is illustrated schematically. If a polarizable object is placed in an electric field, there will be an induced positive charge on one side of the object and an induced negative charge (of the same magnitude as the induced positive charge) on the other side of the object. The positive charge will experience a pulling force; the negative charge will experience a pushing force. In a uniform field, as depicted in Figure 1A, the pulling force will cancel the pushing force, and the net force will be zero. However, in a nonuniform field, as depicted in Figure 1B, the electric field will be stronger on one side of the object and weaker on the other side of the object. Hence, the pulling and pushing

**Figure 1.** Schematic depiction of dielectrophoresis. The direction of the arrows represents the direction of the electric field; the length of the arrows represents the magnitude of the electric field.

forces will not cancel, and there will be a net force on the object.

In this simple overview we have neglected the polarizability of the surrounding medium. If both the medium and the polarizable particle are considered, then one comes to the conclusion that there are two classes of DEP: positive and negative. If the suspended particle has a polarizability higher than that of the surrounding medium, then the DEP force pushes the particle toward the higher electric field region. This is called *positive dielectrophoresis*. If the suspended particle has a polarizability less than the surrounding medium, the particle is pushed toward the region of weaker electric field, and this is called *negative dielectrophoresis*.

## 2.1. Quantitative Force Predictions

In an electric field  $\vec{E}$ , a dielectric particle behaves as an effective dipole with (induced) dipole moment  $\vec{p}$  proportional to the electric field, that is,

$$\vec{p} \propto \vec{E} \quad (1)$$

The constant of proportionality depends in general on the geometry of the dielectric particle. In the presence of an electric field gradient, the force on a dipole is given by

$$\vec{F} = (\vec{p} \cdot \nabla) \vec{E} \quad (2)$$

Combining the two equations, and using known results for the relationship between  $\vec{p}$  and  $\vec{E}$  for a *spherical* particle of radius  $r$  and dielectric constant  $\epsilon_p$ , and taking into account the medium dielectric constant  $\epsilon_m$ , it can be shown that the force acting on a spherical particle (the *dielectrophoresis* force) is given by [2, 11]

$$\vec{F}_{DEP} = 2\pi v \epsilon_m \alpha_r \nabla (\vec{E}_{RMS}^2) \quad (3)$$

where  $v$  is the volume of the particle,  $\vec{E}_{RMS}$  is the RMS value of the electric field (assuming a sinusoidal time dependence), and  $\alpha_r$  is the real part of what is called the *Clausius–Mosotti* factor, which is related to the particle dielectric constant  $\epsilon_p$  and medium dielectric constant  $\epsilon_m$  by

$$\alpha_r \equiv \text{Re} \left( \frac{\epsilon_p^* - \epsilon_m^*}{\epsilon_p^* + 2\epsilon_m^*} \right) \quad (4)$$

Here the star (\*) denotes that the dielectric constant is a complex quantity, and it can be related to the conductivity  $\sigma$  and the angular frequency  $\omega$  through the standard formula

$$\epsilon^* = \epsilon - i \frac{\sigma}{\omega} \quad (5)$$

Equation (5) also takes into account surface conductances [12–14] of the particles.

We must make several comments now about Eq. (3). First of all, the Clausius–Mosotti factor can vary between  $-0.5$  and  $+1.0$ . When it is positive, particles move toward higher electric field regions, and this is termed *positive dielectrophoresis*. When it is negative, the particles move toward smaller electric field regions, and this is termed *negative dielectrophoresis*.

Second, the force grows smaller as the particle volume. This has important implications for the manipulation of nano-sized particles, as we will discuss below. Of course this is a bulk, classical calculation. Surface charges and quantum effects will no doubt be important at the molecular level, and these need to be dealt with. Therefore, the application of Eq. (3) to single molecules may not be quantitatively valid.

Third, the dielectric constants of the medium and particle can be highly frequency dependent. This gives rise to a force that can be different at different frequencies, and this fact can be exploited for practical micro- and nanomanipulations based on dielectrophoresis. For example, at one frequency positive dielectrophoresis may prevail, while at another frequency negative dielectrophoresis may prevail. These effects are all buried in the physics of the dielectric response function  $\epsilon$ .

Fourth, the derivation of Eq. (3) assumes that the electric field does not vary too strongly; this will have implications when we compare to optical tweezers below.

Finally, Eq. (3) is true for both dc *and* ac electric fields. While there are practical advantages to using ac electric fields to be discussed below, the mathematics of the dielectrophoresis force does not differentiate between dc and ac. Furthermore, it should be noted that the *direction* of the electric field does not matter. That is to say, in the dc case, for (e.g.) positive dielectrophoresis, the particle moves from the region of weaker field to the region of stronger field *magnitude*, regardless of the *direction* in which the field is pointing. For an ac field, the particle experiences a time-varying force, but the time-averaged direction of that time-varying force is always the same, even though the direction of the electric field vector is changing in time. In most cases, the ac component of the dielectrophoretic force can be neglected and we need only concern ourselves with the dc (i.e., time-averaged) component, which is the one given by Eq. (3).

## 2.2. Generation of Electric Field Gradients

Historically [2], the use and study of dielectrophoresis was between a sharp pin and a flat surface, because that is the easiest geometry in which one can create a strong field gradient, hence a strong dielectrophoretic force. This has been used to manipulate cells in solution [5, 6], since a cell is polarizable. It has also been used to deflect individual molecules in molecular beams [15]. This application can be considered the first application of nanodielectrophoresis, although the molecular beams were in a high-vacuum system.

Since the advent of optical and then electron-beam lithography, the use of micro- and nanofabricated planar metal electrodes on insulating substrates has achieved much more attention, since it allows many different flexible geometries to be designed, tested, and used. Moreover, by using small gaps between electrodes, large electric field strengths can be achieved, thus further increasing (in general) the achievable dielectrophoretic force.

Although any arbitrary geometry for planar electrodes can be easily designed and fabricated with modern lithography, the three most commonly used geometries are shown in Figure 2. (The DEP force from these and other geometries can be calculated numerically [16, 17].) Part A shows the simplest geometry, a gap between two electrodes. Because the electrodes are planar, there will be fringing fields out of the plane which are very nonuniform. This design is useful for positive dielectrophoresis, in which case particles are attracted to the edges of the electrodes, or negative dielectrophoresis, in which case particles are pushed away from the plane of the electrodes. In order to achieve a higher electric field gradient, geometry B is sometimes used. The castellations can be square (as shown), triangular, or circular. For both geometries A and B, interdigitated fingers are often used. Geometry C is used normally for negative dielectrophoresis. Huang and Pethig showed that particles experiencing negative dielectrophoresis that are in the plane of the electrodes will get trapped in the center of the

**Figure 2.** The most commonly used geometries for the study of dielectrophoresis. The electrodes are usually thin metal films (1–100 nm) fabricated lithographically on an insulating substrate.

electrode geometry [18]. Another design which has received some attention is a spiral electrode design [19].

Modern interest in nanodielectrophoresis, in contrast to that applied to molecular beams in high-vacuum environments, is concerned with the manipulation of molecules in solution, especially for applications in nanobiotechnology, where wet environments are necessary for life itself, but also as methods of nanomanufacturing molecular electronic circuits, integrated with micro- and nanofabricated electrodes. After the dielectrophoresis-assisted nanofabrication occurs, the sample can be dried and the remaining molecules that were placed in position while dissolved now can form the basis of some tailor-designed circuit which in principle was fabricated one molecule at a time. This vision is currently under development but in principle there is no reason it cannot be achieved, as we discuss in the remainder of this article.

## 2.3. Traps for Negative Dielectrophoresis

For negative dielectrophoresis, the polarizable objects feel a force pushing them *away* from the high field region. Therefore, for most planar geometries, the particles are pushed away from the substrate where the electrodes reside. In 1991, Huang and Pethig calculated [18] the necessary geometry that electrodes need to have in order to *trap* particles using negative dielectrophoresis at specific locations on the plane of the substrate. The geometry they found which traps a particle at a specific point in the plane of the electrodes is a quadrupole-like geometry. This trap is only in two dimensions, and in the third dimension (perpendicular to the plane of the electrodes), the particle is still not trapped. Gravity or some other force must be exerted to bring the particle close enough to the plane of the electrodes to feel the dielectrophoretic force of the electrodes.

Later, work of Schnelle and co-workers [20] and Fuhr and co-workers [21] considered geometries necessary for trapping of particles in all three dimensions. They name these traps “cages.” The most straightforward geometry realized and tested consisted of two quadrupole traps fabricated on two microscope slides which were mounted facing each other with a small gap (of about 0.1 mm). In that work, they trapped 10- $\mu\text{m}$  latex particles and cells in three dimensions, with applied ac voltages up to 1 GHz in frequency.

We show in Figure 3 an example realization of a quadrupole trap: four gold electrodes surrounding a central

500 nm beads.  $V = 8$  Volts.

**Figure 3.** Electrodes to trap small particles. Three 500-nm beads can be seen fluorescing but not resolved. We have also been able to trap a single 500-nm bead (not shown).

region with 10- $\mu\text{m}$  gaps are used to trap a 500-nm latex bead [22]. The frequency used for these studies was 1 MHz, with a voltage of 8 V. With smaller gaps it should be possible to trap much smaller particles, as we discuss below.

## 2.4. Scaling with Particle and Electrode Size

In order to calculate the force acting on any given polarizable particle, one can use Eq. (3) as long as the electric field intensity and (more importantly) its spatial gradient are known. For arbitrary electrode geometries it is possible to numerically calculate this force. However, some simple electrode geometries can be calculated analytically in order to give some general insight into what can be expected for a more complicated geometry. The case of two concentric spheres in this regard can be very enlightening, as the radius of curvature can be used as a rough estimate for the smallest feature size of a given electrode.

The electric field between two concentric spheres is straightforward to calculate, and based on this one can calculate the gradient of the electric field intensity. One finds [2]

$$\vec{\nabla}(\vec{E}_{RMS}^2) = -\frac{2r_1^2 r_2^2 V^2}{r^5 (r_2 - r_1)^2} \hat{r} \quad (6)$$

where  $\hat{r}$  is a unit vector in the radial direction,  $r_1$  is the radius of the inner electrode,  $r_2$  is the radius of the outer electrode,  $r$  is the distance from the origin, and  $V$  is the applied voltage, as shown in Figure 4. In the case where the inner electrode is very sharp compared to the distance to the outer electrode (i.e.,  $r_1/r_2 \ll 1$ ), this becomes

$$\vec{\nabla}(\vec{E}_{RMS}^2) \approx -\frac{2r_1^2 V^2}{r^5} \hat{r} \quad (7)$$

In this case the force exerted on a particle is given by

$$\vec{F}_{DEP} = -4\pi v \epsilon_m \alpha_r \frac{r_1^2 V^2}{r^5} \hat{r} \quad (8)$$

Now, if the particle were in a vacuum with no other forces acting upon it, then it would respond only to the DEP force. However, in solution, the particle is undergoing Brownian motion, and is continually being bombarded with other molecules of the solution. This thermal motion exerts

**Figure 4.** Spherical geometry electrodes for analytical calculation of dielectrophoretic force in the text.

an effective random force on the particle, whose maximum value is given roughly by [2]

$$F_{thermal} \approx k_B T / 2r_{particle} \quad (9)$$

where  $k_B$  is the Boltzmann constant,  $T$  is the temperature, and  $r_{particle}$  is the particle radius.

For DEP to be of use, the DEP force must overcome the randomizing thermal motion acting on the particle. In 1978, Pohl used 500  $\mu\text{m}$  for the radius of the inner electrode, 5000 V for the applied voltage, and 1 mm for the particle distance from the electrode, and concluded that particles smaller than 500 nm would not respond very well to the DEP force [2]. These numbers were pessimistic, and it should be possible to trap 1-nm and smaller particles, as we now show.

First, as our experiments [22], as well as other experiments [23–31] show, it is possible to use optical or electron-beam lithography to fabricate electrodes with much smaller radius of curvature than 500  $\mu\text{m}$  (as Pohl originally assumed), and hence to trap submicron particles (see Fig. 3). For example, in our experiments, we trapped 500-nm beads with less than 10 V applied to the electrodes.

Second, it is possible in principle to use carbon nanotubes or other nanowires as the electrodes themselves [22], which would have radius of curvatures of less than 1 nm. In this case, for a 1-nm particle that was a distance 100 nm away from the nanotube electrode, our calculations [32] indicate that the DEP force would exceed the thermal force at an applied voltage of only 50 mV. Experiments to test this scaling prediction with carbon nanotube electrodes are currently underway in the author's lab [22].

## 2.5. Electrorotation

Another effect of an ac electric field on a polarizable object is to *orient* that object with respect to an electric field. Specifically, the induced dipole moment of an object interacts with the electric field to produce a torque given by

$$\vec{T} = \vec{p} \times \vec{E} \quad (10)$$

where  $\vec{p}$  is the induced dipole. This effect can be used to orient DNA and nanotubes in solution, and also nanotubes during growth in gas or vacuum, as we will discuss below. It also can be used to orient cells and other micron-sized objects. The term *electrorotation* is usually applied to a situation where the direction of the electric field is rotating as a function of time. This can be achieved by using four electrodes surrounding a central region, where the ac voltage on each electrode is properly phased. Under the rotating electric field direction, the torque also rotates, and hence the particle rotates. This effect is reviewed in [8, 33].

## 2.6. Traveling Wave Dielectrophoresis

The electrode geometries shown in Figure 2 are useful for trapping particles with either positive or negative dielectrophoresis. However, more sophisticated geometries are possible that allow a particle to be moved. Figure 5 shows schematically a set of electrodes with ac voltages adjusted in such a way as to generate a traveling wave electric field. This traveling wave can act on a polarizable particle and cause

**Figure 5.** Schematic electrode geometry for traveling wave dielectrophoresis.

a net force in the direction of the traveling wave. In [34], Hagedorn et al. analyze geometries optimum for traveling wave dielectrophoresis. Fuhr in 1994 was able to design and demonstrate a particle manipulator that could apply force in two orthogonal directions [35].

## 2.7. Summary

The combined effects of dielectrophoresis, electrorotation, and traveling wave dielectrophoresis (TWD) have all gone under the same name: “pondermotive force,” as they have the same underlying physical origin. The relationship among these effects is explored in more detail in [8, 36–40]. With the combined use of dielectrophoretic traps, traveling wave dielectrophoresis, and electrorotation, it is possible to electronically control (via microfabricated electrodes) the three-dimensional position and orientation of a small micro- or nanoparticle that is suspended in liquid.

## 3. ELECTRONIC VERSUS OPTICAL TWEEZERS

From Eq. (3), we calculate that a typical dielectrophoretic force for a particle of size 100 nm will be roughly 1 fN; the force on a 1- $\mu\text{m}$  particle would be roughly 1 pN. In comparison, the force exerted by optical tweezers [41–46] is also the same order of magnitude. In fact both optical tweezers and dielectrophoresis are the same physical phenomena, only different frequencies. For example, our Eq. (3) is equivalent to Eq. (2) in [44]. (There is a factor of  $4\pi\epsilon_m$  difference due to the units, and an incorrect sign in the denominator of [44].) The equations look a little bit different, because optical engineers like to use the index of refraction, and electrical engineers like to use the dielectric constant; they are of course related through  $n = \sqrt{\epsilon}$ .

A difference between optical tweezers and electronic tweezers is that optical tweezers also affect particles whose size is comparable to the (optical) wavelength, of order  $\mu\text{m}$ , the so-called Mie limit. The analogy with electronic tweezers is more appropriate in the limit where the particle size is

smaller than the optical wavelength  $\lambda$ , the so-called Rayleigh limit. For optical tweezers in the Rayleigh limit (particle size  $\ll \lambda$ ), the force is proportional to the volume of the particle, as in DEP Eq. (3). For optical tweezers in the Mie limit (particle size  $\gg \lambda$ ), the force is independent of the particle size. Furthermore, optical scattering of light in optical tweezers is an important force, whose analog in electronic tweezers is not clear-cut.

One main similarity between optical and electronic tweezers is that, when applied to particles in solution, both must strive to overcome the random forces due to Brownian motion. Hence, it makes sense that the induced forces for both optical and electronic tweezers exert comparable forces. To date, both electronic and optical tweezers have not trapped particles with size below 10 nm. However, with nanowire or nanotube electrodes we predict that electronic tweezers can trap particles down to 1 nm in size, which may be useful for nanoassembly.

An advantage that electronic tweezers have over optical tweezers is *scalability*: millions or even billions of electronic tweezers could be easily, economically integrated onto a silicon chip for low-cost “lab-on-a-chip” systems. Additionally, the electronic trap can in principle hold a particle indefinitely, while the optical tweezers in some cases only last for a few seconds due to laser-induced damage. Third, the use of optical tweezers is not possible in optically opaque systems; in contrast, the use of electronic tweezers is difficult in conducting solutions [47], a severe restriction for *in vivo* operation.

Thus, as with everything, both types of tweezers have their own advantages and disadvantages; the choice of which to use will depend upon the application. In fact, in some applications, both types of tweezers have been used in the same experiment [48].

## 4. TRAPPING AND MANIPULATION OF MICRON-SIZED OBJECTS

### 4.1. Steel Balls

In a pioneering patent [49] granted in 1983, Batchelder proposed the use of lithographically patterned microelectrodes to manipulate and position chemical species, potentially with the ability to manipulate a single molecule, for electronic control of manufacturing. As such, this patent covers the lab-on-a-chip concepts as well as single molecule dielectrophoresis very well, much ahead of its time. Batchelder further described his techniques in a 1983 article [50], where he described one of the first instances of “traveling wave dielectrophoresis.” That was also one of the first instances of photolithographically patterned electrodes for applications in dielectrophoresis. Batchelder’s realization experimental apparatus was capable of manipulating 600- $\mu\text{m}$  steel balls and 1-mm water droplets in heptane.

In 1987, Washizu and co-workers used this effect to manipulate 15- $\mu\text{m}$  solid particles in solution, and also proposed to use it for moving cells [51]. A year later they reported moving blood cells (sheep erythrocytes) using this effect [52]. Those initial experiments were on traditionally machined electrodes.

## 4.2. Cells

Interestingly, in two papers appearing in 1989 and 1990 [53, 54], Masuda and co-workers used photolithography for fabricating microelectrodes in order to use DEP to control the position of living cells. They also developed what they coined “fluidic integrated circuit,” which currently would go by the term “lab-on-a-chip.” They used photolithography and a molding process with silicone to make microfluidic channels capable of handling individual cells, and they made a cell-sorter based on dielectrophoresis: cells entering through one microfabricated inlet could be deflected electronically into one of two microfabricated outlets. We show in Figure 6 an example of using negative dielectrophoresis to trap human breast cancer cells in a planar quadrupole trap [55].

As this review is meant to cover mainly nanodielectrophoresis, we will only briefly highlight some of the applications of dielectrophoresis in cell manipulation. The polarizability of a cell is a complicated function of its membranes and inner workings generally, and generally depends on frequency. By exploiting the difference in the frequency-dependent dielectric properties of different cells, it is possible to separate out many different kinds of cells from one another and from other microorganisms in solution.

The first separation of viable and nonviable (yeast) cells by dielectrophoresis was in 1966 [56]. Chloroplasts were manipulated in 1971 [57]. Cells can undergo both positive and negative dielectrophoresis as was shown in [58, 59]. The separation of viable versus nonviable yeast cells was studied carefully with microfabricated electrodes in [60–62]. Different species of bacteria were separated in [63, 64]. Electrorotation was used to separate leukemia cells from blood in [65]. Electrorotation was used to separate human breast cancer cells from blood in [66]. Concentration of CD34+ from peripheral-stem-cell harvests was achieved in [67].

TWD linear motion of cells was shown in [34, 68]. Viable and nonviable yeast cells were separated with TWD in [69]. TWD was used to separate white blood cells from erythrocytes in [70]. Continuous separation is also possible (viable vs. nonviable yeast cells) [71]. Separation of trophoblast cells from peripheral blood mononuclear cells was achieved in [72]. Separation of breast cancer cells from normal T-lymphocytes (among other things) was achieved using DEP FFF (see next section) in [73]. The manipulation of *E. coli* and other bacteria with photolithography-fabricated electrodes was reported in 1988 in [74]. The *E. coli*

were attracted to the high fringing field regions of interdigitated castellated electrodes. Cervical carcinoma cells were separated from peripheral blood cells in [75]. Living (*Eremosphaera Viridis*) cells were trapped in quadrupole and octopole traps in [20]. An extruded-quadrupole geometry (where the electrodes are metallic posts) was used for cell manipulation in [76]. The effect on cells of the large electric field strengths necessary for DEP (typically  $10^6$  V/m) was investigated by Archer et al. [77], who found a 20–30% increase in the expression of fos protein, as well as up-regulation of unidentified genes. While the large electric fields are not fatal to cells studied, and their long-term effect on cells manipulated with DEP seems to be minimal, at this stage there is insufficient evidence to draw more quantitative conclusions about the effects of exposure to high electric fields.

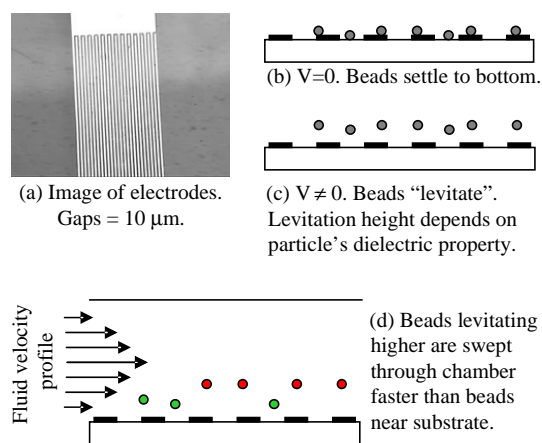

We note that, once the electrodes are in place for the dielectrophoretic manipulation of cells, it is straightforward and economical to integrate further optical and electronic measurements that are complementary to DEP techniques into the same measurement platform. These can include optical and electronic methods of genetic expression profiling using microarrays, with applications in point-of-care clinical diagnostics, biological warfare detection, and many other applications. For example, Cheng and co-workers separated *E. coli* bacteria from a mixture containing human blood cells and integrated this with cell lysing and DNA hybridization analysis on a single chip [78]. The integration of electrophoresis and dielectrophoresis using the same electrodes for manipulating *E. coli* cells with DEP and antibodies with electrophoresis was developed in [79]. DEP was used to separate certain cell types from complex cell populations, which significantly improved the accuracy of gene expression profiling in [80]. In the spirit of integration mentioned above, an integrated system using DEP, DNA amplification, and electronic DNA hybridization for the detection of *E. coli* and other biological agents was recently developed [81].

## 4.3. Field Flow Fractionation (FFF)

Field flow fractionation (FFF) is a very general chromatographic separation technique in chemistry and biology [82]. The use of dielectrophoresis as the force in field flow fractionation was proposed and analyzed by Davis and Giddings in 1986 [83]. The principle of dielectrophoretic field flow fractionation (DEP FFF) is shown schematically in Figure 7. Part A shows interdigitated finger electrodes, and parts B and C depict the levitation of latex beads when an ac voltage is applied to the electrodes. The levitation height is a function of the dielectric properties of the particle being levitated. If these electrodes are introduced into a laminar flow chamber (typically  $100\ \mu\text{m}$  thick), the flow velocity parallel to the chamber walls is also a function of height, as indicated schematically in part D. Thus, the speed at which a particle is swept through the chamber depends on the height at which it is levitated, which in turn is a function of its dielectric properties. Since different types of particles (or cells) generally have different dielectric properties, each takes a different time to traverse the chamber. This dependence can be used to separate different particles or cells, and is termed dielectrophoretic field flow fractionation (DEP FFF).

**Figure 6.** Dielectrophoretic trapping of human breast cancer cells (cell line HCC1806 from ATCC).

**Figure 7.** Schematic depiction of dielectrophoretic field flow fractionation (DEP FFF).

In 1994, Washizu and co-workers constructed a DEP FFF apparatus and used it to trap DNA of various sizes (9–48 kbp) and the protein avidin [84]. They were able to trap each macromolecule with some efficiency, but separation experiments were not reported. Initial experimental demonstration of DEP FFF separation was reported in 1997, where viable and nonviable yeast cells were separated [85], and human leukemia cells were separated from peripheral blood mononuclear cells [86]. In the same year, demonstration experiments on latex beads were performed [87]. Later experiments have demonstrated the separation of erythrocytes from latex beads [88], separation of mixtures of polystyrene beads [89], and the separation of human breast cancer cells from CD34+ stem cells [73, 90].

Thus, DEP FFF has been successfully demonstrated as a viable technique to separate many micron-sized objects such as cells and latex beads. However, the principles should also be applicable at the nanoscale, and it should in principle be possible to separate objects such as DNA, proteins, viruses, nanoparticles, nanowires, nanotubes, quantum dots, and possibly even small molecules.

## 5. TRAPPING AND MANIPULATION OF NANO-SIZED OBJECTS

In principle, all of the above techniques that have so far proved useful for micron-sized objects such as cells could be useful for nano-sized objects, especially if the nanowires or nanotubes could be used as the electrodes themselves.

### 5.1. Latex Beads

Latex beads have been used extensively in order to test various aspects of dielectrophoresis because they are robust and can be fluorescently labeled, and hence imaged. Furthermore, they are readily available in a variety of sizes from 10  $\mu\text{m}$  to 10 nm.

The Fuhr group in Germany has been able to trap aggregates of 14-nm latex beads, aggregates of viruses of diameter around 100 nm, as well as single latex beads down to 650 nm in size [23, 24]. Subsequently the Morgan group in

England achieved trapping of single 93-nm latex beads in 1998 [25, 26]. Green and Morgan used planar microelectrode arrays to separate a mixture of 93-nm and 216-nm latex beads into their constituent components [27].

In 1999, Hughes and Morgan separated unlabeled and protein-labeled 216-nm latex beads [28]. The dielectrophoretic properties of these beads were carefully modeled in [29, 30]. A detailed study of the DEP response of latex beads as a function of electrolyte composition and conductivity, electric field frequency, and particle size for 93-, 216-, and 282-nm latex beads was presented in [31]. The use of latex beads has been and continues to be a good testbed for the use of DEP in manipulating micro- and nanoparticles.

### 5.2. Molecular Dielectrophoresis

One of the most promising applications of dielectrophoresis in nanotechnology is the possible electronic manipulation of individual molecules. Later in this chapter we discuss the applications such an achievement would enable, such as massively parallel nanomanufacturing of new materials, one molecule at a time, with tailor-designed electronic, optical, magnetic, and mechanical properties. However, to date the clear demonstration of the manipulation by dielectrophoresis of a single molecule has not been achieved for any molecule less than 100 nm in size. A large reason, as discussed in Section 2.4, is that (to date) the thermal Brownian force dominates the dielectrophoretic force for such small objects.

While such an achievement may be possible in the future, it is still true that the nonuniform ac and dc electric fields establish *some* force, which, even though less than the thermal Brownian motion, will still cause a tendency for molecules to move in a certain direction, depending on the geometry of the electrodes. The quantitative study of these effects has been termed “molecular dielectrophoresis” [2].

To date all studies of molecular dielectrophoresis have used positive dielectrophoresis: the DEP force tends to push the molecules toward regions of higher electric fields. The geometry which has been studied almost exclusively is that of two concentric cylinders with the molecules dissolved in a solution in between the cylinders. If the density of the molecules as a function of the radial distance changes, this changes the dielectric constant as a function of the radius, and hence the capacitance from the inner to the outer cylindrical electrode.

In 1954, Debye and co-workers used dc dielectrophoresis of polystyrene (molecular weight 600,000) in cyclohexane [91, 92]. They used a dc non uniform electric field in a cylindrical geometry and monitored the capacitance change by measuring the shift in the resonant frequency of an LC circuit; similar studies were carried out by Prock and McConkey in 1960 [93].

In 1955, Lösche and Hultschig [94] used ac dielectrophoresis to study nitrobenzene in carbon tetrachloride, and poly(vinyl acetate) in nitrobenzene; however, both have permanent (instead of induced) dipoles. In 1973 Eisenstadt and Scheinberg [95, 96] studied dielectrophoresis and measured the diffusion constant of the biopolymers poly- $\gamma$ -benzyl-L-glutamate (PBLG, M.W.  $\approx$  120,000) and poly-n-butyl isocyanate dissolved in ethylene dichloride (EDC);

both have permanent dipoles. By measuring the time dependence of the concentration change of the PBLG concentration due to the dielectrophoretic force, Eisenstadt and Scheinberg were able to determine its diffusion constant.

Thus, while the manipulation of a single nanomolecule is still not yet achieved, the ability to affect the concentration of large numbers of nanoscale molecules in solution with dielectrophoresis has been demonstrated over 30 years ago, giving hope to the use of nanodielectrophoresis at the single molecule level.

### 5.3. Conducting Nanoparticles

#### 5.3.1. DC Dielectrophoretic Trapping

The basic principle of dielectrophoresis applies regardless of whether the field is dc or ac. (For example, the first recorded instance of dielectrophoresis was dc dielectrophoresis in 600 B.C., as discussed in Section 2.) Furthermore, Pohl calculated that metal balls in water would have the largest dielectrophoretic force of many different possible particle/solvent combinations [2]. In 1997, Bezryadin and Dekker combined these two ideas and used (positive) *dc dielectrophoresis* to trap 20-nm Pd nanoparticles between lithographically fabricated electrode gaps of about the same distance, that is, 20 nm [97, 98]. The Pd nanoparticles were dissolved in water. Bezryadin applied 4.5 V dc between the gaps, and then investigated the samples with a scanning electron microscope (SEM) after drying. The SEM images showed clearly the presence of one or a few nanoparticles bridging the gap between the electrodes, and this was confirmed by measuring the electrical resistance between the electrodes.

#### 5.3.2. Pearl Chains

Particles undergoing dielectrophoresis often exhibit mutual attraction. This is due to the fact that dielectrophoresis involves an induced dipole moment in each particle, and dipoles interact and form what are called “pearl chains.” The tendency of a group of particles in a field to form lines has been known for over two hundred years [2, 99]. This is, for example, responsible for the behavior of electrorheological fluids [100]. Pohl also studied this effect extensively in his experiments in cells [2]. In 1999, Bezryadin et al. observed this pearl-chaining phenomenon in conducting graphite nanoparticles ( $d = 30$  nm), and named it self-assembled chains [101]. They used dc dielectrophoresis with the nanoparticles dissolved in toluene, and applied 40 V across a gap of 1  $\mu\text{m}$  between Cr and Pt electrodes. They were able to pass current through this pearl chain of nanoparticles, and furthermore observed Coulomb gap (single electron transistor) behavior at temperatures all the way up to 77 K, because the capacitive charging energy of the nanoparticles was still comparable to the physical temperature even at 77 K.

#### 5.3.3. AC Dielectrophoresis

In 2002, Amlani and co-workers used positive *ac dielectrophoresis* to trap 40- to 100-nm gold nanoparticles between a lithographically fabricated 60-nm gap between two gold electrodes [102]. The gold nanoparticles were dissolved in

water, and a 2.5-V p-p ac voltage between 1 and 10 MHz is found to provide a yield of 100%, much higher than the yield if a dc dielectrophoresis is used. These structures were found to conduct electrically when a single gold nanoparticle was trapped, with a resistance of 3 k $\Omega$ . In a second experiment, prior to the dielectrophoretic trapping, the gold electrodes were coated with a self-assembled monolayer of 1-nitro-2,5-di(phenylethynyl-4\*-thioacetyl)benzene, a compound similar to one previously studied using a nanopore configuration and found to exhibit negative differential resistance [103]. In the dielectrophoresis experiment of Amlani, the current flow was presumably electrode-molecule-nanoparticle-molecule-electrode. Amlani and co-workers also observed negative differential resistance at room temperature, presumably due to the intrinsic electronic properties of the molecules in the self-assembled monolayer.

#### 5.3.4. From Nanoparticles to Nanowires

In 1999, Velev and co-workers developed a biosensor which is chemically selective based on gold nanoparticles and latex micron-sized beads. The latex beads (suitably chemically functionalized) were assembled into a “pearl chain” wire between two electrodes with positive dielectrophoresis. The target molecules would then bind with immunoactive sites on the latex particles, and then a further set of chemically functionalized gold nanoparticles would bind to the target molecules. Then a silver enhancer is introduced to complete the circuit. The net result is a large change in conductance if and only if the target molecule is present above some minimum threshold in the test solution.

Later work by the same group used dielectrophoresis to directly assemble microwires from gold nanoparticles [104]. They found that 10- to 15-nm gold nanoparticles in solution, when subjected to 50- to 200-Hz electric fields by electrodes spaced apart by a few millimeters, grew wires of micron size and conducted electricity. This is analogous to the pearl-chain formation discussed earlier.

### 5.4. DNA

#### 5.4.1. Washizu and Co-Workers

Starting in 1990, Washizu and Kurosawa began studies on DNA which showed that it is indeed possible to use dielectrophoresis to manipulate DNA [105]. They used the electric field produced between two parallel, thin-film aluminum electrodes (thickness 1  $\mu\text{m}$ , spacing 60  $\mu\text{m}$ ) to “stretch” DNA molecules. When large concentrations of DNA molecules are used, they form bands due to the complicated and poorly understood DNA–DNA interactions. When low concentrations of DNA are used, one can see individual DNA molecules through fluorescence, and it is clear that the electric fields “stretch” each individual molecule out. The field strength used is approximately 10<sup>6</sup> V/m, and the frequency is varied from 40 kHz to 2 MHz, with only slight frequency dependence of the effect. Washizu and co-workers studied  $\lambda$  phage DNA (48.5 k base pairs, kbp), so that fully stretched they were about 17  $\mu\text{m}$  long.

It is not clear from that data whether the ac electric field needs to be nonuniform for the stretching. It would be an interesting experiment to determine whether DNA is

stretched in uniform electric fields. Finally, they showed that it is possible to attach DNA to electrodes, which they interpret as being due to positive DEP: Near the edges of the thin electrodes, the electric field gradients are large, hence the DNA is attracted there. Once attached to the Al electrode (in this experiment, only one end is attached), it is bound chemically and remains, even after the electric field is switched off. In Figure 8, the results found by Washizu and co-workers are indicated schematically.

In 1995, Washizu and co-workers described several possible applications of this technique [106]. First, they described an optical/DEP technique to size-sort long DNA (with length greater than 10 kb pairs), which is difficult for conventional gel electrophoresis. This was demonstrated with  $\lambda$  phage DNA (size 48.5 kbp). Second, they measured the activity rate of exonuclease digestion of DNA, by measuring the double strand length as a function of time during digestion. DNA lengths of order 10  $\mu\text{m}$  can be measured because DEP caused the DNA to be stretched out. (They found that single strands of DNA are not stretched by DEP.) A further method was developed to stretch DNA molecules and position them at two different electrodes, using a combination of a floating electrode geometry and also chemically treated (biotin and avidin) electrodes. For unknown reasons, without the floating electrode geometry it was possible to attach one end of a DNA molecule to one electrode, but not the other end to the other electrode. Apparently, the high electric fields near the electrode induced currents away from the electrode, preventing the second end of the DNA molecule from binding, but not the first end.

The DNA so immobilized is shown to still be biochemically active. In 1993, Banata and co-workers used the DEP technique to attach one end of DNA to an aluminum electrode; the other end was free but stretched out with DEP. Just after turning off the electric field, and before the DNA had a chance to re-coil, they imaged single fluorescently labeled RNA polymerase molecules sliding along the DNA [107]. The technique was used to study the DNA-protein interaction with other proteins (*Pseudomonas putida* CamR) in 1999 [108]. Future applications of this technique

may lend insight into DNA-protein interactions in general, and the regulation and control of genetic expression in particular.

In 1999 Ueda and co-workers studied the DEP stretched DNA molecules with AFM, after drying the solvent (water). They concluded that the DEP stretched and trapped molecules do not aggregate but in contrast are trapped individually [109].

In 2000, the Washizu group used dielectrophoresis and floating electrodes to attach both ends of  $\lambda$  phage DNA molecules to aluminum electrodes [48, 110], using the floating electrode technique described above. In this work, they etched the glass slide below the gap between the electrodes so that the DNA was freely suspended. (Although it has gone largely unnoticed by the MEMs community, this technique to assemble freely suspended DNA should have many applications in nanomechanical systems made of DNA.) Since the DNA was freely suspended in solution there is no issue of steric hindrance of biochemical activity. Then, in a further set of experiments [48], they used optical tweezers to manipulate 1- $\mu\text{m}$  latex spheres labeled chemically with the digestive enzymes DNaseI (which has no base pair selectivity) and HindIII (a restriction enzyme which cuts DNA at only specific base sequences). They were able to bring the bead up to the DNA. In the case of DNaseI, the DNA was immediately cut. In the case of HindIII, the bead was moved up and down the DNA until it matched the correct sequence, at which point it was cut.

In 1998, the Washizu group studied the polarization of the fluorescent emission from dielectrophoretically stretched DNA [111]. The polarization of the emitted light was quantitatively measured and correlated with the applied electric field intensity, as well as the pH of the solution. Several interesting results were obtained, indicating that the counterion cloud surrounding the DNA molecules has a large influence on the stretching of DNA by electric fields. The details of this influence are still not fully understood. Many of these results from Washizu and co-workers are reviewed in two book chapters [112, 113].

#### 5.4.2. Asbury and Co-Workers

In 1998, Asbury and van den Engh were able to use dielectrophoresis to trap DNA with a floating electrode geometry: The electric field was applied from external electrodes; floating gold electrodes spaced by 30- $\mu\text{m}$  gaps concentrated the electric field, which served to trap the DNA [114]. They also studied  $\lambda$  phage DNA in de-ionized (D.I.) water, but used gold electrodes (thickness 40 nm), and audio frequency (30 Hz) fields. As in the Washizu experiments, the DNA underwent positive dielectrophoresis: it was attracted to regions of high electric field intensity, which occurs near the edges of the electrodes. Asbury used much lower frequency voltages (typically 30 Hz) than Washizu, and found no stretching of the DNA at these frequencies. Furthermore, Asbury found that the DNA did not become stuck to the gold electrodes, in contrast to Washizu's experiments where the DNA did become stuck to aluminum electrodes.

Regarding the frequency, at dc no more than roughly 1 V can be applied across an electrode/water interface; otherwise electrolysis followed by bubbling can occur. Washizu found

**Figure 8.** Schematic representation of the findings of Washizu and co-workers.

that much larger voltages could be applied as the frequency was increased from 1 kHz to 1 MHz (they did not study frequencies below 1 kHz). In Asbury's experiments, the gold electrodes were floating, but there was still less than 0.5 V between each (floating) electrode pair, so that electrolysis did not occur. Asbury's experiments found that DNA could be trapped in deionized water, but not in isotonic saline. They estimate that the force on the DNA was in the femtonewton range. Since the DNA molecules were not stuck to the gold electrodes, Asbury was able to simultaneously apply a dc field and move the stretched DNA molecules with electrophoresis.

In 2002, Asbury and co-workers continued this work by integrating it with a simple microfluidic device, fabricating a 15- $\mu\text{m}$ -wide PDMS channel on top of gold electrodes which, in contrast to their earlier work, were electrically contacted (not floating) [115]. With the gold electrodes and 30-Hz voltages of roughly 3 V p-p, they were able to trap DNA and then release it using positive dielectrophoresis. Their estimates show that 50% of the DNA introduced into the microfluidic channel was trapped.

Asbury found the trapping "efficiency" to decrease with increasing frequency between 5 Hz and 2 kHz, with an effective time constant of 3 ms. The origin of this frequency dependence is attributed to the distortion of the counterion clouds that surround the DNA molecules in solution, although the details of this effect are currently poorly understood.

#### 5.4.3. Ueda and Co-Workers

In 1997 Ueda et al. used much-lower-frequency ac electric fields, and studied the electronic dielectrophoretic stretching of DNA in polymer laden solutions. They found the polymer (polyacrylamide) assisted the stretching of DNA for applied electric fields in the frequency range of 0.1 to 100 Hz [116]. They found this stretching to occur at field strengths as low as  $10^4$  V/m; no net motion of the DNA was reported.

#### 5.4.4. Chou and Co-Workers

In another work with floating electrodes, Chou and co-workers used *insulating* posts fabricated with micro-machining techniques, and electrodes external to the device [117]. The slightly conductive solution served to enhance the electric field near the gaps between the posts, and DNA was found to be trapped there for voltages on the electrodes of roughly 1000 V and frequencies between 50 Hz and 1 kHz. The corresponding electric field strength was  $10^5$  V/m. In this work, the DNA was apparently not stretched at all, presumably because of the constricted geometry used. In contrast to the work of Asbury, Chou found that the trapping force increased with increasing frequency, and also calculated that the trapping force was roughly 1 fN.

#### 5.4.5. Tsukahara and Co-Workers

In recent work [118], Tsukahara and co-workers studied dielectrophoresis of single DNA molecules using frequencies between 1 kHz and 1 MHz and field strengths around  $10^4$  V/m, using quadrupole electrode patterns similar to those shown in Figure 3. They found that the DNA underwent positive dielectrophoresis (i.e., it was attracted to the

high field regions near the edges of the electrodes) for frequencies between 1 kHz and 500 kHz, and negative dielectrophoresis between 500 kHz and 1 MHz, in contrast with the findings of previous work. This is to date the only reported observation of negative dielectrophoresis of DNA; the discrepancy may be related to the different solvents used, although at this point it is still an open question. Furthermore, Tsukahara and co-workers used electric fields that were roughly a factor of 10 smaller than previous workers, and still were able to observe the dielectrophoretic forces on a single DNA molecule. This may again be due to the solvent used, or the fact that Tsukahara used a quadrupole electrode geometry, which is different than previous works. Additionally, Tsukahara did not observe any stretching of the DNA with the application of an ac electric field.

#### 5.4.6. Porath and Co-Workers

In 2000, Porath and co-workers used positive dc dielectrophoresis to putatively trap 10-nm-long poly(G)-poly(C) double strands of DNA between Pt electrodes with 8-nm spacing [119]. Through a series of control experiments, Porath concluded that the trapped object was indeed DNA, and that its electrical properties were semiconducting. Many other researchers up to and since then have considered the electronic properties of DNA as a molecular wire. The issue is still under investigation [120].

#### 5.4.7. Summary

The detailed mechanisms for the frequency dependence, electric field dependence, concentration dependence, pH and ionic dependence of the dielectrophoretic manipulation of DNA are still not explained in a systematic, quantitative way, and many of these dependences have yet to be quantitatively measured. However, it is clear now that it is possible to use dielectrophoresis to manipulate DNA under a variety of conditions and frequencies. This knowledge could be used in a variety of contexts, including lab-on-a-chip diagnoses and genetic expression profiling, as well as electronic methods of controlling DNA chemistry. This latter possibility has the potential to provide a new nanomanufacturing technology based on both chemical self-assembly techniques and integrated, massively parallel, economical electronic control of the same.

### 5.5. Viruses

#### 5.5.1. Influenza

To date two different research groups have succeeded in trapping at least four different species of virus with dielectrophoresis. The first group to trap viruses was that of Fuhr and co-workers in 1996 [121]. They used quadrupole, three-dimensional traps to trap fluorescently labeled influenza viruses ( $d \approx 100$  nm) using negative dielectrophoresis traps, and 1-MHz electric fields with field strength around  $10^5$  V/m. (The gap between electrodes was approximately 5  $\mu\text{m}$  with 11-V p-p voltage.) They also trapped 14-nm latex beads. In these experiments, the viruses formed aggregates in the centers of the traps. In later work with similar geometries, fields, and frequencies, the same group was also able to trap Sendai viruses into aggregates as well [122].

### 5.5.2. Tobacco Mosaic

In later work, Morgan and co-workers used interdigitated electrode fingers spaced by 4  $\mu\text{m}$  with saw-tooth shapes to manipulate tobacco mosaic viruses [123, 124]. The tobacco virus is rod-shaped, with length of 280 nm, and width of 18 nm. Morgan used field strengths of roughly  $10^6$  V/m, and varied the frequency between 1 kHz and 2 MHz. Although they were not able to observe individual virions, they could see a faint haze as the density increased or decreased in response to the applied electric field. They found both positive and negative dielectrophoresis, depending on the frequency used. Positive dielectrophoresis was observed for frequencies below about 1 MHz, and negative dielectrophoresis for higher frequencies. The crossover frequency was very dependent on medium conductivity, which was varied between  $2 \times 10^{-3}$  and  $10^{-1}$  S/m by varying the potassium phosphate buffer concentration.

### 5.5.3. Herpes

In 1998, Hughes and co-workers used planar quadrupole traps such as the one shown in Figure 3 with 6- $\mu\text{m}$  gaps to trap Herpes simplex viruses, which are spherical with diameter of about 250 nm [125]. They studied dielectrophoresis of the virus with frequencies from 10 kHz to 20 MHz, and observed negative dielectrophoresis for frequencies above about 5 MHz. The field strengths required for the trapping were about  $10^6$  V/m. Later work by the same group found that the crossover frequency between positive and negative dielectrophoresis for the herpes virus was very dependent on the medium conductivity in the range between  $10^{-4}$  and  $10^{-1}$  S/m, and this dependence was strongly affected by the presence or absence of manitol [126, 127].

### 5.5.4. Virus Separation

Using the results from their previous studies, Morgan and co-workers studied both tobacco and herpes virus in the same solution, using quadrupole electrode geometry [124, 128]. At 5 MHz, the herpes virus experiences negative dielectrophoresis and is collected in the center of the quadrupole. In contrast, at 5 MHz the tobacco virus experiences positive dielectrophoresis and is collected at the edges of the quadrupole geometry. Thus, two different virus species were physically separated due to their different frequency response to dielectrophoresis.

## 5.6. Proteins

A protein consists of a long chain of subunits (amino acids) which are folded into very complicated three-dimensional structures; the structure is closely related to the function. Most proteins of biological significance are around 1–10 nm in physical size. All species of life are based on only 20 common amino acids [129]. The modern field of *proteomics* seeks to understand, categorize, and tabulate all proteins useful for life [130].

There have been several studies of the effects of moderate electric fields and strong pulsed fields on the conformational state of proteins such as the helix-coil transition [131]. Reviews of the dielectric properties of biopolymers, dealing predominantly with linear response, low field behavior,

are given in [3, 4, 132–134]. However, given the importance of protein chemistry in modern molecular biology, it is surprising how little work to date has been performed on the interaction between strong electric fields and proteins.

### 5.6.1. Protein Trapping

In 1994, Washizu and co-workers studied the effect of dielectrophoresis on the following proteins: avidin (M.W. 68 kDa), concanavalin A (M.W. 52 kDa), chymotrypsinogen A (M.W. 25 kDa), and ribonuclease A (M.W. 13.7 kDa) [84]. These proteins have diameters ranging from 1 to 5 nm. In this series of experiments, they used aluminum (thickness 1  $\mu\text{m}$ ) electrodes in an interdigitated, castellated geometry with gaps ranging from 4 to 55  $\mu\text{m}$ . The solvent was D.I. water. They used fluorescence to observe the positions of the proteins. They observed excess fluorescence near the electrodes (i.e., near the high field regions), so that they observed positive dielectrophoresis. They knew it was DEP because they found a dependence on the field strength, not the voltage, by using different gaps between the electrodes.

According to rough estimates of the DEP force for their electrodes (a quantitative calculation was not performed), the thermal Brownian motion should overwhelm the DEP force so that nothing should be observed. And yet they observed increased fluorescence in the high field regions. This can be interpreted one of two ways: first, that we do not understand why DEP works so well on proteins; second, that the proteins are accumulating and the agglomerate acts as an effectively large polarizable particle that is less susceptible to Brownian motion and can be trapped.

Washizu argues that the second explanation (agglomeration) is not occurring because when they change the initial concentration by a factor of 10, the time to form the “aggregation” does not vary much, and this is inconsistent with a simple aggregation model of dipole–dipole attraction. Dipole–dipole attraction goes as  $d^{-4}$ , so that the time to form the agglomeration should vary as the density  $n^4$ .

If an optical setup with enough sensitivity to image a single fluorescing protein [135] could be achieved, this issue could be resolved. Washizu was able to demonstrate that trapping of various sized proteins depends on their molecular weight, so that separation of chemical species of various sizes could in principle be observed for applications in nanobiotechnology. Thus a “single molecule fluorescence” experiment, if it could be performed, would be definitive proof the DEP can be used with  $10^6$  V/m to manipulate 1- to 5-nm proteins.

In more recent work, Kawabata and Washizu [136] developed a biosensor for the protein AFP (alpha-fetoprotein, 70 kDa), an important diagnostic protein, which is detected in the serum of a liver-cancer patient. There, they used the DEP properties of proteins (antigens and antibodies) as well as 150-nm latex beads with antibodies immobilized on the surface. This is an example of an important point: even though we have organized this review according to the types of nano-objects that can be manipulated with DEP, the application of DEP to a heterogeneous population of objects could provide even more applications than just manipulating one type of object at a time.

## 5.6.2. Protein Folding

The previous section discussed primarily controlling the location of proteins with dielectrophoresis. However, given that the conformational state of a protein is related to its function, it is natural to consider whether an applied electric field can change a protein's conformational state, and possibly even unfold the entire chain of amino acids into a straight line, as Washizu was able to do with DNA. While the latter is still unproven experimentally, Washizu and co-workers have shown that it is indeed possible to use electric fields to change the conformational state of a certain protein, the flagellum of a bacteria.

The flagellum of certain types of bacteria consists of a single, spiral shaped protein about 20 nm wide and 10  $\mu\text{m}$  long. When it is rotated it acts as a corkscrew, propelling the bacteria forward. However, other conformational states of the amino-acid chain are possible; three in particular are called "straight," "curly," and "coiled." Because the flagellum is a long protein, its conformational state can be directly observed under a microscope, if fluorescently labeled.

Washizu and co-workers found that ac electric fields of roughly  $10^6$  V/m could transform flagella from one conformation state to another [112, 113, 137]. Furthermore, they found this process to be *reproducible and reversible*, observing no permanent damage to the flagella after application of the electric field.

Similar work on the electric field-induced conformation changes in other proteins (e.g., poly-(L-lysine) and poly-(L-glutamic acid)) has been reviewed in [134]. There, the work described involves measurements of optical dichroism as a function of applied electric field pulses. The optical dichroism is also strongly affected by electric field-induced orientation, making it difficult to conclusively demonstrate electric field-induced conformational changes in protein structure.

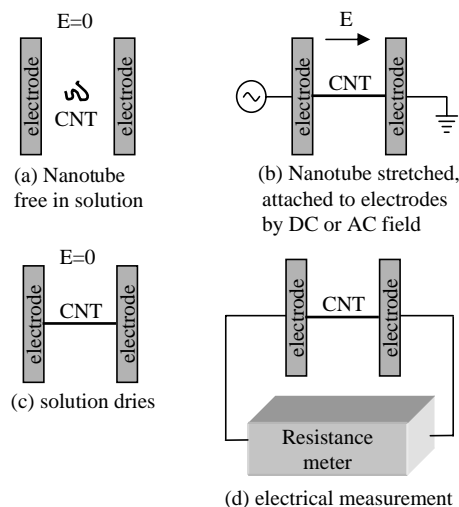

This relatively unexplored area has great potential for the future. By electronically controlling the conformational state of proteins, it may be possible to electronically control their biological function, or even to engineer new functionality into existing or tailor-designed proteins. This future molecular nanotechnology could have broad applications, which will be discussed toward the end of the review, and could also allow for further scientific studies of the process of protein folding.

## 5.7. Carbon Nanotubes

### 5.7.1. Nanotubes in Solution

Several research groups have successfully used dielectrophoresis to manipulate carbon nanotubes in solution. The general procedure is similar to that of Washizu's manipulation of DNA, with the exception that nanotubes are known to be good conductors. Most experiments demonstrating manipulation of carbon nanotubes in solution are a variation of the general process depicted schematically in Figure 9.

Nanotubes are not known to be soluble in any solvent, but can be dispersed by sonication. Once dispersed, a drop of the solution can be placed onto microfabricated electrodes as shown in Figure 9A. Next, either a dc or an ac voltage is applied. This serves two purposes. First, it induces a dipole moment in the carbon nanotube, and this dipole

**Figure 9.** Schematic representation of the manipulation of carbon nanotubes in solution.

experiences a torque, given by Eq. (10). This torque tends to align the nanotube with the axis of the electric field. The electric field need not be nonuniform for this alignment, but to date experiments have not tested the dependence of the alignment on the uniformity of the field in any quantitative fashion.

Simultaneously, the induced dipole [138] in the nanotube experiences a force given by Eq. (2). (Equation (3) is not directly applicable as it assumes a spherical particle.) To date all measurements on carbon nanotubes have found that they undergo *positive* dielectrophoresis; that is, they are attracted to regions of high electric field strength. This can be exploited to electrically contact nanotubes: the electrodes which generate the electric field gradient can also be used as electrical contacts to the nanotube. This is indicated schematically in Figure 9D.

When water is used as the solvent (which is desirable for biologically interesting measurements), as discussed above, the applied voltage to the electrodes should be less than 1 V to avoid hydrolysis (and hence bubbling). By using ac voltages, as Washizu et al. found in 1990 [54], the applied voltage (hence electric field strength) required for hydrolysis increases with increasing frequency. If one is willing to use an insulating solvent, then the applied voltage (hence electric field) can be much larger, even at dc. Pohl, for example, used commonly used applied (ac) voltages of thousands of volts with insulating solvents such as organic solvents and  $\text{CCl}_4$  [2].

### 5.7.2. DC Dielectrophoresis and Electrophoresis

The first dielectrophoretic manipulation of nanotube ropes was done using dc dielectrophoresis in 1997 by Bezryadin and Dekker [97]. Bezryadin used cyclohexane as the solvent, and a dc voltage of 4.5 V between AuPd electrodes spaced by 150 nm. He simultaneously measured the dc current flowing between the electrodes, and was able to see an electric current flow as soon as a nanotube rope was trapped.

Bezryadin found that the trapping was effective, but the nanotube ropes were not aligned parallel to the electric field. This is possibly due to the fact that the length of the trapped ropes was much larger than the gap between the electrodes.

When a dc electric field is used, if the object is charged it will respond to the electric field via conventional electrophoresis. A simple way to test whether the nanotubes are charged and experiencing electrophoresis or neutral and experiencing dielectrophoresis is to observe whether they preferentially move toward the cathode or anode or neither. If the nanotubes do not preferentially conglomerate at one polarity, then the effect is dielectrophoresis. Apparently in Bezryadin's experiments, the nanotubes behaved as neutral objects, and underwent dielectrophoresis. However, in two other experiments, multiwalled nanotubes (MWNTs) are found to behave as positively charged, conglomerating at the cathode [139], and negatively charged, conglomerating at the anode [140]. (Chen et al. found that single-walled nanotubes (SWNTs) also conglomerated at the anode under a dc electric field [141].) These discrepancies may indicate that the electrical properties of nanotubes are sensitive to the chemistry of the solvent. This effect, if it can be further characterized and explained, could prove very useful in nanomanipulation of nanotubes with electric fields in solutions.

### 5.7.3. AC Dielectrophoresis of MWNTs

In 1998, Yamamoto and co-workers studied the effects of ac electric fields on MWNTs of lengths between 1 and 5  $\mu\text{m}$ , and diameter 5–20 nm, using Al electrodes with 400- $\mu\text{m}$  gaps and field strength of  $2 \times 10^5$  V/m [142]. The MWNTs were dispersed in isopropyl alcohol. They found that the nanotubes were both *aligned* and attracted to the electrodes (i.e., underwent positive dielectrophoresis) for ac frequencies between 10 Hz and 10 MHz. Yamamoto and co-workers found that the degree of orientation of the nanotubes increased with increasing frequency, and with increasing nanotube length. Furthermore, they found that graphite impurities had a different frequency-dependent response to the ac electric field, which may be important technologically in separating nanotubes from impurities. Yamamoto also found that the alignment was more effective with ac dielectrophoresis than with dc dielectrophoresis [139], consistent with the findings of Bezryadin. A complementary technique of optical polarization measurements showed that ac electric fields could align nanotubes dispersed in ethanol [143].

### 5.7.4. AC Dielectrophoresis of SWNTs

In 2001, Chen and co-workers carried out a similar study of the effects of ac electric fields on SWNTs dispersed in ethanol [141]. They applied fields of  $5 \times 10^6$  V/m in the frequency range from 500 Hz to 5 MHz. They found the SWNTs to be oriented more strongly at higher frequencies, and they found the SWNTs experienced positive DEP for all frequencies studied. They also found no alignment effect from a dc electric field. Thus SWNTs and MWNTs appear to behave similarly under intense ac electric fields.

The first application of ac dielectrophoresis to attach two ends of SWNTs was reported in an e-print in early 2002 [144]. The authors used Ag and Au electrodes spaced

by 100 nm to trap ropes (bundles) of SWNTs dispersed in N,N-dimethylformamide (DMF). They found the nanotubes formed electrical contact with the Ag electrodes, but not the Au electrodes. The trapping was effective for frequencies between 1 kHz and 1 MHz, at applied fields of  $10^7$  V/m. Krupke was also able to simultaneously measure the ac resistance between two electrodes for the 1-kHz trapping experiments, allowing real-time monitoring of the trapping.

Nagahara et al. found similar results [145], trapping SWNT bundles with gold electrodes spaced by either 20–80 nm or 20  $\mu\text{m}$ , and applying 1 MHz and dc electric fields of strength  $10^7$  V/m. They found that the dc fields trapped bundles of SWNTs and graphite impurities, whereas the ac fields trapped only nanotube bundles. They were also able to electrically measure the current through the nanotubes after drying the Triton solvent.

Diehl and co-workers have taken this process one step further, and fabricated cross-bar structures by first aligning and immobilizing SWNT ropes in one direction and then, aligning and immobilizing nanotube ropes in a perpendicular direction [146]. The distance from one rope to the next was not determined by the lithography, but rather the chemical control of the coulombic interactions between the tubes and between the ropes. Diehl's experiments used frequencies between  $10^4$  and  $10^6$  Hz, with very little frequency dependence. The solvent consisted of a mixture of ortho-chlorobenzene and  $\text{CHCl}_3$ . (The field strength was not reported.) This represents an initial step toward one of the ultimate goals of self-assembled systems and nanotechnology in general: nonlithographic, economical, massively parallel manufacturing of electronic circuits on the nanoscale.

While to date there has been no reported trapping of an individual SWNT between two electrodes (as opposed to a bundle), such an achievement does not seem unreasonable to expect in the near future.

### 5.7.5. Controlling Nanotube Growth

Chemical vapor deposition (CVD) of carbon nanotubes is a promising new technique for the growth of high-quality single- and multiwalled carbon nanotubes [147]. The nanotubes grow from catalyst sites that can be lithographically defined on a chip [148]. However, the *direction* of the nanotube growth from these lithographically patterned catalyst sites is generally random, an issue that needs to be solved before massively parallel integrated nanotube circuits can be realized.

One possible technique to control the direction of nanotube growth is to apply an electric field (dc or ac) *during* the growth. The electric field will induce a dipole moment in the (growing) nanotube, which will experience a torque (see Eq. (10)), hence becoming aligned with the electric field. This technique was first applied to the growth of vertically aligned MWNTs in 2001 by Avigal and co-workers [149].

Later work by Zhang and co-workers [150] used both dc and ac (5 MHz) electric fields to direct the growth of SWNTs parallel to the substrate. The field strengths used were  $5 \times 10^5$  V/m, and freely suspended SWNTs up to 40  $\mu\text{m}$  in length were grown. The fields were generated between thin-film electrodes which were electrically contacted during growth. Later work by the same group achieved aligned

nanotube growth where the end result was a SWNT immobilized on the surface of the substrate [151].

### 5.7.6. Nanotubes as the Electrodes

Ultimately, for nano-DEP, one wants the smallest gap possible, and the smallest electrode radius of curvature possible. We would like to suggest that one way to achieve this would be to use nanotubes themselves as the electrodes. Very high electric field gradients should be possible [32].

## 5.8. Nanowires

### 5.8.1. Metallic Nanowires

In 1999, van der Zande and co-workers studied the orientation effects of uniform electric fields on 15-nm-diameter gold rods of lengths 39–259 nm in water using optical polarization techniques [152]. They found that, for an applied field strength of  $10^5$  V/m and an applied frequency of 10 kHz, significant orientation of the gold nanorods could be achieved.

Later work by Smith and co-workers studied gold nanowires down to 35 nm in diameter, although most work was performed in 350-nm-diameter wires of several microns in length [153]. Smith and co-workers used a combination of floating and electrically contacted electrodes, field strengths of up to  $10^7$  V/m, and frequencies from 20 Hz to 20 kHz. They found strong orientation effects and positive dielectrophoretic trapping of the nanowires to the floating electrodes for frequencies above 200 Hz; higher frequencies were most effective. Due to the floating electrode geometry used, the process was self-limiting: as soon as one wire bridged a particular pair of floating electrodes, it would short out the capacitively induced voltage on that pair of floating electrodes, preventing further trapping across that pair. Post manipulation lithographic contact to the floating electrodes showed the nanowires to be in good electrical contact with the trapping electrodes.

### 5.8.2. Semiconducting Nanowires

In 2001, Duan and co-workers used dc dielectrophoresis to align and electrically contact InP nanowires ( $d = 30$  nm) [154]. There, electric field strengths of  $10^7$  V/m were applied from electrodes spaced by 25- $\mu$ m gaps. The solvent used was chlorobenzene, so that electrolysis was not an issue. (DC voltages of 100 V were used.) By selectively energizing different pairs of electrodes, Duan was able to align InP nanowires into a cross-bar topology using layer-by-layer application of dielectrophoresis.

## 6. APPLICATIONS

### 6.1. Molecular Electronics

Recent work of Chen, Reed, and co-workers [103, 155, 156] has investigated the conducting properties of layers of molecules. The investigation of electronic properties of molecular conductors has been termed *molecular electronics*. The use of lithography alone will not allow for the controlled, rational design and fabrication of single molecule conductors.

One possible application of nanodielectrophoresis is the controlled placement of individual molecules for molecular electronics. If nanotubes and nanowires can be used themselves as the electrodes (and then as the interconnects), our calculations [32] show that it should be possible (based on the scaling consideration presented in Section 2.4) to trap individual molecules as small as 1 nm.

In Figure 10, we show one possible application of our proposed nanotube trapping scheme. An electrically contacted nanotube is cut with an AFM, then a large ac voltage is applied. By the method of images, the electric field gradients are the same as a geometry where a nanotube is in close proximity to a large conducting plane; the field gradients of a reasonable voltage (1 V) on the nanoscale should be quite large, allowing us to trap very small objects, possibly even single molecules. Trapping of DNA at the ends of nanotubes does not seem to be out of the question, nor is it impossible to trap any other number of molecules for nanotube-electrode molecular electronics. This electronically assisted chemical self-assembly contains the ingredients for molecular transistors wired up with nanotube interconnects in a possibly massively parallel process for large-scale integrated molecular electronics (“LIME,” if you will).

In Figure 11, we illustrate one possible application of this nano-trapping. 2'-amino-4-ethynylphenyl-4'-ethynylphenyl-5'-nitro-1-benzenethiolate (AEENBT) is used as a model [155]. Note that the hydrogen atom at the end bonded to sulfur can be replaced by other functional groups, for example,  $-\text{COCH}_3$ . Likewise, the protruding hydrogen atom farthest away from the sulfur atom can also be replaced by another group. By chemically selecting and optimizing the bridging molecule, in particular, the end functional groups, can one achieve ideal contact between the bridging molecule and carbon nanotubes?

Using Au as electrical contact, the Reed group [155] has made a molecular random access memory cell [156]. Multiple read write cycles were realized in a self-assembled monolayer film of AEENBT. The bit retention time was found to be of the order of 15 minutes. However, it is very difficult to combine lithography with 2-nm molecules. Nanodielectrophoresis uses the natural nanometer size of carbon nanotubes. With a defined carbon nanotube gap (2 nm) and diameter (1–2 nm), one will have a chance to electrically contact a single AEENBT.

Another potential advantage of trapping molecules with carbon nanotubes is the potentially better contact quality between carbon and other nonmetal atoms. Most molecule-metal junctions are poor circuit elements. The resistance

**Figure 10.** Schematic representation of an idea of how to trap 1-nm-sized particles or molecules.

**Figure 11.** An overly simplistic schematic view of potential molecular electronics with carbon nanotubes assembled with nanodielectrophoresis. This technique could allow rapid investigation of many such schemes in a massively parallel fashion.

is usually of the order of 1 M $\Omega$  [157], which is far away from the ideal contact. One of the reasons is the different electronegativity between metals and nonmetals. For example, in a S–Au(Ag) junction, an interfacial dipole leads to a Schottky barrier in that sulfur is more electronegative than gold and silver. Carbon, which is also a nonmetal element, may prove better to contact molecules.<sup>1</sup> One can ultimately investigate more complicated geometries and architectures for integrated molecular electronic devices with nanotube interconnects.

## 6.2. Nanomanufacturing

Future applications of nano-DEP do not need to be limited to the manipulation of individual or small numbers of nanoparticles. Rather, it should be possible to scale up these nanomanipulation methods for massively parallel processing at the single molecule level. Even macroscopic quantities of materials could be fabricated one molecule at a time. New materials with tailor-designed electronic, optical, magnetic, and mechanical properties could go from nano-CAD design to reality in a matter of hours or minutes at very low cost. This integration would be a true synthesis of the top-down and bottom-up approaches to nanotechnology.

## 6.3. Nanomachines

Through rotating electric fields generated by microfabricated electrodes, it has been possible to rotate 5- $\mu\text{m}$  latex beads and also cells in solution [8]. One could call such an apparatus a dielectric micromotor, where the electrodes are the stator and the rotating latex bead the rotor. Hagedorn et al. took this concept one step further and microfabricated a large variety of micro “rotors” out of Al and polyimide, which had dimensions of approximately 100  $\mu\text{m}$  [158]. They were able to demonstrate rotor speeds of up to 3000 RPM.

Recently Hughes has presented a theoretical evaluation of the ultimate limits of rotor performance, using nano-DEP to drive rotors down to 1 nm across [159]. He concluded that a 1- $\mu\text{m}$ -long by 100-nm-wide rotor should be able to generate a torque of  $10^{-15}$  N/m, equivalent to that of a bacterial flagellar motor. Although he does not discuss how one might realize such a rotor, we suggest that using carbon nanotubes as both the rotor and stator is one feasible technique to realize this, since it is known that nanotubes can be contacted

by external electrodes. Such a nanomachine would be a step toward Drexler’s vision of molecular nanotechnology [160], proving Feynman’s statement that “there’s plenty of room at the bottom” [161].

## 6.4. Nanobiotechnology

The applications in nanobiotechnology are practically limitless. For example, Washizu has taken the first step toward DEP FFF of proteins [84], on *one* protein. It is natural to speculate that in the future, DEP FFF may find application in the ability to separate *all* proteins from the human proteome, uniquely based on their dielectric spectral properties. If enough sensitivity could be achieved, one could measure genetic expression of the entire human genome in a single cell. This could have numerous applications in drug screening and discovery.

One does not need to consider only passive, scientific or diagnostic-based measurement of biochemical activity. Nano-DEP has already proved capable of manipulating viruses. This leads one naturally to ask the question: Based in part on nano-DEP, can one design an active, electronically controlled artificial immune system? A nano-liver or a nano-kidney? The answer to this question is not yet known, but would have significant impact on humanity in general if it turns out to be “yes.”

## 6.5. Nanochemistry

The force required to break a single chemical bond is roughly 1 nN [162]. Our calculations show that this can be the same order of magnitude that is generated by DEP on a micro- or nanoparticle, if nanotubes are used as the electrodes [32]. While to date AFM and SPM have been used for studying single molecule chemistry, it is also natural to speculate that nano-DEP experiments can be designed to electronically study and control the breaking of a single chemical bond.

## 7. UNANSWERED QUESTIONS

Although DEPs application in nanotechnology is still in its infancy, it can be considered a proven technique to electronically manipulate micro- and nanosized objects. However, the studies performed to date have left some key questions unanswered:

- What is the effect of Joule heating?
- What is the smallest molecule that can be trapped?
- What field strengths are needed for this?
- Since the forces depend on the field gradient only, is it possible to design different electrode geometries to achieve stronger trapping forces for a given applied voltage?
- Can trapping of individual macromolecules occur in biologically relevant solutions, fraught with conduction ions?
- What is the effect of molecule–molecule interactions on traps that hold more than one molecule?
- What is the role of electrohydrodynamics?

<sup>1</sup> We thank Shengdong Li for pointing this issue out to us.

Joule heating occurs due to current flow through the solution. This is especially a question in solutions of biological significance with ionic concentrations that can also carry current. The heating may cause convective fluidic currents which will overcome the dielectrophoretic forces. The amount of Joule heating is difficult to predict, since the conductive properties of the solution at MHz frequencies may not be known.

Macromolecules may not behave as bulk dielectrics, but have deviations from simple bulk behavior. These issues are difficult to address theoretically and more experiments need to be done to push DEP to the single molecule limit.

At the very high electric fields necessary for DEP to overcome Brownian motion of nanoparticles, the electric field may also interact directly with the fluid itself. The study of the interactions between electric fields and fluids is called electrohydrodynamics. Serious, concerted effort to understand electrohydrodynamics at the nanometer scale has only recently begun [163–169]. Understanding these effects will obviously have important implications for the applications and ultimate limits of nano-DEP.

The importance of these effects was made clear by Washizu et al. [106], who found that, while it was possible to stretch and attach DNA to one electrode, electrohydrodynamical effects prevented attaching the other end of the DNA molecule to a second electrode. Instead, a floating electrode geometry was needed to avoid the electrohydrodynamical effects.

The electrohydrodynamic effects of high electric fields at the nanoscale is a difficult problem to investigate both experimentally and theoretically, and will require considerably more effort to quantify, understand, and eventually control.

## 8. CONCLUSIONS

The use of dielectrophoresis has already found numerous applications in biotechnology, nanotechnology, and nanobiotechnology. Using conducting metal and carbon electrodes fabricated with either optical or electron beam lithography, coupled with modern microfluidic integrated circuits, it has been possible to manipulate, trap, separate, and transport DNA, proteins, viruses, cells of various types from many different species, including both plant and animal, metal nanoparticles, latex beads, carbon nanotubes, semiconducting and metallic nanowires, semiconducting nanoparticles, and quantum dots.

In order to bring this vast body of knowledge to fruition, several steps remain to be taken. First, the power and economy of massively parallel fabrication and manufacturing methods, as well as massively parallel operations on a single chip, have not yet been exploited. While the techniques described here are compatible with the processing techniques of modern semiconductor integrated circuits which achieve routinely millions of transistors on a chip at the cost of only a few dollars, to date most studies and demonstrations of nanodielectrophoresis have only been on a few or at most a dozen operations at a given time, such as the separation of viable and nonviable cells. These processes need to be integrated with each other, with microfluidics, and with

existing silicon microelectronics technology for many (millions) of operations for a true, integrated lab-on-a-chip.

Second, new applications must be found for this massively parallel processing, manipulation, and manufacturing capability. To date the manipulation of nano-sized objects has traditionally been painstaking, expensive, and slow. If massively parallel techniques of nanomanipulation can be manufactured and made readily available, many new opportunities which harness this economy of scale will need to be imagined, designed, and realized, such as new materials and devices with tailor-designed electronic, optical, magnetic, and mechanical properties. By integrating these with biological and chemical functions, artificial cell, immune systems, tissues, and even organs may someday be designed, fabricated, and made readily and cheaply available to every human being on the planet, for medical applications such as point-of-care diagnostics, drug discovery, artificial immune systems, and ultimately the treatment and prevention of disease.

Third, and finally, the next step in size reduction must be taken in order to create a true nanomanufacturing technology. The origins of dielectrophoresis allowed the use of traditionally machined electrodes to manipulate micron-sized objects such as cells. With the advent of photolithography and electron beam lithography, the trapping of objects as small as 10 nm has been enabled. The next step will be to use the electrically contacted nanowires and nanotubes themselves as the electrodes in the next generation of nanodielectrophoresis. These nanoelectrodes, perhaps themselves manipulated and interconnected with microelectrodes, will have even larger electric field gradients and will be able to manipulate 1-nm-sized objects. This is one possible route to molecular electronics. Furthermore, this will provide a new, economical, easy to handle, and direct link to the nanometer world, which could lead to many new discoveries and a truly new technology: nanotechnology.

## GLOSSARY

**Carbon nanotube** A nanometer-scale tube of carbon atoms, which can be either metallic or semiconducting, depending on the chirality.

**DEP field flow fractionation** The separation of objects according to their dielectric properties.

**Dielectrophoresis** The force acting on a polarizable object (neutral or charged) due to an ac or dc electric field gradient.

**Nanobiotechnology** The control of biological processes at the nanometer length scale.

**Nanowires** Narrow-diameter metallic or semiconducting wires whose dimensions (typically less than 10 nm) cannot be realized by lithography alone.

**Traveling wave dielectrophoresis** The transport through space in three dimensions of polarizable objects due to a traveling wave electric field.

## ACKNOWLEDGMENTS

Some of the experimental work presented here was performed by Sunan Liu and Lifeng Zheng. We thank J. Brody and Noo Lee Jeon for experimental assistance with the work, and Marc Madou and Shengdong Li for interesting discussions. This work was supported in part by the Army Research Office and the Office of Naval Research.

## 1. INTRODUCTION: FROM MICRO- TO NANO-ELECTROMECHANICAL SYSTEMS (NEMS)

The laws of physics do not forbid the possibility to develop devices and machines at very small scales, even of a few atoms or molecules [1]. Nature is full of examples of such small scale “machines,” which are able to manufacture various substances, to move, and to store information, with everything at very small molecular scale. There are many obvious advantages of making machines and devices as small as possible. Smaller devices are more compact, lighter, faster, and cheaper and they require less power than larger scale devices [2]. Moreover, they offer new capabilities (e.g., access to single molecule properties) not available in larger scale devices.

### 1.1. Microelectromechanical Systems: The First Generation of Small-Scale Mechanical Devices

The first generation of small scale machines and devices appeared in the mid 1980s when the technology of microelectromechanical systems (MEMS) was firmly established [3]. This technology allowed the design and fabrication of electromechanical devices with at least some of their

dimensions in the micrometer range. By “electromechanical” we refer to devices that contain mechanical elements in combination with some electronics that control and read out the mechanical motion or perform some additional functions, as schematically illustrated in Figure 1. In this definition we include microfluidics based MEMS [4–9], which consist of microsystems of channels, pumps, valves, mixers, filters, or separators most often externally controlled by means of electric fields.

MEMS have found many and important commercial applications. Among others we cite arrays of micromechanical mirrors for optical crossbar switches used in the optical communication industry, ink-jet printers using control of fluid jets, accelerometers used as sensors for deploying automobile air bags, microcantilevers for scanning probe microscopes, computer disk read heads, radio switches and filters, and lab-on-a-chip or micro total analytical ( $\mu$ TAS) systems. The latter have found many applications ranging from the life sciences industries for pharmaceuticals and biomedicine (drug design, delivery and detection, diagnostic devices) to industrial applications of combinatorial synthesis (such as chemical analysis and high throughput screening) [6].

Most of the MEMS in practical use today were made with silicon-based technologies [10], because of the well-known methods developed by the microelectronics industry. To this respect, the importance of MEMS technology is not so much the size of the devices, but rather the use of planar processing technologies, related to those used in the fabrication of electronic integrated circuits, that allows simultaneously “machining” of large numbers of relatively simple mechanical devices in an integrated fashion (for a recent example of large-scale integration in microfluidic systems see [11]).

### 1.2. Nanoelectromechanical Systems: The Second Generation of Small Scale Mechanical Devices

With the advent of new nanolithographic techniques (electron and ion beam lithography, nanoimprint lithography, reactive ion etching, etc.), further miniaturization became possible. These techniques allowed scaling down of MEMS into the submicrometer domain thus opening the door to

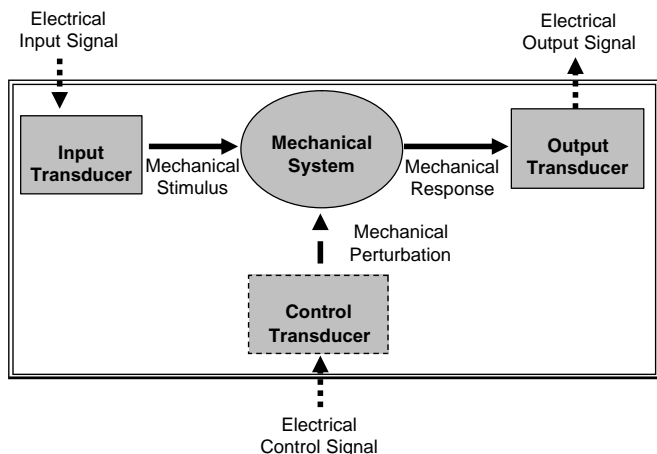

Figure 1. Schematic of an electromechanical device [12].

a new generation of electromechanical devices: nanoelectromechanical systems (NEMS) [12–14]. NEMS can be characterized by critical feature sizes in the range from hundred to a few nanometers, and contrary to the case of MEMS, their small dimensions are relevant for the function of the devices.

In NEMS applications physical properties resulting from the small dimensions may dominate the operation of the devices, and new fabrication approaches may be required, including the use of materials others than Si or the use of fabrication processes with spatial resolution higher than the ones used in the silicon microelectronics industry. In this sense, both top-down (from large to small) and bottom-up (from small to large) fabrication approaches are expected to be necessary in the manufacturing of NEMS.

At present, NEMS are still in a very early stage of development and only elemental devices based on suspended solid-state nanostructures or on nanofluidic systems have been developed. Even though elemental, these developments have shown that NEMS can provide a revolution in applications such as sensors, medical diagnostics, displays, and data storage. In particular, NEMS may enable experiments on the structure and function of individual biomolecules, opening unforeseen biomedical applications. Furthermore, NEMS may offer access to fundamental frequencies in the microwave range, mechanical quality factors in the tens of thousands, active masses in the femtogram range, force sensitivities at the attonewton, mass sensitivity at the level of individual molecules, or heat capacities far below a “yoctocalorie” [12].

### 1.3. Molecular NEMS: The Next Generation

The ultimate limit in the miniaturization of devices and machines will be reached when devices approach molecular or atomistic scales or, more precisely, when the active parts of the devices consist of single molecules or atoms. Fabrication at these scales will generally require a bottom-up approach by using naturally occurring molecules that self-assemble into useful devices or machines. In recent years, the ability to measure and manipulate matter at the level of single molecules has experienced spectacular

advances. Techniques such as scanning probe and tunnelling microscopy or the use of optical tweezers have allowed the characterization of the mechanical and electrical properties of many single molecules, thus making closer to reality the possibility of developing molecular NEMS (i.e., electromechanical devices whose active parts consists of a single molecule or atom). Some preliminary demonstrations based on carbon nanotubes, single proteins, or molecular biomotorson indicate that molecular NEMS can enter into play earlier than expected.

### 1.4. Scope of the Chapter

This chapter will provide an overview of the most relevant advances achieved so far in the emergent field of NEMS. For the purpose of the present chapter we will group NEMS into three main classes: NEMS based on suspended solid-state nanostructures (Section 3), NEMS based on nanofluidic systems (Section 4), and molecular NEMS (Section 5). Fabrication nanotechnologies will be reviewed in Section 1. We end the chapter with some concluding remarks in Section 6.

## 2. NEMS FABRICATION TECHNOLOGIES

The introduction of nonoptical lithography has been announced several times during the last 20 years, but optical methods like projection lithography have always been extended beyond predicted limits. However, a further “simple” downscaling of the optical wavelength beyond 193 nm is not feasible because of the lack of refractive lenses and the problems involved in the fabrication of pure reflective systems with high enough numerical apertures. Hence the need for new lithographic techniques is one of the big challenges for further progress in semiconductor technology. At the moment, several approaches toward sub-100 nm lithography are under discussion that can contribute to nanotechnological development, especially for provision of NEMS. The present section summarizes the principles of operations of some of them.

### 2.1. Electron Beam Nanolithography

Electron beam lithography [15, 16] is at present the essential basis of nanostructure fabrication. Electron beams can be used to write directly onto a substrate using high energy electrons (100 to 200 keV) and a small electron probe size (1 to 10 nm). With electron beams the creation of lines typically 30 nm wide can be satisfactorily produced (widths up to 7 nm have been reported). The resolution limiting factors in electron beam lithography strongly depend on the resist properties. The disadvantages of this technique are the large writing times, causing a low throughput that makes electron beam lithography prohibitively expensive for mass production. However, the approach is certainly useful for making masters for nanoimprinting lithography, which are in turn used multiple times.

## 2.2. Ion Beam Nanolithography

This technique is similar to electron beam nanolithography in terms of application but uses a beam of ions instead of electrons [17]. A fundamental difference is that ions are charged atomic matter that can interact physically and chemically with, and settle into, the exposed material and are many orders of magnitude more massive than electrons. Deep ion beam lithography is a new technique that can be used to produce three-dimensional nanostructures and is particularly good at creating side walls with almost 90-degree angles and slopes.

## 2.3. Nanoimprint Lithography

Nanoimprinting [18, 19] can produce patterns with (sub)micro- and nanometer scales in nanometer thin films in a relatively simple and reliable manner. It makes use of the mechanical deformation of a polymer under pressure and elevated temperature. The master, with its patterned surface, and a sample prepared with a layer of polymer are heated up to the printing temperature, which is above the glass temperature of the polymer to be molded. Then the stamp is pressed against the sample. Stamp and substrate are brought into physical contact and pressure is applied, followed by a down-cooling. After removal from the sample, the resulting polymer relief can be used as a mask for dry etching if the imprinted polymer is resistant enough or as a step in a lift-off process. Figure 2 shows a scheme of this parallel processing technique.

The main advantage of this technique in comparison to electron beam writing is the parallel nature of the process, the high throughput, and the low system costs, because no energetic particle beam generator is needed [20, 21]. In addition, nanoimprinting eliminates a number of adverse effects of conventional lithography techniques [21, 22] like wave diffraction, scattering and interference in the resist, electron backscattering from the substrate, and chemical issues.

**Figure 2.** Schematic of the nanoimprint lithography process.

## 2.4. Microcontact Printing

The principle of microcontact printing [23, 24] is shown in Figure 3. A stamp consisting of an elastomer is covered by an ink, for example an alkanethiol. Upon contact a self-assembling monolayer is formed within a few seconds which protects the substrate so that a selective wet etch can be performed.

The main advantages of this technique result from the conformal contact to nonflat surfaces, which is due to the elasticity of the stamp. As a consequence flatness of the surface over large areas is not a problem, and even three-dimensional surfaces can be printed.

## 2.5. Scanning Probe

Since their invention, scanning tunnelling microscopy (STM) [25] and atomic force microscopy (AFM) [26] have been promising tools for a wide range of applications: imaging nanostructures, manipulating individual molecules or atoms [27], and more recently for lithography process [28, 29] to build nanostructures. In the technique of STM, a sharp metal tip is brought extremely close to a conducting sample surface. When a bias voltage is placed across the tip-sample junction, electrons tunnel quantum mechanically across the gap between them thus giving rise to measurable tunnelling current (from 10 pA to 10 nA). During image acquisition, the tip is scanned across the sample using  $x$ - $y$  piezoelectric elements, and a feedback circuit typically adjusts the tip height ( $z$  piezo) in order to maintain a constant current. On the contrary, in contact AFM mode, the tip and sample are brought into tip-sample force during scanning, usually by maintaining a constant cantilever deflection. In most commercial AFM, this is achieved by focusing a laser onto the back of the cantilever and measuring its reflected intensity using a photodiode. During scanning, the

**Figure 3.** Process for the production of a microcontact stamp and the formation of self-assembled monolayers on a substrate.

cantilever motion is then detected via the photodiode signal and a feedback circuit is used to maintain a constant tip-sample force.

In spite of being very young, lithography techniques employing STM/AFM represent a promising way toward the fabrication of new nanodevices for electronic applications with good reproducibility and positioning accuracy. Unfortunately, the serial nature of the writing process makes it time consuming and not economical for commercial applications. One solution to this problem has been the introduction of multiple tip arrays. Techniques such as dip-pen lithography are adaptable to such an array geometry and may eventually yield viable nanodevices applications.

## 2.6. Fabrication Issues for Nanofluidic Applications

Fabrication of nanofluidic structures requires the improvement of two challenges: reduction of size and creation of sealed fluidic channels [8]. The first challenge can be overcome by the use of electron beam, ion beam, or nanoimprint lithographies described previously. Very recently, the fabrication of 10 nm enclosed nanofluidic channels using nanoimprint lithography has been reported [30]. Techniques based on the use of sacrificial materials to create sealed small hollow fluidic structures have gained popularity in recent years [31]. However, steps needed in removing the sacrificial materials such as heating the substrate up to 200–400 °C or wet etching might not be compatible with downstream fabrication process or may limit the use of certain materials.

Concerning sealing techniques, methods such as wafer bonding or elastomeric sealing are suitable for relatively large planar surfaces and provide an effective seal. Wafer bonding consists of creating a bond between a glass slide and a silicon substrate by gentle heating while applying an electric field across the silicon/glass structure to ensure good contact via the associated electrostatic force. Wafer bonding, also called anodic bonding, requires an absolutely defect-free and flat surface. In addition to silicon and glass materials, elastomeric materials have also been considered for the fabrication of micro/nanofluidic structures [32]. These materials provide good sealing properties, fast design times, low cost, the ability to fabricate nanoscale features, and the possibility of deformable shapes.

## 3. NEMS BASED ON SOLID-STATE SUSPENDED NANOSTRUCTURES

A great part of the research developed so far in NEMS has focused on devices consisting of a freestanding or suspended solid-state nanostructure able to freely move in at least one direction and that can be actuated and sensed by means of electromechanical transducers. Nanostructures such as single clamped nanobeams (also known as nanocantilevers) [33–38], doubly clamped nanobeams [39–46], and nanopaddles [47–51] have been fabricated and electromechanically actuated and sensed. A schematic representation of these nanostructures is shown in Figure 4. These nanostructures present at least one dimension in the tens of nanometer range and can be fabricated out of single crystals

**Figure 4.** Schematic representation of some basic nanostructures for solid-state freestanding NEMS. (a) Single clamped nanobeam, (b) doubly clamped nanobeam, (c) nanopaddle.

or from noncrystalline materials by means of the nanolithographic techniques described in Section 2. Among the materials used in their fabrication we cite Si [39–41], GaAs [47], GaAs/AlGaAs [34, 43, 46], SiC [44], AlN [45], InAs [38], SiN [51], and piezoresistive materials [35]. Very often, the nanostructures are covered with a thin metallic layer for an easier actuation and sensing.

The more relevant physical properties of this class of NEMS, as well as the techniques developed to actuate and sense them, will be described.

### 3.1. Physics of Solid-State Suspended Nanostructures

Solid-state freestanding NEMS are designed basically for two types of applications: very low force measurement and high frequency resonators for communication and sensing applications. For the former application low equivalent elastic spring constants are required. For the latter one, high natural frequencies of oscillation and high quality factors become necessary. The values of these physical properties can vary over a broad range depending on the geometry of the nanostructure, the material used in its fabrication, and the conditions of operation (air, liquid, ultrahigh vacuum). One can estimate these dependencies in the framework of classical elasticity theory [52, 53], which assumes a continuous description of matter, the absence of relevant finite size effects (bulk properties are assumed to hold), and the absence of quantum mechanical effects. Later we will discuss the limitations of this type of description.

#### 3.1.1. Equivalent Elastic Spring Constant

The equivalent elastic spring constant,  $k$ , determines the sensitivity of the nanostructure to external applied forces. It is defined as the force constant a spring would have in order to display an elongation equal to the maximum displacement of the nanostructure in response to a given external force [53]

$$k = \frac{F}{\delta} \quad (1)$$

where  $F$  is the applied force and  $\delta$  is the maximum displacement of the nanostructure. This definition is mainly used for structures of the cantilever type (Fig. 4a). For this type of

nanostructure classical elasticity theory predicts an equivalent elastic spring given by [52]

$$k = \frac{3EI}{L^3} \quad (2)$$

where  $L$  is the length of the beam,  $E$  is the Young elasticity modulus of the material, and  $I$  is the momentum of inertia of the nanobeam cross-section. For the case of a rectangular beam the momentum of inertia is  $I = (1/12)wt^3$ , where  $w$  and  $t$  are the width and thickness of the beam, respectively. The spring constant then reads

$$k = \frac{1}{4} \frac{Et^3w}{L^3} \quad (3)$$

Similar expressions can be obtained for other geometries. The validity of Eq. (3) in the nanorange has been proved for SiC nanorods [54].

By inspection it is clear that structures with large aspect ratios (i.e., large values of the ratio  $L/w$  or  $L/t$ ) will present the smallest spring constants and hence the highest force sensitivity (i.e., they will deform in an appreciable way in response to very small forces). Furthermore, for a given geometry, materials with the lowest values of the Young modulus are expected to give the lowest spring constants. Table 1 presents the values of the equivalent spring constant for different Si nanocantilevers as calculated from Eq. (3).

Suspended solid-state nanostructures are also able to display torsions in response to the action of lateral forces. Torsional phenomena can be described in very much the same way as deflection phenomena. In particular, one can define an equivalent torsional spring constant to characterize the torque sensitivity of the nanostructure as

$$\kappa = \frac{M}{\theta} \quad (4)$$

where  $\theta$  is the maximum angle of twist and  $M$  is the torque producing such a twist. As in the case of deflections, the value of the equivalent spring constant,  $\kappa$ , depends on the properties of the material and on the geometry of the nanostructure. For the simplest case of a single clamped rod classical elasticity theory gives [53]

$$\kappa = \frac{GI_p}{L} = \frac{\pi r^4}{2L} G \quad (5)$$

where  $G$  is the shear modulus of the material,  $I_p$  is the polar momentum of inertia of the rod cross-section, and  $L$  is the length of the nanostructure [in the second equality in Eq. (5) we used that the polar momentum of inertia of a rod is  $I_p = (1/2)\pi r^4$ ]. Similarly, for the case of a single clamped rectangular beam one obtains [52]

$$\kappa = \beta(w/t) \frac{t^3w}{L} G \quad (6)$$

where  $w$  and  $t$  are the width and thickness of the beam, respectively, and  $\beta(w/t)$  is a dimensionless numerical function of the ratio  $w/t$ . Again, in order to reach high torque sensitivity small aspect ratios values are required. The validity of Eq. (6) in the nanorange has been demonstrated with Si nanopaddles [50].

### 3.1.2. Natural Frequencies of Oscillations

The values of the natural frequencies of oscillation of suspended nanostructures determine many of the potential applications of resonant NEMS (e.g., in mass sensors [55–57] or for communication purposes [58, 59]). A very important feature of resonant NEMS is their potential capability to reach the GHz domain (at present, values as high as 380 MHz have been already reported [60]).

The natural frequencies of oscillation of a suspended nanostructure depend basically on the geometry of the nanostructure, on the material used in its fabrication, and on the way the nanostructure is fixed to the supports. Indeed, for the case of transversal oscillations the natural frequencies of oscillation are given by [52]

$$f_n = \frac{C_n^2}{2\pi} \frac{1}{L^2} \sqrt{\frac{EI}{\rho A}} \quad (7)$$

where  $\rho$  is the density of the material,  $A$  is the cross-sectional area, and  $I$  is the momentum of inertia of the cross-sectional area. Moreover,  $C_n$  is a numerical factor that depends on the way the nanostructure is fixed to the supports and on the harmonic considered. For example, for the fundamental mode of oscillation of a rod clamped at one end one has  $C_0 = 1.875$ , while for a rod clamped at both ends one has  $C_0 = 4.730$ . Finally, for a rod clamped at one end and with an external force applied to the free end one has  $C_0 = 1.316$ . For the particular case of a rectangular beam, for which  $I = (1/12)wt^3$ , the natural frequencies of oscillation read

$$f_n = \frac{C_n^2}{2\pi} \sqrt{\frac{E}{12\rho}} \frac{t}{L^2} \quad (8)$$

According to this relationship, the highest frequencies are obtained with nanostructures with the shortest aspect ratios  $L/t$  and the highest  $E/\rho$  ratios. Moreover, doubly clamped structures give frequencies more than one order of magnitude higher than single clamped beams, due to the higher value of the numerical factor  $C_n$ . The validity of Eq. (8) in the nanorange has been tested with SiC [44], AlN [45], and SiN [51] nanobeams. After corrections due to the effects of the thin metallic layer, nonuniform geometries, and tensile stress, good agreement between theory and experiments has been observed.

**Table 1.** Equivalent spring constant for Si nanocantilevers of different geometries as calculated from Eq. (3).

$L \times w \times t$ ( $\mu\text{m} \times \mu\text{m} \times \mu\text{m}$ )	$10 \times 0.2 \times 0.1$	$1 \times 0.2 \times 0.1$	$1 \times 0.05 \times 0.05$
Spring constant, $k$ (N/m)	$9 \times 10^{-3}$	9	0.3

Note: The bulk Si Young modulus is used in the calculations.

Table 2 presents the calculated values of the fundamental frequency of oscillation for Si nanocantilevers of different geometry. We note that high frequencies of oscillation imply in general high force constants. In the MEMS domain this fact has sometimes prevented the possibility of reaching very high frequencies. However, in the NEMS domain very high frequencies seem to be compatible with low force constant [12], as can be seen by comparing Tables 1 and 2.

One of the more relevant applications of resonant solid-state freestanding NEMS is as mass sensors [55–57]. Why these resonators display a so high mass sensitivity can be understood by approximating the nanoresonator by a simple harmonic oscillator. In this case, the fundamental frequency of oscillation is given by

$$f = \frac{1}{2\pi} \sqrt{\frac{k}{m}} \quad (9)$$

where  $k$  is the force constant and  $m$  is the mass. According to this relationship, if a small variation in the mass of a suspended nanostructure,  $\delta m$ , occurs then a frequency shift,  $\delta f$ , on the natural frequency of oscillation,  $f$ , should take place, which is related to the mass increment through the simple relationship

$$\delta m = \frac{k}{4\pi^2} \left( \frac{1}{f^2} - \frac{1}{(f + \delta f)^2} \right) \quad (10)$$

where we have assumed that the value of  $k$  is independent of the mass of the structure. According to Eq. (10), the higher the resonant frequency, the higher the mass sensitivity. With the high frequencies reachable with nanostructures mass variations of the order of single molecules are potentially measurable [55–57].

Suspended nanostructures can also display torsional oscillations. Frequencies up to 18 MHz have been reported for these oscillations [51]. As for the case of transversal oscillations, the values of the frequencies depend on the geometry of the nanostructure and on material properties. A simple method to estimate them is from the relation

$$f = \frac{1}{2\pi} \sqrt{\frac{\kappa}{I_m}} \quad (11)$$

where  $I_m$  is the polar mass momentum of inertia of the system and  $\kappa$  is the torsional spring constant defined previously (this expression is correct except for a numerical factor that can be calculated by using the methods of classical elasticity theory).

It is worth noting that the precise dependence of the torsional frequencies of oscillation on the nanostructure properties is completely different from the one corresponding to transversal oscillations. This fact can be illustrated with a nanopaddle (see Fig. 5), a nanostructure able to display

**Figure 5.** Scanning electron micrograph of a nanopaddle. Reprinted with permission from [50], S. Evoy et al., *J. Appl. Phys.* 86, 6072 (1999). © 1999, American Institute of Physics.

both types of oscillations and which has received some attention in the scientific literature [50, 51, 61]. The equivalent torsional spring constant of the two beams subjected to the central rectangular part can be calculated from Eq. (6); that is,

$$\kappa = 2\beta(a/b) \frac{b^3 a}{L} G \quad (12)$$

where the factor 2 affords for the fact that there are two beams subjected to the central structure. Moreover, the mass momentum of inertia of the central part of the paddle (we neglect here the contribution of the beams) is  $I_m = (1/12)md^2$ . Therefore, according to Eq. (12) the fundamental torsional frequency of oscillation of the nanopaddle can be approximated by

$$f = \frac{1}{2\pi} \sqrt{\frac{G}{\rho}} \sqrt{\frac{b^3}{Lwd^3}} \quad (13)$$

On the other hand, by using Eq. (9) the fundamental frequency of transversal oscillations can be taken to be

$$f = \frac{1}{2\pi} \sqrt{\frac{k}{\rho a w d}} \quad (14)$$

with  $k$  being the equivalent spring constant for deflections and which depends only on the properties of the nanobeams but not on the ones of the nanopaddle. As can be seen the frequencies of the torsional and transversal oscillations depend on the width of the nanopaddle as  $d^{-3/2}$  and  $d^{-1/2}$ ,

**Table 2.** Fundamental frequency of oscillation for a single clamped Si nanocantilever for different geometries as calculated from Eq. (8).

$L \times w \times t$ ( $\mu\text{m} \times \mu\text{m} \times \mu\text{m}$ )	$10 \times 0.2 \times 0.1$	$1 \times 0.2 \times 0.1$	$1 \times 0.05 \times 0.05$
Fundamental frequency (MHz)	0.76	75.7	37.8

*Note:* The bulk Si Young modulus is used in the calculations. The frequencies corresponding to double clamped structures can be obtained by simply multiplying by 12.

respectively. These dependencies have been experimentally verified for Si [50] and SiN [51] nanopaddles.

### 3.1.3. Quality Factor

Real resonant structures lose their mechanical energy due to the action of different energy loss mechanisms, generically known as damping mechanisms. This means that in order to keep the nanostructure in motion, energy must be pumped to the resonant structure. The same energy loss mechanisms also induce a broadening of the response of the nanostructure at the resonant frequency, thus reducing considerably the sensitivity for many applications.

The effects of damping on a resonant nanostructure can be understood in a simple way by approximating it by a simple harmonic oscillator subject to friction (proportional to the velocity) and a sinusoidal external driving force with frequency  $f$  and amplitude  $F_0$ . Under these conditions the structure oscillates with frequency equal to the external forcing frequency and with amplitude given by

$$A(\omega) = \frac{\frac{F_0}{m}}{\sqrt{(\omega^2 - \omega_0^2)^2 + \frac{\omega^2 \omega_0^2}{Q^2}}} \quad (15)$$

where  $\omega_0 = 2\pi f_0$  and  $\omega = 2\pi f$ , with  $f_0$  and  $f$  being the natural and forcing frequencies, respectively,  $m$  the mass of the nanostructure, and  $Q$  a dimensionless parameter known as quality factor whose value is determined by the damping mechanisms. In the absence of any damping effects, the quality factor is infinity and the amplitude diverges at the natural frequencies of oscillation. When damping is present the resonant frequency remains almost unchanged (in the usual case that  $Q \gg 1$ ), but the height and width of the resonance are significantly modified, as illustrated in Figure 6. The height and width of the resonance in the presence of damping can be approximated by

$$A_{\max} \sim \frac{F_0 Q}{m \omega_0} \quad \text{and} \quad \Delta f \sim \frac{f_0}{Q} \quad (16)$$

respectively.

A physical interpretation of the quality factor is that  $Q^{-1}$  gives the fraction of energy loss by the resonator in one oscillation or conversely  $Q$  gives the number of oscillations the oscillator performs before losing completely its energy.

**Figure 6.** Response of a resonator for different levels of damping as a function of frequency.

In resonant nanostructures the values of  $Q$  depend on both intrinsic and extrinsic damping mechanisms [12]. The extrinsic mechanisms include air damping, clamping losses at supports, or coupling losses mediated through the transducers. In particular, viscous damping in ambient conditions is known to be the greatest source of dissipation in MEMS and NEMS structures at atmospheric pressures. Intrinsic damping mechanisms include defects in the bulk or interfaces, fabrication-induced surface damage, adsorbates on the surfaces, or viscoelastic loss mechanisms [62–65] (e.g., thermoelastic damping). Some of these anelastic loss mechanisms can be minimized by a careful choice of the materials, processes, and handling. However, some of them are inherent (e.g., thermoelastic damping), thus imposing an ultimate upper bound to the attainable  $Q$ 's. Intrinsic loss mechanisms related to surface effects have been suggested to play a relevant role in resonant nanostructures due to the high surface to volume ratios [60]. Also the presence of a metallic layer covering the nanostructure has been demonstrated to decrease the quality factor [51, 66].

The relevance of the extrinsic versus intrinsic damping mechanism depends very much on the operation conditions [67]. For pressures in low vacuum extrinsic damping is negligible and only intrinsic damping affects the resonator (internal friction). Experimentally this region happens roughly below 10–100 Pa for microresonators. The highest values of  $Q$  have been obtained under these conditions. For intermediate pressures momentum transfer between the resonator and individual ambient molecules dominates the damping. By neglecting the interaction between the molecules in the ambient the quality factor can be shown to depend inversely on the pressure. This region typically ends around  $10^3$  Pa. Finally for high enough pressures for which the interaction between ambient molecules is relevant, viscous damping dominates. In this regime the quality factor is inversely proportional to the fluid viscosity and takes very low values [68]. In this case, methods of quality factor control can be envisaged to keep functionality of NEMS [68–70].

Experimental results have reported values of  $Q$  in the range from  $10^2$  to  $10^4$  for resonating NEMS [the higher values have been obtained in ultrahigh vacuum (UHV) conditions]. Some of these values greatly exceed those typically available from electrical resonators, although they are orders of magnitude smaller than the values expected from fundamental loss mechanisms. In fact, the maximum attainable value of  $Q$  seems to scale downward with the linear dimension of the resonator when going from the macroscopic to the nanoscale domain [12] (the linear dimension of the resonator is roughly estimated as  $V^{1/3}$ , where  $V$  is the volume of the nanostructure). Currently, there is no clear understanding of the underlying physics determining this unexpected phenomenon.

Damping phenomena always carry with them other phenomena like fluctuations. For instance, a simple harmonic oscillator in the presence of damping experiences random forces whose mean is zero and whose spectral density is given by [12]

$$S_f(f) = \frac{4k_B T \kappa}{2\pi f_0 Q} \quad (17)$$

where  $k$  is the equivalent elastic spring constant of the resonator and  $f_0$  is the fundamental frequency of oscillation. The presence of these fluctuations is unavoidable and limits, among other things, the minimum measurable forces.

Finally, through the quality factor and natural frequencies of oscillation one can estimate the minimum pump energy rate necessary to keep the nanostructure in motion to be [12]

$$P_{\min} \sim \frac{k_B T}{Q} f_0 \quad (18)$$

where  $k_B T$  is the thermal energy and  $f_0/Q$  is the rate at which the resonator exchanges energy. The high  $Q$  values attainable in NEMS imply that a very small amount of power is required to drive the devices, which constitutes one of the big advantages of these systems for communication applications with respect to high frequency microelectronics.

### 3.1.4. Other Factors Determining the Performance of Suspended Solid-State NEMS

In solid-state freestanding NEMS there are other factors, in addition to the ones considered previously, that can alter its performance. These factors should be taken into account when analyzing or designing suspended solid-state NEMS.

**Weight of the Nanostructures** In the estimations performed previously of the equivalent elastic spring constant the effect of the mass of the nanostructure has been neglected. This approximation holds as long as the forces applied to the nanostructure are much larger than the weight of the nanostructure. To give an order of magnitude we note that a  $10 \times 0.2 \times 0.1 \mu\text{m}^3$  Si cantilever weighs  $W = mg = Lwt\rho g = 4.66 \times 10^{-15}$  N while a  $1 \times 0.05 \times 0.05 \mu\text{m}^3$  does  $W = 5.8 \times 10^{-17}$  N (we have taken for the density of Si  $\rho = 2330 \text{ kg/m}^3$ ). Therefore, this effect is not expected to be relevant for most of the applications.

**Phase Noise** The extremely high mass sensitivity of the resonators is predicted to induce a high level of phase noise (i.e., fluctuations in the value of the resonating frequency), the reason being that when operated in air or liquids adsorbates are expected to adsorb and desorb from the surfaces in a random way, thus changing the mass of the resonator and hence the natural resonant frequency. Another source of phase noise can be temperature fluctuations or similar phenomena affecting the resonant frequency [71, 72].

**Nonlinearities** Nonlinear effects are easily observable in suspended solid state nanostructures [42, 44, 60, 73]. The onset of nonlinear effects can occur for small applied forces (and hence lower input power) in large aspect ratio structures. In nanostructures nonlinear effects have been observed for displacements as small as 10–15 nm. A signature of the nonlinear behavior is the presence of an asymmetric resonant response. The nonlinear behavior can be harnessed to create parametric oscillators and possibly could be used to create highly sensitive resonant charge [73], force, and mass sensors [12].

**Strain Effects** In many electromechanical systems bi- or multilayered structures are very often used. In these structures the presence of internal strain or stress is almost unavoidable. Moreover, even for homogeneous mechanical devices (e.g., those patterned from doped semiconductors materials), surface nonidealities may impart significant modifications to the free strain picture. Strain is well known to induce modifications in the values of the equivalent spring constant and resonant frequencies in addition to additional losses. This property has been used to develop state of the art nanomechanical chemical [74] and biological sensors [75]. In the former case use has been made of the fact that analyte molecules chemisorbing or physisorbing on a coated nanocantilever and chemical reactions produce interfacial stress between analyte molecules and the cantilever. In the latter case, the surface strain is induced by a self-assembled monolayer grown on top of one side of a cantilever when it interacts with specific molecules [75]. The induced strain comes from the changes in the configurational entropy and intermolecular energetics of the self-assembled monolayer [76].

**Finite Size Effects** In most of the experiments reported in the literature the values of the Young modulus obtained differ from the value corresponding to bulk materials (usually lower values are observed [37]). It has been suggested that effects due to the finite nature of the structures (finite size effects) could be responsible for such deviations. A theoretical understanding of this phenomenon is still lacking.

**Atomistic Behavior** When going down to smaller scales, one can ask at what scale continuum mechanics breaks down and corrections from atomistic behavior emerge. Molecular dynamics simulations [77] for ideal nanostructures appear to indicate that this becomes manifest only at the truly molecular scale, of the order of tens of lattice constants in cross-section. Hence, for most of the suspended nanostructures the continuum approximation will be adequate.

**Heating Effects** Due to the presence of losses the materials can heat up and as a result the frequency and the spring constant can vary due to changes in dimensions, density, strain, etc. Although it was forecast that these small structures should dissipate heat very efficiently [1], investigations are still on the way to establish the appropriate heat transport laws for nanostructures [47, 78, 79].

**Quantum Effects** The ultimate limit for suspended nanostructures is to operate at, or even beyond, the quantum limit [12, 80]. This regime can be defined by the condition that a mechanical quantum,  $hf_0$ , where  $h$  is the Planck constant and  $f_0$  is the resonant frequency, is of the order of, or greater than, the thermal energy  $k_B T$ . In the quantum regime jumps between discrete quantum mechanical states should be observable. As a rule, very high frequencies and very small temperatures are required (for instance 1 GHz corresponds to 50 mK in temperature). In order to reach the quantum limit a number of challenges have to be overcome, among others, the experimental definition of the resonator discrete quantum states, the development of transducers able to resolve an individual quantum jump, or the cooling of the resonator to very low temperatures in the presence of loss mechanisms [12]. The quantum limit for mechanical

nanoresonators opens fascinating possibilities in the measurement sciences at the molecular level, in the development of new device possibilities for phase coherent measurements and quantum computation or in the control of thermal transport involving the exchange of individual phonons. Furthermore, in this limit the wave nature of matter will become manifest and the division between quantum optics and solid state physics is expected to become increasingly blurred.

### 3.2. Actuating and Sensing Solid State Suspended Nanostructures

Up to now we have focused on the physical properties of suspended solid-state nanostructures for NEMS applications. In addition to the mechanical part, essential components of any NEMS are the transducers in charge of actuating and sensing the mechanical part of the device. For NEMS applications the transducers must be able to detect minute displacements, induce minute forces, detect very high frequencies, or detect very small frequency shifts. Most of these actions are very challenging in the NEMS domain. Below we report the techniques currently available to actuate and sense solid-state suspended nanostructures.

#### 3.2.1. Electrostatic Actuation

Electrostatic transduction is the method most widely employed in MEMS and can also be applied to NEMS [33, 56, 57]. The principle of actuation of this technique is very simple. It consists of charging electrically the nanostructure and then actuating on it by means of the electrostatic interaction with an external charged element (e.g., a charged substrate), often referred to as the driver. To apply this technique the mechanical element has to be a good conductor or have been recovered by a good conductor. Two examples of driver-free standing nanostructures are shown in Figure 7.

This method of actuation allows both static and dynamic actuation depending on whether a constant or variable potential is applied between the nanostructure and the driver. In the latter case, the system can eventually be driven into resonance.

Several factors determine the actual motion induced to the nanostructure by the driver. Among others we cite the geometry of the nanostructure, the geometry of the driver, the coupling between both elements, the environment (air, liquid, UHV), the way the nanostructure is fixed, the damping mechanisms, or even the relevance of the Casimir effect [81, 82].

#### 3.2.2. Magnetomotive Actuation

Magnetomotive actuation [42, 83] makes use of the Lorentz force (i.e., the force exerted by a magnetic field on an electric current). It uses a setup like the one schematically shown in Figure 8, which consists of a closed conducting circuit, which includes the moving mechanical element, located in a strong magnetic field perpendicular to the nanostructure. When a dc current passes through the circuit a force perpendicular to the electric current appears that eventually can bend the suspended nanostructure. For electric current varying with time a dynamic motion can be induced to the nanostructure. This method of actuation also requires electrically conducting nanostructures.

Abadal et al., *Nanotechnology* 12, 100 (2001). © 1999/2001, Institute of Physics Publishing.

#### 3.2.3. Secondary and Local Actuation

The secondary actuation method consists of using a piezoelectric or another actuator to oscillate the supports where the resonant nanostructure is suspended (Fig. 9a). In scanning probe microscopes this is sometimes the method used to set into resonance the tip. Local actuation [84] consists of using a nanoelement whose dimensions are smaller than the nanostructure (e.g., an STM or AFM tip) to locally induce a motion in the nanostructure (Fig. 9b). This method works better the larger the nanostructure. Both methods

**Figure 8.** Schematic drawing of a freestanding nanostructure magnetomotively actuated.

**Figure 9.** Schematic drawing of a nanostructure actuated by (a) secondary actuation and (b) local actuation.

have the advantage of not requiring electrically conducting nanostructures.

### 3.2.4. Actuation by Means of Internal or Superficial Strain

As mentioned before internal or superficial strain can produce the bending of freestanding nanostructures and hence offers a method to actuate them. One way to implement this method has been to use bi- or multilayered structures, with layers having different thermal expansion and light absorption coefficients [85]. When such a nanostructure is irradiated with a continuous wave laser and a standing wave is formed between the freestanding structure and the support, then the more absorbing layer absorbs more energy, and heats up more, than the lower absorbing layer (Fig. 10). Due to the different thermal expansion coefficients of the two layers a strong strain is induced in the nanostructure that eventually can bend it. If the amplitude of the laser light is appropriately modulated a resonant behavior can be induced by this method.

A similar technique can be implemented in a monolayered nanostructure by irradiating only one part of it [86–88]. In this way a temperature gradient can be induced in it that produces the modulation of the elastic constant and hence the bending of the nanostructure.

### 3.2.5. Electrostatic Sensing

Electrostatic sensing of a free suspended nanostructure can be accomplished by measuring the changes in the capacitance of the capacitor formed by the suspended nanostructure and the driver (see Fig. 7). In the case of a resonant structure the equivalent circuit of the system is more complicated than a simple capacitance, but this method can be equally well applied to measure the motion frequencies [56, 57].

Electrostatic sensing, initially developed for MEMS, does not scale well into the domain of NEMS [12]. Very small

**Figure 10.** Schematic drawing of a nanostructure actuated by means of the induction of internal strain.

electrode capacitances are to be expected for electrodes at the nanoscale, thus making parasitic capacitances dominate the dynamical capacitance of interest. One possible solution would be to eliminate the large embedding and parasitic impedances by locating a subsequent amplification stage directly at the capacitive transducer. This would make the NEMS electrode serve a dual purpose, as both the motion sensor for the NEMS and as the gate electrode of a field effect transistor (FET) readout.

### 3.2.6. Optical Sensing

Very small displacements can be detected by optical methods like simple beam deflection methods or more sophisticated optical and fiber-optic interferometry methods.

In the simple beam deflection scheme [89] a laser beam is focused on top of the nanostructure and its reflection is measured on a photodiode (Fig. 11). This method can be applied to both static deflections as well as dynamic ones. In the latter case a spectrum analyzer is usually used to analyze the frequency components of the electrical signal provided by the photodiode. Scaling down this technique to the NEMS regime can be very challenging since the nanostructure cross-section can become smaller than the size of the focused laser spot.

Interferometry methods [36, 40, 90], on the other hand, use the fact that the motion of the nanostructure modulates the reflected signal as a result of interference phenomena, thus allowing one to detect the amplitude and phase of the nanostructure motion.

For very small size NEMS applications, nonconventional optical methods, like integrated and near-field optical displacement sensors, may become a valid alternative to the above-mentioned methods [12].

### 3.2.7. Magnetomotive Sensing

Magnetomotive sensing is based on Faraday's law (i.e., on the induction of an electromotive force in a closed circuit when the magnetic flux through it changes with time). There are different ways to implement this technique.

One of them consists of using the same setup as the one used for magnetomotive actuation [39] (see Fig. 8). In this case, when the nanostructure is set into motion an electromotive force is induced in the closed circuit, whose measurement provides information on the dynamical response of the device. More elaborate versions of this method, which makes use of a balanced electronic detection [91], have been developed for some especially demanding applications.

**Figure 11.** Schematic drawing of a nanostructure sensed by a simple beam deflection scheme.

An alternative implementation of this technique could be done in the case that the moving element behaves like a nanomagnet [12]. In this case, a closed conducting loop located close to the nanostructure can be used to induce an electromotive force in it due to the nanostructure motion. This implementation can be used with nonconducting and both single and doubly clamped nanostructures.

### 3.2.8. Piezoelectric Sensing

In the case that the nanomechanical element displays piezoelectric phenomena sensing of the displacements can be achieved by measuring the voltages generated due to the piezoelectric properties. This method has been implemented with nanostructures fabricated with a piezoelectric material [35] and with GaAs/AlGaAs nanostructures [34, 46]. One advantage of piezoelectric sensing with respect to other methods is that it provides a high degree of integration.

### 3.2.9. Sensing by Means of Electron Tunnelling

Electron tunnelling currents between two conducting materials depend exponentially on the separation between them. This property is used in scanning tunnelling microscopes to image material surfaces up to atomic resolution. This same property can be used to sense small displacements in free-standing nanostructures [33], as illustrated in Figure 12. The same restrictions concerning operation conditions and material properties as for STM will apply by using this method.

### 3.2.10. Sensing by *in-situ* SEM or TEM

Finally, one can also use *in-situ* scanning electron microscopy or transmission electron microscopy to sense directly the bending or the motion of the nanostructures [84]. In this case, the usual requirements of these microscopic techniques should be satisfied by the samples.

## 3.3. Applications of NEMS Based on Solid-State Suspended Nanostructures

There is no doubt that NEMS based on solid-state suspended nanostructures will find a broad range of applications. A number of NEMS applications are being pursued, which might hold immense technological promise for fields such signal processing in very high frequency, ultrahigh frequency, and microwave bands [58, 59], ultrahigh sensitive magnetic resonance force microscopy [12], noninvasive medical diagnostics devices, BioNEMS for single molecule analysis [12], or ultra-high-density data storage systems. At present, however, most of the research efforts are centered on basic studies of fabrication approaches and on the understanding of the science of nanoscale systems. Functional NEMS devices have been demonstrated only for charge detection [49, 73] and thermal transport studies [47, 78] with relevance for metrology and fundamental science. Moreover, significant advances toward functional NEMS for ultra-precise mass sensors [55, 56] and biomolecular recognition [75, 76] have been recently reported. Based on the present developments, one can anticipate that in a decade or so, one may be seeing a prevalence of solid-state NEMS devices at the level one now finds equivalent MEMS systems [13].

## 4. NEMS BASED ON NANOFUIDIC STRUCTURES

Many potential applications of NEMS, like those involving chemical, biological, and biophysical processes, require the presence of a fluid environment and hence the use of nanofluidic structures. Nanofluidic NEMS may have dimensions in the order of hundreds to a few nanometers, thus displaying characteristic dimensions of the order of the diffusion length of molecules, the molecular sizes, or the electrostatic screening lengths of ionic conducting fluids. At these scales fluids are expected to display qualitatively new behaviors that will allow one to perform techniques and experiments not possible on the microscale. Although transport phenomena in nanoscopic structures are not well understood yet, some relevant advances have been achieved in recent years. In the present section we review the more relevant developments achieved so far in this field.

### 4.1. Physics of Nanofluidic Structures

Fluids confined in nanometric spaces (with at least one dimension in the tens to hundred of nanometers regime) have been observed experimentally and theoretically to exhibit unique structural, dynamical, mechanical, and rheological properties [92]. These properties have been shown to depend on the degree of confinement (e.g., load), operational conditions (e.g., shear rate and temperature), nature of the fluid (e.g., molecular shape, molecular size and molecular complexity), and interactions with the boundaries (e.g., chemical or physical binding) [93, 94]. The understanding of the structure and mechanical properties of fluids at these scales is then of fundamental scientific and practical interest for nanofluidics (as well as for other fields of research such as lubrication, adhesion, or wetting). Experimentally, this problem has been addressed essentially by

the use of three techniques, namely open fluid geometries in which two extremely flat surfaces are immersed to come nearly in contact, optical methods able to probe flow properties near a surface in a macroscopic container, and flow experiments in ultrasmall nanofluidic channels. Extensive molecular dynamic simulations have been developed to complement experimental findings.

In nanofluidic structures whose characteristic dimensions exceed some tens of the molecule fluid diameter, simple fluids behave like a continuum. Otherwise, for smaller structures, the molecular graininess of the fluids becomes important and a discrete molecular description must be adopted.

In the continuum regime the main difference between macro- and nano/microflows (both can be described through the Navier–Stokes equation) comes from the relevance of viscous forces. Viscosity represents the tendency of a fluid to undergo deformation when subject to a shear stress. In the case of a pure liquid consisting of simple molecules, viscosity is an intrinsic property and its value is dependent on the temperature of the fluid alone. For complex fluids, such as solutions of macromolecules, viscosity shows a complex dependence on an additional number of parameters, such as the type of solvent and concentration or molecular weight of the solute. In macroflows, the inertia of fluid mass is usually much larger than the viscous force, while in nano/microflows the opposite condition is found. The relevance of inertial versus viscous forces can be quantified through the Reynolds number, defined as the ratio between these two types of forces

$$\text{Re} = \frac{\rho v l}{\mu} \quad (19)$$

where  $\rho$  is the fluid density,  $v$  is the characteristic velocity of the fluid,  $\mu$  is the fluid viscosity, and  $l$  is a characteristic length. In nano/microfluids the Reynolds number takes low enough values as to allow neglect of the nonlinear terms in the Navier–Stokes equation, thus giving rise to laminar flows (as opposed to turbulent flows present in macrofluidics). For instance, the Reynolds number corresponding to water flow [ $\rho = 1 \text{ g/cm}^3$ ,  $\mu = 0.01 \text{ g/(cm s)}$ ,  $v = 1 \text{ cm/s}$ ] through a micropipe of  $50 \text{ }\mu\text{m}$  in diameter with smooth walls is  $\text{Re} = 0.5$ , largely satisfying the experimental condition  $\text{Re} < 2300$  for laminar flow in a pipe. The linear nature of low Reynolds fluid flows, labeled Stokes flows, can be broken in some cases due to the presence of special boundary conditions, as has been shown recently in a T-shaped microfluidic structure [95]. The laminar nature of the fluid flow in nano/microfluidic applications may have important consequences for mixing, sample concentration, and separation of species [4–9].

Although micro- and nanoflows are both laminar, there is an important difference between both, namely that in nanofluidic flows the condition of zero tangential velocity at the walls (i.e., no-slip boundary condition) does not accurately describe the flow properties. It has been recently shown that in any flow the velocity of the fluid at the walls is nonzero. This effect is characterized by means of a phenomenological slip length,  $\lambda$ , which corresponds to the distance outside the channel at which the liquid velocity extrapolates to zero. The experimental values reported

for this length range in the tens to hundred of nanometers, thus being only relevant for nanofluidic flows. The value of the slip length has been shown to depend strongly on the molecular size of the fluid and on the nature and roughness of the surface. One consequence of the presence of slip at the fluid–solid interface is that flows do not satisfy the standard Poiseuille law. The Poiseuille law describes the pressure driven flow of a fluid through a channel and states that the flow rate,  $Q$ , is proportional to the pressure drop across the channel

$$Q = \frac{\Delta P}{R} \quad (20)$$

where  $R$  is the channel resistance. For a circular geometry one has

$$R = \frac{8\mu L}{\pi r^4} \quad (21)$$

where  $L$  is the channel length,  $\mu$  is the fluid viscosity, and  $r$  is the channel radius. For the case of a rectangular channel whose width,  $w$ , and length,  $L$ , are much greater than the height,  $h$  (an appropriate geometry for nanochannels), one has

$$R = \frac{12\mu L}{h^3 w} \quad (22)$$

Recent experiments have reported significant differences between Eq. (22) and the values measured in fluid flows through nanochannels with heights ranging from  $2.7 \text{ }\mu\text{m}$  to  $40 \text{ nm}$  [96]. The discrepancies between standard theory and experiments have been accounted for by the introduction of slip. The values determined for the slip length are  $\lambda \sim 25\text{--}30 \text{ nm}$  for hexadecane,  $\lambda \sim 14 \text{ nm}$  for decane,  $\lambda \sim 9 \text{ nm}$  for hexane, and  $\lambda \sim 0 \text{ nm}$  for water (note that the larger the molecular size, the larger the slip length). At present, it is not clear how to calculate the magnitude of the slip length from fundamental theoretical principles or how it depends on factors such the molecular size, surface properties, or flow nature [97–104].

Other phenomena related to the physicochemical interaction between fluid molecules and wall molecules include “wall depletion” in dilute polymer solutions [105]. Note that, at these scales, and provided the appropriate boundary conditions are used, the nanofluid can be still treated with the Navier–Stokes flow equations in the framework of low-Reynolds hydrodynamics or “microhydrodynamics” [106].

The presence of slip in nanoflows is not the unique effect due to the confinement of fluids in nanometric structures. For very small structures, of the order of ten times the molecule diameter, effects due to the discrete molecular nature of the fluid start appearing, thus breaking down the continuum description of the fluids. A well known example is the ordering of molecules in layers when the liquid is confined by surfaces [93, 94, 107]. These density variations lead to an oscillatory solvation force which decays exponentially [104] and to a high value of the “apparent” viscosity of the fluid as high as  $10^5$  times the regular viscosity [108]. At these scales, then, the fluid loses its liquidlike behavior and assumes solidlike characteristics [107]. In this regime

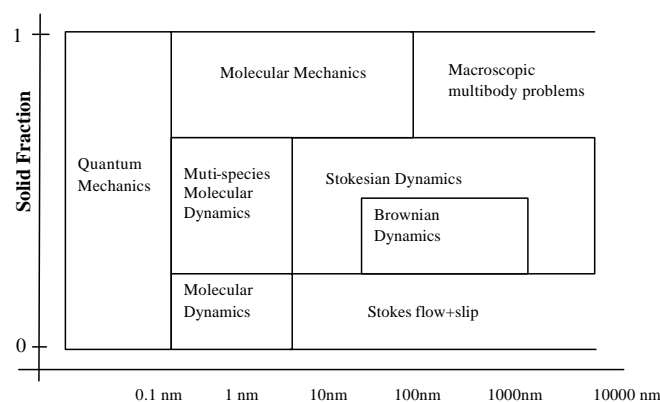

the description of the system can be carried out by means of molecular dynamic simulations.

At smaller scales, below one or two molecule fluid diameters one should resort to a quantum-mechanical description, in which the distinction between solids and fluids loses its meaning.

Nanofluidic applications involve in most of the cases the presence of “particles” embedded in the fluid. The term “particles” is used here in a broad sense and includes [7] organic molecules (a few angstroms in size), protein molecules (typical sizes from 2 to 5 nm), large biopolymers such as DNA, and suspended solid particles or cells (typically 100 nm–10 μm). At these scales, due to the large surface to volume ratios, the motion of the “particles” can be largely influenced by surface forces, thus leading to the appearance of finite size effects, not very well understood yet [7]. Moreover, the presence of even small amounts of particles in suspension can modify the rheological properties of the bulk flow resulting in non-Newtonian fluid properties. In some instances, non-Newtonian fluids at low Reynolds number have been shown to display turbulent-like instabilities (elastic turbulence) that could be advantageous for efficient mixing [109].

The special problems involving particles coming into close proximity can be analyzed using the “Stokesian dynamics” approach, where hydrodynamic effects are split into “far field” and “near field” components [110]. A particular case is the analysis of Brownian effects in the so-called “Brownian dynamics.” Stokesian and Brownian dynamics can be regarded as large-scale versions of the molecular dynamics. The interaction of macromolecules with a surrounding fluid phase and, in general, solvent–solute systems at these scales can be simulated by using multispecies molecular dynamics.

Figure 13 summarizes the different transport regimes encountered in nanofluidics. The vertical axis represents the solid fraction of the fluid (the value 0 corresponds to simple fluids and the value 1 to solids). Intermediate values represent solutions with different degrees of solvent). The horizontal axis, ranging from 0.1 nm to 1 μm, represents the scale of the problem or the level of description.

**Figure 13.** Phase diagram of the different transport regimes as a function of the solid fraction and the characteristic spatial scale of the problem [92].

## 4.2. Driving Forces in Nanofluidic Structures

Driving fluids and “particles” through nanofluidic structures constitute an essential issue in the development of nanofluidic applications. We review the properties of the basic forces used for this purpose. For the sake of clarity, we distinguish between forces used to drive fluids and forces used to drive the particles with respect to the fluids.

### 4.2.1. Driving Forces for Fluid Flows

**Hydrodynamic Pressure** Hydrodynamic pressure is the primary force driving fluids in macroflows, but it may be impractical in nanopassages, since the resistance to fluid flow increases with the inverse of the fourth power of the transversal channel dimensions [see Eq. (22)]. This means that in order to reach practical fluid flows very high pressures may be required that in turn may require specific fabrication processes. Furthermore, the sensitivity of the resistance to channel geometry imperfections becomes very high, thus not enabling accurate control of the fluid flow. Finally, actuators inducing the pressures necessary are not easily integrated in lab-on-a-chip systems.

For these reasons, and because they also allow selective driving of the embedded “particles,” electrokinetic forces have been preferred by many researchers in micro/nanofluidics.

**Electroosmosis** Electroosmotic flow [111] is related to the motion of an ionic fluid induced by a dc potential applied along the stream. The electroosmotic flow arises from the fact that the surfaces of a flow channel are generally charged or can be made so with a suitable coating, thus inducing a layer of charged ions next to them. The ionic layer consists of a space charge region composed by a rigid sheet of solvated ions bound to the charged surface (known as Helmholtz layer) followed by a region of mobile ions beyond the Helmholtz layer, with a characteristic dimension given by the Debye screening length (whose value can range from nanometers for high ionic concentrations to μm for deionized water). This charged mobile layer can be made to move by the application of an electric potential, dragging the neutral fluid along with it. The resulting velocity profile is constant across the channel and its value can be estimated from

$$v = \frac{\epsilon E \xi}{\mu} \quad (23)$$

where  $E$  is the tangential electric field,  $\epsilon$  is the permittivity of the medium, and  $\mu$  its viscosity. Moreover,  $\xi$  is the zeta potential (i.e., the potential difference across the mobile part of the double layer). External electrical control of the zeta potential by the application of a transversal electric field has been recently demonstrated [112], thus offering enhanced performance of electroosmotic control of fluid flows. Note that the fact that the velocity profile is flat (as opposed to the parabolic profile of a Poiseuille flow) is advantageous for nanofluidic applications since it introduces less dispersion in the sample. More complicated, nonuniaxial fluid motion can be generated with electroosmotic forces by creating charged patterns along the walls of the channels [113].

Recently, it has been suggested that an ac electric field can induce a more complicated, and sometimes useful, electroosmotic force [114, 115]. The existing theory is nowadays

still far from exactly matching the experimental data for high voltages and medium conductivities, even in its enhanced version [116], and it is still under controversy with other theories developed [117]. Despite all these drawbacks, this theory still seems able to capture the fundamental features of the frequency behavior of low frequency fluid movement experimentally measured in structures with microelectrodes.

**Electrocapillarity** Capillary forces constitute a valid alternative since they can generate large forces in small channels. They require a discontinuity such as an air/liquid interface or immiscible liquids and seem appropriate for filling devices or single-use applications [6]. In recent years, external electrical control of capillary forces (electrocapillarity) has been demonstrated in micro/nanofluidic structures. Electrocapillary fluid motion refers to the motion induced by electrostatic control of the solid/fluid interfacial tension in a micro/nanochannel [118]. The principle of electrocapillarity actuation is based on the fact that the capillary pressure on a fluid/fluid meniscus inside a micro/nanochannel can be controlled by the charge density accumulated at the solid/fluid interface. Based on this phenomenon, and by inserting electrodes inside the walls, control of the fluid motion can be achieved, in some cases in a more efficient way than with electroosmosis [118].

#### 4.2.2. Driving Forces for “Particles” in Fluids

**Viscous Drag** As is well known any particle moving with respect to a fluid experiences a drag force due to viscous forces. In the case of a rigid particle the drag force can be approximated by (we assume a spherical particle of radius  $a$ )

$$F_{\text{drag}} = 6\pi\mu av \quad (24)$$

where  $v$  is the velocity of the particle relative to the fluid and  $\mu$  is the fluid viscosity. For nonrigid particles (e.g., large polymers and macromolecules) the equivalent of the drag force is more complicated to evaluate. The drag force can be approximated by Eq. (24) as long as the size of the “particle” is much larger than the fluid molecule size.

**Electrophoretic Force** The electrophoretic force refers to the electrostatic force acting on a charged particle embedded in a neutral medium in response to an external applied field. The magnitude of the force is easily calculated as

$$\vec{F} = Q\vec{E} \quad (25)$$

where  $Q$  is the charge of the particle and  $\vec{E}$  is the electric field. Moderate voltages applied to short distances, such as the ones characteristic of nanofluidics, give rise to high enough electrophoretic forces to impart significant velocities to the embedded particles. Electrophoretic forces are very often used to separate different species having different sizes. In ionic or polar fluids the presence of other forces can perturb the simple picture presented.

**Dielectrophoretic Force** For neutral particles one has to resort to dielectrophoretic forces to drive the particles with respect to fluids [119]. The origin of this force is found on the electric dipole induced on a neutral particle when an external electric field is applied. The magnitude of the force can be evaluated as follows. Let us represent the electric properties of a dielectric spherical particle of radius  $a$  by means of a complex permittivity of the form

$$\varepsilon_p^* = \varepsilon_p - j\frac{\sigma_p}{\omega} \quad (26)$$

where  $\varepsilon_p$  is the dielectric constant of the particle,  $\sigma_p$  is its conductivity, and  $\omega$  is the frequency of the applied field. Let us suppose that the particle is immersed in a dielectric fluid medium of permittivity

$$\varepsilon_m^* = \varepsilon_m - j\frac{\sigma_m}{\omega} \quad (27)$$

and subjected to an uniform z-directed ac electric field of magnitude  $E_0$  and radian frequency  $\omega$ . Under these conditions the particle presents an effective dipolar momentum given by

$$p_{\text{eff}} = 4\pi\varepsilon_m a^3 \left( \frac{\varepsilon_p^* - \varepsilon_m^*}{\varepsilon_p^* + 2\varepsilon_m^*} \right) E_0 \quad (28)$$

Due to this effective dipolar momentum, a net force, called dielectrophoretic force, acts on the particle [119]

$$\vec{F}_{\text{DEP}}(\omega) = 2\pi\varepsilon_m a^3 \text{Re} \left( \frac{\varepsilon_p^* - \varepsilon_m^*}{\varepsilon_p^* + 2\varepsilon_m^*} \right) \vec{\nabla} |E_{\text{rms}}|^2 \quad (29)$$

where  $E_{\text{rms}}$  is the root mean square value of the electric field. As can be seen this force, due to its dipolar origin, only appears when spatially nonhomogeneous electric fields are present. One of the most interesting features of the dielectrophoretic force is its frequency-dependent behavior. Depending on the electric field frequency and the particle properties, the dielectrophoretic force can attract or repel the particle to the electrical field minima or maxima. When the particle is attracted to the electric field maxima it is said to have a positive dielectrophoretic behavior ( $p$ -DEP). In the opposite case, one refers to a negative dielectrophoretic behavior ( $n$ -DEP). The two behaviors are illustrated in Figure 14 where we display the simulated frequency dependence of the dielectrophoretic force for a 297 nm latex sphere within a medium of conductivity 17  $\mu\text{S}/\text{cm}$  at three different voltages. As can be seen, at low frequencies a  $p$ -DEP region appears due to the greater conductivity of latex particles in front of that of the medium. At higher frequencies an  $n$ -DEP region is observed due to the fact that the medium has a greater permittivity than the particle for these frequencies.

Dielectrophoretic forces have been shown to be able to manipulate or collect tobacco mosaic virus (about  $300 \text{ nm} \times 18 \text{ nm}$ ) [120], macromolecules [121], or bacteria [122, 123] without significant disturbance from Brownian motion.

**Figure 14.** Simulated dielectrophoretic force acting on submicrometric latex sphere as a function of the frequency of the applied electric field. Both positive and negative dielectrophoretic behaviors are observed.

**Electrothermal and Other Forces** Other forces exist which are also likely to cause movement in the particles or in the fluid. In addition to gravity (which causes sedimentation) and the van der Waals forces responsible for adhesion, there are electrothermal forces [124], which can cause movement of fluid due to gradients in permittivity and conductivity induced by the temperature gradient in the points where the electrical fields have their strongest nonhomogeneities. Although these forces can become significant at high voltages, it seems not to be relevant compared to the other forces at the typical scales. Nevertheless, as not all the experimental effects are yet fully understood, none of them can be absolutely disregarded in advance. Accordingly, each particular micro/nanoelectrofluidic system must accurately analyzed.

**Brownian Motion** Brownian motion is a stochastic process consisting of the irregular motion of a particle embedded in a fluid due to the random forces imparted by the fluid molecules. On average the forces, and hence the displacement, are zero, but the mean square displacement is not. In a simple one-dimensional picture the mean displacement is given by

$$|\Delta x|^2 = 2Dt \quad (30)$$

where  $t$  is the time variable and  $D$  is the diffusion coefficient of the particle whose value is related to the fluid viscosity. For the case of a spherical particle of radius  $a$  this relation is given by

$$D = \frac{k_B T}{6\pi\mu a} \quad (31)$$

Most often, the Brownian motion is seen as a nuisance that induces dispersion of the particles in a fluid. However, in recent years a positive role to this movement has been identified in nanofluidic applications, as will be discussed.

### 4.3. Applications of NEMS Based on Nanofluidic Structures

Nanofluidic structures provide powerful tools for the field of biotechnology. They have been used for the direct manipulation and analysis of single biomolecules such as stretching genomic DNA in extremely small nanochannels, in scanning for bound transcription factors [125], or to sort DNA molecules [126, 127]. The techniques developed so far make use of the particular properties displayed by long biopolymers in confined fluids, in which the structure dimensions are comparable to the diffusion length or the gyration radius of single biomolecules. Present nanofluidic structures used are still simple and very far from the complexity reached with microfluidics [11]. However, they offer fascinating possibilities not available in microfluidics. We describe the more relevant nanofluidic applications developed so far for biotechnology.

#### 4.3.1. Sorting Biomolecules by Rectification of the Brownian Motion

This technique consists of using the fact that an asymmetric disposition of obstacles in a nanofluidic structure is able to rectify the Brownian motion of molecules in structures with characteristic dimensions of the order of the diffusion length of the molecules. Based on this principle, and due to the relationship between diffusion coefficient and molecular size, a technique to separate macromolecules with different sizes can be developed. This technique has been demonstrated in [126], where a sieve consisting of a two-dimensional lattice of microobstacles disposed in an asymmetric way was used to sort DNA molecules according to size. In the system the DNA molecules were driven through the device by electrophoretic forces [128]. A similar principle has been also used to sort phospholipids in a two-dimensional fluid bilayer [129].

#### 4.3.2. Scanning the Local Structure of Single Macromolecules

The fact that long macromolecules stretch when passing through nanochannels makes it possible to locally probe the structure of the molecules as they move through the device. In order to implement this technique two basic requirements have to be satisfied, namely a good stretching of the macromolecules in the channel (this requires channel dimensions smaller than the persistence length of the macromolecule) and a high local sensing resolution. This technique has been implemented recently for analysis of double stranded DNA molecules [128, 130]. The device consists of a flow geometry in which molecules are driven by an external applied bias through a microchannel with narrow slits on it (see Fig. 15). Based on near-field optical effects the molecule can be probed when passing over the slit regions. Initial resolution was limited to 200 nm. Recent progress in the fabrication of smaller channels (fabrication of arrays of millions of nanochannels (10 nm × 50 nm) over a 100 mm wafer using nanoimprinting lithography to stretch, align, and analyze long genomic DNA in a highly parallel fashion has been recently reported [30, 131]) is expected to increase significantly this initial resolution level [125].

#### 4.3.3. Sizing Macromolecules

With present fabrication technologies it is possible to build nanofluidic structures small enough as to facilitate single molecule detection and minimize events of simultaneous passage of more than one molecule through the region of measurement. This opens the possibility to develop devices able to determine the distribution and relative proportions of fragments of individual macromolecules, as well as to determine the overall concentration from a single experiment. This technique has been recently implemented for DNA fragment sizing [132]. The device consisted of a T structure in which the smaller regions presented sub-micrometric dimensions. The DNA molecules were passed through the device by means of an external applied field (electrophoretic force) and were detected by means of fluorescence based optical methods. Speeds as high as 5 mm/s were reached corresponding to a few milliseconds of analysis time per molecule.

#### 4.3.4. Separation of Macromolecules by Means of Entropic Traps

Linear polymers tend to form a compact random coil in free solution. For them, it is thermodynamically unfavorable to spontaneously elongate since large free energies to reduce entropy would be required. In confined nanostructures a different behavior has been observed in recent years, and new insights for understanding the confinement-mediated entropic behavior of biopolymers in ultrasmall nanoscale fluidics have started to emerge [127, 133]. In particular, it has been demonstrated that in channels comprising narrow constrictions and wider regions size dependent trapping of DNA molecules occurs at the onset of the constriction. This process determines electrophoretic mobility differences among different macromolecules (surprisingly enough, longer macromolecules move faster than shorter ones) thus enabling efficient separation methods. A demonstration of this method has already been implemented [134] and developed up to a parallel performance [127, 135].

A similar technique has been implemented in the separation of DNA molecules in a device that presented an abrupt interface between regions of vastly different configuration entropy [133, 136]. Based on the same physical principles a separation method based on the motion of macromolecules within a two-dimensional array of interconnected spherical nanocavities has been suggested recently [137].

## 5. MOLECULAR NEMS: THE ULTIMATE MINIATURIZATION LIMIT

As mentioned in Section 1 the ultimate limit in NEMS miniaturization will be reached when the active parts of the devices consist of single molecules or atoms. In this section, and in order to illustrate the great potentialities of molecular NEMS, we review some of the advances performed in this field in recent years. Most of the cases are based on carbon nanotubes but some of them also refer to other molecules and biomolecules, including nanomechanical structures powered by molecular biomotors.

### 5.1. Molecular NEMS Based on Carbon Nanotubes

Carbon nanotubes constitute ideal molecular nanostructures for the fabrication of NEMS devices due to their exceptional mechanical and electrical properties. Carbon nanotubes present a cross-sectional area in the range from a few nanometers up to tens of nanometers and a molecular length in the range from tens of nanometers to micrometers. Furthermore, they display a very high Young modulus (in the TPa regime) and can be both semiconducting and metallic.

The simplest NEMS based on a carbon nanotube consists of a freestanding nanotube, for instance a single clamped nanotube. Due to its exceptionally high Young modulus very high natural frequencies of oscillation are expected for these structures. A rough estimation of these natural frequencies of oscillation can be obtained from the classical expression of a single clamped empty cylinder,

$$f_n = \frac{C_n^2}{8\pi} \frac{1}{L^2} \sqrt{D^2 + D_i^2} \sqrt{\frac{E}{\rho}} \quad (32)$$

where  $D$  and  $D_i$  are the outer and inner diameter,  $E$  is the elastic modulus (which can be identified with the Young modulus of the material if the beam bends by elongation of the outer arc and compression of the inner arc),  $\rho$  is the density,  $C_n$  is a constant for the  $n$  harmonic ( $C_0 = 1.875$  for the first harmonic), and  $L$  is the length of the nanotube. By substituting characteristic values for a nanotube, frequencies in the GHz domain are naturally obtained. Up to now experiments have been performed with long carbon nanotubes and thus lower frequencies (in the MHz domain) have been measured [138, 139].

In addition to its use in freestanding NEMS, carbon nanotubes offers many other possibilities for NEMS applications. One of these applications is in the development of very low friction nanoscale linear bearings [140]. This device uses the retraction force induced by the van der Waals interaction when different shells of a multiwalled carbon nanotube are

pulled apart. The absence of frictional forces (dissipation) in the process opens the possibility to develop high frequency-high  $Q$  resonators [141].

Other applications of carbon nanotubes to NEMS are based on the possibility to actuate electrically these molecules. Among them we find nanotweezers and nanoelectromechanic memories.

The nanotube based nanotweezers [142] consist of two metal arms with a carbon nanotube attached on each of them (see Fig. 16). By applying a bias between the two metallic arms the nanotubes become electrically charged, and then interact with each other. By an appropriate choice of the value of the applied bias the nanotube separation can be adapted at will. The nanotweezers can be used to grasp nanometric objects or to measure the conducting properties of nanoscale objects (by using the nanotubes tweezers as alligator clips).

The nanoelectromechanic memory concept [143] is based on the same principles as the nanotweezers. It consists of a carbon nanotube suspended on top of another nanotube (or a nanowire) in a crossbar configuration (see Fig. 17). By playing with the elastic energy, the van der Waals energy, and the electrostatic energy, one can create a bistable system in which the nanotubes are either in noncontact (OFF state) or in contact (ON state). In order to sense the state of the system the current flowing between the two nanotubes can be used. Indeed, when the applied bias between the nanotubes is small and the system is in the OFF state (not in contact) the electric current between the nanotubes takes place only by tunnelling and is very small. In contrast, when the applied bias reaches a critical value and the system moves to the ON state (in contact) the electric current between the nanotubes increases significantly, thus allowing one to distinguish between the ON and OFF states.

Finally, carbon nanotubes [144] offer great potential for nanofluidic applications [145, 146]. Carbon nanotubes provide cylindrical nanochannels similar to pipes used in macrofluidics, with inner diameters of less than 10 nm and wall thicknesses that may exceed the inner diameter. At present, a lot of effort is devoted to understanding the nanofluidic properties of carbon nanotubes. On the one hand it is believed that the interaction of fluid molecules with the nanotube walls could be conceivably so strong as to prevent through-flow. On the other hand, capillary forces can facilitate filling of thin channels in case of good wettability of the solid wall surface by the fluid [147]. Wetting of nanotubes by liquid metals, salts, oxides, and  $\text{HNO}_3$  has been studied [148] and it has been shown that some liquids could be sucked into nanotubes due to capillary forces [149,

**Figure 16.** Nanotweezers based on carbon nanotubes.

**Figure 17.** Crossbar configuration for a nanomechanical random access memory.

[150]. Studies of the wetting and capillarity of carbon nanotubes demonstrate that only relatively low-surface-tension materials can be drawn inside nanotubes [151]. The reported cutoff value of surface tension of 100–200 mN/m is sufficiently high to allow water and organic solvents to wet and fill the interior of carbon nanotubes. Simple experiments of placing a water droplet (surface tension 73 mN/m) on the surface of a carbon nanotube bundle showed the water to be readily sucked into the capillary channels, eventually leaving a dry surface [152]. The behavior of fluids in nanotubes may differ fundamentally from that in macroscopic pipes or even microcapillaries [153, 154]. The major obstacle to *in-situ* experimental studies of fluid behavior in nanotubes has been the rarity of such systems filled, at least partially, with fluids [155]. A recently suggested hydrothermal method of nanotube synthesis has produced nanotubes with an encapsulated aqueous fluid, which includes segregated liquid and gas, and well-defined interfaces [156].

## 5.2. Molecular NEMS Based on Other Molecules

In principle, any molecule or biomolecule is suitable to be characterized electrically and mechanically. This opens the possibility to develop molecular NEMS based on practically any single molecule or biomolecule. We illustrate this possibility with two examples that have already been realized in practice.

The first example refers to an electromechanical transistor based on a  $\text{C}_{60}$  molecule [157, 158]. It consists of a  $\text{C}_{60}$  molecule adsorbed onto a conducting substrate which is actuated on the other side by a scanning tunnelling microscope tip (Fig. 18). The conductance of the system can be seen to depend on the compression applied to the molecule. Indeed, when compression is applied to the molecule the molecular orbitals change due to the modification of the interatomic distances. As a result, the highest occupied molecular orbital and the lowest unoccupied molecular orbital broaden and shift, thus increasing the weight of the tails of these levels at the electrode's Fermi

**Figure 18.** Schematic drawing of the operation of a single molecular electromechanical transistor.

**Figure 19.** Schematic drawing of the operation of a single protein nanobiosensor.

energy, and hence the conductance of the system (in the tunnel regime the conductance depends strongly on the occupancy of the energy band at the Fermi energy). Similar behaviors have been found for other molecules [159].

The second example consists of a single protein based nanobiosensor. This nanobiosensor takes advantage of a structural change occurring at the level of a single protein when it binds a ligand [160]. Essentially, the nanobiosensor consists of some proteins anchored onto a conducting surface (previously functionalized) with one “end” free to move and at which a redox center is inserted (Fig. 19). The redox center can exchange electrons with the conducting substrate, with a rate of exchange depending strongly on the distance of the redox center to the substrate. When the protein binds a ligand it suffers a conformational change that modifies the distance between the redox center and the substrate thus inducing a change in the rate of exchange of electrons that can be detected.

In addition to these examples, it is worth noting that naturally occurring molecular structures, such as lipid membrane pores [161] or lipid nanotubes [162], show promising potential for applications in nanofluidics. In particular, the formation of geometrically complex lipid nanotube-vesicle networks has been reported recently [162].

### 5.3. NEMS Powered by Molecular Biomotors

A fascinating possibility of molecular NEMS is to power them by means of molecular biomotors. Molecular biomotors convert chemical energy into mechanical energy and are able to generate forces compatible with currently available nanostructures (the forces generated by molecular biomotors can range from a few pN to tens of pN [163], thus being large enough to actuate on some engineered nanostructures). Examples of molecular biomotors include step-wise motion of single kinesin molecules along a microtubule track, displacement of an actin filament by single myosin molecule, forces and transcriptional pauses associated with RNA polymerase activity, nonlinear elasticity of single polymers, reversible unfolding of single protein domains by

**Figure 20.** Schematic drawing of a nanopropeller powered by a molecular biomotor.

Linear motion of a microsphere powered by RNAP

**Figure 21.** Schematic drawing of the linear motion of a trapped microsphere powered by RNA polymerase [166].

applied force, and discrete rotations of a single  $F_1$  subunit of the  $F_0F_1$ -adenosine triphosphate (ATP) synthase [164]. The properties of these molecular biomotors open the possibility to integrate the power supply in NEMS applications at a molecular level. To illustrate this fact we present below some examples of primitive hybrid nanomechanical systems in which molecular biomotors drive the motion of inorganic nanostructures.

The first example refers to a nanopropeller driven by the  $F_1$ -ATAase biomolecular motor [165]. The device consists basically of three components: an engineered substrate, an  $F_1$ -ATAase biomolecular motor, and a fabricated nanopropeller (Fig. 20). It was demonstrated that rotation of the nanopropeller can be initiated with the addition of adenosine triphosphate to the system and stopped by the addition of sodium azide.

Two other examples refer to RNA polymerase (RNAP). RNAP carries out an essential step of gene expression, the synthesis of an RNA copy out of the template DNA. Each RNA molecule is synthesized in its entirety by a single molecule of RNAP moving progressively along the template. During transcript elongation, RNAP progresses along the DNA at speeds higher than 10 nucleotides per second and generates considerable force, higher than 10 pN. Moreover, rotation at a velocity greater than 100 revolutions per second and torques greater than 5 pN/nm are induced. In the experiments, RNAP was fixed onto a substrate and the forces and torques developed during transcription were used to move [166] and rotate [167] a microsphere trapped in optical tweezers (see Fig. 21) and suspended below a magnet, respectively.

## 6. CONCLUDING REMARKS

Nanoelectromechanical systems offer unique properties for advanced applications in nanoelectronics, biomedicine, and sensor technologies. Among others, NEMS structures may be applied as oscillators for wireless communications, very sensitive mass and magnetic field sensors, devices for single molecule separation, and devices for detection and analysis in lab-on-a-chip systems. The enormous relevance of these applications has made NEMS investigations one of the more active fields of research at present.

NEMS systems exist today at the laboratory level and NEMS production and applications show still many technical obstacles. By comparison with the previous evolution of the MEMS technology, which has taken about 20 years to

become mainstream, the NEMS commercialization opportunities must be considered in a medium term, although in some cases a faster commercial implementation is expected. If NEMS potential is fully realized, there is no doubt that NEMS technology will become a key technology for the 21st century, even surpassing solid-state or biotechnologies.

## GLOSSARY

**Biomotors** Molecular biological motors that convert chemical energy into mechanical energy and are able to generate forces and torques compatible with engineered nanostructures.

**Microelectromechanical system (MEMS)** Device combining mechanical elements with optoelectronic elements, with the mechanical part having at least one dimension in the range from hundred to a few micrometers.

**Nanocantilever** Single clamped freestanding solid-state structure with at least one dimension in the range from a hundred to a few nanometers.

**Nanofluidics** Study of the mechanical and structural properties of fluids confined in structures with at least one dimension in the range from a hundred to a few nanometers.

**Nanoelectromechanical system (NEMS)** Device combining mechanical elements with optoelectronic elements, with the mechanical part having at least one dimension in the range from hundred to a few nanometers.

**Nanoimprint lithography (NIL)** Lithographic technique able to produce patterns with submicro- and nanometer scales based on the mechanical deformation of a polymer under pressure and elevated temperatures.

**Nanoresonator** Electromechanical device whose active part consists of a mechanical nanostructure able to freely oscillate.

## 1. INTRODUCTION

Over the past 40 years, computer hardware performance has improved with such regularity that predictable advances in computer performance have come to be an expectation of the computer hardware industry. This phenomena is captured in the well known Moore's Law, which holds that typical measures of performance, such as processor speed and memory capacity, double about every 18 months. Mathematically this is written

$$(\text{future performance}) = 2^{\frac{n}{1.5}} \times (\text{current performance}) \quad (1)$$

where  $n$  is time in years. So predictable has been the rate of advance in hardware performance that corporate budgeting decisions actually factor in projected advances. For example, given that computers become unmanageably incompatible when they differ in performance by a factor of ten, it follows that hardware must be replaced at intervals no greater than every five years.

As captured in Figure 1, Moore's Law advances have at their root the fact that the typical feature size in electronic device elements has decreased geometrically with time over the past four decades. There has been a contemporaneous "shrinking" of virtually all consumer electronic equipment.

Also shown in Figure 1 is an extrapolation based on Moore's Law, from which one unavoidable conclusion is that in order to maintain the historical progression, in the near future it will be necessary to fabricate devices with feature sizes on the scale of individual molecules.

Herein we discuss both experimental and theoretical efforts to "do electronics" with single molecules [1]. Some of the questions that will be addressed are as follows:

- How are the electrical properties of an individual molecule measured?
- What theoretical techniques may be used to predict the electrical characteristics of an individual molecule?
- What properties of molecules might be exploited to design a functional electronic device?
- What is the mechanism of electron transport in molecular devices?
- What are the current technological roadblocks to molecular electronics?

Since the term "molecular electronics" is applied to a wide range of phenomena, it is important to delineate some of the closely related areas that are sometimes placed under the umbrella of molecular electronics, but will not be addressed here. The first of these categories is "quantum computing." Quantum computing is a nascent technology whereby one capitalizes on the properties of quantum mechanical systems to carry out computations, a completely different paradigm from the digital computing of today. While it is conceivable that molecular quantum states might form the basis for data representation in a quantum computer, this is at best only tangentially related to doing electronics with individual molecules as circuit components. The interested reader may begin study of this area with Ref. [2]. Second, we will not cover the areas of "conducting polymers" or "organic electronics." These are very real current technologies employing polymeric and organic materials with useful electrical properties in the construction of electronic devices, where their material properties give them

**Figure 1.** Historical progress in microelectronics. Data from [91].

an advantage over traditional metals and semiconductors. While there is considerable effort underway to reduce the physical dimension of electronic device elements that are composed of organic or polymeric materials (as has been true for traditional electronic circuitry over the past half-century), these advances are far from reaching the molecular scale. To begin study of these materials, the reader may wish to start with Ref. [3].

## 2. MEASUREMENT TECHNIQUES

Manipulating a single molecule is a daunting task. While there are millions of known stable molecules, covering an enormous range of sizes, in general the molecular domain is characterized by nanometer and subnanometer length scales. This is nine orders of magnitude smaller than the characteristic dimension of a human (about 2 meters). Manipulating an object smaller in dimension than ourselves by a factor of 10 or 100 is relatively straightforward and requires no special technology. A softball (characteristic length  $\approx 0.1$  m) or a paperclip (characteristic length  $\approx 0.01$  m) can be manipulated manually. At about 1000 times smaller, some sort of technology is required. A poppy seed (characteristic length  $\approx 0.001$  m) is difficult to handle without tweezers. At 10,000 times smaller, objects become essentially invisible to the naked eye. Their manipulation requires technology to aid in their observation as well as manipulation. Imagine attempting to manipulate a leg severed from a flea. Certainly this would require a magnifying device just to see it. In addition, it would be nearly impossible to hold ones hand steadily enough for precise manipulation, assuming it could be grabbed with tiny tweezers.

A flea's leg is only  $10^4$  times smaller than a human. To manipulate a single molecule requires precise control on a length scale  $10^5$  times smaller yet. Said another way, a molecule looks much smaller to a flea than a flea does to a human! It is not even possible to "see" a molecule in the traditional sense. The wavelength of visible light is 400–700 nm, hundreds of times longer than the characteristic length of a molecule. This is but one challenge in use of individual molecules for electronic device elements.

A key challenge of measuring the electrical properties of a molecule involves connecting the single molecule into a closed circuit. Conceptually, one would like to affix a nanometer-scale "alligator clip" onto one end of the

molecule and a second nanometer-scale "alligator clip" onto the other end of the molecule. These alligator clips would be attached to micron-scale wires that would in turn be connected to a macroscopic circuit, including a power source and measuring device as shown schematically in Figure 2. Today's computer chips employ two stages of size reduction. As described previously, a molecular device would require at least three [4]. The problem is discussed in some detail in Ref. [5]. There are no bantam alligator clips, but the concept of capturing a molecule between two classical conductors that are part of a macroscopic circuit has been realized in several ways. We will refer to the generic situation of a molecule in contact with two electrodes as a "molecular junction." A key challenge in measuring the electrical properties of a single molecule is therefore the problem of creating a molecular junction.

One conceptually simple technique is to use a break junction. In this method, a thin wire of some ductile material is immersed in a solution containing the molecular species whose conductivity properties one desires to measure. The wire, while in solution, is then drawn or bent to failure to form opposing tips. The opposing tips then become coated with a self-assembled monolayer (SAM) of the molecular species of interest. The coated tips are then withdrawn from the solution (or more conveniently, the solution is allowed to evaporate). Finally, a potential difference is established between the two tips, and the tips are brought together until current flows [6].

There are several disadvantages to the break junction method. First of all, it is only suitable if the molecular species of interest adheres to form a SAM on the material of the wire. Benzene-1,4-dithiol has proven to be an excellent test species for exactly this reason: the dual thiols serve as alligator clips to attach the ring to the electrodes [7]. It is sometimes necessary to employ protecting groups on the thiolate functions until just prior to the self assembly step, owing to the tendency of thiolates to oligomerize [8]. Thiol linkages have become a *de facto* standard for attaching molecules to metal electrodes. (Selenium (-Se-) linkages have been tried as well but appear to introduce a large potential barrier to electron transport [7].) Second, the break junction technique assumes that a solution can be prepared that contains the species of interest in sufficient concentration. Synthetic chemistry can be employed to address both limitations. Functional groups may be added to the molecule that increase its solubility and/or facilitate

**Figure 2.** Schematic of circuit for measurements on a single molecule. One great difficulty is creating "probes" that are small enough to contact the molecule, but large enough connect into the macroscopic circuit.

its adhesion to the wire material. Nevertheless, these limitations still exist, and functionalization of the molecule almost certainly alters its electrical characteristics. Another disadvantage of the break junction is that it is not possible to guarantee that the tip-molecule-tip geometry is the same upon repeat experiments, or even that a single (and the same) molecule is subjected to measurement. Despite these limitations, replicate measurements of molecular conductance that employ the break junction method have yielded good reproducibility [6], suggesting that the chemistry of the system dictates the formation of similar junctions each time the junction contact is made.

A second, more robust technique involves the construction of a molecular junction within a nanopore by employing a combination of techniques from traditional device manufacture and materials chemistry. This technique starts with a 50 nm thick insulating membrane of  $\text{Si}_3\text{N}_4$ , supported on its edges by silicon. A bowl-shaped 30 nm cavity (nanopore) is made in the nitride membrane with reactive ion etching so that the bottom of the “bowl” just barely breaks through the membrane. The bowl-shaped nanopore is then filled with Au by vapor deposition. This leaves gold exposed in a nanometer-scale window through the nitride membrane. The molecular species of interest is then coated onto this tiny area of exposed Au by a SAM technique. Finally, the SAM side of the device is coated with Au by vapor deposition. A device is thereby created where a SAM of the species of interest is sandwiched between Au contacts in a nanometer-scale region. The junction is then incorporated into a measuring circuit. Exact details of the preparation may be found in [9].

A distinct advantage of the nanopore technique is that it creates a structure that is less fragile than a break junction and therefore more akin to a traditional solid state device. The nanopore technique may be suitable for practical devices, not simply as a measurement technique. The nanopore technique probably results in a molecular junction with several (possibly up to 1000) molecules per junction, although some reduction of scale is conceivable [10].

Another technique that employs some features from conventional semiconductor fabrication and others from synthetic chemistry has been presented by Rinaldi et al. [11]. To form a molecular junction, two triangular shaped metal electrodes are fabricated on a  $\text{SiO}_2$  substrate with electron beam lithography and lift-off processing. The two electrodes are oriented so that they point toward each other, that is, they have adjacent vertices separated by 30–120 nm. A microliter drop of solution containing the molecular species of interest is then deposited between the two electrodes and vacuum evaporated. At sufficiently low evaporation rates, an ordered structure self assembles between the two electrodes.  $I/V$  characteristics are then measured by placing an applied potential across the junction. Such devices have been demonstrated to have good reproducibility over a period of months. As a disadvantage, these measurements have been carried out in a vacuum, and it is not clear whether devices can be fabricated that are useful in atmospheric conditions. As reported [11], these devices are nanoscale, but have not been scaled to the single-molecule level.

Other techniques employ the instruments of ultramicroscopy. It was first demonstrated by Becker et al. [12] that a scanning tunneling microscope (STM) may be used to measure the conductance properties ( $I/V$  curves) of a surface with a spatial resolution on the order of 0.1 nm. This high spatial resolution provides the opportunity to investigate the local electronic structure features of surfaces, such as those associated with point defects [13]. The molecular-scale spatial resolution of the STM has been applied to the problem of measurement of the electrical characteristics of molecules. For example, the electrical properties of single-walled nanotubes [14], self-assembled alkanethiol monolayers [15], and even single  $\text{C}_{60}$  molecules [16] have been measured by capturing them between the tip of a scanning tunneling microscope and a conducting substrate. Denoting the tip-to-substrate distance as  $s$ ,  $I(s)$  measurements (current as a function of tip-to-substrate distance) on  $\text{C}_{60}$  exhibit three distinct regimes. At large  $s$ , the current is very low and shows distance dependence characteristic of a vacuum gap. As the tip is brought closer to the substrate, at a critical separation (corresponding to the inner root of the interaction potential between the tip and the  $\text{C}_{60}$  molecule) there is a shift in the slope of  $I(s)$ , indicating opening of new tunneling channels. Finally, true “electrical contact” is made when the  $\text{C}_{60}$  molecule begins to be deformed or crushed under the force of the tip [16].

An extension of the STM technique allows for its application to a wider class of molecules. To do so, a conducting substrate (typically Au) is coated with a SAM of the molecular species of interest. Nanoparticles of gold are then dispersed onto the SAM. If the tip of an STM is positioned above one of these nanoparticles, the  $I/V$  characteristics of the molecules, caught between the nanoparticle and the conducting surface, may be measured by tracking current flow as a function of the potential difference applied between the tip and conducting surface [17]. Like the nanopore technique, this method incorporates several molecules into the junction. It is estimated that about 60 molecules are active [18]. Scaling to the few-molecule level seems possible.

Another microscopy based measurement technique employs a conducting tip atomic force microscope (AFM) probe [19]. First, a SAM of molecules is formed on a Au (111) surface. A fraction of the molecules is then functionalized with a thiol substituent on the top end (farthest from the surface). This thiol functionality allows for chemical bonding to gold nanoparticles that are subsequently dispersed onto the surface. Contact is made between the AFM tip and one of the gold nanoparticles. The AFM tip and conducting surface are then wired into a circuit containing a power supply and measuring device. This allows for the measurement of the  $I/V$  characteristics of the probed molecules that are bonded to both the Au (111) surface and the gold nanoparticle [20]. This measurement technique has the distinct advantage that  $I/V$  curves are found to be integer multiples of a fundamental  $I/V$  curve, allowing for the identification of *single molecule* junctions.

The final microscopy-based technique that we will discuss here was employed by Frank et al. [21] to demonstrate quantum resistance in carbon nanotubes. Arc-produced carbon nanotubes are sometimes found to be embedded in larger fibers composed of graphitic particles and nanotubes. First,

fibers with a single carbon nanotube protruding from the end are selected. One such fiber is affixed in place of the tip of a scanning probe microscope (SPM). The  $z$ -axis (height) control of the SPM probe is then used to lower the carbon nanotube that protrudes from the fiber tip into a pool of liquid mercury. By connecting an electrical lead to the fiber tip and another to the mercury pool, a single carbon nanotube may be incorporated into a macroscopic circuit.

The carbon-fiber/mercury-pool scheme is very elegant and appears to have the best repeatability of all the measurement schemes reviewed here. The major drawback is that it is specific to nanotubes. It is conceivable that it might be possible to functionalize the nanotube tip by employing some clever chemistry. This would open the application of this scheme to use with any molecular system that can be bonded to a nanotube tip, although this remains a future achievement.

In 1991, Joachim discussed the issues associated with measuring the electrical properties of a molecule [5]. At that time the idea was largely hypothetical (although there had been some successful efforts to create circuits with elements at or near the nanometer scale). As reviewed above, in the ensuing decade, several techniques were developed and successfully employed so that the problem of measuring the electrical properties of a molecule is now effectively solved. This is not to suggest that no problems remain. One of the most important is that the molecule must be affixed in some way to two contacts. This inevitably involves functionalizing the molecule to facilitate chemical bonding to the contacts. Such functionalization alters the electrical characteristics of the molecule. We will return to the issue of the influence of contacts later, when we discuss technical roadblocks to molecular electronics.

### 3. THEORETICAL TECHNIQUES

The theoretical description of electron transport across a molecule is fundamentally a problem in scattering theory. In principle, the entire arsenal of weapons for solving traditional gas-phase scattering problems may be brought to bear on the problem of electron transport in molecular junctions. Theoretical treatments of scattering problems may be divided into two broad categories, time independent approaches (that is, those that solve the time-independent Schrödinger equation) and time dependent ones (those that solve the time-dependent Schrödinger equation). To date, the majority of theoretical treatments of electron transport in molecular junctions have been of the time-independent variety.

#### 3.1. Scattering

In a very primitive picture, the junction molecule presents a potential barrier to electron flow between the source and sink of electrons. (Such a picture is closely related to the contact in a scanning tunneling microscope and many aspects of the theory of STM [22] may be applied.) A schematic molecular junction is shown in Figure 3. (Here we treat the junction molecule as presenting a potential barrier to electron flow, although the shape of the potential varies with the details of the nature of the system.) The quantum

**Figure 3.** Primitive model of electron transport across a molecular junction. The molecule presents a potential barrier along the electron transport coordinate.

mechanical treatment of transmission across a potential barrier (or well) is discussed in many quantum mechanics texts [23]. In the asymptotic regions on either side of the barrier, the potential is constant so we may write down the wavefunction  $\psi(x)$  directly,

$$\psi(x) = A \exp(ikx) + B \exp(-ikx) \quad (\text{I}) \quad (2)$$

$$\psi(x) = C \exp(ikx) + D \exp(-ikx) \quad (\text{III}) \quad (3)$$

where  $A$ ,  $B$ ,  $C$ , and  $D$  are the amplitudes of the left and right propagating waves and  $k = \frac{1}{\hbar}(2m_e E)^{1/2}$ ,  $E$  being the total energy, and  $m_e$  the rest mass of the electron. Based on the form of the wavefunction in the region of the barrier (II), we may find a matrix  $M$  that relates the wave amplitudes in the asymptotic regions.

$$\begin{pmatrix} A \\ B \end{pmatrix} = \begin{pmatrix} M_{1,1} & M_{1,2} \\ M_{2,1} & M_{2,2} \end{pmatrix} \begin{pmatrix} C \\ D \end{pmatrix} \quad (4)$$

The matrix  $M$  is called a *transfer* matrix and is closely related to the scattering matrix  $S$ , which relates the amplitudes of the incoming and outgoing waves,

$$\begin{pmatrix} B \\ C \end{pmatrix} = \begin{pmatrix} S_{1,1} & S_{1,2} \\ S_{2,1} & S_{2,2} \end{pmatrix} \begin{pmatrix} A \\ D \end{pmatrix} \quad (5)$$

The inverse of the transfer matrix  $M^{-1}$  is a transfer matrix as well, relating wave amplitudes in the opposite direction. Independent of the formalism used, the quantity

$$T = \left| \frac{C}{A} \right|^2 \quad (6)$$

is termed the *transmissivity* of the barrier and gives the probability that an electron incident from the left (i.e.,  $D = 0$ ) will pass through the barrier and emerge on the right. It follows that  $T = |S_{1,2}|^2$ . In general,  $T$  has energy dependence. If one knows the incident flux of electrons, the product of this flux with  $T$  yields the current.

The barrier shown in Figure 3 is a constant potential, one for which the transmissivity may be determined exactly, and is given in many quantum mechanics texts [23]. Generalization to nonsquare potential barriers is possible. In such a case, an approximate WKB formula is useful for thick barriers of slowly varying potential. In this case,

$$T \approx \exp\left(2 \int_a^b k(x) dx\right) \quad (7)$$

where  $k = \frac{1}{\hbar}(2m_e(V(x) - E)^{1/2})$ , and  $a$  and  $b$  are the left and right classical turning points of the potential barrier for a particle of energy  $E$  [23].

The above conveys the basic physics of electron transport across a molecular junction, but it is a very primitive model. First of all, it assumes that the electron transport takes place along a hypothetical one-dimensional coordinate. It completely neglects the space-filling three-dimensional nature of a real junction molecule. Second, in a real junction, the incident electrons are unlikely to be monochromatic, so it may be necessary to integrate over a distribution of incident electron energies (typically a Fermi distribution). Perhaps most importantly, the molecule where the scattering takes place interacts with both the source and sink of electrons (electrodes), and the form and strength of these interactions depend on the contacts. The theoretical treatment of electron transport in molecular junctions, therefore, includes several complications that typically do not appear in a traditional gas-phase scattering problem.

### 3.2. The Role of the Fermi Distribution

In a molecular junction, the molecule is typically connected to two metallic electrodes. Within these electrodes, the population of orbitals is dictated by a Fermi distribution. This means that the source of electrons is, generally speaking, not monoenergetic. Given that the transmissivity  $T(E)$  of the molecule is known, the current  $I$  is given by

$$I = \frac{e}{\pi\hbar} \int_{-\infty}^{\infty} T(E)[f(E - \mu_a, \tau) - f(E - \mu_b, \tau)] dE \quad (8)$$

where  $f$  is the Fermi function,  $E$  is energy,  $\tau$  is temperature,  $\hbar$  is the Planck constant divided by  $2\pi$ ,  $e$  is the unit of charge, and  $\mu_a$  and  $\mu_b$  are the electrochemical potentials within the two electrodes so that  $\mu_b - \mu_a = eV$  ( $V$  being the applied voltage). The difference of Fermi functions is interesting. At low  $E$ , both  $f(E - \mu_a)$  and  $f(E - \mu_b)$  are equal to one, so their difference is zero. Similarly, at high  $E$ , both are equal to zero and their difference is also zero. The difference in Fermi functions only has appreciable magnitude when  $E$  falls above the lower of  $\mu_a$  and  $\mu_b$  but below the higher. In this region, the orbitals in the high energy electrode are full, and those in the low energy electrode are empty. This is the only energy region in which there can be appreciable current. Below this region, there are no empty orbitals on the acceptor electrode to accept the transferred electrons. Above this region, there are no full orbitals in the high energy electrode from which the electrons may be transferred.

For very low temperatures and small applied voltages, the function  $f(E - \mu_a, \tau) - f(E - \mu_b, \tau)$  is adequately approximated by a delta function. This “finite-voltage finite-temperature” approximation can be seen quite elegantly in the formalism of Bagwell and Orlando [24]. The difference of Fermi functions is written as a difference of two Heaviside step functions ( $h(\theta)$ ) convoluted with a thermal smearing function

$$\begin{aligned} & f(E - \mu_a, \tau) - f(E - \mu_b, \tau) \\ &= [h(E - \mu_a) - h(E - \mu_b)] \otimes \left( -\frac{\partial f}{\partial E}(E, \tau) \right) \end{aligned} \quad (9)$$

Here  $\otimes$  denotes convolution. From this formalism, it is clear that if the applied potential is small and the temperature broadening is minimal, the expression for current reduces to [25]

$$I = \frac{e^2}{\pi\hbar} TV \quad (10)$$

It follows that

$$R = \frac{\pi\hbar}{e^2 T} \quad (11)$$

which shows that the quantum of conductance [21] is

$$G_0 = \frac{e^2}{\pi\hbar} \quad (12)$$

Eq. (11) assumes that the molecule is in contact with a perfect conductor [25] and is valid for  $T \rightarrow 0$ . More complete analysis [26, 27] yields

$$R = \frac{\pi\hbar}{e^2} \frac{(1 - T)}{T} \quad (13)$$

from which it is clear that  $T \rightarrow 0 \Rightarrow R \rightarrow \infty$  and  $T \rightarrow 1 \Rightarrow R \rightarrow 0$ . Eqs. (11) and (13) agree for  $T \ll 1$ , as in high resistance junctions.

In the WKB approximation, we may write

$$G = G_0 \exp\left(2 \int_a^b k(x) dx\right) \quad (14)$$

For a constant potential,

$$\int_a^b k(x) dx = c_1 L \quad (15)$$

where  $c_1$  is a constant and  $L$  is the width of the barrier. If we describe a molecule of width  $L$  as a one-dimensional tunnel barrier we may then write

$$G = G_0 \exp(2c_1 L) = G_0 \exp(\gamma L) \quad (16)$$

This is the “exponential law,” which is widely used to characterize molecular conductance [28].

The finite-voltage finite-temperature approximation is very common in the theoretical description of electron transport across molecular junctions. As discussed by Bagwell and Orlando [24], this approximation is valid if the applied voltage and thermal broadening are less than any of the features in  $T(E)$ . For the theoretical description of practical devices, where applied voltages are presumably as high as several eV, it is desirable to go beyond this approximation.

### 3.3. Multiple Transmission Channels

At the next level of sophistication, we recognize that there exists a plethora of possible initial states  $|i\rangle$  (chemists may think of these roughly as electrons in orbitals of the electron donor electrode) and a plethora of final states as well  $|f\rangle$  (which chemists may think of as electrons in orbitals of the electron acceptor electrode). The transition matrix  $\mathbf{t}$  has elements  $\langle f|t|i\rangle$  that reflect the coupling of  $|i\rangle$  to  $|f\rangle$  and is related to the scattering matrix by [29]

$$S = \mathbf{I} - i\mathbf{t} \quad (17)$$

The transmission coefficient for a wave incident in  $|i\rangle$  to emerge in  $|f\rangle$  is given by  $|t_{i,f}|^2$ . The structure of the  $\mathbf{t}$  matrix is determined by the electronic structure of the junction molecule and its coupling to the electrodes, and can be found with any of numerous electronic structure techniques. (Several approaches are reviewed next.) The overall energy-dependent transmission coefficient is then given by

$$T(E) = \sum_i \sum_{f \neq i} \frac{v_f}{v_i} |t_{i,f}(E)|^2 \quad (18)$$

where the velocity ratio  $\frac{v_f}{v_i}$  accounts for differences in flux due to differences in velocity. In this formalism, it is easy to see that there are multiple scattering channels and that the overall transmissivity depends on the sum over all channels [30]. The current is then given by [30]

$$I = \frac{2\pi e}{\hbar} \sum_{i,f} f(E_i)[1 - f(E_f + eV)] |t_{fi}|^2 \delta(E_i - E_f) \quad (19)$$

where  $f(E)$  is the Fermi function (for the donor  $i$  and acceptor  $f$  electrodes),  $V$  is the applied potential, and  $\delta(E_i - E_f)$  is a Dirac delta function that ensures contributions only from states in energy resonance. Note in particular that for the donor electrode the Fermi function is employed since the electron must be donated from an occupied state, but for the acceptor electrode  $1 - f(E)$  is used since the electron must be accepted into an empty state.

Eq. (19) is quite general. One common simplification is to assume that  $\mathbf{t}$  is independent of any applied potential. This is a reasonable approximation if one is considering small applied potentials, and may be used effectively in conjunction with the small-voltage low-temperature approximation just described.

### 3.4. Fermi Level Alignment

One important problem in developing a theoretical model of electron transport in a molecular junction is that of ‘‘Fermi level alignment,’’ placing the Fermi level of the electrodes relative to that of the molecular orbitals of the junction molecule [31]. The issue is particularly critical because the electrode/molecule interface directly impacts the electron transport properties of the junction [32].

In the simplest approximation, one might start by relating both the electrode Fermi level and the highest occupied molecular orbital (HOMO) of the junction molecule to some common zero of potential. For example, the

energy cost of removing an electron from a relaxed neutral molecule to infinite separation is simply the ionization energy (IE). Using Koopmans’ theorem, IE is approximated by the negative of the energy of the HOMO of the neutral molecule. Similarly, pulling an electron from a metal electrode out to infinity requires paying the work function  $E_w$ . If one defines the zero of potential as that of an electron removed to infinite separation (as is customary in molecular electronic structure calculations), Fermi level alignment can be achieved by placing the Fermi level at  $-E_w$  and the HOMO at  $-IE$ . There are two problems with this approach. The first is that the HOMO energy is only an approximation to  $-IE$ , and sometimes a poor one. The second is that in a molecular junction, the molecule is in direct contact with the electrode. This close contact both alters the electronic structure of the molecule and obviates the need to remove the electron from the metal to infinity before placing it on the molecule.

It is widely accepted that in the case of zero-applied potential, the Fermi level lies somewhere between the HOMO and the lowest unoccupied molecular orbital (LUMO) of the junction molecule. If the electrode Fermi level were below the HOMO, electron charge would flow from the molecule to the electrodes, completely depleting the HOMO. Likewise, if the Fermi level of the electrodes were to fall above the LUMO of the junction molecule, electron charge would flow onto the molecule to fill the LUMO. With the Fermi level between the HOMO and LUMO, the degree of charge transfer between the molecule and the metallic electrodes depends on the exact position of the Fermi level, and it has been shown that charge transfer can, in some instances, be appreciable [33]. Fermi level alignment and charge transfer are therefore intimately tied together. It is correspondingly unsurprising that the most rigorous approaches to Fermi level alignment require iteration of charge transfer and the molecular energy levels to self-consistency.

Closely related to the issue of Fermi level alignment is describing the distribution of an applied potential across the molecular junction. The most common approach has been to introduce an empirical parameter into the formalism to distribute the applied potential, as described quite elegantly by Datta et al. [34]. Given an applied potential  $V_{ap}$ , in the zero-order approximation one may assume that the potential  $V_{mol}$  is constant within the junction molecule, with the potential drop between the electron-donor and electron-acceptor electrodes partitioned at the interfaces such that the chemical potentials within the left and right electrodes ( $\mu_L$  and  $\mu_R$ ) are given by

$$\mu_L = E_f - eV_{mol} = E_f - \eta eV_{ap} \quad (20)$$

and

$$\mu_R = E_f + eV_{ap} - eV_{mol} = E_f + (1 - \eta)eV_{ap} \quad (21)$$

where

$$\eta = \frac{V_{mol}}{V_{ap}} \quad (22)$$

$E_f$  is the equilibrium Fermi level and  $\eta$  is an empirical parameter, commonly taken to be  $\eta \approx 0.5$  [35]. These expressions show that with zero applied potential, the chemical potentials of the electrodes are set to the equilibrium

Fermi level. This formalism implicitly assumes that in the case of zero applied potential, the zero of potential in the molecule (as defined by whatever molecular electronic structure calculation technique is employed) lines up with the equilibrium Fermi level.

Traditional quantum chemistry techniques may be employed to determine the Fermi level alignment in a non-empirical way, at least in the case of zero applied potential. An *ab initio* molecular electronic structure calculation is carried out on the junction molecule, including part of each electrode into the molecular structure. Effectively one is placing a metal cluster on each end of the molecule. The size of these clusters is then increased and the calculation repeated until a common Fermi level is reached that is not significantly displaced in energy from the Fermi level of the pure metal [31, 36, 37]. This method has been applied to the case of a single  $C_{60}$  molecule bound to two Al electrodes of size similar to the  $C_{60}$  itself [36]. An interesting “natural doping” of the junction molecule is found. Electron charge flow occurs from the Al electrodes to the junction molecule until the LUMO (which is threefold degenerate) is half filled. Qualitatively, this is the most “metallic” distribution of electrons in  $C_{60}$ , presumably leading to enhanced conductance.

As discussed later, an added benefit of including a portion of each electrode into the electronic structure description of the junction is that this allows exact atomistic specification of the electrode/molecule contact geometry, which affords investigation of the influence of variations in contact geometry on electron transport [38].

### 3.5. Examples of Theoretical Studies

We now turn to specific examples of theoretical treatments of electron conduction through molecular junctions and similar systems.

Sautet and Joachim studied the closely related problem of the influence of a single impurity on current flow along an otherwise homogeneous repeating chain [39]. The energy-dependent transmission coefficient is written in terms of the diagonal elements of a transfer matrix, which relates wave amplitudes across the defect as in Eq. (6). The transfer matrix is in turn constructed from the elementary site-to-site propagators through the defect. The construction of these site-to-site propagators requires knowledge of the electronic structure of the system. The electronic structure of the chain polymer is described with a tight-binding Hamiltonian. There are five parameters: 1)  $e$  the coupling of two sites away from the defect, 2)  $h$  the energy of a nondefect basis function, 3)  $\omega$  the energy of the defect site basis function, 4)  $\alpha$  the coupling of the defect site to the site immediately adjacent on the left, and 5)  $\beta$  the coupling of the defect site to the site immediately adjacent on the right. The elementary site-to-site propagators  $\mathbf{P}$  are constructed in terms of these Coulomb and resonance parameters to connect the coefficient vectors across a site

$$\begin{pmatrix} C_{n+1} \\ C_n \end{pmatrix} = (\mathbf{P}) \begin{pmatrix} C_n \\ C_{n-1} \end{pmatrix} \quad (23)$$

In overview, the electronic structure of the system determines the elementary site-to-site propagators  $\mathbf{P}$ . The site-to-site propagators determine the transfer matrix  $\mathbf{t}$ . The

transfer matrix determines the ratio of wave amplitudes across the defect and therefore the transmission function  $T$ .

A multichannel transfer matrix technique for the theoretical description of electron transport in a molecular wire with a lateral (transverse to the direction of conduction) confining potential has been described by Sheng and Xia [40]. For a wire aligned along the  $x$  axis with a confining potential  $U(x, y)$  between  $[0 \leq x \leq L]$ , the wavefunction in the asymptotic regions  $[x < 0]$  and  $[x > L]$  may be written

$$\Psi_L(x, y) = \sum_{n=1}^N (a_n^L e^{ik_n x} + b_n^L e^{-ik_n x}) \Phi_n(y) \quad (24)$$

and

$$\Psi_R(x, y) = \sum_{n=1}^N (a_n^R e^{ik_n x} + b_n^R e^{-ik_n x}) \Phi_n(y) \quad (25)$$

in the regions  $[x < 0]$  and  $[x > L]$ , respectively. Here  $k_n$  may be extracted from

$$\frac{\hbar^2 k_n^2}{2m} = E - E_n \quad (26)$$

where  $E$  is the total energy of the system,  $m$  is the effective electron mass, and  $E_n$  is the energy of the  $n$ th transverse mode. The amplitudes in the left and right asymptotic regions are then related by a transfer matrix  $\mathbf{M}$

$$\begin{pmatrix} \mathbf{a}_L \\ \mathbf{b}_L \end{pmatrix} = (\mathbf{M}) \begin{pmatrix} \mathbf{a}_R \\ \mathbf{b}_R \end{pmatrix} = \begin{pmatrix} \mathbf{M}_1 & \mathbf{M}_3 \\ \mathbf{M}_2 & \mathbf{M}_4 \end{pmatrix} \begin{pmatrix} \mathbf{a}_R \\ \mathbf{b}_R \end{pmatrix} \quad (27)$$

where  $\mathbf{a}_L, \mathbf{a}_R, \mathbf{b}_L, \mathbf{b}_R$  are vectors of incident and reflected wave amplitudes, and  $\mathbf{M}$  is partitioned into submatrices  $\mathbf{M}_1, \mathbf{M}_2, \mathbf{M}_3, \mathbf{M}_4$  for convenience. The transfer matrix is related to the transmission ( $\mathbf{t}$ ) and reflectance ( $\mathbf{r}$ ) matrices in the usual way. Typically, one considers the case where  $\mathbf{b}_R = 0$ , that is, there is no incident flux from the right.

Within the scattering region where the potential is described by  $U(x, y)$ , the wavefunction is expanded as

$$\Psi(x, y) = \sum_{n=1}^N f_n(x) \phi_n(y) \quad (28)$$

where  $\phi_n(y)$  describes the transverse modes and  $f_n(x)$  may be thought of as an  $x$ -dependent expansion coefficient. Substituting Eq. (28) into the Schrödinger equation, multiplying by an arbitrary  $\phi_m(y)$ , and integrating over all  $y$  yields

$$\left[ \frac{-\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + \sum_{n=1}^N U_{mn}(x) f_n(x) + \left( \frac{-\hbar^2}{2m} - E \right) \right] f_m(x) = 0 \quad (29)$$

where  $U_{mn}(x)$  is the matrix element of  $U(x, y)$  between transverse states  $n$  and  $m$ ,  $\langle \phi_n | U(x, y) | \phi_m \rangle$ . Integrating these coupled equations from  $R$  to  $L$  for a linearly independent set of initial conditions and matching the asymptotic boundary conditions for  $f_n(x=0)$  and  $f_n'(x=0)$  yields the transfer matrix. The method is particularly useful for investigating the influence of the lateral confining potential on electron transmission.

Perhaps the most widely used theoretical description of electron conduction across a molecule is that presented by Mujica et al. [30]. The method begins with Eq. (19). The system is partitioned into two metallic reservoirs  $A$  and  $B$  and the molecule  $M$ . The Hamiltonian for the system is then partitioned

$$H = H^0 + V \quad (30)$$

where  $H^0$  is assumed to have orthonormal eigenstates:  $|i\rangle$  corresponding to states of  $A$ ,  $|f\rangle$  corresponding to states of  $B$ , and  $|\alpha\rangle$  corresponding to states of  $M$ .  $V$  is the interaction potential connecting  $M$  to  $A$  and  $B$ . It is assumed that there is no direct coupling of  $A$  and  $B$ . Physically, this corresponds to the approximation that thorough space coupling of the two reservoirs is negligible, quite reasonable for all but the smallest molecules  $M$ , where the separation of the electrodes would be correspondingly small. It is then possible to define a transition matrix  $\mathbf{t}$  connecting the states  $|i\rangle$  of the donor reservoir to the states  $|f\rangle$  of the acceptor reservoir in terms of the coupling matrices  $V_{i,\alpha}$  and  $V_{\alpha,f}$  and the eigenstates of  $H^0$ . The current follows directly from Eq. (19).

In this formalism, the current factors into a contribution from the electronic structure of the wire (coupled to the reservoirs through its end sites) and the density of initial and final states. In the original presentation of Ref. [30], a tight-binding Hamiltonian is used and the matrix  $\mathbf{t}$  is assumed to be independent of any applied potential. The latter assumption limits the valid range to low voltages, but the formal expression of the current is quite general, and these assumptions may in principle be relaxed. The basic scheme of Ref. [30] has been generalized to employ a nonorthogonal basis [41, 42], to include vibrational broadening [35], and to include multiple orbital interactions of the molecule with the electrode [42]. A Floquet theory approach to the case where the wire is driven by a monochromatic radiation field has also been reported [43].

Lang has presented an approach for calculating the current flow across a few-atom wire connecting two metals that is essentially fully first principles [44]. Fermi level alignment and charge transfer are handled in an entirely self-consistent manner. Density-functional theory calculations are employed to produce an initial electronic wavefunction. The electrostatic potential distribution across the junction is computed self-consistently. That is, the charge density distribution resulting from the electronic wavefunction is used in the Poisson equation, which in turn produces the applied electrostatic potential. The electronic structure and applied potential are iterated to self-consistency. Current is calculated from the final self-consistent wavefunction. Electrostatic self-consistency is key to moving beyond the small-voltage low-temperature approximation. The method of Lang and colleagues is therefore one of only a few to be formally applicable to cases of large bias voltage. The technique has been generalized for molecular junctions [32], applied to a hypothetical multiterminal molecular electronic device [45], and used to study temperature effects on electron transport properties of molecules [46].

A different scattering-theory approach has been taken by Emberly and Kirczenow [47, 48]. They start by dividing

the electrode-molecule-electrode system into five conceptual components. The electrodes on the left and right are labeled  $L$  and  $R$ , respectively. Each electrode terminates in a gold cluster, each denoted  $C$ . The molecule  $m$  is trapped between the two clusters so that the overall system may be written symbolically  $LCmCR$ . For the purposes of the theoretical description, three components are identified: the left “lead”  $L$ , the  $CmC$  central supermolecule (shorthand  $M$ ), and the right lead  $R$ . The wavefunction  $|\Psi^\alpha\rangle$  is expanded in a basis of orbitals  $\{|n, j\rangle\}$  where  $n$  denotes the site ( $A$  “site” is a unit cell in  $L$  and  $R$ , and is  $n = 0$  for  $M$ ), and  $j$  denotes the orbital index on the specific site. The overall wavefunction is then a sum over expansions for all three components

$$|\Psi^\alpha\rangle = |\Psi_L^\alpha\rangle + |\Psi_M^\alpha\rangle + |\Psi_R^\alpha\rangle \quad (31)$$

where the superscript  $\alpha$  is a mode index. To find the scattering  $\mathbf{t}$  matrix,  $|\Psi^\alpha\rangle$  is written as a right-propagating wave and a sum over reflected waves whose amplitudes are specified by the reflection matrix  $\mathbf{r}$

$$|\Psi^\alpha\rangle = \sum_{n=-\infty}^{-1} \sum_j \left( c_j^\alpha e^{ink^\alpha} + \sum_{\beta} r_{\beta,\alpha} c_j^\beta e^{ink^\beta} \right) |n, j\rangle \quad (32)$$

Here  $k^q$  is the unitless signed wavenumber for mode  $q$ , and  $c_j^q$  are the expansion coefficients. The index  $j$  sums over molecular orbitals of a unit cell in the lead. The unit cells are indexed  $n$ , ( $n < 0$  for  $L$ ,  $n = 0$  for  $M$ , and  $n > 0$  for  $R$ ).  $|\Psi_M^\alpha\rangle$  is written as a sum over the orbitals in  $M$

$$|\Psi_M^\alpha\rangle = \sum_j a_j^\alpha |0, j\rangle \quad (33)$$

where the site label is denoted 0 for convenience.  $|\Psi_R^\alpha\rangle$  is written as a sum over transmitted waves whose amplitudes are specified by the transmission matrix  $\mathbf{t}$

$$|\Psi_R^\alpha\rangle = \sum_{n=1}^{\infty} \sum_j \sum_{\beta} t_{\alpha,\beta} d_j^\beta e^{ink^\beta} |n, j\rangle \quad (34)$$

Eq. (31), expanded in  $\{|n, j\rangle\}$ , is then substituted into the Schrödinger equation

$$H|\Psi^\alpha\rangle = E|\Psi^\alpha\rangle \quad (35)$$

and closed with the bra  $\langle n, i|$ . This produces a system of equations whose unknowns are the elements of the  $\mathbf{r}$  and  $\mathbf{t}$  matrices

$$\sum_{\beta \in L} r_{\beta,\alpha} \sum_{m,j} A_{n,m}^{i,j} c_j^\beta e^{imk^\beta} + \sum_j A_{n,0}^{i,j} a_j^\alpha + \sum_{\beta \in R} t_{\beta,\alpha} \sum_{m,j} A_{n,m}^{i,j} d_j^\beta e^{imk^\beta} = - \sum_{m,j} A_{n,m}^{i,j} c_j^\alpha e^{imk^\beta} \quad (36)$$

where  $A_{n,m}^{i,j} = \langle n, i|H|m, j\rangle - E\langle n, i|m, j\rangle$  [47]. The current is then related to the  $\mathbf{t}$  matrix in the finite-voltage finite-temperature approximation.

The Hamiltonian  $H$  is expanded as  $H = H^0 + W$ , where  $H^0$  is the Hamiltonian for  $L$ ,  $M$ , and  $R$ , and  $W$  is the coupling of  $L$  to  $M$  and of  $M$  to  $R$ . In the implementation of Emberly and Kirczenow [47],  $H^0$  is based on a tight-binding Hamiltonian. The coupling  $W$  is composed of Hückel (tight binding) matrix elements between the

orbitals of the cluster-molecule-cluster system and the adjacent orbitals in the leads. More sophisticated electronic structure descriptions could in principle be employed within the same formalism. One of the benefits of this method is that the explicit treatment of atoms in the contacts allows for direct investigation of different contact geometries.

A chemically intuitive method of directly relating the electronic structure of a molecule to its resistivity has been discussed by González and Morales [27]. The technique is again based on the inverse relationship between the transmission probability through the molecule and its resistance, Eq. (13). As the transmission nears unit probability, the resistance approaches zero. As the transmission probability approaches zero, the resistance increases without bound. The transmission probability is approximated by the normalized charge-transfer across the molecule from an electron-donor functional group to an electron-acceptor functional group, upon electronic excitation.

A long “wire” molecule is functionalized with a donor substituent on one end ( $D = -\text{CH}_3$ ) and an acceptor substituent on the other ( $A = -\text{CHO}$ ). The charge distribution is analyzed in the molecular ground state and again in the charge-transfer photoexcited state. During photoexcitation, charge is transferred from the Donor  $D$  to the acceptor  $A$ . In the presentation of González and Morales [27], the wire is taken to be  $n$  ethene units ( $-\text{HC}=\text{CH}-$ ) $_n$ . A hypothetical charge transfer for a zero-length molecule  $\Delta Q_0$  may be extrapolated by plotting charge transfer  $\Delta Q_n$  versus  $n$ . The hypothetical zero-length molecule is assumed to have unit transmissivity  $T = 1$ . It follows that for the transmissivity for a wire of  $n$  units one may write,  $T_n \approx \frac{\Delta Q_n}{\Delta Q_0}$ . In principle any molecular wire could be treated within this formalism. The qualitative variation in transmissivity with molecule length predicted by the method of González and Morales [27] is completely consistent with that given by much more sophisticated multichannel scattering calculations [28].

A unique feature of this technique is that it yields information about the resistance *intrinsic* to the molecule, with no contribution from contacts. One shortcoming of this method is that it does not allow the prediction of the  $I(V)$  characteristics of the molecule. Nonlinear effects may be investigated to first order by taking advantage of the fact that the charge transferred differs for different donor and acceptor groups. If calculations are carried out for several pairs of donor and acceptor groups, the resulting molecular resistance  $R$  versus molecule length  $l$  data may be fit to

$$R(l) = \theta_L l + \theta_{NL} l^2 \quad (37)$$

where  $\theta_L$  and  $\theta_{NL}$  are the linear and nonlinear resistance coefficients, respectively.

Other groups have taken the approach of concentrating on the electronic structure of the junction molecule or wire instead of explicit calculation of the current. Molecular orbital studies can provide considerable insight into the electrical behavior.

Seminario et al. [49, 50] have used first principles methods to investigate the influence of torsional distortions on the electronic structure of conjugated oligo(phenylene ethynylene) systems, such as 1,4-(ethynylphenyl)phenylene. (See Fig. 4.) Knowledge of the energy barrier to torsional

Figure 4. 1,4-(ethynylphenyl)phenylene.

distortion (which is typically quite low, on the order of a few kcal/mole), and of the changes in molecular electronic structure with torsional distortion, allow for a qualitative prediction of the effects of temperature on the electrical transport properties of the system. In an extension of this work, Derosa and Seminario [51] have combined the DFT electronic structure description of the molecule plus a number of Au atoms from each adjacent electrode with a modification of the formalism for transport properties presented by Samanta et al. [41] to describe electron transport through single-molecule junctions.

In related work [52,53], semiempirical methods were employed to investigate the effect of interspersing valence-saturated “spacer” atoms along the otherwise conjugated wire. In particular, the formation of resonances due to changes in the energetic alignment of the molecular orbitals with applied static electric field is discussed.

## 4. PROPOSED ARCHITECTURES

Today, molecules with extended  $\pi$  conjugation are most often identified as candidates for molecular electronic devices [28,54,55]. The property of conjugation allows for effective electron delocalization over great distances, presumably facilitating low resistance electron transport [56,57]. This is most easily visualized with Lewis structure diagrams. Consider a long conjugated chain as depicted in Figure 5. If a charge is introduced at one end (here by removing  $\text{H}^-$  to form a primary carbocation), it is easy to

Figure 5. Schematic of electron transfer across linear polyene. (a) A linear polyene. (b)  $\text{H}^-$  is removed from the left-most carbon atom inducing a formal charge of +1. The electrons in the double bonds may then shift as shown by the arrows to transfer the positive charge to the right-most carbon atom. (c) Right-most carbon carries formal charge of +1.

see how the charge can be transported across the molecule by successively shifting the double bonds. In unconjugated systems, such transport can only occur by migration of atoms, or by violating the rules of valence. Since even the lightest atom, hydrogen, is 1836 times heavier than an electron, atom migration is a much less facile method of charge transport. If the system is unconjugated, charge transport by electron transfer requires violating the rules of valence. Such processes are therefore energetically unfavorable.

From the perspective of molecular orbital theory, a conjugated  $\pi$  system can be described through the construction of the molecular  $\pi$  orbitals as linear combinations of atomic  $p$ -orbitals. The atoms forming the conjugated domain must all lie in a plane (or nearly so), here taken to be the  $yz$  plane. To describe the conjugated  $\pi$  system, one may take as a basis a single atomic  $p_x$ -orbital on each atom in this domain. In the construction of molecular orbitals from this basis, there will always be one molecular orbital that consists of a positive contribution from each atomic orbital, that is, a nodeless molecular orbital delocalized over the entire conjugated domain. (See Fig. 6.) Such a structure is widely believed to be favorable for low-resistance electron transport.

Conjugated organic molecules are a particularly attractive choice for molecular electronics, not only because of their electronic structure properties, but also because the chemistry community has more than a century of experience in their synthesis and handling, which should facilitate the fabrication of devices composed of conjugated organic components. The use of individual molecules as device elements has another potentially revolutionary advantage. In a chemical synthesis, a large number of molecules is produced (on the order of Avogadro's number  $6 \times 10^{23}$ ), and they are all absolutely identical (notwithstanding isotopomers, whose chemical properties are essentially indistinguishable). There is the potential, therefore, for the inexpensive fabrication of a staggering number of individual units with near perfect uniformity [54]. Numerous examples may be found in [55].

**Figure 6.** A linear polyene with the  $p_x$ ,  $\pi$  orbital structure shown. (a) Highly antibonding linear combination of  $p_x$  orbitals; (b) fully bonding linear combination of  $p_x$  orbitals leads to nodeless  $\pi$  orbital extending across the entire molecule.

## 4.1. Wires

Perhaps the most fundamental component of any circuit is the wire. Molecular electronic circuits will require wires also, and numerous species have been proposed to fill the need. Samanta et al. [41] have proposed molecules consisting of multiple paralinked benzene rings as molecular wires. The generic formula is  $\text{HS}-(\text{C}_6\text{H}_4)_n-\text{SH}$ , where the thiol terminators are the molecular equivalent of alligator clips, which are used to attach the wire to electrodes. Their calculations predict an exponential dependence of resistance on molecular length. This has been observed experimentally for similar molecular species [57,58] and is a consequence of tunneling-dominated electron transport. This feature of molecular wires is qualitatively different from conventional macroscopic wires. Conventional metal wires exhibit a linear dependence of resistance on length. (A wire of length  $l$  and resistance  $R$  when clipped into two halves, produces two wires of length  $l/2$  each with resistance  $R/2$ .) A commonly used descriptor for molecular wires is the  $\beta$  factor. One writes the electron transfer rate constant  $k_{ET}$  as [57]

$$k_{ET} = k_0 \exp(-\beta r_{da}) \quad (38)$$

where  $k_0$  is a kinetic prefactor,  $r_{da}$  is the distance between the electron donor and the electron acceptor (basically the wire length), and  $\beta$  is the characteristic parameter.

Davis et al. [57] have carried out measurements of the electron transfer rate in molecules of the form  $-(\text{C}_6\text{H}_4-\text{CHCH})_n-(\text{C}_6\text{H}_2(\text{OR})_2)-(\text{CHCH}-\text{C}_6\text{H}_4)_n-$ . For these systems, they find  $\beta \approx 0.04 \text{ \AA}^{-1}$ . Sikes et al. [58] have reported similar studies for ferrocene oligophenylenevinylene methyl thiols and report  $\beta \approx 0.06 \text{ \AA}^{-1}$ . This class of molecules is shown in Figure 7. These low  $\beta$  values indicate remarkably weak length dependence in these systems, a desirable characteristic for molecular wires. By contrast, typical  $\beta$  values for unsaturated and saturated electron transfer bridges are  $0.5 \text{ \AA}^{-1}$  and  $1.0 \text{ \AA}^{-1}$ , respectively [58].

As discussed previously, González and Morales [27] have considered polyenic molecules of the form  $\text{D}-(\text{CH}=\text{CH})_n-\text{A}$  as molecular wires. Rather than employing the  $\beta$  parameter, they use Eq. (37) to describe the length dependence of resistance.

**Figure 7.** Ferrocene oligophenylenevinylene methyl thiols. One possible repeat unit is enclosed in brackets.

## 4.2. Devices

The electronic devices themselves can be broadly classified into two categories: i) those with nonlinear  $I/V$  characteristics, and ii) those whose  $I/V$  characteristics can be influenced by an external stimulus. An example of the first type is a diode. Under positive bias, (forward current flow) the device presents a constant (typically small) resistance to current flow so that the current flow is linearly dependent on the applied potential. Under negative bias, however, the device presents a large resistance to current flow. There is a significant nonlinearity in the  $I/V$  characteristics, near zero applied potential. An example of the second class of devices is a switch. In the closed position, the device presents an essentially infinite (or at least very large) resistance to current flow of either bias, but after the action of some external stimulus (depressing a button for example), a new state is accessed where the device presents little resistance to current flow. Architectures have been proposed for molecular devices of both types.

The idea of creating molecule-sized electronic components has almost certainly been around in science fiction literature for many years. The first serious attempt to identify molecular properties on which one might capitalize to create real molecular devices is widely attributed to Aviram et al. [59].

Much early work focused extensively on the potential use of hydrogen bonds for information storage [60]. In some systems, the hydrogen atom, caught between two highly electronegative atoms in a hydrogen bond, is governed by a double well potential. The system has a local minimum in potential energy when the hydrogen is more closely associated with either one or the other of the two highly electronegative atoms, and these two local minima are separated by a potential barrier. This situation is known as asymmetric hydrogen bonding. Such a situation has two physically distinct states. If the system can be induced to switch from one state to the other by some external stimulus, a binary information storage device has been created. This idea is motivated in part by the observation that DNA accomplishes information storage with hydrogen bonds [59]. While conceptually appealing, experimental studies of 9-hydroxyphenalenones [61] and theoretical and experimental studies of hemiquinones [59] show that in these systems the proton tunneling rate is too high for enduring information storage. This problem might be resolved with massive redundancy or a heavier switching group.

A switching scheme based on enol-keto isomerization in N-salicylidenaniline was studied by Sautet and Joachim [62]. The molecule exhibits qualitatively different transmission properties  $T(E)$  in the enol versus keto tautomers. It is proposed that if this system is embedded into a polyene chain by replacing one of the  $-C=C-$  linkages in the chain with one of the  $C-C$  edges of the  $C_6$  ring in N-salicylidenaniline, then switching between the keto and enol tautomers will change the resistance of the polyene molecular wire. The enol form is shown in Figure 8.

One particularly intriguing idea is to capitalize on the conductivity change that accompanies changes in the relative alignment of phenyl rings along a polyphenyl chain, in a spirit similar to the “conformational switching” concept of

**Figure 8.** N-salicylidenaniline inserted into a polyene chain. The enol tautomer is shown.

Joachim and Launay [63]. Theoretical work has predicted that the conductivity of such a conjugated chain may be varied by  $10^4$  simply by varying the torsional alignment of two adjacent phenyl rings along a polyphenyl chain [41]. More recent studies by Olson et al. [64] have expanded upon this concept, exploring the influence on conduction of molecular vibrations in general along normal mode coordinates. It was reported that for the p-benzene-dithiol molecule, none of the vibrations lead to appreciable changes in current, owing to the rigidity of the molecule. By contrast, DiVentra et al. [46] note that when the molecule is modified with a  $NO_2$  substituent (2-nitro-1,4-benzene-dithiol), twisting of the  $NO_2$  substituent can lead to appreciable changes in the molecular orbital energies and potentially observable changes in the  $I/V$  characteristics. Theoretical studies of atomic-scale aluminum wires have shown that atomic disorder in general alters the electron transport properties, and the effect is stronger for “thin” wires [37, 65]. Clearly there will be some cases where molecular vibrations will have appreciable impact on electron transport. Molecules that exhibit vibronic coupling (coupling of intramolecular vibration to electronic structure) are especially strong candidates. In fact, the Jahn–Teller effect has been implicated as the origin of key features in the tunneling spectroscopy of  $C_{60}$  [66]. If the electron transport properties depend sensitively on a vibrational mode (or modes) with sufficiently low characteristic vibrational frequency, any molecular device incorporating such a component will display temperature-dependent electrical characteristics. Conceivably one might capitalize on such temperature sensitivity to fabricate an extremely sensitive temperature sensor.

When a molecule exhibits changes in its electrical characteristics with vibrational excitation, it results from differences in the electronic structure when vibrationally distorted. Such distorted structures may, in principle, also be sampled mechanically by applying a force to the molecule. This suggests a novel way to control conductivity in a molecular junction, with an applied force. A theoretical formalism to investigate the effect of stretching molecular wires on their electronic properties has been presented by Mikrajuddin et al. [67] and used to demonstrate mechanical/electronic coupling.

A beautiful example of the influence of vibrational motion on electron transport has been demonstrated in  $C_{60}$  transistors [68]. The fabrication of these devices starts with a thin insulating  $SiO_2$  layer on a conducting (doped) Si substrate. A pair of connected nanometer-scale gold electrodes are then fabricated on top of the  $SiO_2$  by electron-beam lithography. A toluene solution of  $C_{60}$  is deposited on the electrodes, and the connection is broken to form a break junction. The conducting Si substrate then serves as the gate and the gold electrodes as the source and drain. The  $I/V$  characteristics between the source and drain are observed to be highly dependent on the gate potential. In addition, the differential conductance of the device exhibits peaks with an energy spacing characteristic of the frequency of the oscillation of the  $C_{60}$  relative to the gold surface, about 1.2 THz. Fabrication of a molecular transistor is, of course, a key step in the advance of molecular electronics. The “transistor effect” in  $C_{60}$  has been the subject to detailed theoretical investigation as well [69, 70].

More recently, a new paradigm for molecular scale electronics capitalizing on changes in the electrostatic potential for information storage and transport has been presented by Tour et al. [54, 71]. The electrostatic potential within a molecule is influenced by the presence of charge. Such changes in the electrostatic potential extend sufficiently far from the molecule that they could, in principle, be used to transfer information to an adjacent molecule. Based on this concept, Tour et al. [54] have proposed architectures for molecular logic gates.

Of the many potential molecular electronics applications, data storage is one of the most advanced, and the first practical implementations of molecular electronics technology quite possibly will evolve in this area. Several actual demonstrations of binary data storage near the single molecule threshold have been reported by a team from the Beijing Laboratory of Vacuum Physics [72–75].

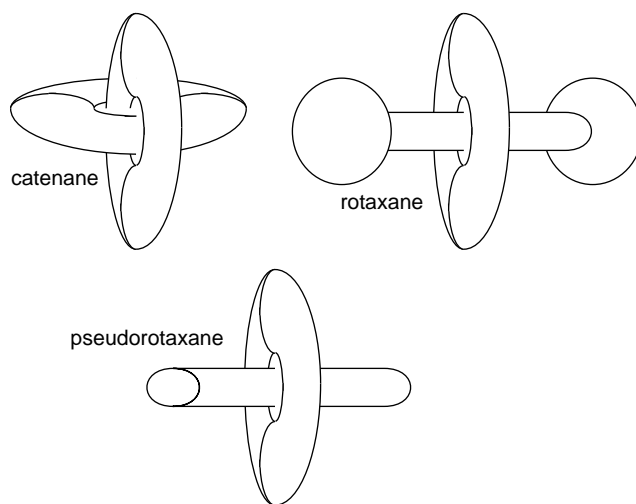

High resistivity polycrystalline thin films of a conjugated organic compound (or binary mixture of compounds) are prepared by vacuum evaporation onto room temperature substrates at a rate  $\leq 5$  nm/min to a thickness of 20 nm on freshly cleaved, highly oriented pyrolytic graphite (HOPG). Local conductance transitions are then induced in the film with a scanning tunneling microscope (STM). A potential pulse (square waveform  $\approx 4$  V  $\times 10$   $\mu$ s) is applied between the STM tip and the conducting graphitic substrate. This pulse induces local changes into the electrical characteristics of the thin film so that an area comparable in size to the crystal unit cell increases conductivity by about  $\times 10^4$ . These tiny regions of high conductivity can be thought of as binary data storage units. Bit densities of  $10^{14}$  cm $^{-2}$  have been reported [72]. The technique has been demonstrated for several materials, including N-(3-nitrobenzylidene)-p-phenylenediamine [73] (NBPDA), 3-phenyl-1-ureidionitrile [72] (PUN), and a 50:50 mixture of 3-nitrobenzal malononitrile (NBMN) and 1,4-phenylenediamine [74, 75] (pDA). (See Fig. 9.) The reverse transition in *individual* marks may be achieved in the latter material by applying a reverse-polarity voltage pulse of  $-4.5$  V for 50  $\mu$ s [76, 77].

Another molecular-scale switching technology has been demonstrated by Collier et al. [78–80]. This technology is based on topologically interesting assemblies of molecules

**Figure 9.** Several systems used to form thin polycrystalline films with switchable electrical properties on the nano scale. The boxed pair are used in a 50:50 mixture. N-(3-nitrobenzylidene)-p-phenylenediamine [73] (NBPDA), 3-phenyl-1-ureidionitrile [72] (PUN), 3-nitrobenzal malononitrile (NBMN), and 1,4-phenylenediamine [74, 75] (pDA).

known as catenanes and rotaxanes. These are nanosystems that are composed of two or more molecular components, wherein the components are linked mechanically but not chemically. For example, a  $(CH_2)_n$  ring may be “threaded” with an alkane chain when  $n \geq 18$  [81]. Two such rings, when interlocked, form a catenane. When a single ring is threaded by a linear chain molecule, a rotaxane results. (Note that in a rotaxane, the linear chain component is terminated on each end by a bulky substituent, which prevents the unthreading of the ring. In contrast, a pseudo-rotaxane lacks one or both of these bulky end-groups and thus can be unthreaded.) A catenane, rotaxane, and pseudorotaxane are shown schematically in Figure 10. As shown in Figure 11,

**Figure 10.** Schematic diagrams of a catenane, rotaxane, and pseudo-rotaxane.

Figure 11. A switchable catenane [80].

Collier et al. [79] have selected a catenane in which one of the rings has charged centers. In this way, the relative orientation of the rings may be influenced by the presence of an applied electric field. The applied bias may then be used to switch the system between two co-conformations. A solid state device is created by sandwiching a monolayer of these catenanes between an *n*-type silicon electrode and a metallic electrode. The device exhibits negligible deterioration after numerous cycles. Collier et al. [78] have employed a similar fabrication to create molecular logic gates. The device is created by sandwiching a monolayer of redox-active rotaxanes between two metal electrodes. By wiring several such devices together, they were able to demonstrate AND and OR logic gates.

A different approach to molecular scale data storage has been presented by Rueckes et al. [82]. The device architecture starts with a conducting substrate topped with a thin layer of SiO<sub>2</sub>. Single-walled carbon nanotubes (SWNT) of diameter *d* are then placed on the surface and aligned in parallel. Separating the nanotubes is an array of insulating organic blocks of thickness *s* arrayed on the surface. This array of blocks is used to support a second set of parallel nanotubes that is perpendicular to the first set. The insulating blocks are sufficiently thick that the upper nanotubes do not contact the lower nanotubes at the crossing points (*s* > *d*), but are still sufficiently close for electrostatic interaction. Each crossing point will therefore have two locally stable minimum energy configurations. In the state described above, elastic forces hold the two nanotubes separated by *s* - *d*. There is also a minimum dictated by van der Waals interactions between the two tubes. By charging two tubes, attractive forces can be generated that will deflect the upper tube down toward the lower tube near the crossing point and bring their separation at the crossing point into this van der Waals minimum. Oppositely charging the tubes can produce repulsive forces to return the junction to the *s* - *d* separation. It has been shown that the resistance between one nanotube and a perpendicular one varies by many orders of magnitude between these two states [82]. Such a device, therefore, represents a rewritable random access memory array on the molecular scale. An array

of  $2N$  nanotubes arranged with  $N$  tubes in the lower layer perpendicular to  $N$  tubes in the upper layer has  $N^2$  addressable junctions. Given the dimensions of carbon nanotubes, data density near  $10^{12}$  bits/cm<sup>2</sup> is possible.

The nanotube-based memory device has two advantages over the thin-film architecture of Ma et al. already described. First, the switching time for the nanotube-based memory is reported to be  $10^{-11}$  s, much faster than  $80 \times 10^{-9}$  s as reported for the thin film case. Secondly, the nanotube-based memory, being based on the intersections of parallel nanotubes, solves the problem of addressing a multitude of spatially separated physical memory locations efficiently. The thin film technology has only been demonstrated with an STM tip for read/write operations and would require some technological innovation to incorporate into a solid-state device with multiple addressable bits.

Carbon nanotubes have also been used to construct logic gates, specifically NOT gates [83]. The construction capitalizes on a fortuitous property of semiconducting SWNTs; they may be made *n*-type (electron carriers) or *p*-type (hole carriers) with proper doping and/or annealing. The logic gates consist of two complementary carbon-nanotube field-effect transistors (CNTFETs). To fabricate the device, gold electrodes are patterned on an oxidized silicon substrate. The unoxidized reverse side of the Si wafer forms the gate. Semiconducting SWNTs are the dispersed onto the surface. One of a pair of SWNTs positioned over Au electrodes is then protected with the common resist material PMMA. Vacuum annealing then converts both SWNT into *n*-CNTFETs. Finally, exposing the system to  $10^{-3}$  Torr of oxygen converts the unprotected *n*-CNTFET to a *p*-type CNTFET, yielding a complementary *n*-type/*p*-type pair. The devices are unstable in air, but air-stable devices can be produced by employing a 10 nm SiO<sub>2</sub> capping layer.

While not strictly single-molecule devices, nanoscale logic storage devices have been fabricated from molecule-gated nanowires [84]. In these devices, nanowires of *p*-type silicon, *n*-type InP, or *n*-type GaN are coated with a layer of cobalt phthalocyanine (CoPc), a redox active species. These nanowires lie on a SiO<sub>2</sub> layer on silicon, the back silicon layer serving as the gate. An applied gate voltage, or source-drain voltage pulse, injects charge into the molecular layer. The nanowire is then switchable between a high and low conductance state, depending on the charge state of the CoPc coating. Assigning each conductance state to a logic "on" or "off" state, yields a logic storage device. Storage times of >20 min have been reported.

## 5. THE MECHANISM OF ELECTRON TRANSPORT

As noted in the preceding section, a considerable array of device architectures has been proposed, and some realized. The mechanism by which electrons are transported in these systems is of great interest, since knowledge of this mechanism would facilitate *a priori* design of molecular electronic devices.

Studies of potential molecular wires have revealed an interesting difference between conventional wires and molecular wires. In a conventional wire, the resistance of the wire to current flow is linearly dependent on its length.

For a given material and cross section, a wire of length  $l$  has twice the resistance (half the conductance) of a wire of length  $\frac{l}{2}$ . Molecular wires, by contrast, exhibit an exponential dependence of current flow on molecular length [27, 56, 57]. If current flow were to take place by a classical transport mechanism, resistance would depend linearly on length, and such current versus length measurements would be expected to show a linear dependence. This is an indication that the actual mechanism of electron transport in molecular wires differs from that in conventional wires, and is probably dominated by tunneling, as supported by the derivation of Eq. (16).

One likely clue to the transport mechanism is the fact that certain molecules, when employed as molecular junctions, exhibit negative differential resistance (NDR) behavior. NDR describes the situation where the current ( $I$ ) passing through a device decreases as the potential difference ( $V$ ) applied across the device is increased. Since  $I/V$  typically has a positive slope, NDR gives rise to peaks in the  $I/V$  curve. The measured  $I/V$  characteristics of these molecular junctions show highly nonlinear characteristics, with current peaking sharply at a critical applied voltage. It has been postulated that as the applied potential ( $V_{ap}$ ) is increased, the junction molecule becomes charged. It is assumed that the uncharged junction molecule is insulating, the singly charged ( $-1$ ) anion is conducting, and the doubly charged ( $-2$ ) anion is again insulating. In the presence of a critical applied potential, the junction molecule would be reduced to its ( $-1$ ) anion and become conducting. Higher applied potentials would further reduce the junction molecule to its ( $-2$ ) anionic state, shutting down the conduction. A simple time-scale analysis, however, suggests that this picture is incomplete. Transit times for transfer of an electron through a molecular junction are estimated at  $10^{-16}$ – $10^{-15}$  s [64, 70]. On the other hand, device currents are typically less than 1 nA. This converts to less than  $10^{10}$  electrons per second, or one electron every  $10^{-10}$  seconds [5]. With five orders of magnitude between the transit time and the time delay between electrons, the electrons are unlikely to interact. In fact, based on theoretical calculations on p-benzene-dithiol as a resonant tunneling transistor, it has been suggested that the electrons do not spend enough time on the junction molecule to charge it [45].

Another proposed mechanism [4] identifies the changes in conductivity that accompany changes in the torsional alignment of adjacent phenyl rings in a conjugated chain as critical to controlling current flow [41]. For example, in 2'-amino-4'-ethynylphenyl-4'-ethynylphenyl-5'-nitro-1-benzenethiolate, (hereafter referred to as AEENB; see Fig. 12) while the system is conjugated, there is little rigidity in the relative alignment of the rings.

**Figure 12.** 2'-amino-4'-ethynylphenyl-4'-ethynylphenyl-5'-nitro-1-benzenethiolate.

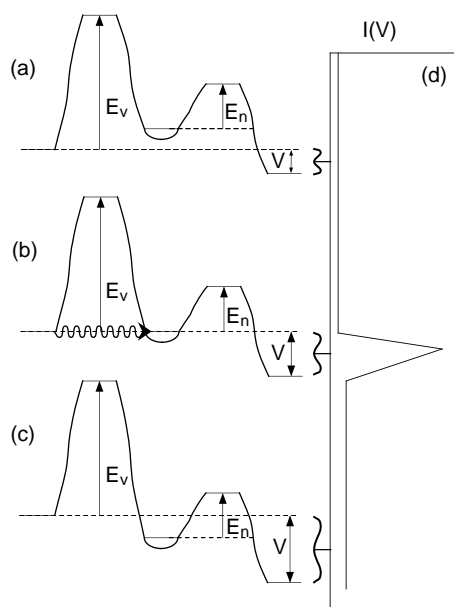

The presence of a large dipole moment due to the amino and nitro substituents affords relatively easy twisting of the central ring through the application of an external electric field [4]. In the natural coplanar arrangement, current flows with relative ease compared to the situation where the rings are in a twisted configuration. This mechanism is consistent with attenuating the conductivity with increasing applied potential. As the applied potential is increased, the torsional misalignment is forced to increase, and conductivity drops. It is more difficult to rationalize, based on this mechanism, why current flow remains negligible up to a critical applied potential, then increases by many orders of magnitude as reported for molecular junctions of AEENB [9].

One intriguing question that remains open is whether charge is carried in molecular junctions by electrons or holes. Both possibilities have been considered by Karzazi et al. [52]. This question is not simply a matter of semantics in the case of conduction in molecular junctions. If the current is carried by electrons, then applied potentials that bring the LUMO of the junction molecule into resonance with the electrode Fermi level may lead to resonance effects, while if the charge is transported by holes, applied potentials that bring the HOMO of the junction molecule into energetic alignment with the electrode Fermi level are key to resonance effects. Since the energy cost to make an ion from a neutral (negative of electron affinity) is generally different than the ionization potential of the molecule, the nature of the charge carrier will play a role in determining the energetics of electron transfer across the junction.

Quantum resonance effects could logically give rise to large increases in conductivity near a critical applied potential as alluded to in [52]. A mechanism based in part on this concept has been given considerable theoretical scrutiny by the present authors [85]. The mechanism is shown schematically in Figure 13.

Consider a molecular junction in the case of no applied potential. Here the two electrodes line up in energy. In the absence of tunneling, for an electron extracted from the left electrode to jump to the molecule forming the junction, it must have sufficient energy to access the ground state of the corresponding molecular anion, at the minimum energy geometry of the neutral molecule. This is the vertical attachment energy  $E_v$  of the junction molecule. Once the anion is formed, it naturally relaxes into its own minimum energy conformation. The difference between this energy and the energy of the relaxed neutral molecule is denoted  $E_a$ , the adiabatic attachment energy of the junction molecule. For the electron to jump from the junction molecule to the right electrode, it must have sufficient energy to reach the ground electronic state of the neutral junction molecule, at the geometry of the relaxed anion. This is denoted  $E_n$ , the vertical detachment energy or vertical reneutralization energy of the anion.

In the case  $\{E_v > E_a \text{ and } E_n > 0\}$ , there is a potential well between the electron-attachment and electron-detachment barriers, which contains resonances. Resonances are solutions of the one-dimensional Schrödinger equation that have a finite lifetime (energy width) owing to the fact that an electron, confined by the two barriers into a resonant state, may escape by tunneling.

**Figure 13.** Energy variation along the electron transfer coordinate for three representative applied potentials (a)–(c). (d) Schematic  $I/V$  characteristic of a resonant tunneling junction. There will be a dramatic increase in current due to resonant tunneling in the case where the applied potential brings the relaxed anion into resonance with the incident electron energy.

Figure 13 depicts three different cases of an applied potential ( $V$ ). When a potential difference is applied between the two electrodes, the individual electrodes are separated in energy by this difference (shown as  $V$  in Fig. 13). The minimum energy of the potential well between the electron-attachment and electron-detachment barriers will thereby be lowered with respect to the electron-donor (hole acceptor) electrode by some fraction of the applied potential [34]. (Note that since we are considering electron energy, “lowered” here means that the molecule is actually at a higher electrostatic potential.) At some applied potential, a resonant state of the potential well between the barriers will match the incident electron energy. At this point, a large increase in current due to quantum mechanical tunneling through the barrier is expected [86]. This is depicted in Figure 13b. As the applied potential is increased further, the resonant state of the molecular junction will move out of alignment with the incident electron energy and correspondingly, the tunneling current will drop. This is shown in Figure 13c. Clearly, such resonant tunneling will give rise to peaks in the  $I/V$  curve, as shown schematically in Figure 13d. The peak in the  $I/V$  curve will have a finite width due to lifetime broadening.

This mechanism has been tested by computing the values of  $E_v$ ,  $E_a$ , and  $E_n$  for several molecules for which the molecular junctions’ electronic behavior has been reported. In all cases, a highly stable anion, as indicated by a large value of  $E_n$ , correlates with the observation of NDR in the corresponding molecular junction. The origin of this correlation is clear. If the molecular junction molecule exhibits a negative vertical detachment energy, reneutralization is spontaneous and barrier free. In this case, therefore, the junction will not

give rise to a double barrier along the electron transport coordinate, and there is no resonance-enhanced tunneling.

It is interesting to consider the difference between a molecular device and traditional semiconductor band device. To the first approximation, in a molecular device the conducting electron comes from one of the valence atomic orbitals of a gold atom with which the junction molecule is in direct contact. In the case of a thiol-gold contact, for example, the  $S$  atom bonds in an  $fcc$  site [87], giving three adjacent Au atoms. The local density of states for the contact, set by just a few Au atoms, is more molecular in nature than metallic, and therefore sharply peaked. This feature, whereby the density of states is sharply peaked for the species on either side of an interface (electrode and junction molecule here), is key to a molecular device that manifests NDR [88, 89].

Much remains to be developed for this model. First of all, the partitioning of the applied potential drop across the junction molecule and associated contacts is implemented empirically, following Datta et al. [34]. A complete treatment would determine the variations in potential with first-principles theory. Secondly, the model considers a one-dimensional electron transport coordinate. A complete model would incorporate the full three spatial dimensions of the molecular junction. Finally, the model treats only the electronic properties that are *intrinsic* to the junction molecule. Ideally, one would like to include effects due to the molecule/electrode interfaces, which are known to be important [32]. Despite these shortcomings, however, the model gives important insight into the mechanism by which substituents on the junction molecule influence the presence of NDR characteristics in its  $I/V$  performance.

## 6. TECHNOLOGICAL ROADBLOCKS

Just over a decade ago, the principal challenge to molecular electronics appeared to be the problem of manipulation of matter on the nanometer scale. In the ensuing decade, this barrier was breached. This is not to suggest that it is now possible to construct any imaginable molecular device, but several techniques have been demonstrated for measuring and manipulating the electrical properties of individual molecules and molecular-scale domains of bulk material. New techniques and novel modifications of these existing techniques are being reported frequently.

Today, molecular-scale binary data storage appears to be the nearest-term application of molecular electronics technology. Data storage densities well in excess of 10 terabit  $\cdot$   $\text{cm}^{-2}$  have been shown to be possible. Such high data capacities bring a new challenge. How can one read and/or write such enormous amounts of information? Even at the blazing pace of one gigabit per second (1 ns write time), it would take 20 min to write a terabit of information. High-speed massively parallel data I/O technology will be required to take advantage of the data densities possible with molecular electronics technology.

A second major challenge to molecular-scale data storage is data integrity. Molecular-scale data storage techniques have been demonstrated with retention times of a period of days [76, 82]. This duration of data integrity is suitable for random access memory where frequent refreshes may be

employed, but is not suitable for semipermanent storage as with today's hard disk and CD technology.

It seems likely that practical molecular electronic circuits will be realized in the more distant future. The promise of creating circuits by chemical synthesis is great. Even laboratory-scale synthesis produces near-molar quantities ( $\approx 10^{23}$  units) of product. Moreover, all units are identical [4]. This level of reproducibility is unheard of in conventional manufacturing. The technical challenge lies in incorporating each of these units into a practical device. The units must be connected in some predetermined (or at least well known) manner, and the network of interacting units must be connected to a conventional macroscopic system that controls the circuitry and utilizes its interconnectivity. To date, no commercially practical analogue of the three-terminal solid state transistor has been demonstrated at the single-molecule level, although several devices with interesting nonlinear  $I/V$  characteristics have been reported (some of which have been reviewed herein) including some devices with transistor-like functionality.

The development of molecular electronics technology will certainly be guided and accelerated by parallel theoretical work. As reviewed here, the theoretical techniques for describing electron transport in molecular junctions are reasonably mature. Certainly there is great room for further development, but existing techniques are already valuable for yielding physical insight into the nature of electron transport, investigating the influence of different contact geometries on device performance, identifying the effects of changing substituent functional groups on the junction molecule, etc.

Beyond the technical challenges, however, are two other important considerations. First of all, it is possible, likely in fact, that quantum effects will be so important at the molecular level that the laws of conventional electronic circuitry simply will not apply. If Ohm's law, Kirchoff's laws, etc. can not be employed, an entirely new paradigm will be required for molecular electronic circuitry, with new devices, new design equations, etc. Quantum mechanics will serve as the starting point for the development of design equations, of course. Perhaps the computing circuitry will take advantage of the quantum mechanical nature of molecules, but this is in the realm of "quantum computing" and beyond the scope of this chapter. The second consideration is fiscal. Even if molecular scale electronics can be demonstrated, manufacturing costs may dictate the breadth of their applications. When digital computers were first available, they were so costly that they were purchased and used only by governments. Later, the price-to-performance ratio dropped to the point where their acquisition was cost-effective for large corporations, then mid-size institutions, then individuals. Today, digital computers are so inexpensive that they are used even in inexpensive consumer products. It is plausible that computing based on molecular electronics may follow a similar life cycle. A detailed discussion of cost considerations may be found in Ref. [90].

In brief, it is now possible to make a great variety of molecules with interesting electronic properties, and even to measure their electrical characteristics directly, but wiring them together into a circuit, then wiring the circuit to a robust macroscopic system, are outstanding challenges.

Beyond these technical challenges, cost considerations will play a large role in the future of molecular electronics.

## GLOSSARY

**Break junction** A junction formed by breaking a thin conductor, then closing the gap between the two ends until current flows under an applied potential difference.

**Catenane** An assembly of two or more ring molecules that are chemically independent, but mechanically linked, i.e., interlocked rings.

**Chain polymer** Linear molecule with a repeating fundamental unit.

**Conformational switching** A scheme for altering the electrical properties of a molecule by altering its geometric conformation.

**Functional group** A group of atoms that act collectively in forming molecules (Ex:  $-\text{CH}_3$ ,  $-\text{OH}$ ,  $-\text{NO}_2$ ,  $-\text{NH}_2 \dots$ ).

**Molecular junction** A single molecule captured between two metal electrodes.

**Molecular wire** A molecule with physical and electrical properties suitable for charge transport: high aspect ratio and high conductance.

**Moore's Law** A formal statement of the empirical observation that quantitative measures of computer performance (such as processor speed or memory capacity) double every 18–24 months.

**Nanoparticle** A particle of matter with characteristic dimensions in the nanometer range. Nanoparticles are characterized by a high fraction of atoms on the surface, and by electronic properties that are dependent on the size of the particle.

**Nanopore** A cavity in a solid material with characteristic dimensions in the nanometer range.

**Nanotube** Cylindrical arrangement of atoms with a diameter in the nanometer range. Most nanotubes are pure carbon and may be described as sheets of graphite rolled up and joined along opposite edges.

**Negative differential resistance (NDR)** Voltage increase is accompanied by a decrease in current,  $dI/dV < 0$ .

**Pseudorotaxane** A rotaxane that lacks one or both bulky terminal groups and therefore may spontaneously unthread.

**Quantum of conductance** The fundamental unit of conductance,  $G_0 = e^2/(\pi\hbar)$ .

**Rotaxane** An assembly of two or more chemically independent molecules in which a long chain molecule is encircled by one or more rings. The chain component is terminated on both ends with bulky functional groups to prevent unthreading of the ring(s).

**Self-assembled monolayer (SAM)** A single molecular layer that spontaneously forms on a surface, typically in a regular arrangement of molecules.

**Thin film** A thin (typically 1–100 nm) layer of material.

**Thiol** A molecule containing the  $-\text{SH}$  group.

## ACKNOWLEDGMENTS

K. S. acknowledges support from the National Science Foundation Nanoscale Exploratory Research program, Drexel University in the form of generous startup support, and Dupont Corp. for a Dupont Young Professor Award. Computations were partially supported by the National Center for Supercomputing Applications (NCSA) under grant CHE010012N to N.M. and utilized the SGI Origin2000 at NCSA, University of Illinois at Urbana-Champaign.

## 1. INTRODUCTION

The ability to fabricate well defined large area nanostructures has important implications for both fundamental research and industrial applications [1–3]. In fact, the state of the art microelectronic circuits are made of semiconductor features of a critical dimension close to 100 nm which can only be produced cost-effectively by using high performance optical lithography tools. To extend the current CMOS (complementary metal oxide semiconductor field effect transistor) technology with a critical dimension down to 20 nm, new manufacturing tools will be required because of the diffraction limit of the conventional optical methods. For this reason, the semiconductor industry has developed the so-called next generation lithography by considering new irradiation sources such as extreme ultraviolet (UV) light, X-rays, as well as projection electron or ion beams.

Not only the microelectronic industry but also many research and other industry branches need more and more nanofabrication tools. For example, patterned nanostructures such as photonic crystals are becoming attractive for the development of new optical and optoelectronic devices [4]. Patterned magnetic nanostructures are now studied for ultrahigh density storage and for the fabrication of the emerging spin–electronic devices [5]. In the domain of biology and biomedical research, microarray chips and microfluidic devices are in rapid progress toward a high degree of functionality and integration [6]. In all these areas,

flexible and low-cost manufacturing techniques are required for research, prototyping, and low volume production.

A broad range of conventional and nonconventional nanofabrication methods is under investigation [7]. The challenge is to develop straightforward fabrication tools and processes that allow one to produce patterns with a minimum feature size down to a few nanometers and to integrate various functionalities over large areas. Here, the requirement of the nanometer scale is important for both current research and future development. For example, the fabrication of molecular electronic circuits will be based on molecular self-assembly with high density nanoelectrodes [8].

Nanoembossing is one of the most studied nanofabrication methods during the last few years [9–16]. Unlike conventional lithography methods which use photons or charged particles to expose a resist layer in a way similar to photography [17, 18], nanoembossing relies on pattern replication by physical deformation of a thin polymer layer with a rigid mold. Although the classic embossing techniques have been widely used for many years, only quite recently attention has been paid to the replication ability of ultrasmall features. Compared to the sophisticated optical lithography methods, nanoembossing is more flexible and much less expensive. Compared to electron beam (e-beam) lithography and scanning probe lithography, nanoembossing is well suited for large scale and high throughput production. Due to these advantages, nanoembossing techniques are now considered a new strategy for future nanotechnology development [16].

Nanoembossing technologies include mold fabrication, polymer design, pattern replication, and subsequential pattern transfer. Molds are generally obtained by e-beam lithography which defines pattern in a thin layer of resist and reactive ion etching (RIE) or electroplating for the pattern transfer. Either thermoplastic or thermosetting polymers can be embossed at elevated temperatures but embossing can also be performed at room temperature with photocurable polymers and UV irradiation. In general, the embossed nanostructures can be used directly in plastic device making or as masks for a subsequent pattern transfer. This latter technique, namely nanoimprint lithography, consists of embossing first a thin layer of polymer spin coated on a substrate and then removing the recessed area by reactive

ion etching (Fig. 1). Thus, the resulting resist profiles are comparable to those obtained by optical or e-beam lithography so that a large number of applications can be developed. In this chapter, several nanoembossing techniques are described, including discussions of their fabrication performances and application examples.

## 2. MOLD FABRICATION

All embossing techniques rely on the fabrication of molds which defines the original patterns to be replicated. For nanoscale features, molds are produced by advanced nanofabrication methods. A silicon wafer, with or without a covering of a thin film of dielectric or metal material such as silicon dioxide ( $\text{SiO}_2$ ), silicon nitride ( $\text{Si}_3\text{N}_4$ ), or tungsten (W), can be used as substrate. E-beam lithography is commonly used to expose a resist layer on the substrate [18]. Then, reactive ion etching or electroplating is used for the pattern transfer. Finally, an antisticking film is coated on the mold surface to promote the mold-sample separation.

Commercial e-beam systems working at 50 keV electron energy provide a routine resolution of 50 nm or smaller [19]. Features of higher resolution can be obtained by using the state of the art e-beam systems at high beam energy (100–200 keV) [20, 21]. Under optimal conditions, 10-nm [22] and sub-10-nm features [23–25] can be obtained but particular attention has to be paid to the resist development and the pattern transfer processes. Poly(methylmethacrylate) (PMMA) is commonly used as e-beams resist but the recent development showed that other polymers such as hydrogen silsesquioxane (HSQ) are also suitable for very high resolution patterning [20, 26, 27].

The resist pattern defined by e-beam lithography can then be transferred by reactive ion etching into the underlayer material or by electroplating [28, 29]. If reactive ion etching is used, an etching mask, commonly obtained by a thin metal film deposition and lift-off, is required for high resolution pattern transfer [18]. The quality of the lift-off is mainly affected by the resist profile and the thickness of the deposited metal film is typically three times less than the resist thickness. The reactive ion etching is based on simultaneous exposure of the sample to chemical reaction species and fluxes of energetic particles. The etched materials are then pumped away as volatile gaseous species. For polymers, silicon, silicon-based dielectric materials, and some

metals,  $\text{SF}_6$ ,  $\text{CHF}_3$ , and  $\text{O}_2$  gas mixtures are commonly used to obtain vertically etched sidewalls with an accurate control of the etch depth. If electroplating is used, as a thin layer of metal is first evaporated on the embossed surface, followed by electroplating until a desired thickness is obtained. Then, the electroplated sheet is separated from the resist sample and can then be used as metal mold for embossing. Patterning can also be done with a focused ion beam directly but this method is time consuming and suited only for particular applications.

As mentioned, high resolution patterns can be obtained by high energy e-beam lithography. It is, however, difficult to obtain high density features over large areas. A spatial frequency doubling technique has been tested for the fabrication of gratings of 100-nm period [30]. This technique consists of exposing a grating of 200-nm period by interferometric lithography and then processing a sequence of standard microfabrication steps to double the grating's spatial frequency. Other techniques such as edge defining [31] and photoelectrochemical etching [32] can be used to obtain some specific sub-10-nm features.

To emboss photocurable polymers, transparent molds are generally required which can be obtained by patterning a quartz plate either with or without an indium tin oxide (ITO) thin film coating. More sophisticated mold configurations such as a  $\text{SiO}_2$ /ITO double layer on a substrate have also been tested, showing several advantages in terms of e-beam writing performance (no charging), electron microscope inspection, and pattern transfer because of the high selectivity of dioxide to ITO during a dry etching process [33].

Silicon molds of large etch depth can be obtained by deep RIE [34]. Conventional RIE with SU-8 resist as etch mask has also been used to achieve an etch depth of more than 10  $\mu\text{m}$  and silicon molds containing both shallow and deep features could be obtained using mix and match techniques [12]. Finally, three-dimensional (3D) structures can be obtained by anisotropic wet etching of a silicon substrate [35] or two-step RIE [36, 37]. More complex 3D structures can be obtained by e-beam lithography with a modulated dosage distribution [38]. For example, Ni molds with curved cross-sectional structures could be obtained and tested for the fabrication of diffractive optical elements [39].

Once a master mold has been made, it can be reproduced by nanoimprint lithography, followed by either RIE or electroplating for the hard material pattern transfer. With a well controlled fabrication process, the quality of the copied molds can be comparable to the original ones. Finally, full plastic molds can be obtained by casting-and-molding a thermosetting polymer, which can then be used as conventional molds [40].

In general, a surface treatment of the mold is necessary to avoid the sticking problem. It is known that the sticking or adhesion strength between a mold and a polymer coated sample depends on the physical and chemical properties of the surfaces of the two materials in contact. Physical adhesion is related to the van der Waals force and hydrogen bonds, while chemical adhesion is due to ionic, atomic, or metal bonds between surfaces. The larger the contact area, the stronger the adhesion. An antistick layer deposited on

**Figure 1.** Schematic representation of nanoimprint lithography.

the mold is generally necessary to promote the mold separation. A number of layers have been tested including a deposition of metal thin films [41], Teflon-like molecules [42], or fluorinated silanes [43]. Commercial release agents such as manufactured by Dow Corning (DC20) can also be used and a detailed analysis of the antisticking methods can be found in [14]. In practice, the choice of the antisticking treatment depends on the type of the mold and the polymer in use as well as the embossing conditions. For nanoembossing of photocurable polymers for example, specific polymer mixtures and fabrication sequences are required because of the chemical reaction involved during photopolymerization [14].

### 3. NANOEMBOSSING AT ELEVATED TEMPERATURES

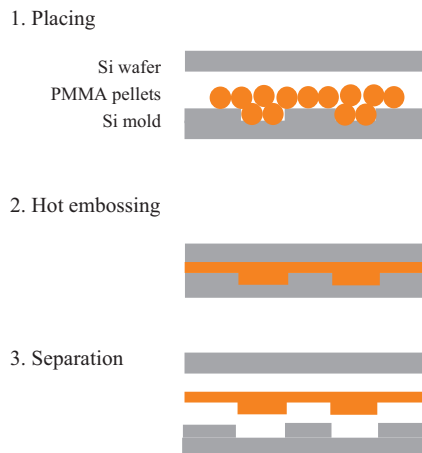

Both thermoplastic and thermosetting polymers can be embossed at elevated temperatures. Commercial embossing systems [44, 45] as well as a cheap hydraulic press equipped with a pair of hot plates [46] have been used for nanoembossing with a wide range of working temperatures and pressures. In this section, we focus on “hot embossing” of high resolution polymer features. In the next two sections, we will discuss nanoimprint lithography and nanoembossing of photocurable polymers.

#### 3.1. Nanoembossing of Thermoplastic Polymers

Thermoplastic polymers such as PMMA, polycarbonate (PC), polyvinylchloride, and poly(ethylene terephthalate glycol) can be used for the fabrication of miniaturized plastic pieces [29]. They soften and eventually liquefy when heated and harden when cooled. Nanoembossing of thermoplastic polymers can be performed in different ways: (a) imprinting a commercial plastic plate, (b) imprinting a thin polymer film spin coated on a substrate, and (c) compressing polymer pellets. The first technique is the simplest one. A rigid mold is pressed into a heat-softened polymer plate at temperatures slightly above  $T_g$  under moderate pressure or below  $T_g$  under elevated pressure [47, 48]. The second technique, imprinting a thin polymer film spin coated on a substrate, will be discussed in detail in the next section. The third technique is based on thermal compression of cheap polymer pellets, which takes advantage of both injection molding and imprinting techniques [12, 49] (Fig. 2). Here, polymer pellets are placed on a silicon mold and covered by a flat silicon wafer. They are then inserted between two hot plates of a hydraulic press and the temperature is raised to a value well above the polymer’s  $T_g$ . At the embossing temperature, a pressure is applied and maintained during cooling down. Below  $T_g$ , the pressure is released and the patterned plastic sheet is removed from the mold.

Let us first consider some general properties of thermoplastic polymers. Thermoplastic polymers are formed from monomers via chemical bonding. When an amorphous thermoplastic polymer is heated above its glass transition temperature,  $T_g$ , it behaves like a viscous liquid.  $T_g$  depends on the molecule weight of the polymer [50],

$$T_g(M_w) = T_g(\infty) - \frac{A}{M_w} \quad (1)$$

**Figure 2.** Schematic representation of the fabrication method involving hot embossing of thermoplastic polymer pellets.

where  $A$  is a constant and  $T_g(\infty)$  is the value of large molecular weight. For example,  $T_g$  is 113 °C for 50 kg/mol PMMA and 120 °C for 950 kg/mol PMMA.

The deformation rate of a perfect viscous liquid is proportional to the shear stress,

$$\frac{\partial \epsilon}{\partial t} = \frac{1}{\eta} \sigma \quad (2)$$

where  $\eta$  is the viscosity parameter of the liquid which also depends on the molecule weight of the polymer. For small shear,

$$\eta \propto M \quad (M < M_c) \quad (3a)$$

$$\eta \propto M^{3.4} \quad (M > M_c) \quad (3b)$$

where  $M_c$  is the critical value of the molecular weight for the given polymer type. For PMMA,  $M_c = 30$  kg/mol [50].

The viscosity parameter of a polymers decreases rapidly with temperature. For the temperature range well above  $T_g$ , the Arrhénius law can be applied,

$$\eta = \eta_0 \exp\left(\frac{\Delta E}{RT}\right) \quad (4)$$

where  $R$  is the universal gas constant (8.3 J/mol K) and  $\Delta E$  is the activation energy of the viscous flow which is of the order of  $10^4$  J/mol and depends on the specificity of the polymer. Typically, nanoembossing can be done at a temperature of about  $T_g + 60$  °C and the applied pressure must be maintained during cooling so that the embossed articles will retain their sharp sidewall.

We have embossed PMMA pellets (Oroglas V825T,  $T_g = 108$  °C from Atofina) at 180 °C with a pressure of 100 bar for a few minutes. For thick PMMA plates, a metallic frame for lateral confinement is added. Typically, 4 to 5 pellets of roughly  $3 \times 3 \times 3$  mm<sup>3</sup> are needed to produce a  $3 \times 4$  cm<sup>2</sup> PMMA sheet of thickness of several hundred micrometers, while roughly 40 pellets are needed for millimeter-thick plates [12]. The fabricated structures showed well-defined shapes and excellent surface quality, exhibiting a roughness less than 5 nm, as on the mold. Figure 3a displays a scanning

**Figure 3.** Scanning electron micrograph of micro- and nanostructures simultaneously embossed on a PMMA plate: (a) the intersection of two 11- $\mu\text{m}$ -deep and 50- $\mu\text{m}$ -wide microchannels with an excellent surface roughness and (b) a portion of a 300-nm-period triangular array of 150-nm-diameter nanopillars of 200-nm thickness. Reprinted with permission from [12], V. Studer et al., *Appl. Phys. Lett.* 80, 3641 (2002), © 2002, American Institute of Physics.

electron microscopy (SEM) image of the intersection of two 10- $\mu\text{m}$ -deep and 50- $\mu\text{m}$ -wide microfluidic channels. These channels reproduce the high surface quality and vertical sidewalls of the Si master. Figure 3b shows a SEM image of a 300-nm-period triangular array of 150-nm-diameter nanopillars of 200-nm height, created inside a channel of 200-nm depth and 50- $\mu\text{m}$  width, extended over a total length of 7 mm. This structure was initially designed as an artificial gel for DNA molecule separation [51]. The embossed features show extremely good uniformity and can be covered by another PMMA sheet via thermal bonding. Our experiences showed that complex features can be obtained without carefully adjusting process parameters, indicating the simplicity of the process and the ability to produce high resolution plastic devices. Thermoplastic polymers other than PMMA such as cyclo-olefin copolymers have also been used, showing also the ability to replicate nanostructures.

Compared to injection molding which is the common manufacturing technique of plastic articles [52], nanoembossing is more suitable for prototyping and the replication of high aspect ratio features. In practice, all injection machines are designed for high volume production and the fabrication of injection molds requires high accuracy machining and careful mold adaptation. Besides, the large sizes of the injection molding machines are not compatible to the laboratory scale experimentation. Nevertheless, the production rate of injection molding is substantially high which should also enable one to produce nanometer features [53, 54].

### 3.2. Nanoembossing of Thermosetting Polymers

Thermosetting polymers become permanently hard once cured by a chemical reaction at elevated temperatures. Embossing of a thermosetting polymer consists of first filling a mold cavity with a liquid prepolymer (linear polymer with a low molecular weight) and then converting it into hard product with the desired shape. During curing, chemical and structural changes occur by cross-linking which makes the final product dimensionally stable. Compared to

thermoplastic polymers, thermosetting polymers are generally inert and difficult to remove chemically [55]. A number of thermosetting polymers, including epoxies, phenolics, and polyester, can be useful for the embossing experiments [55, 56].

In particular, poly(dimethylsiloxane) (PDMS), which consists of repeated units of  $-\text{OSi}(\text{CH}_3)_2\text{O}-$ , is now widely used for the fabrication of microfluidic devices and stamps for microcontact printing [57–64]. PDMS is attractive because it is mechanically deformable (elastomer), nontoxic, chemically inert, and optically transparent. High resolution PDMS structures can be obtained by casting a liquid prepolymer mixed with a cross-linking catalyzer. After curing at 80 °C for one hour, the solidified PDMS is separated from the mold which can then be used for various applications.

To obtain PDMS thin films, the mold is coated with PDMS prepolymer solution and then covered with a plastic film. After curing under a desired pressure and cooling down, the plastic film is removed. By placing a thicker PDMS carrier on the top of the embossed thin film and thermal bonding, a bilayer PDMS structure is obtained. Repeating this process several times, a multilayer PDMS device can be made [60, 61]. The bilayer PDMS structure can be used for example as a stamp for high resolution microcontact printing [58, 62]. Here, the stamp is first inked with thiol molecules [hexadecanethiol ( $\text{C}_{16}\text{H}_{33}\text{SH}$ ) in ethanol] and then placed on a gold coated substrate for a few seconds. This results in a self-assembled monolayer of the thiol molecules in certain portions which can then be used as a mask for chemical etching. In order to make the microcontact printing fully compatible to other pattern transfer techniques, a resist film can be introduced before depositing the gold layer. After chemical etching of the gold, the pattern can then be transferred into the resist [63, 64]. The advantage of using a bilayer PDMS stamp relies on its enhanced bulk stiffness so that a large area stamp cavity is allowed.

By spin coating PDMS prepolymer liquid on both mold and substrate surfaces and then bonding them together thermally, high quality features can be obtained after removal of the mold [65]. For very thin PDMS structures, the embossed features can be used for pattern transfer via RIE or lift-off [66].

### 3.3. Nanoembossing of Other Types of Materials

Nanoembossing can also be applied to other types of materials. One of the examples is direct embossing of silicon nanostructures with a high power laser irradiation [13]. In the first experience, an excimer laser of 308 nm wavelength and 20 ns pulse duration is used which passes through a quartz mold and melts the silicon surface to a depth of a few hundreds of nanometers. Under pressure, the melt silicon is deformed and then solidified rapidly, resulting in a perfect replication of the mold surface structures. The total processing time including heating, embossing, and cooling is short (250 ns). To illustrate the high resolution ability, replication of a grating of 300-nm period and 110-nm depth has been demonstrated. Under a scanning electron microscope, one can observe a reproduction of 10-nm edge features. The same process has been used to emboss large mesa areas as

well as a polysilicon layer deposited on a silicon wafer separated by a 200-nm silicon dioxide. These results have largely enhanced the interest of nanoembossing techniques because of the direct embossing strategy and fast processing. This technique could be extendable to other materials and fabrication processes [67].

More generally, materials including functional polymers [68–70], photoresists [71], block copolymers [72], liquids [73], metals [74], as well as sol–gels [75] and piezoelectric materials [76] can be directly embossed. In the case of photoresist embossing, for example, a small amount of solvent (<1 mL) is applied to a PDMS mold and then the mold is placed on a layer of photoresist spin coated on a substrate. In this way, the solvent swells the photoresist and forms a gel that conforms to the mold surface relief. After the solvent has diffused into the resist, the mold is removed and a flood illumination can be applied which results in sub-100-nm features [71]. In the case of liquid embossing, isolated features can be obtained by placing a PDMS mold on a sufficiently thin film of liquid (<500 nm). After removing the mold, the liquid remains patterned which enables the rapid patterning of inorganic nanocrystal solution, as capping groups and solvents can volatilize efficiently at the exposed liquid surface [73]. In the case of SiO<sub>2</sub>-TiO<sub>2</sub> sol–gel embossing, a mixture of tetraethoxysilane, titanium tetrabutoxide, catalyst, solvent, and surfactant is first spin-coated onto a silicon wafer and then embossed under high pressure and a ramp of temperature from 17 to 200 °C, followed by a 400 °C annealing for 15 min in air. The embossed structures showed 300 nm gratings without cracking over a few cm<sup>2</sup> [75]. Finally, for embossing piezoelectric materials, a specific process, namely a lost silicon mold process which consists of casting of lead zirconate titanate slurry, drying, and calcinations, followed by a hot isostatic pressing after a glass encapsulation [76], has to be used because of large volume shrinking.

#### 4. NANOIMPRINT LITHOGRAPHY

Nanoimprint lithography was invented in 1995 by Chou et al. [9] and has quickly become a widely applied technique [33, 35, 77–82]. As shown in Figure 1, the main advantage of this technique relies on its simplicity and versatility which is, in particular, fully compatible to most semiconductor fabrication steps. Although the imprinting condition can be optimized experimentally, some simple considerations are helpful for the determination of the important processing parameters.

##### 4.1. General Considerations

The imprint condition changes with the polymer type and the pattern specification. In general, the mold etch depth is in the order of 100 nm and the polymer thickness of the recessed areas after imprinting should be small enough, typically 20 nm, for keeping the imprinted polymer shape during RIE. For a large area pattern replication, polymer flows can take place over a long distance in the mold and sample confined narrow space. A fundamental understanding of how a viscous polymer travels through this narrow space is interesting but a simple schematic of the mold cavity filling is

helpful for the mold design and the determination of first imprinting conditions.

Let us split the imprinting process into three periods, as shown in Figure 4. At the beginning, the imprint speed is high since the mold–sample contact area is small (regime 1). The transient period (regime 2) is characterized by the complete filling of the mold cavity, but no polymer is pushed outside of the mold area. In the end, the total mold area is pressed into the polymer so that a part of the polymer is forced to flow to outside of the mold area (regime 3). Considering a constant polymer volume, we obtain for regime 2

$$h_i = h_c + fh_m \tag{5}$$

where  $h_i$ ,  $h_c$ , and  $h_m$  are respectively the initial thickness of the polymer layer, the final thickness of the recessed area, and the mold etch depth;  $f = A_e/A_t$ ,  $A_e$  and  $A_t$  being the etched area and the total area of the mold, respectively.

If the etched portion of the mold is substantially large ( $A_e \sim A_t$ ), a complete mold filling is obtained when  $h_i \approx h_c + h_m$ . On the contract, if  $A_e \ll A_t$ , a complete filling is difficult and additional etch areas can be introduced to increase the embossing speed.

For periodic structures, the factor  $f$  can be calculated, allowing a close correlation between  $h_i$ ,  $h_c$ , and  $h_m$ . For example, when  $h_m = 150$  nm and  $h_c = 20$  nm, the initial polymer layer thickness should be  $h_i = 95$  nm for a line grating,  $h_i = 140$  nm for a dot array, and  $h_i = 50$  nm for an antidot array of equal line and spacing.

To estimate the imprinting speed, the Navier–Stokes equation reduced for a noncompressive liquid ( $\nabla \cdot \mathbf{v} = 0$ ) and small Reynolds number conditions can be used [83],

$$\eta \Delta \mathbf{v} = \nabla p \tag{6}$$

**Figure 4.** Schematic representation of the three regimes describing the mass transport in nanoimprint lithography.

where  $\eta$  is the viscosity of the polymer,  $v$  is the velocity, and  $p$  is the pressure. Assuming a single dot of radius  $a$  located in the center of a disk of radius  $R$ , the pressure under the dot is given by

$$p(r) = p_0 + \frac{3u\eta}{2h^3}(a^2 - r^2) \quad (r < a) \quad (7)$$

where  $h$  is the polymer thickness of the recessing area, and  $u = dh/dt$  is the imprinting speed.  $p_0$  refers to the pressure value outside of the dot area. For a homogenous load, the imprint speed at the beginning (regime 1) and at the end (regime 3) are obtained as

$$u_a = \frac{4h^3}{3\pi\eta a^4}F \quad \text{and} \quad u_R = \frac{4(h + h_m)^3}{3\pi\eta R^4}F \quad (8)$$

where  $F$  is the force applied to the mold. Clearly, at the beginning the load is charged over a small area ( $\pi a^2$ ) and the polymer flow occurs only in the proximity of the dot. In the end, the load is charged over the entire mold area ( $\pi R^2$ ) and the mass transport occurs over a long distance. Obviously, when  $a \ll R$ ,  $u_a \gg u_R$ , suggesting a fast imprinting at the beginning and a very slow deformation in the end.

To estimate the imprint speed, we consider a mold of diameter 10 mm with 100 dots of diameter 100  $\mu\text{m}$  and etch depth 150 nm. When a force of 20 kg is applied to a 100 kg/mol PMMA layer of initial thickness 200 nm heated at 200 °C ( $\eta = 5 \times 10^4$  N s/m<sup>2</sup>), we obtain an imprint speed of 54  $\mu\text{m/s}$  at the beginning ( $h \sim 200$  nm) but only 0.8  $\mu\text{m/s}$  at the end ( $h \sim 150$  nm). When the mold is entirely pressed in the polymer, the imprint speed becomes much slower ( $8 \times 10^{-9}$   $\mu\text{m/s}$ ).

For a more realistic modeling, surface tension, capillary force, as well as size of the polymer molecules have to be taken into account [84, 85]. The later effect is particularly important when the imprinting recessed area is comparable to the molecule size. It is known that polymers are formed of large number of molecular chains; each may bend, coil, and kink. For a linear polymer molecule, the gyration radius  $R_g$  is equal to [53]

$$R_g = \frac{1}{6}l\sqrt{N} \quad (9)$$

where  $l$  is the bond length between chain “atoms” and  $N$  is the total number of bonds in the molecule. For 50 kg/mol (950 kg/mol) PMMA,  $R_g = 20$  nm (100 nm), which are both comparable to the thickness of the imprinting recessed area. It is therefore necessary to solve the Navier–Stokes equation taking into account this effect. Suppose that all contact points between the polymer molecules and the solid surface are fixed; the effective viscosity can be obtained [84] as

$$\eta(z) = \eta_b/W(z) \quad (10)$$

where  $\eta_b$  is the viscosity of the polymer without strain and  $W(z)$  is the probability that a monomer is not in contact with the wall. The solution of the Reynolds problem is then the same as obtained previously [Eqs. (7) and (8)], except that  $\eta$  is replaced by  $\eta_b/\delta$  and

$$\delta = \frac{3}{\pi} \sum_{n=1}^{\infty} \left[ \frac{1}{2n^2} - \frac{4}{\pi^2} \frac{1}{n^2} \right] \exp\left(-\frac{\pi^2 R_g^2 n^2}{h^2}\right) \quad (11)$$

## 4.2. Imprinting Conditions

A number of polymers have been used in nanoimprint lithography. Because of their different characteristics, the imprint conditions must be evaluated for each polymer and each particular pattern [86–88]. For most applications, polymers with a low molecular weight and a low glass transition temperature are preferable because of their low viscosity. For example, the imprinting temperature for the 950 kg/mol PMMA is typically 175 °C while it is only 150 °C for the 50 kg/mol PMMA with the same applied pressure. In general, small and homogenously distributed features can be more easily replicated compared to large features. For example, 1  $\mu\text{m}$  features can be replicated into the 50 kg/mol PMMA at 150 °C but 100  $\mu\text{m}$  features can only be replicated at 175 °C for the same applied pressure. When different types of patterns are presented on the same mold, the imprinting condition has been evaluated for the largest features because it is more difficult to evacuate the polymer from large imprinting areas. Under optimal conditions, features of sizes ranging from 50 nm to 100  $\mu\text{m}$  could be simultaneously replicated over an area of several mm<sup>2</sup> [86].

The RIE resistance of the polymer should be high enough for an easy process control. In addition to PMMA, a number of thermoplastic polymers such as polycarbonate and polystyrene have shown imprinting performances similar to that of PMMA. Commercial resists for both optical and e-beam lithography have also been tested [88, 89]. For example, Shipley resist S1805 which is based on novolac resin allowed the replication of 50-nm features with a better etching resistance to oxygen plasma compared to PMMA and thus a better process control [88].

Several aromatic polymers based on methacrylates (linear polymers) and multifunctional allylestere (crossing polymers) also showed comparable behaviors of the PMMA. In particular, the thermoplastic prepolymer MRT-9000 can be cross-linked during or after embossing to form a patterned polymer layer with a pretty high thermal and chemical stability [90–92].

Hyperbranched polyesteramides (hybranes) were synthesized from di-isopropanolamine and an anhydride of choice; end-capping of the obtained poly-ol with a carboxylic is optional [93]. Depending on the molecules presented in the branched groups, the glass transition temperature of the hybranes varies from 10 to 70 °C [94, 95]. Accordingly, nanoimprinting can be done at relatively low temperatures. Besides, the viscosity of the hybrane polymers decreases more rapidly with temperature compared to PMMA and the etch resistance of hybranes to O<sub>2</sub> plasma is almost twice that of PMMA, allowing a more accurate etch control of the recessed area. Another advantage is that some of the hybrane polymers can be used for low temperature and/or low pressure imprinting. In particular, 75 nm line and space gratings have been successfully replicated at room temperature (RT) with a semicrystalline hybrane (2550).

Generally, semicrystalline polymers are ductile in the temperature range between the glass transition and the melting temperature. For hybrane 2550, the glass transition temperature and the melting temperature are respectively 10 and 40 °C so that at RT nanoimprinting is performed at a solid state. Above the melt temperature ( $\sim 50$  °C), it is a

liquid so that the imprinting can be done under low pressures. Other types of semicrystalline polymers have shown similar behaviors, for example, solid state and melt embossing at 220 and 330 °C for the poly(tetrafluoroethylene-co-hexafluoropropylene) (PEF), 90 and 180 °C and for the polyethylene, and 90 and 300 °C for the polyester, respectively. In particular, submicrometer surface structures have been obtained on a PEF thin film by combining melt (first) and solid state (second) embossing to demonstrate the feasibility of a two level fabrication [96].

Another RT approach is to use a polystyrene (PS) film after a solvent vapor treatment. Since a solvent treated polymer has a decreased glass transition temperature and viscosity, embossing is possible at RT under a high enough pressure. Without solvent treatment, imprinting is still possible due to the plastic flow along with free-volume contraction and plastic deformation of the resist layer. Submicrometer features could be replicated at RT at a pressure between 300 and 1500 bar for 5 to 40 min [97, 98].

Finally, RT imprinting has been demonstrated using a spin on glass (SOG) resist [99]. Here, solution of organosilica [ $\text{Si}(\text{OH})_4 + \text{R}_1\text{COOR}_2$ ] in alcohol was first spin coated on a silicon substrate and then embossed at RT with a typical pressure of 25 bar. Features of 200-nm linewidth could be obtained and transferred into the substrate via lift-off or direct RIE. Because of the presence of silicon, the etch selectivity of SOG is clearly better than that of the PMMA.

Most nanoimprint lithography was performed by imprinting a thin polymer layer on a substrate. Alternatively, one can first spin coat PMMA on both mold and wafer and then transfer the polymer layer of the mold to the wafer substrate. After spin coating, the polymer layers on the mold and the wafer are annealed and the mold and the wafer are pressed against each other at a temperature above  $T_g$  of the polymer. After cooling, the mold is separated from the wafer, leaving a replicated pattern on the surface of the wafer [100]. To promote the adhesion of the polymer film to the substrate, a release agent has to be coated on the mold and an adhesion layer on the wafer. The bonding occurs at pressure and temperatures lower than those of standard nanoimprinting and the problems related to the lateral transport of the polymer disappear in the present configuration. Quite similarly, a reversal imprint lithography has been studied which consists of simply spin coating a polymer layer on a mold and then transferring it onto the substrate by thermal bonding [101]. Either suspended structures over wide gaps or supported patterns on raised features of the substrate could be obtained in this way [102], thus providing a way to form multilayer and three-dimensional polymer structures.

Alignment is required for multilevel applications. So far, most demonstrations have been based on experiences using optical aligners outside the imprint apparatus. For example, multilayer nanoimprint lithography has been performed over 4 in. silicon wafers which showed an alignment accuracy of 1  $\mu\text{m}$  [103]. The mold and the wafer were first aligned with an optical aligner and then fixed with a hold and placed in an imprint machine. An average alignment accuracy of 1  $\mu\text{m}$  with a standard deviation of 0.4  $\mu\text{m}$  in both  $X$  and  $Y$  direction was obtained in 10 consecutive tests. For a higher accuracy, alignment and imprint should be performed with the same machine but no commercial system is

now available. Another problem for high accuracy alignment is the wafer distortion due to different thermal coefficients between mold and an imprint substrate. A method was proposed which consists of comparing directly the mold and wafer alignment marks without intermediate optics [104]. The mold is deliberately deformed with a system of piezoelectric actuators in such a way that the induced distortions precisely match those on the wafer and all of the alignment marks are pulled into registration simultaneously. Experimental demonstration with sophisticated optics and piezoelectric actuators is expected.

Actually, *mix-and-match* processes are more suitable for the fabrication of multilevel devices [105–107]. Whereas nanoimprint lithography is often used for the first level high resolution patterning, UV lithography with alignment can be used to pattern features such as bond pads for electric wiring. In some cases, this order can be inverted but an alignment is generally required before imprinting [106]. Finally, the *mix-and-match* techniques can also be used by combining nanoimprint lithography and other high resolution methods such as X-ray [80], e-beam, focused ion beam, and scanning probe lithography techniques [107].

### 4.3. Pattern Transfer Techniques

The commonly used transfer techniques are lift-off, electroplating, and reactive ion etching. In general, the quality of the transfer depends not only on the imprinted resist profile but also the RIE of the recessed area.

For lift-off, a resist profile of undercut or vertical sidewall is required and the thickness of the deposited metal film should be significantly smaller than the resist thickness. For high quality fabrication, the metal evaporation process has to be optimized to avoid asymmetric deposition, thickness inhomogeneity or crown forms. For gold deposition, an adhesion layer of Ti or Cr is needed. To produce three-dimensional structures such as  $T$  gate and air-bridge structures, sophisticated lift-off techniques can be used [108]. For features of high aspect ratio, a trilayer process is preferable but electroplating can also be used for a number of metals (gold, nickel, cobalt, iron, etc.). Here, the height of the plated metal can be close to or larger than the resist thickness and features of sizes down to 20 nm can be obtained [109, 110]. The third technique of the pattern transfer is RIE by using either resist or metal patterns as etch masks. Polymers containing silicon are studied as etch masks because of their high etch resistivity. Whereas fluorine based gas mixtures are used to etch Si,  $\text{SiO}_2$ ,  $\text{Si}_3\text{N}_4$ ,  $\text{TiO}_2$ , W, and various polymers, chlorine based gas mixtures are commonly used for III–V semiconductors. To etch metallic structures, ion milling is more suitable.

In nanoimprint lithography, high resolution features can only be obtained with a thin resist layer. In order to achieve both high resolution and high aspect ratio, trilayer systems have been developed [64, 88]. A typical trilayer system consists of a thick bottom layer which is thermostable at the imprint temperature PMGI (polymethylglutarimide) [111], a thin intermediate layer (10-nm thick Ge), and a top imaging layer (PMMA) (Fig. 5). After imprinting, the thickness contrast of the top layer is amplified by a sequential etching

**Figure 5.** Schematic representation of the trilayer nanoimprint process.

of the whole trilayer system with  $O_2$ ,  $SF_6$ , and  $O_2$  plasmas. This trilayer process is particularly useful for systematic studies where different metal thicknesses are required. Moreover, by overetching the bottom polymer layer, structures of different sizes can be obtained with the same mold [88]. Because of the high aspect ratio at the bottom layer, electroplating and direct etching can also be applied for hard material pattern transfer. Besides, trilayer nanoimprint lithography can have large process latitude and good pattern homogeneity over large areas.

Other combinations of multilayer resists have also been tested, including PMMA/Al/novolac resin [85], PS/PMMA, PMMA/novolac resin [112], and P(MMA-MAA)/PMMA systems [113]. For example, the PMMA/Al/novolac resin trilayer system can be etched by a sequential etching with  $O_2$ ,  $BCl_3$ , and  $O_2$  plasma and the patterned structures were studied for metal oxide silicon field effect transistor (MOSFET) fabrication using a silicon on insulator (SOI) substrate with  $0.1 \mu\text{m}$  gate length, showing no degradation of the device performance [85].

## 4.4. Lithography Performances

The performance of nanoimprint lithography depends on a number of factors: the quality of the mold, the characteristics of the polymer, the imprinting parameters, and the details of the etching and lift-off processes [86]. The following assessments outline the state of the art achievements.

### 4.4.1. Resolution

In the earliest reports, Chou et al. have demonstrated a replication of dot arrays with a minimum feature size as small as 6 nm and a pitch size down to 40 nm [10, 77]. More complicated patterns such as Fresnel zone plates with a minimum feature size 75 nm and circuit gratings of 20-nm minimum linewidth were obtained later, by using a silicon mold of etch depth of 100 nm and 70-nm thick and 15 kg/mol PMMA, followed by metal evaporation and lift-off [114]. So far no better result has been reported in terms of the feature size and the pattern complexity. For a routine fabrication, feature sizes down to 50 nm (100-nm pitch) can easily

be achieved with several types of polymers [88]. Figure 6 shows a nickel dot array of 60-nm pitch, obtained by nanoimprint and lift-off. It is believed that within the limit of a few nanometers, the achievable feature size depends mainly on the mold fabrication, (i.e., e-beam lithography patterning). Much effort has to be devoted to ultrahigh resolution patterning over large areas. Other factors such as polymer characteristics (molecule size, viscosity, etching resistance, etc.) and imprint and etching conditions also have to be controlled carefully for sub-50-nm resolution patterning. In general, it is more difficult to replicate large areas and dense lines than dot arrays because of the lift-off difficulty. The minimum linewidth of line and space gratings reported so far is around 100 nm. Replication of 100-nm period grating is currently studied for advanced optical applications [30]. Fine lines can be obtained by overetching the nanoimprint defined structures. Figure 7 shows sub-10-nm silicon lines obtained by trilayer nanoimprint lithography and a sequential RIE of the silicon layer of a SOI substrate.

### 4.4.2. Control of the Critical Dimension

Both the reproducibility and the control accuracy of the critical dimension (CD) depend on the process latitude and the replication environment. The trilayer technique we described provides large process latitude and excellent CD control. In general, polymers with a high etch resistance are preferable for better CD control. With hybrane polymer  $T_g$  of 70 °C for example, the replicated patterns showed a CD control accuracy better than 10 nm; increasing the etch time from 15 to 45 s results in a size increase of 60% for lift-off dots of 100-nm diameter [88] (Fig. 8).

Concerning the reproducibility, no systematic evaluation has been reported so far. With manual loading and down-loading, a mold can be used at least several tens of times without being damaged. Statistic analyses of replication data obtained by several experiments showed that the size variation of 100-nm features is within 10 nm. Since defects can be introduced in molds, substrates, and polymers during manual handling and repeated experimentation, particular attention has to be paid to the free contamination process

**Figure 6.** SEM image of a 60-nm-period dot array obtained by nanoimprint and lift-off of 20-nm-thick nickel. Reprinted with permission from [167], J. Moritz et al., *J. Appl. Phys.* 91 7314 (2002). © 2002, American Institute of Physics.

**Figure 7.** SEM image of a silicon line grating of linewidth less than 10 nm obtained by nanoimprint lithography and overetching of silicon layer in a SOI substrate.

but also to the correlation between mold etch depth, polymer layer thickness, and applied press and temperature, as discussed.

#### 4.4.3. Homogeneity and Pattern Placement Accuracy

The homogeneity of nanoimprint lithography depends on the homogeneity of the imprinting pressure, temperature, and feature density over the mold. Under pressure, the mold and the sample should be perfectly parallel. Patterning homogeneity has been studied with 4 [41, 80, 103] and 6-inch [115] wafers. For example, the first experiments on 4-inch wafers performed with a hydraulic press showed no remarkable imprinting inhomogeneity nor pattern distortion

**Figure 8.** SEM images of PMGI resist patterns obtained from trilayer nanoimprinting: (a) hybrane etching time 15 s, and (b) hybrane etching time 45.

for the feature sizes ranging from 100 nm to 100  $\mu\text{m}$ . A commercial wafer bonding system has also been used to evaluate more systematically the imprint performance over large areas [116]. Indeed, mixture features of 400 nm to 100  $\mu\text{m}$  can be homogeneously replicated over the whole wafer area, with a typical temperature of 225  $^{\circ}\text{C}$  and pressure of 55 bar for 5 min.

To investigate the accuracy of the pattern placement, an X-ray stepper has been used to compare a set of alignment marks on of a sample fabricated by nanoimprint lithography to the complementary set on an X-ray mask [80]. The nanoimprint mold and the X-ray mask were first fabricated on 4 inch silicon wafers by e-beam lithography and related pattern transfer techniques. Then, the mold patterns were replicated into a silicon wafer by nanoimprint lithography, followed by a metal film evaporation and lift-off. Afterward, the sample and the fabricated X-ray mask were aligned with the X-ray stepper, showing an alignment accuracy better than 30 nm ( $3\sigma$ ) for a field size of  $30 \times 30 \text{ mm}^2$ . Since both X-ray mask and nanoimprint mold were designed in a similar manner, nanoimprint lithography has not induced notable pattern distortion within the accuracy of the measurements.

#### 4.4.4. Process Latitude

The process latitude refers to the range of acceptable imprinting parameters (pressure, temperature, and etching and lift-off). For conventional lithography methods, the process latitude is limited by the depth of focus (optical lithography) or the range of the dose modulation (e-beam lithography). In nanoimprint, only low pressure and temperature limits are meaningful since within the polymer decomposition limits a higher temperature and pressure are generally more favorable for an easy polymer flow. Depending on the polymer type, pattern density, and distribution, the lowest temperature and/or pressure which can be used to replicate a given pattern can be determined experimentally. For a good pattern transfer, etch parameters need to be controlled accurately but both bilayer and trilayer systems provide larger process latitudes.

#### 4.4.5. Throughput

The production rate of nanoimprint lithography is a function of time required for the wafer loading, alignment, imprinting, separation, and unloading. Without taking into account wafer loading, alignment, and unloading, the imprint step itself needs a few minutes because of the thermal processes. So far, most experiments were performed manually and one can reasonably expect a speed of 10–20 wafers per hour if an automatic wafer loading and unloading system is used. Nevertheless, imprint speed can be significantly higher for the replication of homogeneously distributed features, as discussed in the previous sections. Using low viscosity polymers and trilayer imprint techniques, the imprint speed can also be increased but questions such as the mold lifetime and the total number of imprintings without further antistick mold treatment are still open.

Alternative approaches such as *step-and-flash* (see Section 5) and *step-and-stamp* imprint can be used to considerably increase the throughput. *Step-and-stamp* imprint

lithography has been tested with a commercial flip-chip bonder [117]. A mold is pressed into a polymer layer to create the first imprint and then lifted and moved to the next site to create the second imprint and so forth. Only the mold and the mold pressed polymer area are heated above the glass transition temperature of the resist to assure that the quality of the already imprinted features must not be degraded during the sequential imprinting. As a result, 36 consecutive imprints could be done over a large area, with patterns of 300-nm line and spacing. Obviously, this technique can also be used together with UV lithography for mix-and-match fabrication and large area as well as multilayer imprinting.

Two approaches of roller nanoimprint lithography have been proposed [118]. The first one consists of rolling a cylinder mold on a flat and solid substrate; the second rolls a smooth roller over a flat mold which is placed on a substrate. Both showed sub-100-nm resolution and good imprint uniformity. Because of the reduced pressing area, less force is required and the mold can be continuously used on a large area substrate. The mold fabrication in rolling imprint lithography is one of the main issues in terms of both design and implementation.

## 5. NANOEMBOSSING OF PHOTOCURABLE POLYMERS

The “hot embossing” techniques described in the previous sections are generally performed above the glass transition temperature of a polymer and under high pressure. Because of the heating and cooling processes, the embossing speed as well as the alignment accuracy cannot be very high. Besides, it is difficult to perform step and repeat imprinting with high resolution features. With particular polymers, RT imprinting is possible but high pressure is required. Alternatively, RT nanoembossing can be performed under a moderate pressure with photocurable polymers. In this case, a transparent mask is used to emboss a low viscosity liquid prepolymer, followed by a photocuring with a UV light. Due to the mold release agent, the separation of the sample and the mold is possible and the process can be fast. This technique also makes a fine layer-to-layer alignment possible due to much reduced pressure, low viscosity of the liquid polymer, and the absence of thermal distortion. Despite these advantages, however, only a few groups have been involved in the development of this technique [33, 119–123].

### 5.1. Mold Assisted Photopolymerization

Mold assisted photopolymerization (2P) is performed in the following way. First, a mixture of prepolymer which contains monomers of low molecular weight and photoinitiator is prepared and poured or spin coated on a substrate. Then, a transparent mold is pressed into the prepolymer mixture and the mold is held until the liquid flows into the mold cavities, followed by a 2P process with UV light. By curing, the liquid monomer is solidified which provides a copy of the mold relief. After separation from the mold, the sample is treated by RIE. At this stage, it is important to have the recessed layer as thin as possible, in order to preserve the embossed shape during the dry etching process.

Transparent molds can be obtained by e-beam lithography and RIE of a quartz plate with or without covering of a  $\text{TiO}_2$  layer. Other types of molds including  $\text{SiO}_2/\text{TiO}_2$  double layer on a quartz plate [33], soft molds made of PDMS, and multilayer systems with more specified characteristics are currently under investigation [124]. In all cases, the mold surface has to be treated to prevent sticking of the embossing resist to the mold during detachment.

The prepolymer mixture used for embossing should have a high rate of photopolymerization, low viscosity, good adhesion to the substrate, and low surface energy for the easy separation from the mold. The first experience of the mold assisted 2P of nanoscale features was reported by Haisma et al. in 1996 [119] who used a mixture of pentacythritol-triacrylate and 1,6-hexanediol-diacrylate as photopolymerizable monomers and dimethoxy-phenyl-acetophenone as photoinitiator for UV light. The surface of the mold and the substrate are respectively coated with a release layer and an adhesion primer. A pressure of only 0.1 bar was applied to conform the mold into the liquid because of its low viscosity. Then, the patterned polymer layer was used as dry etching mask for RIE of a quartz plate.

The same method has been used to demonstrate the feasibility of replicating nanocompact disk patterns [120]. Features of 100-nm pitch size could be reproduced by photopolymerization, corresponding to a storage density 100 times of the current compact disks. With the same method, mold assisted 2P has been tested under near-field configurations with an enhanced lithography ability [121].

Contrary to the hot embossing where a large number of polymers have been used, only a few photocurable polymers have been tested. One of the proposed systems is based on a low viscosity organic-anorganic sol-gel which has good adhesion on both silicon and quartz plates. Fluorine-based additives can be used which migrate to the surface during spin-on processes and thus promote the mold-sample separation. It was shown that both polar and dispersive components of the surface energy were significantly reduced by adding 1–2% of fluorine in the sol-gel resist [125, 126]. Consequently, more than 80% of the mold area could be imprinted under a typical pressure of 0.8 bar. Up to 50 times of multiple imprints were tested with one mold, showing no degradation of the mold or the imprint quality. In addition, a self-cleaning effect has been observed due to the involved 2P processes.

In principle, a fine alignment is possible before polymerization due to much reduced pressure and low viscosity of the resist. The mold which is separated from the substrate with a thin film of monomer liquid can be moved laterally with a sub-20-nm accuracy. However, problems arise because of the difficulty to make a perfect contact between the mold and the substrate, keeping the thin layer prepolymer homogeneously distributed. To overcome this technological liability, two strategies are under investigation. The first one, namely step and flash imprint lithography, consists of using a small mold to emboss locally a portion of a large wafer and then repeating the same process many times in different places of the wafer area [122]. The second strategy is based on the use of soft or multilayer molds to achieve a uniform embossing over a large area [124].

## 5.2. Step and Flash UV-Imprint Lithography

Step and flash UV-imprint lithography has been studied for several years [11, 33, 127–129]. A quartz mold of a small size ( $1 \times 1$  inch<sup>2</sup>) is first aligned over a substrate. Then, a drop of a low viscosity liquid is dispensed in the narrow space between the mold and the sample which allows one to fill the mold area by capillary forces. Afterward, the mold is pressed and the prepolymer is irradiated by UV light, resulting in a single field of the mold pattern on the substrate. The whole wafer area can then be filled by step and repeat processing.

Commercial components, including acrylate-based monomer, silylated monomer, dimethyl siloxane derivative, cross-linking agent, and free radical generator, were mixed as prepolymer liquids [127]. Here, the silicon rich organics were introduced to enhance the etch resistance to oxygen plasma. Molds were treated with tridecafluoro-1,1,2,2, tetrahydrooctyl trichlorosilanes [ $\text{CF}_3-(\text{CF}_2)_5-\text{CH}_2-\text{CH}_2\text{SiCl}_3$ ] and a low surface energy, self-assembled monolayer was formed on the mold surface to ensure a selective release of the mold and the polymer. Various aspects have been studied, showing good performance in terms of the nanoscale pattern replication and mold self-cleaning. In addition, the UV imprint lithography has been tested on curved surface [128]. More recently, fabrication of high resolution molds has been demonstrated on an ITO coated quartz plate, and features as small as 20 nm could be replicated by step and flash imprint lithography [33].

To obtain high aspect ratio features, a bilayer system can be used which consists of an underlayer of PMMA and an image layer of the photocurable polymer. With an imprint force of 2 bar, 60-nm features were obtained with 50-nm height in the recessed layer. These features could be then transferred into a 350-nm thick PMMA layer, resulting a mask with an aspect ratio of up to 6:1 [129]. Another advantage of the two-layer technique is its applicability over nonplanar substrates. Finally, an automated stepper is now available allowing for multiple imprints over a 200-mm-diameter wafer and has been employed for defect investigation.

## 5.3. Near-Field Contrast Enhancement

Alternatively, mold assisted photopolymerization can be performed using an improved mold configuration. In this method, the top portions of the mold are coated with a thin layer absorber, which is sufficient to stop the light propagation but allows optical tunneling through small holes. Therefore, a high contrast aerial image can be obtained at the downstream space of the mold. Figure 9 shows a comparison between three different mold configurations. In mold 1, no absorber is coated on the etched quartz plate which will result in a pure thickness contrast as produced in 2P processes. In mode 2, the absorber thickness is too large so that the light intensity downstream of the openings will not be sufficient for a complete polymerization because of the inefficiency of the optical tunneling. On the contrary, in mode 2 no polymerization will take place in the masked areas because of the absorption while the light intensity will remain sufficiently high for the polymerization inside and downstream of the openings. As a result, the residual layer

**Figure 9.** Schematic representation of the mold assisted optical lithography with three mold configurations: Whereas type 1 provides a polymer relief and type 3 results in a chemical contrast, type 2 gives rise to both thickness and chemical contrast.

could be easily removed by a solvent dip thus preserving the cured pattern slopes. Both numerical simulation and experimental data showed the feasibility to pattern features of critical dimension as small as 70 nm [121] (Fig. 10).

Other types of masks for near field optical patterning have also been tested under conformal contact printing conditions [130–132]. For example, flexible masks made of a thin membrane or elastomer permits a perfect contact between patterned absorber and the resist layer to be exposed so that the diffraction defined minimum feature size,  $l = 0.5\sqrt{\lambda h}$  ( $h$  being the thickness of the resist layer), can be reached. By using deep UV laser beams and a trilayer resist stack on a substrate, patterns of feature sizes close to 100 nm could be obtainable [133, 134]. Comparable to this technique, nano-embossing of photocurable polymer is more robust which

**Figure 10.** SEM images of nanoembossed patterns of 70-nm minimum feature size, obtained by mold assisted near-field photopolymerization. Reprinted with permission from [121], Y. Chen et al., *Microelectron. Eng.* 46, 69 (1999). © 1999, Elsevier.

does not require a sophisticated mask or a deep UV light source for curing.

## 6. APPLICATIONS

Nanoscience and nanotechnology are the most explosive research areas which involve a large number of scientific communities and considerable industrial efforts. As a potential tool for high volume manufacturing, nanoembossing is attractive for many applications. During the past few years, the capability and the feasibility of fabricating nanodevices and nanosystems have been demonstrated in the following areas.

### 6.1. Nanoelectronics

Lithography plays the most critical role for the development of nanoelectronic devices. For the development of ultimate CMOS technology as well as the quantum and molecular electronics, new fabrication tools are required. For this reason, nanoimprint lithography has been used to demonstrate its fabrication ability of MOSFET transistors [77], T-gate transistors [135, 136], quantum contact devices [106], etc. Whereas the advantage of nanoimprint lithography is obvious due to its high speed and low cost, all fabricated electronic devices have shown no evidence of performance degradation compared to those obtained by e-beam lithography.

MOSFET transistors have been obtained by nanoimprint lithography and etching a 110-nm-thick silicon layer of a SOI substrate. A variety of transistor features, including 100-nm wire channels, 250-nm diameter quantum dots, and ring structures with 100-nm ring width [135], were obtained. As expected, the room temperature measurements of the fabricated MOSFET showed common characteristics to those obtained by more conventional fabrication techniques while the quantum dot devices showed oscillations due to the electron Coulomb blockade effect.

High frequency and low noise transistors are commonly fabricated with III–V materials and T-gates which provide a combination of short gate length and low gate resistance. A bilayer resist imprinting procedure has been used to produce 120-nm T-gate transistors for high electron mobility transistors at a temperature and force that are not detrimental to the III–V substrate. Again, the fabricated transistors provided similar characteristics to those obtained on the same materials with gates realized by electron beam lithography [136].

Three-terminal ballistic junctions (TBJ) have also fabricated by nanoimprint lithography. After imprinting, the resist residues were removed in oxygen plasma, followed by wet etching of InP/GaInAs to define the TBJ structures with a high mobility, two-dimensional electron gas with sub-100-nm feature sizes [137]. In agreement with a theoretical prediction, highly nonlinear electrical responses were observed.

The fabrication of split-gate quantum contact point structures has been demonstrated using a mix-and-match technique [106]. The whole process included three optical lithography steps for the Hall bar and ohmic contact definition and one step of nanoimprint lithography for the fabrication of a split-gate pattern over a modulated-doped

GaAs/AlGaAs heterostructure. Before imprinting, the mold and the sample were aligned under backside infrared illumination with an optical aligner and brought into soft contact by slightly pressing the mold into the polymer. Then, the mold-sample assembly was placed onto the imprint machine processing. After imprinting, the split gates in the range between 180 and 400 nm were obtained by metal evaporation and lift-off. Low temperature transport measurements of the fabricated sample showed a well defined conductance quantization as a function of gate voltage, similar to that obtained with split gates defined by e-beam lithography.

More recently, nanoimprint lithography has been used to fabricate short channel polymer organic thin-film transistors. By nanoimprint lithography, interdigitated gold source and drain terminals were produced by lift-off, providing a channel length down to 70 nm. After depositing a layer of SiO<sub>x</sub> to protect the gate oxide and large gold pads for *I*–*V* measurements, a *p*-type semiconducting polymer, poly(3-hexylthiophene), was deposited by spin coating or casting, followed by a capping layer deposition of SiO<sub>x</sub>. The fabricated devices showed the expected increase of drive current density [138].

Finally, nanoimprint lithography holds considerable promise for the fabrication of molecular electronic devices. It is particularly suitable for the fabrication of electrodes for molecular self-assembly. For example, nanoimprint lithography has been used to produce 20-nm wide gold wires on a substrate of silicon dioxide. Applying a pulse of electric current, these nanowire can be broken, resulting in a well defined sub-10-nm gap which should be useful for single molecular electronic device fabrication [36]. Nanoimprint lithography has also been used for the fabrication of electronically addressable crossbar memory circuits. Metal electrodes were first obtained at the sub-50-nm scale. Then, Landmuir–Blodgett molecular thin films with switchable electronic properties were sandwiched between nanoelectrodes, showing a memory density as high as 6.4 Gbit/cm<sup>2</sup> [139].

### 6.2. Nanooptics

Much effort has been devoted to the fabrication of optic and optoelectronic devices such as photodetectors, polarizers, binary diffractive elements, as well as more conventional microoptical components.

Using standard nanoimprint lithography, followed by Cr/Au thin film evaporation and lift-off, GaAs metal-semiconductor-metal photodetectors (MSM PDs) could be realized [140]. The electrode fingers of line and spacing between 200 and 600 nm could be produced by adjusting the etch depth of the imprint mold between 193 and 330 nm. Comparing to the devices obtained by e-beam lithography, these MSM PDs showed no significant difference in the measured dark currents and the *I*–*V* curve under illumination.

A reflective polarizer based on a stacked double layer subwavelength grating has been obtained by imprinting a 200-nm thick PMMA layer and then evaporating in a high vacuum chamber (better than  $5 \times 10^{-6}$  Torr) 5-nm Cr and 70-nm Au thin films [141]. The fabricated gratings of 190-nm period showed a polarization extinction ratio

of over 200 for the normal incidence at 632.8 nm wavelength (54% reflection for transverse magnetic (TM) mode against 0.25% reflection for transverse electric (TE) mode). Similar gratings were realized in the waveguide configuration and showed the expected performance of a broadband waveguide polarizer [142]. In order to develop subwavelength applications, a spatial frequency doubling technique has been used to generate gratings of 100-nm period on a silicon mold [30]. The mold pattern should then be replicated into the PMMA resist layer by nanoimprint lithography for subsequent material processing.

Polymer microring resonators have been fabricated by either direct imprinting of a polymer film (PMMA, PS, PC) or filling the cavity of an imprinted polymer layer, followed by a buffered HF etching to remove partially the supporting SiO<sub>2</sub> layer on a silicon substrate. Optical filtering with a  $Q$  factor of 5800 has been demonstrated [143]. Nanoimprint lithography has also been used to fabricate crossed dipole resonant filters for the infrared frequencies. Using a bilayer system of MMA/PMMA, which is more suitable to obtain undercut for lift-off, filters for 6- $\mu$ m wavelengths were obtained [144].

Photonic crystals are artificial materials in which the dielectric constant is periodically modulated at length scale comparable to optical wavelengths. Various functionalities can be obtained by engineering nanostructures based the concept of photonic crystals, including waveguides, microresonators, etc. Nanoimprinting has been used to test the feasibility of replicating large area photonic structures. For example, a Y-branch defined by a two-dimensional photonic crystal with a hexagonal lattice has been imprinted into polystyrene on oxidized silicon [145] which could be transferable into the substrate.

For the fabrication of binary diffractive elements, nanoimprinting is clearly advantageous because of the requirement of high resolution. Previously, we have replicated binary diffractive elements of various characteristics, followed by lift-off and RIE of a thin TiO<sub>2</sub> layer [146]. Patterned structures with a minimum feature size of 80 nm and an etch depth of 400 nm showed optical properties of the arrays defined by e-beam lithography [147].

Antireflection layers for visible light have been fabricated by embossing high density lines and dots into PC sheets. Nickel molds were first obtained by e-beam lithography and electroplating which include gratings of 200-nm pitch, 200- and 100-nm etch depth, and different duty cycles. The replication has been done by direct embossing of a 1-mm thick PC sheet at 150 °C. The embossed PC gratings showed significantly reduced reflections for both TE and TM polarizations [148].

More conventional diffractive optical elements are widely used and manufactured by injection molding. Although injection molding is a low cost for high volume production, nanoembossing is more convenient for research, prototyping, and the fabrication of nanoscale features. Previously, the ability to replicate diffractive optical elements with curved sectional structures has been demonstrated using a 3D Ni mold [29, 148].

For high density data storage, nanocompact disks have been produced by nanoimprinting with a storage density as high as 400 Gbit/in<sup>2</sup>. Here, a SiO<sub>2</sub> mold of 75-nm etch depth

has been used to imprint a 90-nm thick PMMA layer at 175 °C. The replicated pattern showed a 10-nm feature size and 50-nm track width after a Ti(5 nm)/Au(10 nm) thin film deposition and lift-off [149]. Similarly, read-only disk patterns of 100-nm track pitch have been replicated by using nanoembossing of an acrylate-based 2P process [120].

Nanoembossing has also been used to replicate a diffraction grating of 0.6- $\mu$ m period on a film of bis-benzocyclobutene [150]. Then, a thin film of Alq<sub>3</sub> doped with DCM (4-(dicyanomethylene)-2methyl-6-(*p*-dimethylaminostyryl)-4H-pyran) dye molecules is deposited on the diffraction grating, resulting in an optical pumped laser emission occurring at 655 nm which corresponds to the third order of the grating diffraction. Alternatively, nanoembossing has been used for direct formation of organic light emission structures. PMMA blended with various semiconductor molecules like Alq<sub>3</sub> and DCMI was embossed into 200-nm period and 300-nm height gratings. Embossing was performed in a vacuum of  $\sim$ 1 Torr at a pressure of 54 bar and a temperature of 150 °C. The resulting structures showed no optical degradation of the imprinted films. Moreover, a molecular alignment in the polymer matrix has been observed which may have applications in the field of nonlinear optics and organic optoelectronics [151]. More recently, organic polymer light-emitting pixels have been obtained with feature sizes ranging from 50 down to 2  $\mu$ m. These pixel arrays were first obtained by imprinting a PMMA (insulating) layer spin coated on an ITO glass. Then, a hole transport layer, poly(3,4-ethylenedioxythiophene)-polystyrene sulfonate, and a red emissive polyfluorene derivative polymer layer were consecutively spin coated on the patterned surface, followed by a cathode metal deposition [152].

### 6.3. Nanomagnetism

Patterned magnetic structures can be used for both ultra-high density recording and the fabrication of spin-electronic devices such as randomly accessible memories, spin transistors, resonant tunnel, and nonvolatile programmable logic devices [153–156].

Initially, nanoimprint lithography was proposed by Chou et al. for fabrication of the so-called planar quantum magnetic disks (QMD) which consist of single domain magnetic nanopillars (Ni) uniformly embedded in a disk of nonmagnetic matrix (SiO<sub>2</sub>) [154]. In a QMD, each nanopillar contains two discrete magnetic states with equal but opposite magnetic moments, thus allowing one to store one bit of information. The proposed fabrication sequence is the following: (i) deposition of a thin metal base and then a film of silicon dioxide, (ii) nanoimprint lithography with 200-nm thick PMMA, (iii) shallow evaporation of a chrome layer (on the top of the resist layer but not in the embossed PMMA trenches), (iv) RIE of SiO<sub>2</sub>, (v) removal of the remaining PMMA resist, (vi) electroplating of nickel or cobalt, and finally (vii) chemical mechanical polishing. Now, the concept of planar QMD structures has been proven experimentally [157] and the reported results showed 70-nm diameter and 400-nm height single domain nickel pillars embedded in a SiO<sub>2</sub> matrix, corresponding to a storage density of 18 Gbit/in<sup>2</sup> [157, 158].

Co/Pt and CoNi/Pt multilayers with magnetization perpendicular to the plane have been patterned by nanoimprint lithography and ion milling techniques. We found that the magnetization in these systems depends on the dot size through the spatial distribution of the nucleation centers and that the hysteresis loops become more rounded with a larger coercive field as the diameter decreases [86].

More generally, nanoimprint lithography has been used to study magnetic properties of patterned structures with in-plane magnetization and different geometries (dot, rings, squares, etc.) [159–162]. For example, Co dots of diameter varying in the range 100 to 500 nm and thickness 10 to 100 nm were obtained by trilayer nanoimprint and lift-off techniques, revealing the size and the thickness dependences of the remnant state and the magnetization reversal processes (Fig. 11). Two types of hysteresis loops were found, characterized by the formation of a single domain or a vortex state [159]. Further investigation has been focused on the interdot coupling of densely packed cobalt arrays, showing a number of interesting phenomena due to magnetic dipolar coupling between dots [160, 161].

Magnetic microrings have attracted a particular attention because of the more stable flux close (FC) magnetization states without the formation of the central vortex core. Consequently, undesired interactions between adjacent magnets of the device are minimized because of the absence of the stray field in the FC states. Submicrometer rings were obtained by nanoimprint and lift-off of Co films of thicknesses varying in the range of 10 to 100 nm. Experimental data and simulations all confirmed the formation of stable FC states in microrings. Similar to the case of Co dots, two kinds of magnetization behavior have been observed: one involving the FC state and another near-single domain state (Fig. 11). The observed size and thickness dependencies of the rings are comparable to those obtained with Co rings made by e-beam lithography, from which a phase diagram in ring diameter and thickness could be established [162, 163].

**Figure 11.** MFM images of a cobalt dot of 500-nm diameter and 15-nm thickness showing a single domain (a) and same diameter but 30-nm thickness showing a vortex (b) at remnant states; and a cobalt ring of 400-nm diameter, 200-nm linewidth and 20-nm thickness showing respectively a single domain state under applied field (c) and a vortex state at remnant state (d). The octagonal ring shape was intentionally designed for easy contrast identification. (a) and (b) were reprinted with permission from [159], A. Lebib et al., *J. Appl. Phys.* 89, 3892 (2002). © 2002, American Institute of Physics.

There are other techniques to pattern planar magnetic structures (e.g., ion irradiation induced mixing which can be used to change locally the magnetic properties for ultrathin Co/Pt multilayer thin films) [164, 165]. Here, masks for irradiation can be obtained by lithography methods. The ion irradiation in unmasked areas induces atomic displacements at the Co/Pt interfaces (intermixing), which results in a remarkable change of the magnetic properties in the irradiated zone. Both patterned polymer and dielectric material can be used as masks for ion irradiation. With 450-nm thick SiO<sub>2</sub> layer for example, we obtained a mask feature size as small as 30 nm. Stencil masks can also be used for ion induced mixing [166]. Nanoimprint lithography should be useful for the fabrication of the two types of ion implantation masks.

High quality magnetic nanostructures can also be obtained by depositing magnetic thin films directly on a prepatterned substrate such as silicon, GaAs, etc. The commonly used technique for the substrate patterning is RIE [167] but chemical printing has shown to have a good performance as well [168, 169]. The advantage of using etched substrates is that various deposition techniques such as sputtering and molecular beam epitaxy can be applied, allowing the fabrication of high quality magnetic structures. Embossed polymer structures can also be used as patterned substrates for magnetic thin film deposition. Because of its low cost and flexibility, nanoembossing of full plastic features is well suited for high volume fabrication.

To pattern homogeneously magnetic structures over a very large surface area, a flexible mold which consisted of a 10- $\mu$ m thick polymer mold on an acrylic backing plate obtained by photocuring an acrylate mixture over a SiO<sub>2</sub> master has been used. As a result, 50-nm diameter single domain magnetic islands over 3 cm areas have been demonstrated very recently by the IBM group at Almaden Research Center [170].

In comparison to the study of patterned magnetic structures, much less effort has been devoted to the fabrication of spin devices using nanoimprint lithography. Spin valve structures consisting of a NiFe/Cu/Co multilayer and sizes down to 70 nm  $\times$  1  $\mu$ m have been fabricated by nanoimprint lithography, ion milling, or lift-off [171]. They showed characteristic behaviors in the measured magnetotransport curves and magnetic force microscopy (MFM) images. Both ion milling and lift-off patterning affected the device performance because of the important edge effect and further improvements are expected.

## 6.4. Applications in Biology

During the past decade, a substantial progress has been made in the development of nanotechnology for biological and chemistry applications [172–176]. For example, new methods and tools such as DNA chips and microfluidic devices have been invented for biomedical (gene sequencing, drug discovery, and diagnostics) and medical (minimally invasive therapy, precision surgery, drug delivery, and biosensors) research and applications. While many of them have relied on micro- and nanofabrication technologies, nanoembossing offers some new possibilities. For example,

nanoembossing can be used to produce high density plastic assays as well as functional microfluidic devices. It can also be used to modify the physical or chemical properties of a surface which is useful in a controlled cell culture and neurological studies. Finally, it can be used to fabricate new sensors and biocompatible electronic, microwave, or optical components.

For biological applications, it is often necessary to engineer the properties of the surface at a molecular level. This can be achieved by nanoimprint lithography in a way similar to metal structure fabrication via lift-off. For example, nanoimprint lithography has been used to pattern a 75 kg/mol PMMA layer of thickness 80–120 nm on a silicon dioxide substrate [177]. After imprinting and removal of the recessed area by RIE, a silane layer was deposited and lifted off in acetone. Thus, a patterned silane layer was obtained, showing distinct wetting properties between patterned and unpatterned areas: large water drops were observed mainly in the areas without silanization. Note that silanes are available with various functional groups and they can be deposited by either gas evaporation or solution dip. Therefore, the chemical properties of a surface can be tailored precisely which can then be used for various applications [178, 179]. In addition, once a silane pattern is formed, the unsilanized part can be functionalized with other groups of silanes in such a way that the two regions either promote or resist the adhesion of proteins or cells. Of course, soft lithography is also well suited for the surface modification but nanoembossing can offer a higher resolution and more robust and versatile processes.

Another example is the fabrication of topographic features for cellular engineering. It was found, for example, that cells are guided along micrometer sized grooves but do not adhere to the surface of nanopillars. Nanoembossing of biodegradable polymers showed excellent resolution. It is believed that such patterned topographic features can be used for the fabrication of therapeutic devices such as tendon repair [180].

DNA chips and other types of biochips are now widely used in genetic disease diagnostics, drug design, and biomedical research. The first DNA chips have been manufactured using optical lithography and bioengineering [181]. Different single-stranded DNA sequences are placed selectively on a substrate to form a microarray that allows a later detection of complementary DNA targets by hybridization. Considerable efforts have been made to improve the sensibility of detection and the reliability of data statistics. Further progress is expected based on, for example, a continuous scaling down of the reaction area, which would allow a larger variety of probes and thus increase both hybridization and identification speed. Similarly, proteins and cell chips can be fabricated but they are still challenging because of the increased complicity. In both cases, nanoembossing techniques could be explored for a great diversity of improvements and new functionality implementations.

One of the important applications of the nanoimprint lithography is the fabrication of biosensors, where high resolution patterning techniques are sometimes needed. As one example, biosensors with large area interdigitated nanoelectrodes have been fabricated using a mix-and-match fabrication process [105]. Standard nanoimprint lithography

has been used first to define the interdigitated electrodes of 100-nm linewidth with different spacing over a  $200 \times 200 \mu\text{m}^2$  area, a  $\text{SiO}_2/\text{Si}$  substrate followed by a 20-nm Cr thick evaporation and lift-off. Afterward, UV lithography with alignment was used to pattern the Al contacting areas via lift-off. The fabricated devices showed no creeping current on the surface and a capacitance of about 17 pF was found which did not vary significantly between 1 kHz and 1 MHz.

The most relevant application of nanoembossing in biology areas is perhaps the development of microfluidic devices, also known as lab-on-a chip, bio microelectromechanic systems, and micro total analysis systems. In a microfluidic device, elements such as fluid injectors, filters, pumps, valves, mixers, and detectors are also made on a chip. Previously, several fabrication technologies have been developed, including silicon and glass based micromachining, plastic forming, and soft lithography prototyping [43, 151, 178, 179, 182]. For many applications such as point-of-care clinical diagnostics, disposable assays are needed to avoid cross-contamination. For this reason, biocompatible polymers are the materials of choice and both nanoembossing and soft lithography can be used for the device fabrication.

Compared to laboratory scale experimentation, an on-chip processing of chemical and biological species offers many advantages such as much reduced reagent cost, power consumption, and space occupation. High throughput and high efficiency screening are expected because of the system integration. Moreover, the reaction efficiency can be largely enhanced due significant increases of the surface to volume ratio. For these reasons, a large number of research and industrial laboratories are involved in the development of microfluidic devices, with clear perspectives for a very broad application area, including high throughput screening, clinical diagnostics, environmental analysis, cell analysis, drug discovery to portable devices for minimally invasive therapy, precision surgery, as well as drug delivery [6, 7, 172–175].

All nanoembossing techniques can be used for the development of microfluidic devices. To fabricate all plastic devices for example, nanoembossing can be used in different ways. One of the examples is direct embossing of plastic structures, followed by thermal bonding, as described in [12]. First, a thin plastic plate is first formed by hot embossing which provides microchannels and other desired geometries. Similarly, a thick plastic plate with microfluidic connection sockets can be formed with the help of an additional metallic frame. Then the two plastic plates are thermally bonded, being ready for immediate electrophoresis applications.

Electrophoresis is widely used for the separation of charged molecules (DNA, proteins, etc.) of different sizes according to their different migration velocities [183]. The motion of a charged molecule is also influenced by the electroosmotic flow (EOF) which in turn depends on the surface properties of the microchannel. Basically, EOF is due to the presence of the so-called electric double layer (i.e., an adsorbed layer of cations and a diffuse layer near the microchannel wall). When a voltage drop is applied externally between the two ends of the channel, a force toward the cathode is exerted on the diffuse charge layer, which results in a fluid motion by viscous drag. To improve the

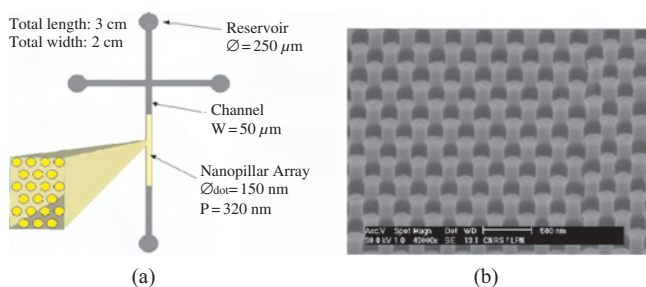

device performance, various surface treatments of the plastic materials have been proposed and a detailed analysis can be found in [43, 179].
