## 1. INTRODUCTION

Nanotechnology has been a fast-developing field over the last decade. Features of dimensions below 100 nm are an interesting and important field of studies in a world of miniaturization in engineering but as well in the already small world of biology. New methods of analysis have to be developed along the way, as conventional light microscopy techniques are unable to resolve features of these dimensions.

In this chapter recent progress in nanoanalytics in biomaterial respectively biointerface research is reviewed, focusing on publications that are relevant for the characterization of the surfaces of biomaterials rather than the characterization of biofilms on biomaterials.

Scanning probe microscopy (SPM) methods, that is, scanning force microscopy (SFM), scanning tunneling microscopy (STM), and related techniques are unique to investigate on a molecular and even on an atomic level surfaces and molecules interacting with them. Morphology and roughness are important parameters that can be characterized with them. Further fields are the spatial arrangement of chemical functional groups and their interaction with the surrounding medium.

The techniques based on the electron-sample interaction like scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are also able to achieve material- or morphology-dependent information with nanometer resolution and are therefore important tools in biological and materials science.

The issue of nanotechnology has become also part of the world of biomaterials for production as well as for analysis to investigate phenomena occurring on this scale. Biomaterials include a wide range of metals and alloys, glasses and ceramics, natural and synthetic polymers, biomimetics, composites, and natural materials, including combinations of synthetic and living tissue components. Materials in contact with biological systems are of great relevance not only in medicine but for many applications in engineering, food processing [1], marine environments [2], and biosensing [3]. The use of biomaterials is therefore part of the larger area of biological surface science (BioSS) that stretches as well into areas like tissue engineering, biosensors and biochips for diagnostics, artificial photosynthesis, bioelectronics, and biomimetic materials [4]. The market volume for medical biomaterials exceeds a billion Euro per year. In the United States alone the current value is over 700 million Euro [5]. More than 500,000 arthroplastic procedures and total joint replacements are performed annually in the United States [6]. Clinical implants like artificial tooth replica, knee and hip joints, blood vessels, heart valves, and intraocular lenses are in use for many years now and applied with hundreds of thousands of patients improving their quality of life. A lot of materials consist of metals and ceramics but the use of polymers for new medical products and materials has increased strongly over the last decades to keep improving current health care procedures.

These biomaterials must meet the demands of materials science on various length scales as well as clinical requirement. The mechanical specifications range from high loads in implantology for hip and knee replacements to high elasticity of artificial blood vessels. They have to be accompanied by others, for example, high transmittance in intraocular or contact lenses. In many cases blood compatibility with suppression of blood coagulation between the physiological environment and the biomaterial surface is necessary. A good understanding of the interaction with the biological environment, namely with biomolecules like proteins, cells and tissue, is crucial in order to be able to improve the functionality of biointerfaces. This interaction is essential for many applications like lubrication, adhesion, and recognition

in biological systems and for biocompatibility of the implant interface [7].

The interface is important for biomaterials, as it defines the interaction with the environment. The knowledge of the surface structure, the surrounding medium in direct contact (e.g., water structure [8]), and the chemical composition is essential to understand further reactions taking place at the biomaterial's surface. The interface structures are in dimensions of a few nanometers for proteins up to the micrometer range for cells in the field of biomaterials. In Figure 1 an overview of the interfaces on different scales is presented to show the parameters that can be of interest.

Macroscopically, the shape of an implant, the structure, and its mechanical stability are important. The microscopic level is determined by the morphology (i.e., the domain structure, the presence of ionic groups, and the chemical composition respectively modification), the topography (i.e., the surface roughness, planarity, and feature dimensions), and the hardness respectively elasticity (Young's modulus). These characteristics determine other features like wetting behavior and interaction forces (inter- and intramolecular) including cell-surface or cell-cell interactions. Various degrees of information about these properties can be

**Figure 1.** Different relevant length scales in biomaterials research demonstrated at hand of a bone implant. The biomaterial-tissue interaction is based on molecular events, which affect meso- and macroscopic material properties. On larger scales additional (e.g., cellular, mechanical) effects resulting from combining individual units (molecules, cells, crystallites) to a more extended ensemble arise.

obtained using different analysis methods including microscopic and spectroscopic methods.

The field of investigation is extending further as the material properties have to be characterized after manufacturing, sterilization, before and after clinical insertion, and before, after, and especially during the immersion in simulated natural environments. The resulting changes of the interaction, namely corrosion and the buildup of a biofilm, have to be characterized. The surface properties as well should be characterized thoroughly as it is essential for correlating any surface modifications with changes in biological performance.

In the following, techniques that are able to resolve features of materials on the nanometer scale (Section 3) as well as applications for biomaterial research (Section 4) are presented. The whole topic is introduced by a more general discussion of functionality, properties, and types of biomaterials (see Section 2). The focus in experimental work will be put on methods investigating materials on the nanometer scale, that apply to nanometer resolution in x-, y-, and z-direction. Methods leading to a resolution in the nanometer regime in only one or two dimensions will be described only shortly.

Investigations of the above introduced groups of biomaterials including metals, ceramics, polymers as well as biological specimens are presented. In the context of this review biomaterials are defined as materials used in medicine which are in contact with the tissue of the patient. Therefore special emphasis will be put on medical implant materials and the characterization with scanning probe techniques. Experiments dealing with hard tissues like teeth and bone and the influences of substrates on biofilm formation will be briefly mentioned.

## 2. BIOMATERIALS

Biomaterials can be classified with respect to their chemical composition and their use. Generally, the following criteria have to be fulfilled by biomaterials:

- **Functionality:** The biomaterial must replace at least in the important parts natural body functions. This means that, for example, for bone substitution a suitable mechanical stability has to be achieved.
- **Biocompatibility:** The biomaterial must not cause negative body reactions resulting, for example, in inflammation. Furthermore, a good integration into the body environment is favorable.
- **Aesthetical aspects:** Biomaterials used for external implants should not deface the patient. Preferably, they should look like the replaced tissue.

Surface properties influence strongly the mechanical function, the biochemical interaction, and the optical appearance of the biomaterial. Therefore the interface of the materials deserves special interest in investigation, control, and modification of properties to reach the criteria mentioned above.

Mechanical aspects are relevant for applications which require force transfer (e.g., bone substitution), which impose dynamic loads on, for example, artificial joints, and which, for example, in the case of substitutes for blood vessels, meet certain hydrodynamic respectively fluid-mechanical properties. The interaction of the biomaterial with the body

environment concerns the tissue contact (cell adhesion and fixation), the tissue organization (cell-to-cell linkage and communication), and the exchange of substances across the interface. Optical appearance is determined by light transmission (e.g., of contact lenses) or light reflection (e.g., of natural looking tooth replacements). Mechanical, biochemical, and optical properties depend mainly on the topography and the chemistry of the surface.

Topography may be defined as size, shape, distribution, and hierarchy of surface features. These features are either discrete (holes and peaks) or continuous (furrows and ridges) in random (statistical), fractal (self-similar on different length scales), or periodic distribution across the surface. Rough surfaces exhibit a larger surface area and more contact points for biological molecules and cells. The reason for larger entities like cells to adhere to the surface and how they arrange their layer growth is dependent on the size and distribution of the surface features: Cavities which are smaller than single cells cannot be colonized, while larger structures regulate the direction, connectivity, and differentiation of the growing cell layer. A hierarchical surface consists of structure elements with increasing complexity, for example, two-dimensional planes scrolled up to three-dimensional fibers which are organized in three-dimensional fiber composites. Examples of those materials were synthesized with carbon nanotubes with increased mechanical stability and electrical conductivity and decreased thickness compared to common wires [9–11]. In principle such materials are also interesting for biomaterials as on one hand they show a very large surface area and on the other hand they enable combinations of surface sections with different properties and therefore different cell types within a single superstructure.

The chemical properties of the interface between biomaterial and body environment determine the interaction of the surface with water molecules, ions, biological macromolecules, and cells. The surface reactivity depends on the chemical composition, the production process, and the pretreatment before use of the materials and is essential for fixation, growth, and proliferation of tissue and bone cells. Cell adherence via membrane receptors and adhesion proteins is influenced by active surface groups (generated, e.g., by oxidation of metals or coating of materials with specially designed polymer layers) which regulate the adsorption of the anchoring protein layer. The functionalization of the substrate additionally controls the wetting behavior where particularly hydrophilic surfaces show enhanced cell adhesion. The latter is due to the fact that systems like cells and hydrophilic surfaces reach a thermodynamically favorable state by combining their high-energy surfaces. In addition, even hydrophobic interfaces like gold can get more hydrophilic by protein adsorption [12] which may help to increase biocompatibility. Polarizability and charging of the interface affect electrostatic interactions between charged species and the surface. Charge screening and complexation by multivalent ions present in all types of body fluids allow attraction between molecular and surface groups of like charges and stabilize the biological layers. At conductive interfaces electrochemical reactions with charge transfer between the electrolyte solution and the substrate may occur, which interfere with the cellular metabolism and the

conformation of adsorbed adhesion proteins. This can set free toxic substances and cause allergic and inflammatory body reactions.

Topographical as well as chemical effects play a role for tribological properties of biomaterials. Tribology describes the behavior of interfaces in motion and gets important when implants are designed to support body movements. In this case friction, wear, and lubrication of implant and body respectively different moving implant elements influence function and longevity of the applied biomaterial. Interfacial friction depends on kind and strength of interaction forces, the clasping of surface uprisings and troughs, and force transfer properties of intermediate fluids. Hardness, cohesion, and adhesion of the individual surfaces in contact determine to what extent the materials are worn off by abrasion (e.g., scratch and particle formation), adhesion (e.g., welding processes), and surface fatigue (e.g., crack formation). Liquid films in the crevice between two hard surfaces can reduce friction and wear. The effect of such lubricants is influenced by surface chemistry and separation as well as by the viscoelastic and hence force transferring properties of the fluids themselves.

This comprehensive discussion of biomaterials in view of surface properties shows that the interplay between implant and body environment can be very complex and includes a large variety of parameters from materials science, biology, and medicine explained in more detail in [7]. The need of surface analysis with nanometer resolution arises on one hand from the importance of the interface between natural and artificial material and on the other hand from the high dependence of the macroscopic behavior on the microscopic appearance of the biomaterial.

In the following the main different chemical substance classes for biomaterials will be described shortly.

Biomaterials can be divided into native materials like teeth and bone, and artificial biomaterials which are in contact with biological systems like implants in medicine. Within these fields the materials in their actual state of occurrence and model surfaces like thin layers on supports are under investigation.

The three *metal* systems mainly utilized in implantology are stainless steel, cobalt-chromium alloys, and titanium. Such metals are mainly used in bone replacement and here titanium is the most important metal because of its good biocompatibility and nearly bonelike mechanical properties. That is why titanium and its alloys TiAl6V4 and TiAl6Nb7 are frequently applied as biomaterials for hard tissue replacement such as dental and orthopedic (e.g., hip and knee joint prosthesis) implants, in the audiological field, and for cardiovascular applications such as mechanical heart valves and as material for surgical instruments such as vascular clamps, needle holders, and forceps [13]. Titanium surfaces are covered by a 2- to 6-nm-thick oxide layer that is formed spontaneously in the presence of oxygen. This layer contributes to the biocompatibility of titanium by preventing corrosion and the release of ions from the metal surface [7]. The oxide layer thickness and surface morphology can be altered by according treatment or coatings applied to change the physicochemical properties and the biological response [13].

Stainless steel is also used for orthopedic implants. Its lower biocompatibility and its mechanical properties, which are less bonelike than titanium, reduce the use as human implant material, but it is cheaper than other metals and therefore is still used in animal medicine and for surgical instruments. Other applications of steel are cardiovascular stents.

Cobalt-chromium-molybdenum alloys are very hard and in combination with other smooth surfaces very abrasion-proof. They are therefore an ideal material for joint implants. In many patients Co-Cr-Mo, that is sintered from Co-Cr-Mo beads, is used as a femoral hip implant.

Gold as one of the oldest implant materials is used not only as dental restorative material but also as electrode material for implantable biosensors or to increase the contrast in electron microscopy. An overview on studies concerning metals as biomaterials is given in Section 4.1.

Bone, tooth enamel, and dentin have a composition which is very similar to that of special *ceramic materials* like hydroxyapatite, calcium phosphate, and calcium carbonate. These materials in their natural or manmade origin are used as coatings to increase the biocompatibility of implant materials. On the other hand they can replace parts of bones; for example, porous hydroxyapatite is a good basis for new bone growth. Biologically active glass or *bioglass* is similar to ceramics and assists actively new bone formation. It is therefore used in every place where bone has to be built up. This is necessary after tumor surgery or if natural bone is destroyed by an inflammation. Ceramic and glassy materials are further considered in Section 4.2.

Another kind of biomaterials are the *polymers*. They can be tailor-made for many different applications as their properties and their composition are variable in a large range. Polymers can be used as manufactured or treated with different techniques to yield special functional groups at the surface for specific interaction, increased surface energy, hydrophilicity respectively hydrophobicity, or chemical inertness. Furthermore, such surface layers may induce cross-linking to increase hardness, remove weak boundary layers or contaminants, modify the surface morphology (increase or decrease of surface crystallinity and roughness), or increase surface electrical conductivity or lubricity. A review of these modifications, examples, and characterization is given in [14]. Polymers like high molecular weight polyethylene (HMWPE) are used as counterpart for the titanium ball head in artificial hip joints. Poly(tetrafluoro ethylene) (PTFE) and other fluorinated polymers are used for blood vessel replacements and catheters, poly(methyl methacrylate) (PMMA) for intraocular lenses, silicone acrylate for contact lenses, polyurethane for pacemakers and left ventricular assist devices, cellulose for renal dialyzers, and silicone for catheters and breast implants [15]. Biodegradable polymers like poly(sebacic anhydride) (PSA) and poly(DL-lactic acid) (PLA) are naturally removed from the body after a definitive time span and can be used for controlled drug delivery [16]. Generally, carbon in different forms (e.g., diamond, graphite, or activated carbon) is an important biomaterial particularly because of its high blood compatibility. Glassy polymeric carbon (GPC) made from phenolic resins by pyrolyzation, is mostly used as coating, for example, in prosthetic heart valves and other prosthetic devices [17, 18]. Some selected studies on polymers are discussed in Section 4.3.

A newer group of materials used in implantology are composites, especially composites of inorganic material and polymers which combine the advantages of both. Examples can be found in Section 4.4.

### 3. NANOANALYTICAL TOOLS

A wide range of applications use the methods described in this section as nanoanalytical tools. This field is extending rapidly and new applications and methods are developed constantly. A short description will be given of the methods and the parameters investigated with them. The possible areas of application and examples are given in Section 4. Particularly, scanning force microscopy (SFM) is stressed which has proven to be a valuable and easy to handle method for studies on biomaterials. Additional advantages can be found in the nondestroying operation which is applicable under ambient conditions. Experimental setups revealing nanometer resolution in only one dimension are discussed at the end of this section.

#### 3.1. Scanning Probe Techniques

Scanning probe techniques have been a valuable tool since their invention in the 1980s [19, 20]. In these experimental methods distance-dependent interactions like tunneling current, force, or light transmission between a sharp needle (“tip” or “probe”) in close proximity to a surface (“sample”) are utilized to produce an image of the sample. Two principal measurement modes were implemented: (i) to maintain a constant vertical probe position while measuring the interaction change often due to surface topography (“constant distance mode”), and (ii) to maintain constant interaction while adjusting the distance with the feedback signal reflecting surface topography (“constant interaction mode”). Both modes offer the possibility to characterize surfaces down to the atomic scale in a great variety of environments from ultrahigh vacuum to aqueous solutions. It is as well possible to characterize time-dependent reactions like crystallization or corrosion processes, as it can be done continuously and hence on-line. To scan a probe over a surface in the desired way while reacting to the topography of the sample, positioning tools with spatial resolution in the 0.1-nm regime are necessary. The latter is fulfilled by piezoelectric actuators made of ceramics like PZT (lead zirconate titanate) or PMN (lead magnesium niobate), which in different directions can be extended by less than the size of one crystal unit cell. With a suitable detection unit to measure small interaction changes connected to a distance feedback circuit and digital data representation, an image of the surface can be portrayed. Experimental adaptations and extensions based on the interaction mechanisms originally used for imaging purposes lead the way to monitor more complex features than the topography as described below.

In scanning tunneling microscopy (STM) the current of electrons tunneling between a conductive wire (preferentially heavy metals like tungsten, platinum, or iridium) with an atomically sharp tip and a (semi-) conductive surface across vacuum is measured (Fig. 2). The tunneling current decays exponentially with increasing distance between tip

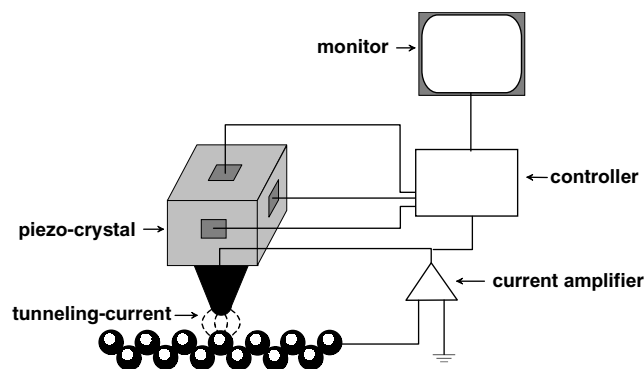

Figure 2. Schematic drawing of the STM principle.

and surface and additionally depends on the local densities of electronic states of the tunneling partners and the work function of the sample. Because of its strong distance behavior only the atom at the very end of the tip and the nearest surface atom are involved within the tunneling event. A slight change in distance according to progression along rows of surface atoms alters the tunneling current in a measurable manner so that true atomic resolution can be achieved.

Experimentally the onset of a tunneling current is obtained by approaching tip and surface to less than a few tenths of a nanometer under a constant bias voltage. The sign of the bias determines the direction of the tunneling current; this means unoccupied electronic surface states are probed with occupied electronic tip states or vice versa. Scanning the surface row by row either at constant height or constant current (see above) reveals the surface topography.

Additionally, STM can be applied to probe electronic structures. Modulating the tip-surface distance and measuring the change of the tunneling current at constant bias allows to extract the local work function of the sample. Modulating the bias and measuring the corresponding current changes at a constant tip-surface distance allows to extract the electronic states around the Fermi level of the sample (STS, scanning tunneling spectroscopy). This can lead to some chemical information about the surface, but for more detailed information electronic core levels have to be sensed, which is not possible with the STM (see [21] and especially references therein).

Scanning electrochemical microscopy (SECM) measures highly localized electrochemical currents associated with charge transfer reactions on metallic sample surfaces under liquid environment [22, 23]. In macroscopic measurements it can be compared with cyclic voltammetry. The reactions occur in a four-electrode electrochemical cell under bipotentiostatic control. There are two mechanisms respectively pathways of image production. Electron tunneling and electrochemical reactions via a water bridge occur according to the applied voltage. It can be used for the detection of localized electrochemical reactions at surfaces. It can also be used for microstructuring biomaterials like titanium [24]. In addition SECM is also capable of probing the kinetics of solution reactions and adsorption phenomena and monitoring heterogeneous electron transfer kinetics associated with processes on conducting surfaces [25].

The invention of the scanning force microscopy (SFM) was a breakthrough for these techniques as it is possible to image nonconducting substrates with a resolution of 0.2 nm laterally and 0.001 nm vertically. It does not require specimens to be metal coated or stained. Noninvasive imaging can be performed on surfaces in their native states and under near physiological conditions. It has been proven to be particularly successful for imaging biological samples, such as proteins, nucleic acids, and whole cells. By scanning, dynamic processes can be imaged, such as erosion, hydration, physicochemical changes, and adsorption at interfaces. Therefore the SFM is currently the SPM technique with the widest applicability for biomaterial research.

In SFM a small tip attached to a micro beam (cantilever) is scanned across the surface of the specimen and deflected by topographic features. The force of interaction may be repulsive or attractive, giving rise to different modes of operation. Moving the cantilever from the interaction free zone far above the surface, it snaps into contact (Fig. 3) due to the attractive force between the tip and the sample, which can be described in a simple way by the Lennard Jones potential. The piezo pushes the tip further towards the sample and the positive repulsive force reaches a maximum. As the piezo is retracted the repulsive force is reduced and the force changes sign. If the bending force of the cantilever gets larger than the attractive force towards the surface, the tip loses contact. The tip can be held in the repulsive regime of the Lennard Jones potential or oscillated in the attractive or repulsive regime, resulting in different interactions [26, 27]. These differences are important as biomolecules are deformed by applying a load of some nanonewtons as present in contact mode [28].

The deflection is usually monitored by a laser beam that is reflected and detected with a four split photodiode. This signal is used to maintain a constant force via a feedback loop and to monitor the height data. The SFM can be operated in a variety of modes that can provide different information about the sample. Usually the z-deflection is monitored and interpreted according to the parameters under investigation. An easy to read overview covering many scanning probe

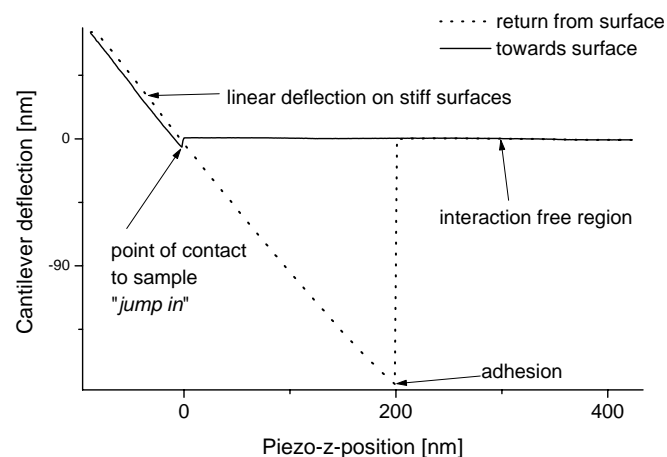

Figure 3. Cantilever deflection versus sample-z-position curve on a stiff surface monitored via SFM.

techniques is given in [29] while in [30] results obtained by SFM in the field of nanotribology are reviewed.

Sensing of the z-position is usually done via the monitoring of the z-piezo voltage. This can cause ambiguities as piezo crystals exhibit hysteresis. This is overcome by monitoring the distance separately via inductive or fiber-optical sensors [31].

For dynamic modes [32] the application of an additional oscillation to the cantilever by a piezo crystal has to be performed. Magnetically driven cantilevers are used as well for actuation [33].

The quality of SFM data is essentially determined by the cantilever and the tip, influencing the resolution of topography and force measurements. Micromechanical properties of the cantilever and the shape and chemical composition of the tip, which comes into direct contact with the sample, are essential. High aspect ratios and small tip radii are desirable for imaging steep slopes and deep crevices. Depending on the mode of operation, different parameters have to be optimized, which can be realized according to the methods described in the following.

Silicon and silicon nitride cantilever fabrication based on photolithographic techniques is well established. Metal-based (Ni) cantilevers [34] and cantilevers made of piezoelectric material (lead zirconate titanate) are produced as well for independent actuation and sensing [35]. Cantilevers of various shapes (e.g., rectangular or V-shaped) and dimensions (usually 100 to 200  $\mu\text{m}$  in length) are available. New approaches to a further miniaturization of the system have been made on microfabricated aluminum probes with length scales of 9  $\mu\text{m}$  [36–39].

Coatings (Cr-Au, Pt, Al, TiN,  $\text{W}_2\text{C}$ ,  $\text{TiO}_2$ , Co, Ni, Fe, Au with biological coating) can be applied to the cantilever to modify it against corrosion in the liquid phase or for different applications when conductive, magnetic, or biological properties are necessary.

The resonance frequency of the cantilever ranges between several kHz to several hundred kHz. Cantilevers with high resonance frequencies are used in dynamic modes as the tip oscillates with several hundred kHz above the surface.

The stiffness of the cantilever is defined by the force constant  $k$  and ranges between 0.01 and 100 N/m for the vertical deflection. The soft ( $k < 0.1$  N/m) cantilevers are used in contact modes to minimize the disturbance of the sample. Rigid cantilevers with a force constant larger than 1 N/m are used in noncontact or dynamic modes since they exhibit high resonant frequencies and small oscillation amplitudes of about several nanometers. The force constant for the lateral twisting can be determined for friction measurements [40] and the movement of the cantilever has been modeled accordingly with finite element analysis [41]. The mechanical behavior and the determination of the spring constant are well described in literature [42–49].

The tip itself can consist of different materials or is coated according to the application. For some applications a hard surface is necessary and a diamond-like coating (DLC) is applied [34]. The production of DLC coatings is described in [50]. Different functionalities [51–53] can be applied. Cantilever tips can be modified by chemical [54] and biochemical [55] functionalization. Via silanization [56, 57] or via thiols, self-assembled monolayers (SAMs) are produced for

further modification [53]. Proteins and bacteria [58] can be attached to the tip.

Additional materials which vary the shape of the tip can be deposited, such as polystyrene, borosilicate and silica spheres,  $\text{C}_{60}$  molecules [59], carbon-nanotubes in general [60–63], or single-wall nanotubes with diameters of  $< 3$  nm [64] or functionalized nanotubes [65]. The first are, for example, used to have a defined contact area. The latter are important because tips produced by lithographic methods are of pyramidal shape but do not present the necessary sharpness for high-resolution images. As the tip convolutes with the surface features [66], its shape determines accordingly the lateral resolution, and the width the possibility to enter small features. Electrochemical etching can produce sharper tips with an open angle near the apex of  $20^\circ$ . For sharper tips an extra tip is grown on the apex of the conventional pyramidal tip using electron beam deposition (EBD) [67], which leads to a curvature radius of 2 to 20 nm, or the above-mentioned nanotube-functionalized tips are used. The real tip shape can be calculated and, by deconvolution, hidden information extracted [68–71]. The resolution of steep slopes can additionally be improved by slow scanning and a repeated z positioning at each pixel [72].

Usually the typical scan range is up to 150  $\mu\text{m}$  but also larger scan areas can be reached with a scan area up to 25  $\text{mm}^2$  [72].

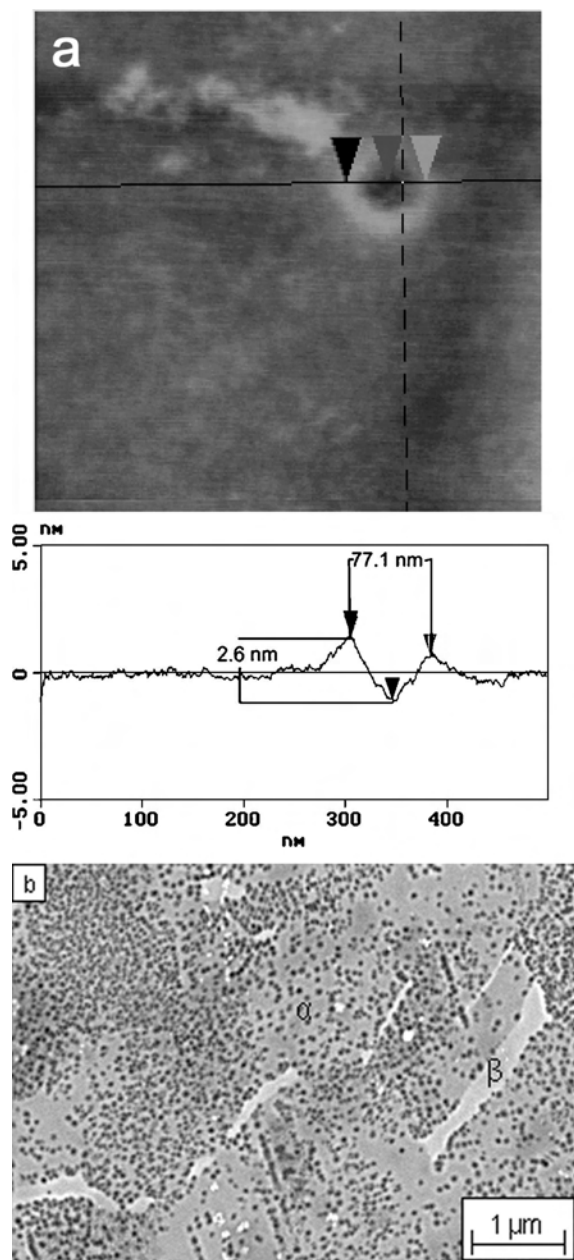

### 3.1.1. Contact Mode

Topography and roughness can be characterized by monitoring the vertical excursion of the cantilever in contact with the surface. Assigning a deflection signal in z-direction to each point while scanning leads to the image. Two typical examples, one of a biological and one of a biomaterial surface, are shown in Figure 4 respectively in Figure 5a. Roughness can be calculated from the acquired data.

**Figure 4.** Typical contact mode SFM image of human enamel showing different crystals. Unpublished data with kind permission from M. Hannig, Clinic for Dentistry, Stomatology, and Oral Maxillo-Facial Surgery, Saarland University.

**Figure 5.** Comparison of (a) SFM and (b) SEM images of TiAl6Nb7 alloy treated with anodic oxidation under galvanostatic conditions in 1 M H<sub>2</sub>SO<sub>4</sub> at room temperature with a current density of 10 mA/cm<sup>2</sup> up to a final potential of 40 V. The SEM image shows the surface on a larger scale exhibiting the differences of the  $\alpha$  and  $\beta$  phase of the alloy. The small black dots that cannot be further identified with this technique are characterized further with SFM to yield topographical information of the structure. SEM image reprinted with permission from [245], C. Leinenbach et al., *Mater. Sci. Eng. Technol.* 8, 442 (2002). © 2002, Wiley-VCH.

Friction force microscopy is done by monitoring the twist of the cantilever while scanning over the surface [73]. With this nanomechanical measurement the shear strength can be determined. An overview on friction on the atomic scale is given in [74]. After chemical modification, the tip of the cantilever can be used to gain information about the chemical

properties, respectively forces between a biomolecule and a biomaterial surface. Images are produced that display predictable contrast and correspond to the spatial distribution of functional groups on the sample surface. Surfaces can be imaged in friction mode down to a resolution of about 0.5 nm [21]. An overview over several different chemical interactions of model surfaces with different chemical modifications is given in [75]. An image contrast is achieved between regions terminated by different functional groups [76] but can be influenced by topographical features. Hydrophobic and hydrophilic parts of the surface can be distinguished [77]. It is even possible to gain information about chirality [78], which in this case was done, on immobilized molecules by investigation of the friction and adhesion force. The load dependency is another important parameter. The atomic stick slip mechanism and interfacial friction, adhesion, and elastic properties measured by friction force microscopy are reviewed in [30].

In scanning spreading resistance microscopy (SSRM), different conductivity of the substrate surface is monitored by applying a voltage and measuring the resistance while scanning in contact mode with DLC-coated tips for better wear properties [79].

In force modulation mode (FM), the force between the cantilever and the sample surface is modulated by vibrating the sample respectively the tip in vertical direction while scanning in contact mode. The modulation frequency is in the range of 5 to 30 kHz with a cantilever resonance frequency of more than 200 kHz. The lateral distribution of the hardness can be obtained by monitoring the amplitude changes [80].

Imaging at the resonance frequency of the tip in contact with the surface is called contact resonance imaging (CRI) [81] and can be used for imaging soft and sticky surfaces like proteins on surfaces.

The modulation of the probe can also be carried out just above the resonance frequency of the cantilever to monitor viscoelastic and anelastic properties of submicron phases. This mode, which can also be done with temperature ramping, is called scanning local-acceleration microscopy (SLAM) [82].

A new technique called atomic force acoustic microscopy (AFAM) uses ultrasonic actuation of the cantilever while scanning in contact mode above its resonance frequency. It is possible to measure the contact stiffness and to distinguish between different orientations of a silicon wafer surface [83].

Besides the actuation of the sample in the normal direction, a high-frequency lateral vibration can be applied. By doing so, local measurements of shear strength and Young's modulus can be undertaken. The indentation of the tip into the surface is reduced and accordingly the possible damage. This method was introduced as harmonically modulated lateral force microscopy (HM-LFM) in [84, 85].

### 3.1.2. Dynamic Modes

In the dynamic modes [86–88] the cantilever is oscillated near its resonance frequency by an additional piezo crystal. The amplitude signal of the oscillating cantilever yields the information about the interaction.

A distinction between noncontact and the dynamic mode in the repulsive regime is often made. In real noncontact

mode attractive forces are measured while the tip is oscillated above the sample with an amplitude of about 10 nm, never touching the sample surface.

In the dynamic mode [89], the tip is oscillated with an amplitude of 20 to 100 nm and touches the surface at some point. The feedback loop works as in contact mode maintaining a constant amplitude. Topography and roughness information are obtained as described earlier. Additionally and simultaneously, a phase image can be recorded.

In phase imaging the phase lag between the excitation frequency and the cantilever response signal is monitored. If the cantilever is oscillating freely in air, the waveform signal detected by the photodiode should be in phase with the signal driving the piezo element. This signal is sensitive to the interaction force between the cantilever and the surface. The phase contrast arises from the different amount of energy dissipated by the tip while oscillating on surface areas with different elastic properties. A short overview of experiments and theoretical descriptions is given in [90]. The mechanical properties [91–93] as well as chemical differences can yield a phase lag, which has been correlated quantitatively to the chemical interactions on chemically microstructured surfaces [90, 94].

In pulsed force mode (PFM), force distance respectively indentation curves are recorded in z-direction continuously [95]. A sinusoidal modulation far below the resonance frequency of the cantilever is applied to the z-piezo. Typical parameters are for the amplitudes 10 to 500 nm and for the frequency values between 0.1 and 2 kHz. A complete force distance cycle from the interaction free distance to the direct contact with the probe respectively the indentation is carried out. By measuring the maximum adhesion force an adhesion image is obtained; the slope in the repulsive regime is correlated with the stiffness of the substrate and long-range forces like electrostatic forces caused by surface charges influence the baseline. Accordingly it is possible to gain information about adhesive, elastic, and electrostatic sample properties. By chemical modification of the tip it is also possible to image differences between chemically different areas on a sample surface. Typical PFM images are given in Figure 6.

Electrostatic contributions to the tip-sample interaction can be isolated to yield surface charge density information. A theoretical and analytical framework for determining relative charge densities from arrays of SFM force curves without the need for an absolute measurement of the tip-sample separation is presented in [96] labeling it D-D method.

Polar interactions probed with SFM using a charged tip can lead in the future to atomic resolution of polar surfaces [97].

Magnetic interactions can be measured with magnetically coated cantilevers [98] but are, in the further investigations of biomaterials, of lesser importance.

In addition SFM is also being used for applications in which no scanning is required, where the tip is used as a sensitive force sensor (force spectroscopy) [99–101]. Loads of 1 to 1000 nN can be applied with tips that have tip radii of up to 1  $\mu\text{m}$ , leading to an investigation of the first 0.1 to 10 nm [102]. Forces on a larger scale can also be measured by using the force apparatus by Israelachvili [103, 104]. This

**Figure 6.** Pulsed force mode images of blends of PS/PMMA spin-coated on silicon substrate [95]: topography (a), (c) and adhesion (b), (d) images; lighter color corresponds to lower adhesive forces. The composition of PS/PMMA is 58/42 (a), (b); and 69/31 (c), (d), scan range: 10  $\mu\text{m}$ .

will cover larger areas and the limitation to mica or a modification of it is given. However, absolute force values can be determined with high accuracy because the interaction area is well known.

With the setup of an SFM, surface and adhesion forces [105] between two surfaces and the elasticity respectively hardness by indentation of the substrate can be obtained. The data are investigated by plotting the bending of the cantilever versus the load applied to the sample. By indenting the surface it is possible to gain information about the elasticity and Young's modulus [28, 106] as well as time-dependent processes happening on polymers [102]. By monitoring the forces between the tip and the surface, chemical patterns on a surface can be characterized [52].

To monitor hardness by nanoindentation usually blunter tips are used to be able to relate to macroscopical hardness testing. The Berkovich tip with nominal radius of 150 nm is used to monitor the hardness, which is defined as the ratio of the maximum load to the projected contact area [107].

By force mapping, two-dimensional arrays of force curves are recorded while scanning the tip across the sample. By this the elastic properties can be monitored over the whole scan area. From the force curves Young's modulus can be calculated according to Sneddon's modification of the Hertzian model for elastic indentation [108].

Viscoelastic properties can be also monitored on a micrometer and submicrometer scale by microrheological measurements done with magnetic beads [109]. The loads applied are in the range of 10 nN. Mainly it is applied to monitor viscoelastic properties of cells using the parameters of an effective elastic constant, a viscosity, and a relaxation time. Viscoelastic properties can also be monitored via laser-tracking microrheology by looking at the Brownian motion

of individual spherical particles embedded in the viscoelastic material by monitoring the forward scattered light [110]. As particles, polystyrene beads of 0.27  $\mu\text{m}$  diameter are used.

### 3.2. Electron Microscopies

A totally different approach to get information in the nanometer regime is based on the particle-wave dualism of the electron, which was proposed in 1924 by de Broglie [111]. This offers the possibility to use electrons as a probe in a similar way as light with a wavelength  $\lambda$  depending on the electron mass  $m$  and velocity  $v$ :

$$\lambda = \frac{h}{mv}$$

According to Abbe, the resolution  $A$  of an imaging system depends on the wavelength, the diffraction index of the area between sample and objective  $n$ , and the angle  $\alpha$  under which the light passes through the objective:

$$A = 0.61 \frac{\lambda}{n \cdot \sin \alpha}$$

The term  $n \cdot \sin \alpha$  is called numerical aperture. This could only be varied to a small extent, so the resolution of light microscopy with typical wavelengths around 500 nm is limited to 200 nm. The much lower wavelength, which electrons can reach, offers therefore a much better resolution. In electron microscopy the glass lenses have to be replaced by electrical and magnetical lenses, which deflect the electron beam in the same way as glass lenses do the light. Because of the aberration of these electromagnetic lenses, the resolution in electron microscopy is limited to 0.2 nm.

In the sample a variety of different interactions between the probe electrons and the sample atoms take place:

- transmission of primary electrons
- secondary electron emission
- Auger electron emission, a special type of secondary electron emission
- electron backscattering
- absorption of electrons
- characteristic X-ray emission
- emission of light

One big disadvantage of electrons as a probe is the charging of the sample during electron bombardment. In principle only conducting samples can be imaged. In a special case nonconducting samples can be imaged if the number of the absorbed electrons is equal to the number of secondary electrons leaving the sample. In all other cases the sample has to be coated by metal or a conducting replica has to be made. Both methods may give artifacts.

There are two approaches to using electron beams for microscopy. The first is the transmission electron microscope realized by Ernst Ruska in 1933 [112, 113]. The TEM can be compared with a transmitted-light microscope: the electrons pass through a thin sample [114] and can be detected at a fluorescence screen. Because of the strong absorption and scattering processes which take place if free electrons interact with matter, only very thin samples in the range of 10 nm to 100 nm thickness can be passed by electrons.

As in a light microscope, there are different mapping modes [111]:

1. *Bright-field Image*: The image is made of electrons which directly pass through the sample. The image plane of the objective is mapped by the projector lens. The contrast is given by the loss of electrons by scattering and absorption on their way through the sample. It depends on the density of the sample and the atomic number of the sample components. In Figure 7 two examples of this imaging technique are presented.
2. *Diffraction Image*: This uses also the electrons which directly pass through the sample. But in this mode the focal plane of the objective is imaged by the projector lens. By this one gets a diffraction image which yields information on the crystal structure of the sample in a similar way to an X-ray-Laue-diffraction image (Fig. 8).
3. *Dark-field Image*: The electrons which scattered inside the sample are imaged on the screen and the electrons which pass the sample in a direct way are filtered out.

The TEM should theoretically reach a resolution which is 1,000,000 times better than light microscopes. The lens aberration, especially the spherical and chromatical aberration, decreases this theoretical value to 1,000 times better resolution in practice. Therefore, points which are separated by 0.2 nm can be imaged.

Furthermore, energy-filtering transmission electron microscopy [115] or TEM with attached energy dispersive X-ray analysis (EDX) is used which gives the elemental composition.

There are three main disadvantages of the TEM:

1. Only very thin samples can be investigated.
2. The samples have to be stable under electron irradiation.
3. The whole TEM has to be held under high vacuum conditions or one has to build a special environmental cell for the sample which is differentially pumped against the other parts.

The second approach to use electrons as a probe for imaging is the scanning electron microscope (SEM) [116],

**Figure 7.** Two typical TEM images of  $\text{TiO}_2$  nanoparticles (particle diameter 16 nm, crystal modification anatase). Picture (a) is a low-resolution image where the distribution of the nanoparticles is visible, while the resolution in picture (b) is much higher with clearly visible crystal plates (line-shaped structures) inside the nanoparticles (round structures) [246].

**Figure 8.** Diffraction pattern of the sample in Figure 7. The rings have their origin in the diffraction at different crystal planes. The radii of the rings are correlated with the Miller indices of their diffraction plane [246].

which was invented by Knoll and v. Ardenne [117] in the 1930s. The first realization to image a surface was described by Knoll and Thiele [118]. This microscope scans a very well-focused electron beam over the sample surface. The electrons which leave the sample surface are accelerated by a voltage to the detector, for example, an Everhart–Thornley detector [111], which transforms the electrons into an electrical signal. This is used to control the intensity in a cathode-ray oscillograph while the same signal that scans the electron beam in SEM is used as deflection signal in the oscillograph. So an image of the electrons leaving the sample is obtained.

The resolution in SEM is estimated by the area where the electrons leave the sample. The dimensions of this area depend on the spot radius of the electron beam on the sample surface and the scattering processes inside the sample.

In SEM there are several kinds of electrons which could be detected:

1. Secondary electrons which are produced by primary electrons near the surface with enough energy to pass through the surface barrier. These produce the highest resolution.
2. Secondary electrons which are produced by backscattered electrons. These produce the lowest resolution.
3. Secondary electrons which are produced from the backscattered electrons out of the pole shoes of the last lens.
4. Primary electrons which hit the aperture and produce there secondary electrons.

The last two cases increase only the noise without any further information on the sample.

The backscattered electrons themselves are too fast to reach the secondary electron detector. They can, however, be also used for imaging with a different detector. The backscattered electrons give a high material contrast because their number depends on the nuclear charge.

The resolution of the SEM depends on how well the electron beam is focused on the sample. This could give a resolution of 3–6 nm. The depth of focus can reach up to 1 mm, compared to only 100–1000 nm in a light microscope. An example of a SEM image is given in Figure 5b.

A review of spatially resolved spectroscopies in electron microscopy for the study of nanostructures of different metals, semiconductors, and biomaterials is given in [119].

### 3.3. Other Methods

One problem of the techniques presented so far is the lack of chemical information, except in TEM with additional EDX or energy filter characteristics. Because the surface chemistry is a very important parameter determining the properties of biomaterials, often additional methods are applied. They have usually a high surface sensitivity, but their lateral resolution is limited. These complementary methods are in particular:

- X-ray photoelectron spectroscopy (XPS) in which the kinetic energy of photoemitted core electrons gives information on the elemental composition and the binding state of these elements. Thus metals can be distinguished from their oxides because they present another oxidation state. The surface sensitivity is several tens of nanometers; the lateral resolution is poor (between 100  $\mu\text{m}$  and 5 mm). Quantification is possible within an accuracy of 5–10%.
- Auger electron spectroscopy (AES) in which also the kinetic energy of electrons is measured. These electrons are electrons which arise from a special intra-atomic relaxation process, the Auger process. After a core electron hole is produced in an atom (by X-rays, primary electrons, or ions), an electron with higher binding energy relaxes into the deep hole. This energy can then be transferred to an electron which has now enough energy to overcome the binding energy and leave the material. The energy of Auger electrons is also characteristic for the elemental composition, and the surface sensitivity is similar to XPS. There are two main differences: Because in the Auger process more electrons are involved, there is usually no easy interpretation of the chemical state of the electrons. However, because in Auger electron spectroscopy the primary hole-producing process can be by a focused electron beam, the lateral resolution can be in the tens of nanometers range.
- Secondary ion mass spectrometry (SIMS), the third important technique, in which, through ion bombardment, secondary ions are sputtered from the surface which are further analyzed in a mass spectrometer. Because there are also molecular ionic fragments, a huge amount of chemical information can be obtained. If a time-of-flight detector is used, also very large and heavy molecules, for example, biomolecules and polymers, can be detected. The surface sensitivity can be tuned by the ion bombardment and can be restricted to the first monolayer. By harsh bombardment also depth profiles can be measured. The lateral resolution is usually several hundred nanometers. However, the current limit is therefore well below 100 nm.

## 4. NANOANALYSIS OF BIOMATERIALS

### 4.1. Metals and Oxides

#### 4.1.1. Titanium and Titanium Alloys

Titanium is one of the most important materials in implantology. Therefore, many investigations with nanoanalytical tools are performed on titanium or titanium-containing implants.

**Single Crystalline Model Surfaces** To get insight into the basic material interactions, a defined surface has to be prepared. In the case of titanium and its natural surface oxide, these standards are TiO<sub>2</sub> single crystals.

An overview covering atomic resolution investigations with STM and SFM of different TiO<sub>2</sub> modifications is given in [120].

Intrinsic defects on single crystals of TiO<sub>2</sub> were characterized with STM [121–123]. In these investigations STM was also combined with other techniques like XPS and low-energy electron diffraction (LEED) to investigate the structure after argon sputtering and annealing in oxygen plasma and to detect calcium impurities. These are eliminated after the treatment, which improves the surface morphology of the TiO<sub>2</sub> (110) crystal [124].

TiO<sub>2</sub> as substrate and the structure of the adhering biofilm were monitored also via SFM [125].

**Surface Treated Titanium** The high biocompatibility of titanium has its origin in the natural oxide layer on the titanium surface. A further property that influences the ingrowths of titanium implants into bone is their surface roughness. So different surface treatments, for example, chemical, electrochemical, or mechanical techniques, are used to increase the biocompatibility of titanium.

The oxide layer at electropolished and anodically oxidized titanium was investigated in different ways, for example, by SEM, XPS, AES, SIMS [126]. This showed that the oxide formed is mainly TiO<sub>2</sub>, but the chemical composition can be modified by anion adsorption when H<sub>2</sub>SO<sub>4</sub> or H<sub>3</sub>PO<sub>4</sub> electrolytes are used. The hydrophilicity of TiO<sub>2</sub> films obtained by different techniques (radio frequency magnetron sputtering (RFMSD) and plasma enhanced chemical vapor deposition (PECVD)) and the influence of UV irradiation were monitored via SFM. The interaction caused by the capillary water bridge formed at the tip-sample interface was investigated [127]. The adhesive force shows a highly inhomogeneous surface for RFMSD films and an increase in adhesion force upon UV irradiation. For PECVD a more homogeneous surface was observed. Surface characterization of a titanium oxide layer, grown on commercial Ti substrates by metal organic chemical vapor deposition (MOCVD) technique, was monitored with STM and the chemical composition with XPS [128].

Another widely used surface modification method is sandblasting. This not only increases the surface roughness but also changes the chemical composition because some shot particles remain adhered on the metal. In [129] the percentage of surface area covered by the remaining shot particles was ascertained by SEM and a following digital image analysis.

Titanium surfaces used in oral implantology were submitted to various treatments such as mechanical polishing, acid attack in HCl/H<sub>2</sub>SO<sub>4</sub>, after mechanical polishing or sandblasting, and titanium plasma-spray. Polished titanium exhibits a peak-to-valley roughness of 81 nm; the acid-treated surfaces show an increased roughness in the micrometer range (2100 nm for polished and acid attacked; 3600 nm for sandblasted and acid attacked). The chemical composition has been measured by Auger electron spectroscopy. The treatments had no major influence on the surface chemical composition [130].

Titanium implants with different surface properties reached by various surface treatments (mechanically polished, mechanically ground, sandblasted with alumina and etched in HF/HNO<sub>3</sub>, sandblasted with alumina and etched in HCl/H<sub>2</sub>SO<sub>4</sub>, mechanically polished and etched in HCl/H<sub>2</sub>SO<sub>4</sub>, and plasma-sprayed) were investigated according to roughness and morphology and the subsequent biofilm formation [131]. The adsorption of human plasma fibrinogen (HPF) was tested but the SFM phase imaging technique could only detect HPF on the first two of the investigated seven samples due to resolution problems. Additionally, the chemical composition was examined by XPS and ToF-SIMS and some impurities used during sample production and treatment were detected.

A further item of investigation are titanium alloys and, in this field, the cell attachment to the implants [132]. As on Ti, there are different ways to prepare the alloy surface, for example, thermal oxidation, machining, or electrochemical polishing. TEM and STEM studies [133] show that the microstructure of the anodic oxide films is rather heterogeneous with areas of different porosity, which can be correlated with the grain structure of the bulk metals. These oxides on Ti alloys are more heterogeneous than that on pure Ti, due to the more complex microstructure of the bulk material. TiO<sub>x</sub> films deposited on TiAl6V4 by plasma immersion ion implantation (PIII) with different compositions and properties were fabricated as model for artificial heart valve implants. They were evaluated with SFM revealing a dense surface. Microhardness was tested and related to the oxygen pressure upon production. A maximum hardness of 17 GPa is obtained with an oxygen partial pressure of  $3 \times 10^{-2}$  Pa [134]. This is also correlated with a development of Ti<sub>3</sub>O<sub>5</sub> and TiO<sub>2</sub> phases as monitored with XPS.

The effect of sterilization with different techniques such as dry heat, steam autoclaving, ethylene oxide, peracetic acid, and plasma-based sterilization techniques on the surface properties of NiTi (Nitinol) was investigated with AES and SFM. Dry heated, steam autoclaved, and ethylene oxide treated surfaces present thicker oxide layers where the first two treatments yield a threefold increase in surface roughness. Plasma-based sterilization has a lesser effect on the oxide layer thickness, roughness, and morphology [135].

The influence of functionalization of titanium surfaces was monitored in [136]. No change in surface structure was observed upon coating with silanes.

The corrosion of titanium surfaces was monitored *in-situ* with electrochemical SFM by changing the applied voltage on the titanium. The growth of oxide domes could be observed [137]. Further STM experiments are presented

in [120]. Titanium surfaces exposed to conditions of corrosion in a biological environment were examined with STM *ex-situ* and nanoscale topographical changes could be determined [138].

**Structured Titanium Surfaces** Nanostructured Ti films were characterized with respect to interaction with proteins like F-actin via SFM. An influence of the structure height between 1 and 4 nm on the alignment and adsorption amount (scan ranges: 0.158, 6, and 17.8  $\mu\text{m}$ ) [24] could be determined. Using a photolithographic technique, the flanks of Ti-implant screws were patterned with round etched regions of 10  $\mu\text{m}$  diameter, and placed in a square matrix with a pitch of 20  $\mu\text{m}$  [139]. This surface morphology was investigated by SEM after implantation, but no statistically significant differences were seen in fixation, with respect to bone-to-implant contact, between the patterned and control implants. In another study 1-, 2-, 5-, and 10- $\mu\text{m}$ -wide Ti gratings were produced by microtechnology and plasma etching [140]. The biocompatibility was tested via incubation of rat dermal fibroblasts (RDFs) on the surfaces for 3 days. Observation by SEM, TEM, and confocal laser scanning microscopy showed that the RDFs as a whole and their stress fibers oriented strictly parallel to the surface pattern on the 1- and 2- $\mu\text{m}$  surface, while on the 5- and 10- $\mu\text{m}$  surfaces this orientation was not observed.

**Coated Titanium Surfaces** A further approach to increase the biocompatibility is to form a new surface consisting of more tissue-like material; especially phosphate (Ca-P) and hydroxyapatite (HA) deposited by different techniques are used to reach this [120, 136, 141–148].

One of these techniques is the ion-beam assisted sputter deposition (IBASD). Ca-P coatings yield columns of 40 to 80 nm on the flat surface as monitored with SFM. The quality of the coatings was monitored with XPS, AES, and FTIR studies [141]. IBASD was also used for the production of  $\text{TiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and HA films. These were investigated concerning the roughness via SFM yielding a higher roughness of  $\text{TiO}_2$  surfaces [142].

Another deposition technique for Ca-P coatings was developed in [149]. This study showed proliferation of the osteoblast-like cells which was significantly higher on non-coated than on Ca-P-coated samples. On the other hand, more mineralized extracellular matrix (ECM) was formed on the coated surfaces. TEM confirmed that the cells on the coated substrates were surrounded by ECM.

Plasma-spray, sol-gel, and sputtering techniques were compared in [144] by SEM, XPS and X-ray diffraction (XRD). All coatings exhibited a rough morphology suitable for implant applications. The sputtered coatings were found to have a composition most similar to HA; the sol-gel deposits also showed a high concentration of hydroxyl ions. Plasma-spraying also results in a porous titanium coating in which  $\text{Ti}_3\text{O}_5$  was formed in the outermost surface due to oxidation [150]. The macropores in the outermost layer reached a diameter and even surpassed 150  $\mu\text{m}$ , which could be beneficial for tissue growth into the coating. Also plasma-sprayed coatings were investigated in [147] by TEM. Six months after insertion, an occasional lack of HA coating and phagocytosis of HA particles were noted. The implant was surrounded by well-mineralized bone investing the smallest

cavities of the plasma-sprayed layer. Plasma-sprayed hydroxy-apatite was also used to increase the biocompatibility of these materials. But there was no obvious difference in the *in vitro* and *in vivo* reactions of pure and coated Ti alloys [151].

In [145] different surface treatments were investigated by SEM. Here the HA coating on grid blasted Ti surfaces significantly improved fixation to the bone, while HA onto porous coating did not compared to pure Ti surfaces. Further SEM studies were performed on plasma sputtered HA thin coatings on Ti alloys [146]. For deposition temperatures as low as 67  $^\circ\text{C}$ , the crystalline phase of the HA coating is detectable and an underlying (TiAlV)N coating increases the crystallinity and thermostability of the HA coating before and after heat treatment. In a combined TEM, SEM, XRD, and FTIR study [148] it was shown that the morphology and composition of a plasma assisted electrophoretic deposited HA layer were significantly influenced by the solution pH values. SEM images out of this investigation are given in Figure 9. The electrophoretic method performed with ultrahigh surface area HA powder produces dense coatings when sintered at 875–1000  $^\circ\text{C}$ . SEM inspection of these layers showed that the use of dual coatings solves the problem of cracking HA layers during sintering [152]. Sol-gel derived hydroxyapatite coating morphology was also investigated with SFM and SEM in [143], revealing good homogeneity and a high surface roughness.

Other investigations on HA are presented in [120]. In [153] bioactive calcium phosphate invert glass-ceramic coatings on substrates such as pure titanium, conventional Ti-6Al-4V, or Ti-29Nb-13Ta-4.6Zr were analyzed to determine the optimum condition for preparation of fine joining. Cross-sectional SEM photographs and EDX measurements around the joining interface between substrate and coating show gradient zones of 3–4  $\mu\text{m}$  in thickness between substrate and ceramic layers. Ti concentrations in the zones decrease with decreasing distance from the glass-ceramic layers.

Another approach to increase the biocompatibility of Ti alloys is a laminin-5-coating which enhances cell attachment, spreading, and hemidesmosome assembly [154]. This may reflect better integration between epithelial cells and titanium alloy. TEM analysis of such a compound showed that cells formed significantly more hemidesmosomes on the surface of laminin-5 coated and passivated than on the surface of laminin-5 coated, unpassivated Ti alloys.

In some cases inert areas and areas of high biocompatibility are needed on the same substrate. Teflon (PTFE)

**Figure 9.** SEM micrographs of plasma-assisted electrophoretic deposited coatings [148]. (a) Calcium-phosphate coating, cathodic deposition by electrochemical reaction in a HA solution of pH 4–5. (b) HA coating anodic deposited at pH 10–11.

coatings on titanium substrates are an approach to build up an inert layer on a biocompatible titanium substrate. In Figures 10 and 11, SFM pictures of a Teflon layer on commercially pure titanium are shown [155]. In Figure 10 the Teflon is deposited by a dip coating technique. The structure of the underlying polished titanium surface is not visible. It is possible to compensate substrate roughness by this method. In Figure 11 an additional surface structure is caused by powder coating a Teflon layer, which increases the surface roughness.

**Implanted Materials** Implants can also be investigated after implantation.

SEM investigations showed that failed oral titanium implants [156] contained varying amounts of tissue residues while two control samples were essentially free from macroscopic contamination. The efficacy of cell adhesion on Ti, Ti-alloy, dental gold, and ceramic implants were also investigated by SEM [132]. By this investigation the better adhesion and spreading of the cells on metallic surfaces could be shown. One result of TEM is that the attachment zone between bone and implanted biomaterials consists of a mineralized collagen fiber matrix associated with an inorganic (hydroxyapatite) matrix [157, 158].

An important field of investigation is the drift of titanium far away from the dental implant into the surrounding bone tissue [159]. The same happened at metal-metal interfaces, for example, in hip implants, as was shown by TEM [160].

#### 4.1.2. Other Metals

Surface structure on the atomic level, the change of it by adsorption of ethane and other model molecules, and the techniques to monitor it are presented for Pt and Rh model surfaces in [161].

A copper (110) surface with homo- and heterochiral domains of adsorbed glycine could be distinguished with submolecular resolution via STM [162].

A Co-Cr-Mo (ASTM F-75) alloy and its corrosion were investigated by SECM in NaCl solutions. Corrosion took

**Figure 10.** SFM image of a titanium substrate coated with Teflon (PTFE) by dip coating [155]. The underlying substrate surface is not visible. The coating flattens all the substrate roughness.

**Figure 11.** SFM image of a titanium substrate coated with Teflon (PTFE) by a powder method [155]. The Teflon layer forms a strongly structured surface.

place mainly at grain boundaries. Corroded material was additionally characterized by X-ray energy dispersive spectroscopy (EDX) analysis for chemical composition. Two types of corrosion products were seen as flakes on the surface, one with Co 3%, Cr 72%, Mo 24% and the other with Co 12%, Cr 88%, Mo 0%; on the tip abrasion flakes were determined as Co 11%, Cr 66%, Mo 24% [22].

Stainless steel, copper and alloys, and the corrosion processes induced by bacterial attachment including freshwater bacteria monitored with SFM are described in [163]. The electrostatic forces on the surfaces of stainless steel (316), gold, and an electropolished Nitinol surface were investigated via force curves with the SFM. Gold and stainless steel exhibit repulsive forces at pH 7, Nitinol a slight attractive force. Nitinol surfaces show a heterogeneity in the distribution of surface charges that is rendered more homogeneous upon oxidative treatment [164].

Although gold has been studied for a long time, it is still an actual field of investigation. Comparison of the cell adhesion properties with other materials is made, for example, by SEM examinations as mentioned earlier [132]. But Au is also useful in other applications. The protein adsorption on gold colloid particles, for example, is widely used in biotechnology for diagnostics and separations, for example, in combined fluorescent and gold immunoprobes for correlative light and electron microscopy [165]. To visualize the protein film on nanosized particles, a TEM approach was applied [166]. These proteins cause a significant scattering absorption contrast in TEM based on the materials' electron density. Thus the film thickness was directly measurable in planar projection and the shape of these films was visualized without negative staining methods.

Alkali- and heat-treated tantalum as implant material has been shown to bond to bone, for example, by SEM [167]. The treated implants showed weak bonding to bone after 8 weeks of implantation and exhibited significantly higher tensile failure loads compared with untreated Ta after 16 weeks. In contrast, the untreated TA implants had a intervening

fibrous tissue layer between the bone and the Ta and did not bond to bone after 8 and 16 weeks.

Techniques of SEM and light microscopy deal with retrieval analysis of different implanted biomaterials, for example, cobalt-chromium-molybdenum alloys [168]. Cases included both orthopedic and dental implants, as well as entire mandibles and portions of maxillae obtained at autopsy.

## 4.2. Ceramics and Glasses

Ceramics and their use as biomaterials is a hot topic of current research [132, 157, 169–176]. A review of the recent improvements in TEM to characterize microstructures in advanced ceramics is given in [173].

A disadvantage of ceramics is their sensitivity to microscopic cracks as investigated in [170]. The manufacturing process can introduce these cracks. This makes it critical to have analytical methods to detect such cracks. In an investigation light-optical microscopy, fluorescence microscopy, and SEM were compared. It was found that microscopic cracks of critical size could be detected using the fluorescent penetrant method, but not by light-optical microscopy and even not by SEM.

The results of an experimental process in which ceramic is formed without heating are investigated in [177]. Three calcium-deficient apatites (CDA: two powders and a fibrous compound) and a biphasic calcium phosphate (BCP) were examined. In this investigation the size of the single ceramic particles was studied by SEM showing that one powder CDA and the fibrous CDA had larger diameters (nearly  $24.65\ \mu\text{m}$ ) than the other powder CDA ( $13.2\ \mu\text{m}$ ) and the BCP ( $6.6\ \mu\text{m}$ ).

Precipitation of calcium phosphate in the presence of double-hydrophilic block copolymers leads to nontrivial superstructures of organized inorganic/organic hybrid material, as characterized in [178]. The polymer micelles act as interactive templates where the organic/inorganic superstructure can range between nested clusters of fine nanofibers to compact mesostructures in which nanoscaled calcium phosphate entities are interspersed with ordered polymers. TEM images of these structures are shown in Figure 12.

Ceramics used in dentistry, such as IPS-Empress 2<sup>TM</sup>, were characterized testing the influence of different immersion times in hydrofluoric acid. The increasing roughness was monitored after etching [179]. In [180] it was found that calcium complexation by albumin plays a key role in early mineralization kinetics of commercial hydroxyapatite and synthesized biphasic ceramics in a bufferless simulated inorganic plasma (HBSS). Mineralization is favored when albumin is preadsorbed and hindered when it is dissolved in HBSS. A review of the interaction between different mica glass-ceramics and bone was presented in [174].

Alumina (sapphire) fatigue was tested in the course of validation as a bioceramic. Corrosion morphologies and fracture surfaces were investigated via SEM and SFM. The fatigue limit was found to be decreased upon stress in isotonic solution with regard to the behavior in air [181].

The biocompatibility of ceramics could be influenced by a variety of parameters. By investigating the cell cytotoxicity and biomechanical strength of the ceramic diopside

**Figure 12.** TEM images showing the growth of neuron-like calcium-phosphate/polymer mesostructures at pH 4.5 and 5.0 [178].

( $\text{CaOMgO}_2\text{SiO}_2$ ) [171], TEM photographs of osteogenic cells MC3T3-E1 on diopside after 14 days of incubation showed active secretion of crystals from osteoblast-like cells. The cells formed multiple cell layers similar to those on the control coverslips (Thermanox<sup>TM</sup> from NUNC Inc. Roskilde, Denmark). In so-called organoceramics the morphology and properties are significantly changed by the organic macromolecules [175]. In the absence of organics a flakelike morphology of the ceramic was obtained, while rosette-shaped composite particles were obtained in the presence of poly (vinyl alcohol). It is believed that the molecular manipulation of microstructure occurs through the role of polymer chains in nucleation of the inorganic layers.

Hydroxyapatite (HA) in its natural and synthetic origin is an interesting biomaterial not only as coating material as mentioned in Section 5.1 [140–147, 182]. Hydroxyapatite can be fabricated in a porous form. In [183] the authors presented a new method, which is based on the swelling ability of starch when it is heated to  $80\ ^\circ\text{C}$  in the presence of water. Different starch volume fractions and starch particle sizes were added on the HA slurries which were then heat-treated to promote consolidation by starch gelification. SEM pictures reveal the presence of interconnected pores with shape and sizes corresponding to the starch granules used. A degradation study in an acellular synthetic body fluid has shown that the prepared bodies keep their integrity under physiological conditions. The strength of interfacial attachment between bone and HA is related to the crystallinity, the grain size, the stability, and the morphology of the calcium phosphate coating. Post-heat treatment is an essential process of controlling the crystallinity and the grain size of HA coating [184]. The stability of hydroxyapatite was also tested in a saturated citric acid solution (pH1). Highly crystalline hydroxyapatite [185] was used which was produced in a novel pressurized hydrothermal post-plasma-spray process, that converts the amorphous components back to a 96% content of crystalline HA. These samples were compared to coatings with crystalline HA contents ranging from 37.5 to 82%. All coatings showed very similar steady-state dissolution rates except for highly amorphous coating, which was

significantly higher. A result of SEM analysis was that the amorphous coating was degraded substantially more than the other samples, resulting in partial coating exfoliation. The investigation suggests that the treated coating is significantly more resistant to degradation from aggressive detoxification procedures.

Because bioactive glasses (calcium phosphate ceramics) are one of the most biocompatible materials in relation to vertebrate tooth, enamel, dentin, and bone, they have gained a wide acceptance in dentistry and restorative orthopedics, for example, in middle ear reconstruction. Of special interest are the bonelike apatite layers that grow on such glass surface in biological environment [186–192], which is attributed to the catalytic effect of the Si-OH groups, which are formed on the surface of SiO<sub>2</sub>-based glasses [188]. TEM with attached energy dispersive X-ray spectrometer showed that the Ti-OH functional groups of TiO<sub>2</sub> induce apatite nucleation not directly, but through transformation of their calcium compounds and subsequent formation of amorphous calcium phosphate.

A content of recombinant mouse amelogenin (rM179) [186] and recombinant porcine amelogenin (rP172) [187] in a supersaturated calcification solution (SCS) was examined as to its effect on the growth of apatite crystals nucleated on Bioglass<sup>R</sup> 45S5; see also Figure 13. The purpose of this study was to gain a better understanding of the role of amelogenin protein in tooth enamel formation. Under SEM the rM179-containing solution leads to elongated, curve-shaped (500 nm long and 120 nm thick) crystals, while the immersion in blank and bovine serum albumin-containing solution results in smaller plate-shaped respectively needle-shaped crystals. TEM observations showed that the crystals generated by the rM179 immersion appeared to be composed of bundles of longish crystals (15–20 nm thick) orientated parallel to one other. During 0.5–4 h of rP172 solution immersion, the protein assemblies of rP172 remarkably induced the formation of orientated silica gel plates and subsequently of long and thin apatite needle crystals. In [169] bioactive glass discs were produced by forming thin polymeric sheets (100 μm thickness) loaded with jet-milled Bioglass<sup>R</sup> 45S5 particulate (1–10 μm). After heating the discs in air to remove the organic phase, they were sintered at 800, 900, or 1000 °C. The bioactivity was then assessed in Tris buffer. The discs sintered at 900 °C and 1000 °C formed crystalline HA layers after 24 h in Tris as indicated by FTIR, SEM, and EDX analysis. At a lower surface-area-to-volume ratio also on 800 °C sintered ceramic, the formation of HA could be observed. A comparison between ceramic and metal surfaces showed that epithelial cells adhere more on

**Figure 13.** SEM micrographs of a bioglass surface [187] after (a) 2 and (b) 4 h of SCS immersion. Arrows point to apatite minerals.

metallic surfaces [132] (see also Section 4.1). A combined XRD, FTIR, EDX, and SEM examination of the *in vitro* reactivity of a sol-gel glass (80S20C) to simulated body fluid (SBF) was presented in [192]. Because of the partial dissolution of the glass in contact with SBF, there are remarkable variations in ionic concentration and pH of the solution. To avoid this behavior, a protocol for tests with continuous exchange was proposed. In a static control experiment a faster formation of the phosphate layer was detected only within the first 6 h. After 7 days large crystalline aggregates and apatite crystals were found on the freshly formed layer. Another form of bioactive glass is silica fibers, which provide alternatives for the design of novel products used in tissue guiding or bone repairs. In [190] the ability of such fibers to induce formation of bonelike calcium phosphate was investigated. The fibers were prepared by dry spinning. The structure of the fibers was varied using three different factors: (1) spinnable sols with different structures and sizes of polymers to establish varying viscosity levels; (2) aging of green-state fibers, and (3) heat treatment. The bioactivity tests were also done in SBF. Different fibers obtained clearly different properties. The fibers spun at about  $\eta > 3$  Pas had the best properties, especially when they were heat treated at 175 °C.

Controlled release glass (CRG) based on calcium and sodium phosphates differs substantially from commercial glass in that it dissolves completely in aqueous environment. The solution rate can be predetermined and adjusted by altering the chemical composition. A SEM study of the hemocompatibility [189] of such glass indicated that selected and controlled compositions of these materials might provide good blood-contacting surfaces.

### 4.3. Polymers

Many different ways to use polymers as biomaterial are reported. This field spreads from vascular implants [193–196] and bone replacement [197–200] to intraocular lenses [201].

#### 4.3.1. Structure and Mechanical Properties

High- and low-density polyethylene (HDPE and LDPE), isotactic and atactic polypropylene (iPP and aPP), and polymer blends were investigated regarding the friction coefficient and the elastic modulus via SFM. Structural changes and the mechanical property changes around the glass transition temperature have been monitored during temperature runs. The enhanced ordering of the backbone correlates to the increased surface modulus. Additionally, the elastic modulus, the time-dependent relaxation process, and the friction properties were measured as a function of pressure. Loads between 1 and 1000 nN were applied. At low pressure the deformation of the polymer is elastic. With increasing pressure there is a phase transition to a plastic behavior attributed to a polymer alignment effect. Friction properties were investigated concerning the contact pressure and contact area, revealing an increased elastic modulus with increased density and crystallinity and a linear increase with contact pressure. Stretching of LDPE was shown to lead to surface roughening and alteration of surface mechanical properties. These experiments show that a material subject

to complex mechanical stresses will change continuously its surface mechanical properties as the nature of the stress changes [102].

Polyethylene and the influence of low molecular weight additives that are added to prevent oxidation were investigated via friction versus load curves. For loads of 1000 nm, the lower friction of the polymer with additives gives way to friction properties of the different samples that are identical [102].

Polyurethane copolymers with hydrophobic and hydrophilic side chains were investigated regarding the mechanical properties changing with the hydrogen bonding between soft (SS) and hard segments (HS). The adhesion force showed a maximum at 57% HS correlated with the highest number of nonassociated urethane groups. The friction mechanisms were investigated as well, showing different mechanisms for the different compositions [102]. The surface structure of six different polycarbonate polyurethane copolymers was investigated with SFM in topography and phase modes. The stoichiometry of the reagents and the chemistry of the hard segment were changed, varying the contribution of diisocyanate, poly(hexyl, ethyl) carbonate, and butane diol. The 1,6-hexane diisocyanate showed a stronger phase separation and the highest values of mean square roughness (RMS) with 3.3 to 10.0 nm with regard to methylene bis(p-phenyl isocyanate) and methylene bis(p-cyclohexyl isocyanate) that have RMS values of 0.8 respectively 0.25 nm. These values have to be viewed with respect to the image processing of a third-order flatten. This is only obvious in this article as the image processing is usually not mentioned, and therefore the values of the other investigations must be examined closely as well. The polymers presented relatively stiff rodlike structures with dimensions of 12 nm in width and 170 nm in length [202].

Investigations on polyurethane and rubber were done with force indentation curves [28].

Differences between polystyrene (PS) and poly(methylmethacrylate) (PMMA) could be determined by measuring the adhesion differences of the different polymers by PFM [95]. Polymer blends of poly(styrene)-block-poly(ethene-co-but-1-ene)-block-poly(styrene) with isotactic and atactic polypropylenes were characterized observing the morphology according to different thermal treatments. It was possible to monitor microphase separations with tapping mode in the phase image [203]. Interfaces between PMMA and polystyrene (PS) could be identified with HM-LFM [84] as well as interfaces between poly(acrylonitrile-co-styrene) and polybutadiene respectively between polypropylene and poly(propylene-co-ethylene) [85].

Fractographic investigations looking at the surfaces after a fracture of dental composites consisting of silicon dioxide fillers in a matrix of dimethacrylate resins are presented in [107]. The pristine surfaces and the results of different preparation methods for poly(ethylene glycol) (PEGMA) grafted poly(tetrafluoro ethylene) (PTFE) surfaces were investigated with SFM. The PEGMA treated surfaces exhibited a larger RMS of 144 nm with regard to 129 nm RMS of the pristine PTFE [204]. Hexafluoroethane and tetrafluoroethylene films produced by glow discharge plasma deposition show with SFM a pinhole free and smooth surface

with a RMS roughness of 0.4 to 2 nm. Scanning in contact mode with moderate applied loads yields rippled films. At small scan sizes, and high velocities and load, the film disrupts. The surface modulus was estimated between 1.2 and 5.5 GPa [205]. Poly(vinylidene difluoride) (PVDF) and poly(vinylidene fluoride/hexafluoropropylene) [P(VDF-HFP)] polymers were radiation grafted with polystyrene (PS) yielding an increase in surface roughness upon irradiation and a smoothing of the valleys by further functionalization by chlorosulfonation and sulfonamidation [206].

#### 4.3.2. Response to Proteins

In the field of ultrafiltration of biological fluids such as blood, biofouling respectively membrane fouling is an important issue resulting in pore plugging, pore narrowing, and cake deposition. Hydrophobic polysulfone membrane interactions with hen egg lysozyme were investigated with the surface force apparatus and the topography with SFM [207]. Forces between cellulose acetate films and human serum albumin, HSA, respectively ribonuclease A, RNase, were investigated in the same way [208]. The comparison of forces between the proteins fibronectin, fibrinogen, and albumin and a hydrophilic cellulosic membrane, a hydrophilic glass surface, and a hydrophobic polystyrene surface showed that the forces on hydrophobic surfaces are an order of magnitude larger than the ones on hydrophilic surfaces. Additionally, the influence of surface structure on hydrophilic surfaces was described [209].

Collagen on native and oxidized poly(ethylene terephthalate) (PET) was investigated with the aid of X-ray photoelectron spectroscopy (XPS). Time-dependent differences were observed in stability at times between 5 s and 5 min with an easy-to-disturb surface structure (scan ranges from 2 to 5  $\mu\text{m}$ ) as monitored via SFM. The investigations were done in air, leaving the results ambiguous, as the topographical information can be altered by drying leading to different structures and orientations on the surface [210].

#### 4.3.3. Tissue Response

The tissue response to polymers is investigated in a variety of studies [200, 211–214].

There are different attributes, which complicate the use of polymer vascular implants. Especially for small-diameter vascular grafts the blocking is an important problem. For example, calcification decreases the vascular diameter. So calcification of subdermally implanted polyurethane is enhanced by calciphylaxis as shown by SEM [194]. Another aim is to decrease the thrombogenicity [195] of polymeric biomaterials. These “heparin-like” polymers have a specific affinity for antithrombin III and thus are able to catalyze the inhibition of thrombin. In this study sulfur, sodium, fluorine, and carbon are determined by SEM combined with energy dispersive X-ray analysis. The objective of another project [196] was to define a series of assays for the evaluation of hemocompatibility of cardiovascular devices. In [193] a polyamino-acid urethane copolymer coated vascular prosthesis (1.5 mm diameter) was developed to enhance endothelialization. SEM showed the homogeneous coating of clinically available synthetic PTFE grafts. Prosthetic heart valves made of isotropic pyrolytic carbon (LTIC) are

a successful biomaterial application which is investigated together with other difficult-to-image biomaterials in [17]. Low-voltage, high-resolution scanning electron microscopy shows that LTIC valve leaflets are significantly rougher than previously described, and that LTIC induces extensive platelet spreading *in vitro*, even in the presence of considerable albumin.

Calcification is also crucial in the use of intraocular lenses [201]. To assess this, intraocular lens optic materials were implanted intramuscularly and/or subcutaneously in rabbits for up to 90 days. SEM and energy dispersive X-ray spectroscopy (EDX) were used to detect discrete nodules containing both calcium and phosphate. Calcification only was noted on intramuscularly, subcutaneously, and intraocularly implanted experimental acrylic and intramuscularly implanted hydrogel material. In contrast, the intramuscularly or subcutaneously implanted silicon, PMMA, and acrylic optic materials showed no calcification.

Glassy polymeric carbon was treated by bombardment with energetic ions in different curing states. The roughness that leads to a better thromboresistance was monitored with SFM [18].

An approach to manage chronic osteomyelitis (inflammation of the periosteum) utilizes the implementation of antibiotic-impregnated PMMA beads for local delivery of antibiotics. The study of the getamycin sulphate release from a commercial acrylic bone cement was presented in [197].

A very interesting feature is the biodegradability of some polymers either natural or synthetic. The surface structure of blends with different composition of poly lactic acid (PLA) and poly sebaic acid (PSA) and their degradation properties were investigated. Single component PLA exhibits a smooth surface whereas PSA films possess spherulites at the surface. Blends of 70%, 50%, and 30% PLA exhibited granular respectively pitted surface structures but no fibrous structures visible in SFM. The monitoring of the erosion within 10 minutes showed that PLA is present in granules [16]. Phase imaging with the SFM yields phase shifts at different compositions ranging between 45° and 52°. The presence of PSA microdomains in blend of 50% PSA could be confirmed [215].

Screws, made of poly-L-lactic acid, were inserted axially into the right distal femur in 18 rabbits. The degradation and phagocytosis were assessed histologically and by TEM [198]. In the TEM specimens, polymeric particles of an average area of 2  $\mu\text{m}^2$  were seen to be located intercellularly with phagocytic cells. In 4.5-year specimens, the size of the polymeric particles, measured as area and perimeter, was significantly smaller than that of the 3-year specimens. The findings indicate that the ultimate degradation process of PLA is much longer than it was previously thought. Porous structured polymers to mimic natural extracellular matrix were investigated in [216] and in [217]. A biodegradable blend of starch with ethylene-vinyl alcohol copolymer (SEVA-C) with hydroxyapatite as filler was investigated, monitoring the degradation and the buildup of calcium phosphate crystals over a time span of up to 30 days in simulated body fluid. Only with the filler the buildup of the calcium phosphate layer could be observed. Within 8 hours

the roughness increased, after 24 hours calcium phosphate nuclei covered the surface, and after 126 hours a dense and uniform layer was present [218].

#### 4.4. Composites

Composites of different material systems can combine the advantages of both. Therefore a variety of composite materials have been developed. One distinguishes composites which work as bone cements [172, 219, 220] and those that include living cells and were used for tissue engineering [176, 221].

To quantify the bone-implant interface of high-strength HA/poly(L-lactide) (PLA) composite rods an affinity index was calculated, which was the length of bone directly joined to the rods, expressed as a percentage of the total length of the rod's surface [219]. Calcined and uncalcined HA particles which amount to 30 or 40% by weight of the composite were implanted in the distal femora of 50 rabbits and after 2, 4, 8, and 25 weeks they were examined by SEM, TEM, and light microscopy. In all composites new bone formation could be examined after 2 weeks. SEM showed direct bone contact with the composites without intervening fibrous tissue. The affinity indices of all the composite rods were significantly higher than those of unfilled control PLA rods. The maximum affinity index (41%) was attained at 4 weeks in 40% calcinated HA-containing rods.

Another approach to use composites is to increase the compressive strength of calcium phosphate cement (CPC) [220], which limits their use to non-load-bearing applications, by the means of water-soluble polymers. Composites formulated with the polycations poly(ethylenimine) and poly(allylamine hydrochloride) exhibited compressive strengths up to six times greater than that of pure CPC material. SEM results indicate a denser, more interdigitated microstructure. The increased strength was attributed to the polymer's capacity to bridge between multiple crystallites and to absorb energy through plastic flow. Glass-ceramic, as mentioned previously, is also used in composites with bisphenol-a-glycidyl dimethacrylate (Bis-GMA)-based resin. These were compared with composites containing HA or  $\beta$ -tricalcium phosphate (TCP) as the inorganic filler [172]. After 10 weeks of implantation into tibial metaphyses of rabbits, the ceramic-containing sample was in direct contact with bone and ceramic particles were partially adsorbed at the surface. The HA-containing cement was in contact with partially mineralized extracellular matrix. In 25-week specimens, ceramic particles were completely absorbed and replaced by new bone, and there was no intervening soft tissue. The tissue response of nano-hydroxyapatite/collagen composite was investigated in [176]. At the interface of the implant and marrow tissue, solution-mediated dissolution and giant-cell-mediated resorption led to the degradation of the composite. Interfacial bone formation by osteoblasts was also evident. The composite can be incorporated into bone metabolism instead of being a permanent implant. Nano-HA was also used in a porous collagen composite, to build up a three-dimensional osteogenic cell/nano-HA-collagen construct [221]. SEM and histological examination have demonstrated the development of the cell/material complex. Other biodegradable composites are

based on polyhydroxybutyrate-polyhydroxyvalerate (PHB-PHV) [222]. SEM showed that the intended compositions of composites were achieved and bioceramic particles were well distributed in the polymer.

#### 4.5. Biological Samples

In the dental field enamel and dentin are materials under investigation. Effects of demineralization, for example, by soft drinks on the natural tooth structure, and improvements of resin adhesion important in dental therapy were studied.

Topographical changes of human teeth in various liquids were characterized in [223]. The initially smooth and finely grained surfaces were changed to a rougher and more coarsely grained surface. Dissolution rates for soda pops with pH values between 4 and 5 were calculated to be 3 mm/year in contrast to water with a rate of 0.4 mm/year. The change in mechanical properties of tooth enamel induced by demineralization via soft drinks was investigated in [224]. The changes in hardness are the first step in the dissolution process. The influence of different drinks (orange juice, a black currant drink, and water) could be determined in hardness and topography, where orange juice showed the strongest demineralization. A small critical discussion about the applicability of the model of enamel erosion characterized via SFM topography measurements is given in [225].

The influence of sodium hypochloride on dentin and dentin collagen was characterized by checking on the topography and the hardness respectively the reduced elastic modulus via an SFM in contact mode respectively a nanoindenter [226]. Dentin was removed, leaving a remnant collagen matrix and resulting in a hardness of 75% of its original value. The enhanced roughness could provide a better bonding substrate because of the enhanced surface area. The mechanism of the bonding via the adhesive Gluma consisting of glutardialdehyde and hydroxyethylmethacrylate (HEMA) could be elucidated with SFM imaging of the interaction taking place upon introduction of the adhesive to the tooth hard tissue. It forms a solid layer covering the dentin tubules. The mechanism of the amide-induced polymerization of aqueous HEMA glutardialdehyde mixtures could be confirmed by SFM [227]. Other similar SFM investigations on dentin are published in [107] and a detailed review of characterization of dentin, enamel, and collagen covering as well macroscopical features is given in [120]. The ultrastructure and nanoleakage of dentin bonding by the use of a two-step, polyalkenoic acid-containing, self-priming dentin adhesive in human molars was observed by TEM [228] to also check the effect of a 5% sodium hypochlorite solution (NaOCl) treatment. The NaOCl should remove the collagen fibrils at demineralized dentin and so may facilitate the infiltration of adhesive resins into a dentin substrate. To get a comparison, dentin was also acid-etched by 35%  $H_3PO_4$ ; the leakage manifestations were similar for both treatments. So no additional advantage in using NaOCl with the used adhesives was found.

Some final features of surface investigations by nanoanalytical tools discussed in the remainder of this section show in which broad range of biologically modified surfaces scanning probe techniques can be used. These studies include molecular layers like lipids or proteins and extend to cellular

arrangements. They are only a small selection showing the principal ability of the technique.

The activity of a liposome layer with ganglioside G(M1) was tested with SFM [229]. Supported phospholipid bilayers (SPBs) as model substrates for cell membranes are imaged with SFM in [230]. The height, adhesion, and friction of mixed phospholipid layers is monitored in [231].

Microelastic mapping of living cells was done by SFM [28, 232].

A recent overview of the characterization of bacterial biofilms is given in [163].

Still a lot of experiments were done in ambient conditions and biological materials such as hexagonal packed intermediate (HPI) layers, DNA, tobacco mosaic virus, and collagen deposited on various substrates were imaged with noncontact dynamic force modes with little destruction but not in native states [233].

STM as well is usually used for investigations of biological films in air, leaving a change in structure. Pictures could be taken from C-phycocyanin (C-PC) which was isolated from the blue-green alga *Spirulina platensis* [234], and tobacco mosaic virus [235].

Nonhuman hard tissue like abalone nacre [236] was imaged and mineralization pathways revealed to form single crystals [237], and the elasticity of cow cartilage was tested [28].

The magnetic force from a magnetotactic bacterium [238] could be imaged with the magnetic force mode with SFM. Membrane deformation of living glial cells [239] or fibroblasts [240] were done via SFM. Other measurements are mentioned in [241] where local elastic properties respectively Young's modulus were mapped via force mapping.

The viscous properties of cells have been investigated on kidney epithelial cells with laser tracking microrheology. Comparisons with other authors are given, revealing cytoplasmic viscosities that range for different experiments within five orders of magnitude around  $2 \cdot 10^3$  Pa·s [110]. Also viscous properties of fibroblasts were measured with magnetic bead microrheometry [109].

An overview of renal cell characterization with the SFM is given in [242]. Immobilized antibodies have been characterized by SECM to monitor the active binding sites [243].

Microelastic properties of bone marrow (cow tibia) were measured via SFM in [244].

This demonstrates that nanoanalytical tools not only are useful for characterizing the pure biomaterial surface alone but are also helpful for investigating surfaces in contact with biological materials of all kinds.

## 5. CONCLUSIONS

This chapter illustrates the impact of new imaging techniques such as SPMs on biointerface analysis of biomaterials. SFM and STM investigations provide structural, rheological, and functional information about surfaces. Force distance curves contain complex information about interactions of biofilms with the substrate. Electron microscopy as a "classical" tool complements the techniques, in particular because imaging artifacts are much better known than in SPM.

There are two trends to be seen. First, new methods are being developed, such as scanning near-field optical microscopy, another member of the SPM family. This method will combine all possibilities of optical microscopies, in particular all labelling techniques, but without the diffraction limit of resolution. However, there are still technological hurdles, in particular to produce bright and narrow light sources routinely. As soon as these problems are overcome, this method will play an increasing role in biomaterial research.

The second trend goes to multifunctional analysis on the nanometer scale, which will allow the understanding of the basic mechanisms of interaction between biological and synthetic materials. This will further help to improve biointerfaces used for biomaterials. The challenge is now to develop multifunctional tools that are easily accessible and suitable for the analysis of biomaterials based on SPM techniques, as well as in combinations with methods characterizing macroscopic properties to bridge the gap between these two worlds.

Still, all these new methods are in their infancies in their use on biomaterials. However, in the near future they will become much more common and effective and will influence the field substantially.

## GLOSSARY

**Arene cavity** The cavity formed by the enclosure of the aromatic rings in a calixarene.

**Calix[n]arenes** A group of phenolic macrocyclic molecules resulted from the condensation of *para*-substituted phenol and formaldehyde. ('n' refers to the number of phenolic units.)

**Crystal structure** Three-dimensional arrangement of atoms derived from single crystal X-ray diffraction that provides information about the structure, conformation, and geometry of the molecule.

**Functionalization** Chemical modification on the lower or upper rim leading to the formation of derivatives containing appropriate functional groups.

**Lower rim** The rim containing the phenolic -OH groups in a *para*-substituted calixarene.

**Metalloenzymes** Those enzymes that exhibit their function as a result of the presence of a specific metal ion.

**Receptor** A molecule that possesses the ability to bind to neutral or ionic species through recognition.

**Upper rim** The rim containing the groups present at the *para*-position in a calixarene.

## 1. INTRODUCTION

The self-assembly (SA) of nanoparticles in an organized array has become increasingly important. The current methods used for the design of ultra-thin films include: spin-coating and solution-casting, thermal deposition, polyion layer-by-layer assembly, chemical self-assembly, the Langmuir-Blodgett technique, and free-standing films. The optimal combination of molecular order and stability of films determines the practical usefulness of these technologies [1–6].

The most ordered macromolecular films are free-standing liquid crystalline films, but they are very unstable. The Langmuir-Blodgett method allows to construct lipid multilayers with a thickness from 5 to 500 nm, but only flat substrates can be covered by this film and it has intrinsic defects at the lipid grain borders. Another method that can be

applied to surface modification is a monolayer self-assembly, based on thiol or silane compounds [1]. By this method, one can achieve self-assembly of 2–5 nm thick organic layers on silicon or gold surfaces, but there is no simple means for thicker film construction. Other widely used methods for the industrial manufacture of thin films are spin-coating and thermal deposition of macromolecules onto a substrate. Unfortunately, unlike the methods considered above, these methods do not allow one to control a film composition in the direction perpendicular to the surface.

Finally, there is a newer method for film self-assembly that makes use of the alternate adsorption of oppositely charged components (polymers, nanoparticles, and proteins) [2–9]. The assembly of alternating layers of oppositely charged linear or branched polyions and nanoparticles is simple and provides the means to form 5–500-nm thick films with monolayers of various substances growing in a preset sequence on any substrate at a growth step of about 1 nm. Mallouk [4] has called this technique “molecular beaker epitaxy,” meaning that with simple instruments (exploiting the materials’ self-assembly tendency), one can produce molecularly organized films similar to the ones obtained with sophisticated and expensive molecular beam epitaxy technology.

One can assemble on a standard silicon wafer, multilayers containing different nanoparticles and polymers and then apply lithography to manufacture microdevices with nanostructured elements. Such a combination of nano-assembly with traditional micromanufacturing is the topic of this review.

## 2. POLYCATION/POLYANION LAYER-BY-LAYER ASSEMBLY

### 2.1. General Procedure

A cleaned substrate of any shape and dimension is immersed into a dilute solution of a cationic polyelectrolyte, for a time optimized for the adsorption of a single monolayer

(ca 1 nm thick), and then it is rinsed and dried. The next step is the immersion of the polycation-covered substrate into a dilute dispersion of polyanions or negatively charged nanoparticles (or any other nanosize-charged species) also for a time optimized for the adsorption of a monolayer; then it is rinsed and dried. These operations complete the self-assembly of a polyelectrolyte monolayer and monoparticulate layer sandwich unit onto the substrate (Fig. 1). Subsequent sandwich units are self-assembled analogously. Different nanoparticles, enzymes, and polyions may be assembled in a preplanned order in a single film.

The forces between nanoparticles and binder layers govern the spontaneous layer-by-layer self-assembly of ultra-thin films. These forces are primarily electrostatic and covalent in nature, but they can also involve hydrogen bonding, hydrophobic, and other types of interactions. The properties of the self-assembled multilayers depend on the choice of building blocks used and their rational organization and integration along the axis perpendicular to the substrate.

The sequential adsorption of oppositely charged colloids was reported in a seminal paper in 1966 by Iler [2]. The electrostatic self-assembly was subsequently “rediscovered” in the mid-nineties and extended to the preparation of multilayers of polycations and phosphonate ions, as well as to the layering of linear polyions, proteins, and nanoparticles by Decher, Mallouk, Möhwal, Lvov, Rubner, Fendler, Hammond, Kunitake, Schlenoff, Kotov, and others. This self-assembly is now employed in the fabrication of ultra-thin films from charged polymers (polyions) [3–47], dyes [48–51], nanoparticles (metallic, semiconducting, magnetic, insulating) and clay nanoplates [52–75], proteins [76–96], and other supramolecular species [79]. The greatest advantage of this self-assembly is that any of these species can be absorbed layer-by-layer in any order. The oppositely charged species

are held together by strong ionic bonds and they form long-lasting, uniform, and stable films. Self-assembly is economical and readily amenable to scaling-up for the fabrication of large-area, defect-free devices on any kind and shape of surfaces.

The main idea of this method is the resaturation of polyion adsorption, which results in the alternation of the terminal charge after each layer is deposited. This idea is general and implies that there are no major restrictions in the choice of polyelectrolytes. It is possible to design composite polymeric films in the range of 5 to 1000 nm, with a definite knowledge of their composition. For the successful assembly of nanoparticle or protein multilayers, the alternation with linear polyion layers is important. Flexible linear polyions penetrate between nanoparticles and act as electrostatic glue. The concept of “electrostatic polyion glue,” which keeps together neighboring arrays of nanoparticles, is central to this approach [77, 79]. The self-assembled film contains amorphous polyion interlayers, and this organization “heals” defects that arise because of the introduction of foreign particles during the process of film formation (dust, microbes) [13, 79].

### 2.1.1. Standard Assembly Procedure

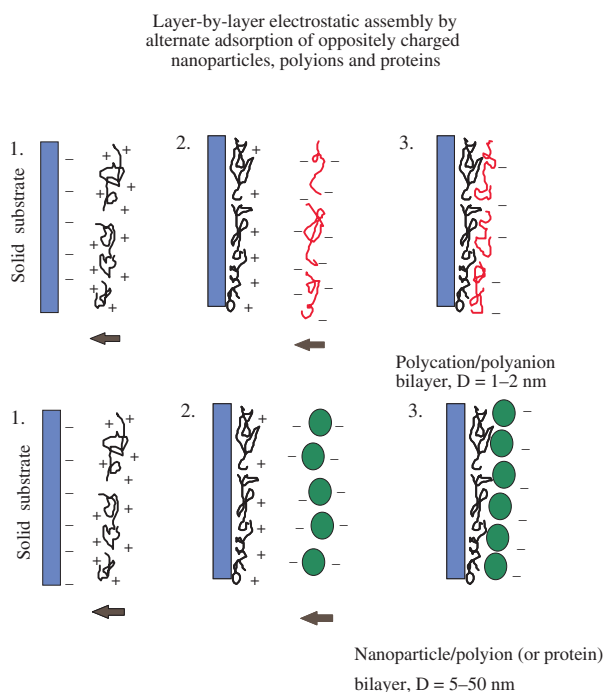

As a standard approach to film preparation, we employ the following steps:

1. Take aqueous solutions of polyion, nanoparticles, or protein at a concentration of 0.1–1 mg/mL and adjust the pH in such a way that the components are oppositely charged.
2. Take a substrate carrying a surface charge (e.g., plates or polymer films covered by a layer of cationic poly(ethylenimine) that may be readily attached to many surfaces).
3. Carry out alternate immersion of the substrate in the component’s solutions for 10 min with 1 min intermediate water rinsing. To rinse a sample, use a solution with pH that keeps the polyions ionized.
4. Dry the sample using a stream of nitrogen (*Note*: drying may hinder the assembly process and it is not necessary for the procedure).

Linear polyions predominately used in the assembly are as follows: polycations—poly(ethylenimine) (PEI), poly(dimethyldiallylammonium chloride) (PDDA), poly(allylamine) (PAH), polylysine, chitosan, polyanions—poly(styrenesulfonate) (PSS), poly(vinylsulfate), poly(acrylic acid), dextran sulfate, sodium alginate, heparin, and DNA. One can grow polymer nanocomposite films by means of the sequential adsorption of different material monolayers that employ hundreds of commercially available polyions. The only requirement is that there be a proper (positive/negative) alternation of the component charges.

## 2.2. Kinetics of Polyion Adsorption

For the time-dependent control of adsorption and monitoring of the assembly *in-situ*, the quartz crystal microbalance method is quite suitable [23, 46, 86]. The kinetics of

**Figure 1.** A scheme of the layer-by-layer assembly.

the adsorption process could be delineated by the QCM-technique, which is indispensable for establishing proper assembly conditions (e.g., a saturation adsorption time).

The multilayer assemblies are characterized by means of a quartz crystal microbalance technique in two ways:

1. After drying a sample in a nitrogen stream, we measured the resonance frequency shift and calculated an adsorbed mass by the Sauerbrey equation; or
2. By monitoring the resonator frequency during the adsorption process onto one side of the resonator, which was in permanent contact with polyion solutions. While performing experiments in permanent contact with the polyion solution, we touched the surface of solutions with one side of the resonator, while the upper electrode was kept open to air and the upper contact wire was insulated from the solution by a silicone paint covering.

The fitting of adsorption to an exponential law yields a first-order rate of adsorption for PSS  $\tau = 2.5 \pm 0.2$  min and for PAH  $\tau = 2.1 \pm 0.2$  min. This means that during the first 5 min ca 87% of the material is adsorbed onto the charged support and  $t = 8$  min ( $t = 3\tau$ ) gives 95% full coverage. Typically, in most publications on polyion assembly, adsorption times of 5 to 20 min are used. One does not need to maintain an adsorption time with great precision: a minute more or less does not influence the layer thickness if we are at the saturation region. For other species, PDDA, PEI, montmorillonite clay, myoglobin, lysozyme, and glucose oxidase, the first-order rate of adsorption onto an oppositely charged surface was found to be 2, 3, 1.8, 3, 4, and 5 min, respectively. Interestingly, 5–20 min is essentially greater than the diffusion-limited time (mass transport limitation), which is necessary for complete surface covering (for the used linear polyion concentrations it is a few seconds). Only for 45-nm silica/PDDA assembly do we have an example when 2 s time corresponds to the diffusion limited time for the SiO<sub>2</sub> monolayer adsorption.

One could suppose that linear polyion adsorption occurs in two stages: quick anchoring to a surface and slow relaxation. To reach a surface-charge reversion during linear polyion adsorption, one needs a concentration greater than  $10^{-5}$  M [23]. The dependence of polyion layer thickness on concentration is not great: thus, in the concentration range of 0.1–5 mg/mL PSS/PAH pair yielded a similar bilayer thickness. A further decrease in polyion concentration (using 0.01 mg/mL) decreases the layer thickness of the adsorbed polyion. An increase in the component concentrations to 20–30 mg/ml may result in the nonlinear (exponential) enlargement of the growth rate with adsorption steps, especially if an intermediate sample rinsing is not long enough [47].

### 2.3. First Layers and Precursor Film

At the very beginning of the alternate assembly process, one often sees nonlinear film growth [13, 23, 41]. At the first 2–3 layers, smaller amounts of polyion are adsorbed as compared with further assembly, when the film mass and thickness increase linearly with the number of adsorption cycles. Tsukruk et al. [41] explained this as an island-type

adsorption of the first polyion layer on a weakly charged solid support. In the following two-three adsorption cycles, these islands spread and cover the entire surface, and further multilayer growth occurs linearly. If a substrate is well charged, then a linear growth with repeatable steps begins earlier.

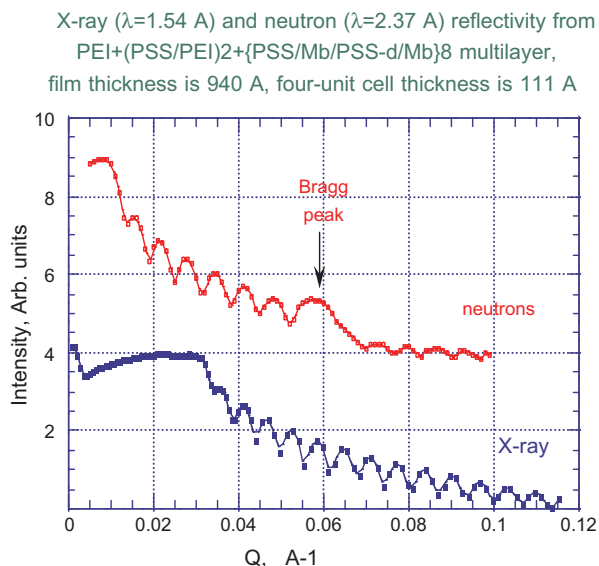

In studying the possibility of using new compound in approach [6, 13, 23]. On a substrate (silver electrode of quartz crystal microbalance (QCM) resonator or quartz slide), we deposited 2–3 layers of polyions, and on this “polyion blanket,” with a well-defined charge of the outermost layer, an assembly of proteins, nanoparticles, or other compounds was produced. In a typical procedure, precursor films were assembled by repeating two or three alternate adsorptions of PEI and PSS. The outermost layer became “negative,” or “positive,” respectively.

Quartz crystal microbalance monitoring of multilayer growth was often the first stage of the assembly procedure elaboration. Initially, we estimated the time needed for a component’s saturated adsorption in a kinetic experiment. Then we performed the assembly typically with 10 min alternate adsorption. After every other adsorption step, a layer was dried by a nitrogen stream and the QCM resonator frequency was registered. The frequency shift with adsorption cycles gave us the adsorbed mass at every assembly step. A linear film mass increase with the number of assembly steps indicated a successful procedure.

The following relationship is obtained between adsorbed mass  $M$  (g) and frequency shift  $\Delta F$  (Hz) by taking into account the characteristics of the 9 MHz quartz resonators used [23]:  $\Delta F = -1.83 \times 10^8 M/A$ , where  $A = 0.16 \pm 0.01$  cm<sup>2</sup> is the surface area of the resonator. One finds that a 1 Hz change in  $\Delta F$  corresponds to 0.9 ng, and the thickness of a film may be calculated from its mass. The adsorbed film thickness at both faces of the electrodes ( $d$ ) is obtainable from the density of the protein/polyion film (ca 1.3 g/cm<sup>3</sup>) and the real film area:  $d$  (nm) =  $-(0.016 \pm 0.02)\Delta F$  (Hz). The scanning electron microscopy data from a number of protein/polyion and linear polycation/polyanion film cross-sections permitted us to confirm the validity of this equation. Another powerful method for polyion film characterization was small-angle X-ray and neutron reflectivity.

### 2.4. Multilayer Structure

X-ray or neutron reflectivity measurements of polyion films show patterns with profound intensity oscillations, as demonstrated in Figure 2. They are so-called Kiessig fringes, due to the interference of radiation beams reflected from interfaces solid support/film and air/film. From the periodicity of these oscillations, one can calculate the film thickness (with the help of the Bragg-like equation and taking into account refraction phenomena that are essential at small angles). Growth steps for a bilayer of 1.1–2.0 nm are typical for alternate linear polyion assembly, and a thickness of one layer often equals to half of this value [6–14]. These values correspond to a polyion cross-section and show that in one cycle of excessive adsorption we have approximately one monolayer coverage of the substrate. The nanoparticle/polyion bilayer thickness is determined by the diameter of the particle. Model fitting of X-ray data gives

**Figure 2.** Small-angle X-ray and neutron reflectivity curves from (PSS/myoglobin/deuterated PSS/myoglobin)<sub>8</sub> multilayer.

a surface roughness of the polyion film on an order of 1 nm. Atomic force microscopy (AFM) and scanning electron microscopy (SEM) data revealed a surface roughness of 1–2 nm [42]. Polyion films are insoluble in water and in many organic solvents and are stable to 280 °C [38, 95].

Neutron reflectivity analysis of the films composed of alternate layers of deuterated PSS and hydrogen containing PAH has proved that polyanion/polycation films possess not only a high uniform thickness but a multilayer structure, too [19–22]. The interfaces between layers in polyion films are not sharp and partial interpenetration (30–40% of their thickness) between neighboring polymeric layers takes place [21–22]. A distinct spatial component separation may be reached between the first and the third or fourth neighboring polyion layers. In the neutron reflectivity experiments with the selectively deuterated component (usually d-PSS), it was possible to observe 1–3 Bragg reflections in addition to Kiessig fringes. This was not possible in the X-ray reflectivity experiments because of a small scattering contrast of neighboring polycations and polyanions, and because of their large interpenetration. X-ray Bragg reflections from the alternate gold nanoparticle/poly(allylamine) multilayers were observed by Schmitt et al. [55]. They demonstrated that in order to have good spatial separation between gold layers in the film, one needs to make a thicker polyion interlayer (of 3–4 PSS/PAH bilayers). In a similar approach, we formed the four-step unit cell multilayers of myoglobin, deuterated, and “usual” poly(styrenesulfonate): (myoglobin/deuterated-PSS/myoglobin/PSS)<sub>8</sub>. A Bragg reflection in the neutron reflectivity curve of this four-step unit cell multilayer was observed (Fig. 2). The film’s total thickness was calculated at 94.0 nm, and the four-unit cell thickness was 11.1 nm.

The polycation/polyanion bilayer thickness depends on the charge density of the polyions. It was shown that more than 10% of polyion side groups have to be ionized for a stable reproducible multilayer assembly via alternate electrostatic adsorption [34]. High ionization of polyions results

in a smaller step of film growth (1–2 nm) and lower ionization gives a larger growth step (3–6 nm). It can be reached either by adding salt to a polyion solution (as previously discussed for strong polyelectrolytes, such as PDDA and PSS), or by varying the pH for weak polyelectrolytes (e.g., polyacrylic acid (PAA) and PAH, as was analyzed by Yoo et al. [30]). Direct zeta-potential measurements confirmed a symmetric positive/negative alternation of the polycation/polyanion multilayer’s outermost charge with adsorption cycles [34].

## 2.5. Stoichiometry of the Components and Polyion Molecular Weight

A multilayer film has to be totally neutral, that is, a stoichiometry of charged groups in neighboring polycation and polyanion layers has to be 1:1. In many cases, we confirmed this (for PSS/PDDA, PSS/PEI, PSS/chitosan, DNA/PAH multilayers), but for PSS/PAH a deviation from 1:1 stoichiometry was found [34]. This is probably due to the incomplete dissociation of the polyions. It is difficult to control polyion dissociation because it depends on a concentration and on the presence of oppositely charged compounds in solution [97]. The complex stoichiometry did not depend on the ionic strength of polyion solutions, which indicates an absence of low molecular weight ions ( $K^+$ ,  $Na^+$ ,  $Cl^-$ ) in the films.

For deposition from water solutions, the PSS/PAH growth step was similar for PSS molecular weights varying from 40,000 to 1,000,000 [21]. The influence of the polymerization degree on the formation of stable interpolyelectrolyte bulk complexes was analyzed by Kabanov [97]. He found that such complexes were stable when a polyion contained more than 20 charged groups in the sequence. We used polyions, such as PSS, PVS, PDDA, PEI with molecular weights of 50,000–200,000. They contain hundreds of ionized groups in the pH range from 3 to 9. A cooperative electrostatic interaction between the polycations and polyanions used is strong and prevents the dissolution of the multilayers even in high ionic strength solvents.

## 2.6. Nonequilibrium Growth and Admixed Polyion Complexes

When the polyion assembly was performed at equilibrium conditions, a saturated adsorption was achieved at every deposition step and a careful intermediate sample washing removed all nonspecific polyion adsorption. Next, one has the permanent increment of the multilayer growth (i.e., the film mass and thickness increased linearly with the cycles of adsorption). In some cases, we encountered the situation when the film growth step exponentially increased with the number of adsorbed layers. We recognized such conditions as nonstable and usually reached a stable growth step by optimizing the solution pH or by decreasing the polyion concentration.

As we previously discussed, one can increase the speed of growth from 1–2 nm to 5–10 nm in 10 min by increasing the ionic strength of the polyion solutions. Another way to increase the assembly speed is by using preformed interpolyelectrolyte complexes (coacervates) [92]. The formation of

water-soluble polyelectrolyte complexes has been intensively studied by means of turbidity measurements [58]. Aqueous mixtures of oppositely charged polyelectrolytes are usually homogenous at the stoichiometry far from the neutralization point. First, such complexes permit an increase in the size of the assembly construction blocks. Second, they make it possible to immobilize with polyion, which were impossible to use in the assembly directly (poor charged nanoparticles, dyes, and proteins).

## 2.7. Polyion Films for Biocompatible Coverage

Multilayer assemblies of natural polyions, such as DNA, polynucleotides, polylysine, and polysaccharides (e.g., heparin, chondroitine, and chitosan) are interesting for biological and medical applications. DNA and polynucleotides (polyuridylic and polyadenylic acids) can be readily assembled in alternation with polycations (PEI, PAH, polylysine). The assembly of polysaccharides with oppositely charged polyions is possible as a means of biocompatible surface preparation. A chitosan and albumin/heparin multilayer assembly for such coatings has been developed [42–44].

## 2.8. Multipolar Dye and Liposome Assembly

The layer-by-layer assembly by alternate adsorption of oppositely charged molecules was applicable for multipolar dyes with symmetric charges possessing conjugated rings and other hydrophobic fragments [48–51]. Hydrophobic fragments probably enhance dye stacking. Interestingly, the dye/polyion bilayer has the same thickness in a wide range of dye concentrations. For Congo Red/PDDA films, the bilayer thickness was 1.5 nm for dye concentrations from 0.01 up to 10 mg/mL, that is, below and above the critical micelle concentration (CMC) of the dye.

The characteristic feature of the assembly of some dye multilayers was greater than the monolayer adsorption at the dye adsorption cycle followed by a depletion of the material during the following linear polyion adsorption step. In this process, we have substantial nonspecific adsorption at the dye adsorption step, and then the removal of nonspecific bond material by complexation with an oppositely charged polyion (at the next assembly step). The graph of the film mass against the number of adsorption steps, such as a growth mode, looks like “a large step up followed by a small step down” [46, 50]. A similar growth mode was observed for protein/polyion and nanoparticle/polyion assemblies, especially with a short intermediate sample washing time [58, 77].

## 3. NANOPARTICLE/POLYION MULTILAYERS

The construction of organic/inorganic nanostructured materials is an important goal of modern materials research. An alternate adsorption procedure was used for the following charged nanoparticles: clay and ceramic plates, nanotubes, 10, 20, 45, 75-nm silica spheres, 50, 150, 300-nm latex, 15-nm gold, 30-nm magnetic  $\text{Fe}_3\text{O}_4$ , 20–30 nm  $\text{CeO}_2$ ,  $\text{MnO}_2$ ,  $\text{ZrO}_2$ ,  $\text{SnO}_2$ ,  $\text{TiO}_2$  particles [23, 52–71], as well as

34-nm diameter spherical plant viruses [12]. Many oxide particles have a zero-charge point at pH 4–5. They are negatively charged at pH 7–8, and can be readily assembled by means of alternate adsorption with such polycations as PEI or PDDA. The number of particle monolayers in such “sandwich” multilayers is exactly known, and any profile across the film can be constructed with a resolution of 5–10 nm. Using a “soft” polymeric interlayer was important for the composite multilayers formation: flexible linear or branched polyions optimize electrostatic attraction. An organic component can change electrical properties of nanostructured material. Therefore, after the assembly is completed, organic interlayers can be removed by a 2-hour thermal treatment above 320 °C in air (calcination process), which results in direct contacts between the nanoparticles needed for improved electric or magnetic properties. Nanoparticles, such as gold, silver, and fullerenes may be “sandwiched” in multilayers with proteins providing electrically or optically induced electron donor-acceptor properties. Semiconductor nanoparticles, such as PbS, CdS, and CdSe, were used in this assembly [54, 67–69]. An assembly of core-shell nanoparticles, such as  $\text{Ag/TiO}_2$  or  $\text{Fe}_3\text{O}_4/\text{Au}$ , was also possible [71, 73].

## 3.1. Silica Multilayers

As an example of the nanoparticle architecture, let us analyze a 45-nm silica assembly by alternate adsorption with PDDA [58–59]. *In-situ* QCM monitoring of alternate PDDA and  $\text{SiO}_2$  adsorption gave the kinetics of the assembly process. In the first step, PDDA was adsorbed onto a Ag-electrode. The QCM frequency decreased during the first 60 s, after which a slower change was observed as adsorption saturation set in. Then the resonator was immersed in pure water for washing. Next, the film was immersed in  $\text{SiO}_2$  dispersion and silica adsorption saturation occurred within several seconds. After subsequent water rinsing, the film was immersed again in a PDDA solution, and so on. Each growth step was reproducible, and the adsorption process reached 90% saturation in 10 s for  $\text{SiO}_2$  and 30 s for PDDA. The film assembly was not possible simply by the multiple immersion of the substrate in the silica solution. An alternation with an oppositely charged polyion was necessary. At every assembly step, the component monolayers were formed, as was recorded by QCM, SEM (Fig. 3).

The average density of  $\text{SiO}_2$ /PDDA multilayers is  $\langle\rho\rangle = 1.43 \pm 0.05 \text{ g/cm}^3$ .  $\text{SiO}_2$ /PDDA film volume composition is: 60%  $\text{SiO}_2$  + 10% polycation + 30% air-filled pores. These pores are formed by closely packed 45-nm  $\text{SiO}_2$  and have a typical dimension of 20 nm. The films have controlled pores, which can be varied by the selection of the nanoparticle diameter. We estimated the diffusion limitation for surface coverage  $A(t)$  by adsorption from solution of particles with the diffusion coefficient  $D$  from  $A(t) = 2/\pi C\sqrt{Dt}$ . For  $t = 2 \text{ s}$ ,  $C = 10 \text{ mg/cm}^3$ , and assuming for 45-nm silica  $D = 1.1 \times 10^{-7} \text{ cm}^2/\text{s}$ ,  $A \approx 3 \times 10^{-6} \text{ g/cm}^2$  and the layer thickness:  $L = A(t)/\langle\rho\rangle \approx 21 \text{ nm}$ . This is reasonably close to the experimental silica monolayer thickness of 24.6 nm. Thus, 2 s corresponds roughly to the diffusion-limited time for the  $\text{SiO}_2$  monolayer adsorption; this time is the fastest nanoparticle monolayer formation rate that we have achieved.

**Figure 3.** SEM image of multilayer containing 18 monolayers of 45-nm-diameter silica alternated with polycation PDDA.

### 3.2. Latex Assembly

Charged latex is a good building block for an electrostatic layer-by-layer assembly. Positively or negatively charged monodisperse lattices with diameters of 30, 40, 45, 50, or 75-nm and with different colors are commercially available, for example, from Seradyn Inc. or IDC-Ultraclean Uniform Latex Inc. For the first time, a multilayer assembly of negative latex spheres (carboxyl-modified or sulfate polystyrene) in alternation with positive latex (amidine-modified polystyrene) was reported by Bliznyuk and Tsukruk [57]. They have described a strong tethering of charged nanoparticles to the surface, which prevents surface diffusion and the rearrangement required for formation of perfect lateral ordering. This situation is different from the one with the formation of the ordered 3D-mesocrystals by slow crystallization of the monodispersed aqueous colloids [72]. In the nanoparticle/polyion multilayers, one loses the crystal-like ordering, but gains control of the process, preparing multilayers of close-packed nanoparticles with a precisely known number of monolayers. We demonstrated a regular layer-by-layer assembly of carboxylated 45-nm diameter Seradyn latex in alternation with PEI.

### 3.3. Compact Nanoparticle/ Poly(ethyleneimine) Multilayers

Figure 4 shows the assembly QCM monitoring and scanning electron micrographs of film cross-sections and a partial top view of a film with architecture PDDA/PSS/PDDA + (MnO<sub>2</sub>/PDDA)<sub>9</sub> and 190 nm thick SnO<sub>2</sub>/PDDA multilayer.

MnO<sub>2</sub>-film has a remarkably smooth surface and uniform thickness. The total frequency shift by QCM was 11,000 Hz and film thickness from SEM was 170 nm. Dividing the film

**Figure 4.** (a–b) SEM cross-sectional images of (MnO<sub>2</sub>/PDDA)<sub>9</sub> and, on right, (12-nm diameter SnO<sub>2</sub>/PDDA)<sub>18</sub> films. The films formed on a silver electrode.

thickness by the number of manganese oxide/PDDA bilayers, we obtain values slightly less than the 23-nm bilayer thickness found above from QCM because the first two layers of manganese oxide are thinner. We cannot detect separate layers in the film by SEM, but individual structures of about 20 nm dimensions are clearly visible and may be attached to nanoparticles.

We analyzed the chemical composition and the chemical state of Mn and N atoms on the surface of a film with architecture PDDA/PSS/PDDA + (MnO<sub>2</sub>/PDDA)<sub>9</sub> by XPS. Spectra revealed a surface rich in carbon and oxygen with manganese and nitrogen present in concentrations less than 7% and trace amounts of chlorine. The Mn (2p) region consists of a spin-orbit doublet with a Mn (2p<sub>1/2</sub>) binding energy of 653.30 eV and Mn (2p<sub>3/2</sub>) binding energy of 641.63 eV. This doublet can be assigned to a mixed valent manganese system, most likely Mn (4+) and Mn (3+) since the average oxidation state of Mn in the nanoparticles is 3.7. The N 1s region showed two peaks at 402.04 eV and 399.12 eV, indicating two different chemical environments for the nitrogen atoms. The difference in the chemical environment may reflect the formation of contact ion pairs and long-distance charge pairs between the MnO<sub>2</sub> particles and the polycation PDDA.

### 3.4. Open-Structured TiO<sub>2</sub>-Nanoparticle/ Poly(styrenesulfonate) Films

The assembly of 35-nm diameter TiO<sub>2</sub> (Degussa P25) was possible at pH 3.8 (when the particles were positive) in alternation with PSS. TiO<sub>2</sub> assembly with polycation PDDA at this pH was not possible. The saturation adsorption time for TiO<sub>2</sub> nanoparticles was 5 min. The growth step of the TiO<sub>2</sub>/PDDA multilayer was stable and linear, with the mass adsorption increment corresponding to the monolayer surface coverage. The SEM of the TiO<sub>2</sub>/PSS multilayer shows not a close-packed but an open structure of the film. It was possible to vary the porosity of the film by changing the ionic strength of nanoparticle dispersions. Such porous structures can be useful for catalytic applications.

### 3.5. Organized Gold/Polycation Multilayers

In [55–56], the self-assembly of 15-nm-diameter gold particles in alternation with polycation PAH was demonstrated. Gold alternation with the polycation was possible because

of negative nanoparticle charge (surface potential  $-35$  mV) due to the synthesis procedure. The saturation time needed for the formation of close-packed gold nanoparticle monolayer (full coverage) was 2 h because of the low particle concentration in solution [55]. An approach to a spatial separation of nanoparticle layers in such sandwich-like films was elaborated: three- to five polycation/polyanion interlayers were assembled between gold layers (e.g., Au/{PAH + (PSS/PAH)<sub>3-5</sub>}/Au). The gold surface (with a roughness of the order of the radius of nanoparticles) was covered and smoothed by the 6–10 nm polyion layer. Further “sandwiching” of gold nanoparticles with the thick polyion interlayers resulted in the ordered gold/polymer heterostructure. The low-angle, X-ray reflectivity of these samples gave 2–3 orders of Bragg reflections with the spacing corresponding to such a complex unit cell. We think that this is a general approach to creating ordered inorganic/organic heterostructure multilayers, and we have used it also for the formation of protein/polyion heterostructures [77, 79].

### 3.6. Layered Ceramics

Mica-type layered silicates can bear a natural negative charge because of the isomorphous substitution of silicon in octahedral sheets by aluminum or magnesium. The charge is generally balanced by potassium cations that reside in the galleries between layers. The intercalation of organic polymers between sheets of layered ceramics provides access to novel polymer-ceramic nanocomposites. These nanocomposites exhibit unique physical and mechanical properties attributable to the synergism of the individual components. The build-up of the multilayers in a stepwise manner rather than in the bulk “all-at-once” manner is of special interest. Kleinfeld and Ferguson [52] were first to apply the electrostatic layer-by-layer adsorption to produce multilayers of anionic synthetic silicate—hectorite and cationic PDDA. We used the polyion assembly to build up multilayers with alternating 1-nm-thick montmorillonite sheets and cationic PEI or PDDA [64–65]. The film thickness increase for the montmorillonite adsorption cycle was 1.1 nm and for PEI 2 nm. After 20 cycles, the resultant film had a permanent thickness of 63 nm.

### 3.7. Multilayer Reactors for Metallic and Semiconducting Particles. Microporous Films

This process was recently introduced by Joly et al. [75]. First, polyelectrolyte multilayers with controlled content of free nonionized carboxylic acid groups were fabricated with weak polyions (e.g., poly(acrylic acid) via suitable pH-adjustments of the processing solutions). These groups were then used to bind various inorganic ions that were subsequently converted into 2-nm diameter particles (e.g., Ag, Pb, or PbS). The spatial control over the growth of the nanoparticles was achieved by the use of multilayer heterostructures which also contain bilayer blocks that are not able to bind inorganic ions. These nonbonding bilayers were fabricated from strong polyions, such as poly(styrenesulfonate). A density

modulation with a few nanometer-resolution across the polymeric films is possible by selective synthesis of heavy atom nanoparticles.

A simple process to convert multilayers of weak polyelectrolytes (e.g., poly(acrylic acid) and poly(allylamine)) into uniform microporous films has been developed by Mendelsohn et al. [76]. These multilayers were immersed briefly into acidic solution (pH 2.4) to effect an irreversible transformation of the film morphology. The resulting microporous structure thickness is 2–3 times less than the thickness of the original films, and possesses reduced relative density of 1/2 to 1/3. The interconnected pores ranging in size from 100 to 500 nm. A refractive index of the porous PAA/PAH film was  $n = 1.18 \pm 0.01$ . It is much less than the origin  $n = 1.54$  for the untreated polyion multilayer. Correspondingly, a dielectric constant of the porous PAA/PAH film dropped to  $\epsilon' = 2$  from the initial  $\epsilon' = 5-7$ .

### 3.8. Protein Multilayers

In many cases, one can consider proteins as hard monodisperse nanoparticles with dimensions of 2–10 nm. Taking protein solution at pH well apart from its isoelectric point, one can provide 10–60 elemental charges for a protein globule due to ionization of its carboxyl or amine groups [77]. Multilayer films that contain ordered layers of protein species were assembled by means of alternate electrostatic adsorption mostly with positively charged PEI, PAH, PDDA, and chitosan or with negatively charged PSS, DNA, and heparin [77–96]. The pH of the protein solutions was set apart from the isoelectric point so that proteins were sufficiently charged under the experimental conditions. The assembly of 20 different proteins was successfully achieved (including cytochrome, carbonic anhydrase, myoglobin, hemoglobin, bacteriorhodopsin, pepsin, peroxidase, alcohol dehydrogenase, glucoamylase, glucose oxidase, immunoglobulin, catalase, and urease) (Fig. 5) [79]. The mass increment at each

**Figure 5.** SEM image of cross-section of glucose oxidase/PEI multilayer (24 bilayers, thickness 270 nm) on quartz support.

step was quite reproducible. Proteins immobilized in multilayers with strong polyions such as PSS, PEI, and PDDA were insoluble in buffer for a pH range between 3 and 10. The assembled proteins are in most cases not denatured [77–78, 82, 87–88]. Moreover, the layer-by-layer immobilization with linear or branched polyions enhanced the enzymatic stability [95].

The enzymatic activity in multilayers increased linearly with the number of layers up to 10–15 protein layers, at which point the film bioactivity became saturated. This saturation was probably due to substrate diffusion limitations into the film, that is, accessibility to the protein requires a substrate transport through the multilayer [95]. For the antigen-antibody reaction in immunoglobulin (IgG)/PSS multilayers, the activity increased up to five immunoglobulin layers. Compactness or openness of protein multilayers may be regulated. Thus, glucose oxidase, myoglobin, and albumin multilayer films were compact, but immunoglobulin/PSS multilayers had an open structure with areas as large as 100-nm in diameter unfilled in the upper layers of the film [87].

Drying of polyion films exerts unclear influences on the structure. We do not need drying for the assembly process; samples were dried for control of the assembly. From the other hand, the importance of film drying (as a separate process) is still not fully understood. The assembly with a regular film, drying at every other adsorption step, gave polar multilayers with nonlinear optical properties [99]. A similarly prepared Photosynthetic Reaction Center/PDDA multilayer demonstrated second harmonic light generation [89]. Regular immunoglobulin/PSS assembly with the film drying at every adsorption cycle was possible at a pH close to the IgG isoelectric point, which again indicates an importance of hydrophobic interactions [87].

### 3.9. Different Proteins in Alternation with Polyions

An elaboration of the assembly technique for a variety of proteins makes it possible to construct multicomponent protein films (superlattices) [77, 79, 83]. We have described the formation of two types of superlattices:

1. The alternation of similarly charged proteins at identical pH conditions; both positively charged myoglobin and lysozyme in alternation with polyanion {myoglobin<sup>+</sup>/PSS/lysozyme<sup>+</sup>/PSS}; negatively charged glucose oxidase (GOx) and glucoamylase (GA) with polycation {glucose oxidase<sup>-</sup>/PDDA/glucoamylase<sup>-</sup>/PDDA}.
2. The combination of negative and positive proteins in the two-block film with the insertion of an additional polyion layer to change the assembly mode: {(lysozyme/PSS)<sub>3</sub> + PEI + (glucose oxidase/PEI)<sub>6</sub>}. The protein multicomponent films are extremely interesting as novel biologically active materials. One can arrange given protein layers according to a specific biological activity. Sequential enzymatic reactions and vectorial transfer of electrons and energy become feasible targets by the preparation of anisotropic protein layers with the precise control of the distances of active layers.

## 4. SPIN-COATING FOR LAYER-BY-LAYER ASSEMBLY

Spin coating, a technique used for casting chemical layers onto a rotating substrate, has been used extensively to prepare thin films for diverse industrial applications such as photolithography [100], light emission [101, 102], nuclear track detection [103], and gas sensing [104, 105]. Since the 1950s, monolayer film formation dynamics by spin-coating has been studied both experimentally and theoretically. Recently, ultra-thin multiplayer films have attracted much interest because of their wide applications as sensors, integrated optics, friction-reducing coatings, biological surfaces, light emitting devices (LEDs), or surface-orientation layers [106–110]. Most of these applications require preparation of stable and well-organized films with fast fabrication. The simplicity, time-efficiency, and cost-effectiveness of spin-coating have made it a practical method for the deposition of polymer thin films. Spin-assembly is a specialized application of spin-coating, in which a polyelectrolyte multilayered thin film is self-assembled onto a spinning substrate. The spin self-assembly method as an alternative for making well-organized multiplayer films in a very short process time has been described [111–113].

### 4.1. The Concentration and Spinning Rate Effect

Deposition of organic material by spin-coating has been done for almost a century [114]. Solution flow dynamics [115–117], film surface topography [118–120], and evaporate effects [121–123] has been explored both theoretically and experimentally. The two main parameters that control the amount of polyelectrolyte adsorbed onto the substrate are solute concentration and spin rate. These have been shown to directly influence the thickness of monolayer films [125, 126]. Dubas and Schlenoff have fabricated multiplayer polyelectrolyte films by immersing spinning substrate into polyelectrolyte solution. Peter and Malkiat investigated those variables in multiplayer polyelectrolyte films that are spin-assembled by dropping a solution onto a spinning substrate [113]. The materials used include the polyanion PAZO and polycation PEI. The thickness of a film of a single polyelectrolyte can be easily controlled by varying the concentration of polyelectrolyte and spin rates. Higher concentrations of PEI most likely lead to a greater amount of adsorbed PEI, and therefore lead to greater amounts of PAZO deposited on the film.

At faster spin rates, the films experience increased mechanical forces, which lead to shorter contact time between the polyelectrolyte [115]. The forces acting on a spinning film have been studied in detail [127, 128]. The effects of spin rate on both monolayer thickness [124, 125] and multiplayer thickness [113] have been studied.

### 4.2. Comparison of Spin SA Method and Dip SA Method

#### 4.2.1. The Adsorbed Amount Mechanism

The adsorbed amount between the dipping and the spinning methods is significantly different [113]. This is caused by different adsorption mechanisms. Fast elimination of water

in the spinning process significantly increased the molar concentration of the polyelectrolyte solution during the short deposition time [129] and this increases in the polyelectrolyte concentration yields of thick layers, despite the thin film formation typically provided by the centrifugal force and air shear force [130–132]. It also increases the electrostatic attraction between oppositely charged polymers because the presence of water molecules in the assemblies generally screens the electrostatic attraction. When water molecules are adsorbed onto the substrate, the preadsorbed water molecules may block polyelectrolyte adsorption onto the surface, and thus the surface coverage with polyelectrolyte chains may be incomplete. However, if polymer adsorption and water drainage are almost simultaneously realized in a short time, as in the case of the spin SA process, there would be more room for polyelectrolyte to adsorb onto the substrate.

#### 4.2.2. The Structure

The spin SA method has been found to have a significant effect on the surface roughness of prepared multiplayer films, presumably because of the air shear force caused by the spinning process [110]. It was proved that the internal structure of the spin SA films is highly ordered and the film prepared with the spin process contains rather distinct interfaces between respective layers in contrast to the film obtained by the dipping method. The distinct difference in the dip and spin SA multiplayer structure indicates that the spin SA method can easily provide the well-ordered internal structure, which cannot be achieved with the dip SA even containing a high ionic strength of the polyelectrolyte solution or multiple organic layers between inorganic particle layers [112].

#### 4.2.3. Single-Species Deposition

Another important advantage of spin assembly is that the film formation process is not solely dependent on electrostatics to induce deposition. The linear growth of a PAZO layer over 10 deposition cycles on top of a single positively charged PEI underlayer has been reported [113]. A thick PEI layer on a bare, negatively charged substrate using 10 deposition cycles of 10 Mm PEI was also built [111]. Whereas film formation in the case of ionic self-assembly is governed by electrostatics and entropy; the underlying mechanism for film formation in spin-assembly involves the mechanically induced entanglement between polyelectrolyte chains of different layers. Electrostatics, therefore, takes a supplementary role in spin-assembly, enhancing the deposition process when alternating charges are used. Single-species multiple deposition do not show linear growth when carried out using conventional dipping techniques [111].

In summary, a new ultra-thin film-forming process, spin-assembly, is an excellent method for controlling the amount and thickness of adsorbed polyelectrolyte in fabricating multiplayer thin film with highly ordered internal structure far superior to the structure obtained with the dip SA process. It also allows us to build multiplayer polyelectrolyte multilayered films without the absolute requirement of alternating charges.

## 5. SOFT LITHOGRAPHY TO PATTERN 2D PATTERNS ON POLYION MULTILAYERS

Soft lithography is an alternative, nonphotolithographic set of microfabrication methods [134–136]. All of its members share the common feature of using a patterned elastomer as the stamp, mold, or mask (rather than a rigid photomask) to generate micropatterns and microstructures. Such techniques include: microcontact printing ( $\mu$ CP) [137], replica molding (REM) [138], microtransfer molding ( $\mu$ TM) [139], micromolding in capillaries (MIMIC) [140], solvent-assisted micromolding (SAMIM) [141], phase-shift photolithography [142], cast molding [143, 144], embossing [145, 146], and injection molding [147–149]. These techniques have been explored and developed by The Whitesides Group and several other groups.

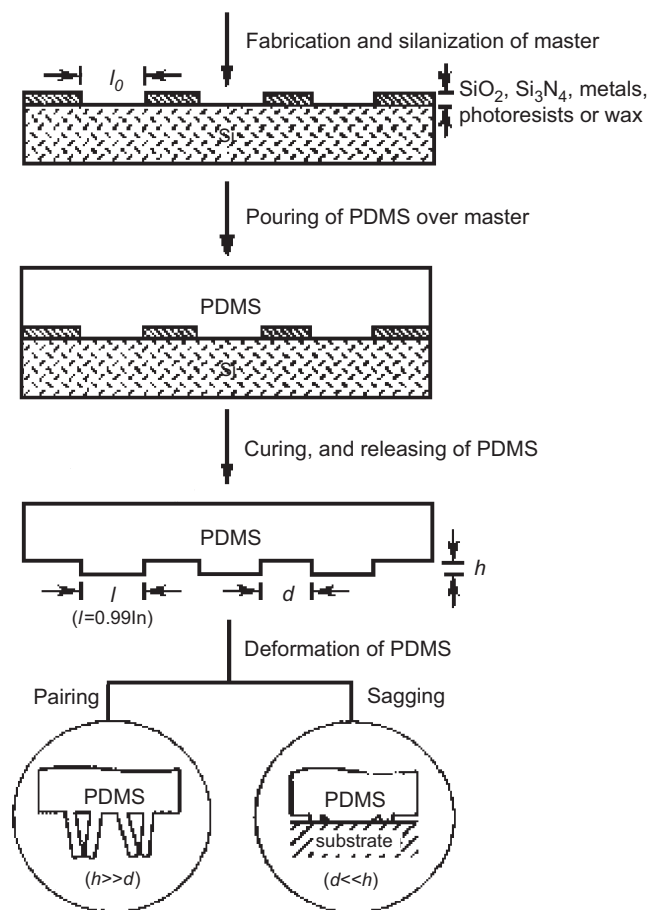

The key element of soft lithography is an elastomeric block with a patterned relief structure on its surface and poly(dimethylsiloxane) (PDMS) elastomers (or silicone rubbers) are used in most demonstrations. Poly(dimethylsiloxanes) have a unique combination of properties resulting from the presence of an inorganic siloxane backbone and organic methyl groups attached to silicon [150]. These liquid materials can be poured over a master having a relief structure on its surface, then easily converted into solid elastomer by curing and peeling off. Poly(dimethylsiloxane) has been widely used because they can make conformal contact with surfaces over relatively large areas and they can be released easily from rigid masters or from complex structures. The formulation, fabrication, and applications of PDMS elastomers have been extensively studied and are well-documented in the literature [150]. The master is, in turn, fabricated using microlithography techniques such as photolithography, micromachining, e-beam writing, or from available relief structures such as diffraction gratings [151], and relief structures etched in metals or Si [151, 152], or even by directly printing. Figure 6 illustrates the procedure for fabricating PDMS stamps.

Microcontact printing ( $\mu$ CP) is a flexible, nonphotolithographic method that routinely forms patterned SAMs containing regions terminated by different chemical functionalities with submicron lateral dimensions [153–158]. An elastomeric PDMS stamp is used to transfer molecules of the “ink” to the surface of the substrate by contact. After printing, a different SAM can be formed on the relief pattern on the surface of a PDMS stamp to form patterns. However, it differs from other printing methods [159] in the use of self-assembly (especially, the use of SAMS) to form micropatterns and microstructures of various materials.

Self-assembly is the spontaneous aggregation and organization of subunits (molecule or meso-scale objects) into a stable, well-defined structure via noncovalent interactions. The information that guides the assembly is coded in the properties (e.g., topologies, shapes, and surface functionalities) of the subunits; the individual subunits will reach the final structure simply by equilibrating to the lowest energy form.

Self-assembled monolayers are one of the most intensively studied examples of nonbiological self-assembling systems [161]. Self-assembled monolayers can be easily prepared by

**Figure 6.** The procedures for fabricating PDMS stamps. Reprinted with permission from [160], Y. Xia, *Ann. Rev. Mater. Sci.* 28, 153 (1998). © 1998, Annual Reviews.

immersion of a substrate in the solution containing a ligand reactive toward the surface, or by exposure of the substrate to the vapor of a reactive species. The self-assembled multilayer can be formed by electrostatic layer-by-layer assembly process via the alternate adsorption of oppositely charged polyelectrolytes, as first demonstrated by Decher and Hong [162–165].

An important difference between traditional SAMs and the multilayer surfaces is that polyelectrolyte multilayers can be tuned during the layer-by-layer assembly process to vary surface charge density, density of functional groups at the surface, film thickness, and wetting properties [166–169].

The Hammond group at MIT has been investigating the use of this  $\mu$ CP technique on the self-assembly monolayer or multilayer for the formation of various patterns.

Their early studies were still on the Au substrate. The substrate was patterned by the chemically modified PDMS stamp. A polyelectrolyte multilayer film has been deposited on the chemically patterned surface via alternate adsorption of a polyanion and polycation. The polyelectrolyte used here include poly(diallyldimethylammonium chloride) (PDAC), a strong polycation and sulfonated polystyrene (SPS), a strong polyanion. Weak polyelectrolyte multilayers were formed from linear poly(ethylene imine) (LPEI), a weak polycation, and PAA, a weak polyanion. Five-and-one-half

polyelectrolyte pairs were deposited for each multilayer, such that each stack is terminated by the polycationic species. A net positive surface charge is thus presented to the microspheres. Solution pH and ionic strength were adjusted to achieve optimal selective deposition of the polyelectrolyte films. For the LPEI/PAA system, the optimum selectivity of polyelectrolyte adsorption onto the patterned SAM surface occurs at pH = 4.8 for the weak polyelectrolytes. For the PDAC/PSS system, the addition of NaCl electrolyte causes partial screening of charges for the strong polyelectrolyte, resulting in thick, loopy films and optimal selective adsorption onto the COOH regions.

The polyelectrolyte is subsequently immersed in an aqueous colloidal suspension of bare  $SiO_2$  microspheres or functionalized polystyrene latex particles. The colloids self-organized at the surface, are driven by the spatially varied electrostatic and secondary interactions between the colloid and the substrate. The polyelectrolyte multilayer platform provides a strong bond to the colloids and introduces the functionality into the underlying layers [170].

Three mechanisms have been demonstrated to control the adsorption—pH of the colloid suspension, ionic strength of the suspension, and concentration of added surfactant. By adjusting the pH of the colloidal slurry, it is possible to alter the strength of the electrostatic attraction between the colloid and the surface in weak polyelectrolyte systems. Adjusting the pH alters the equilibrium balance of the ionization reaction which occurs on the polyelectrolyte backbone. For the PDAC/SPS strong polyelectrolyte system, adjustment of electrolyte concentration in the colloid slurry results in varying strengths of the adsorption. When there is no electrolyte used, a strong electrostatic attraction exists between the polyelectrolyte surface and the  $SiO_2$  spheres, and results in the adsorption selectivity. When a small amount of NaCl is added, the counterions form a double layer that screen surface charges from the colloids. The double-layer screening also reduces interparticle repulsion, so that the spheres are more likely to form multiple layers. As the electrostatic repulsion between spheres decreases, the relatively neutral surface also becomes a more likely site for the deposition of particles on the basis of the secondary interaction. The net result is decreased selectivity. Further increasing the salt concentration will provide additional surface charge screening and then result in further reduced selectivity. However, the suspension aggregation limit will be approached upon increasing electrolyte. So manipulation of the pH appears to be a more effective way of controlling the selectivity and density of adsorption. The degree of ionization of the surface can be altered almost independently of  $SiO_2$  surface charge, and the stability of the colloidal suspension is maintained.

On the basis of  $\mu$ CP and LBL assembly techniques, a polymer on polymer stamping (POPS) process was developed to create the chemical pattern by direct stamping of functional polymers onto a surface containing complementary functional groups, which is illustrated in Figure 7. A polymer is transferred directly to the top surface of a polyelectrolyte multilayer thin film, based on covalent and/or noncovalent interactions. For example, a polyanion can be stamped directly onto a charged polycation top multilayer surface to create alternating regions of plus and minus

**Figure 7.** Schematic illustrating the transfer of a functional polymer to a surface with complementary functional using polymer-on-polymer stamping. Reprinted with permission from [172], X. Jiang et al., *Langmuir* 18, 2607 (2002). © 2002, American Chemical Society.

charge. On the other hand, blocks and graft copolymers can present both a reactive functional group for attachment to the surface and a second functional group to modify the surface. In either case, the goal is to create a stable functional surface, which is either charged or contains reactive functional groups. This approach can be applied to various functional polymer and substrate systems as well as different thin film deposition technique. The concept of polymer on polymer stamping was first illustrated by stamping a functional graft polymer onto a polyelectrolyte multilayer film [171], which utilized the polymers with anhydride groups that can react with the polymer surface.

Copolymers contain two different types of functional groups—one functional group that can attach itself to the polymer surface and a second functionality acting as the desired surface modifier onto polyelectrolyte multilayer surfaces. Such multifunctional molecules include a block and random copolymer, a graft copolymer, and some surfactants. The patterning of polyelectrolyte multilayer surfaces can be a stepping point to the creation of composite, multilevel structures [171].

To create templates for layer-by-layer adsorption, it is necessary to form surface regions that resist polyion adsorption. A random graft copolymer of oligoethylene oxide allylether and maleic anhydride (EO-MAL) was used as a multifunctional polymer. It is demonstrated that EO-MAL can be used to direct selective adsorption on various substrates, including plastic surfaces, and to create three-dimensional complex microstructures of multilayered polymer films. pH adjustment was used to control the effectiveness of EO-MAL templates.

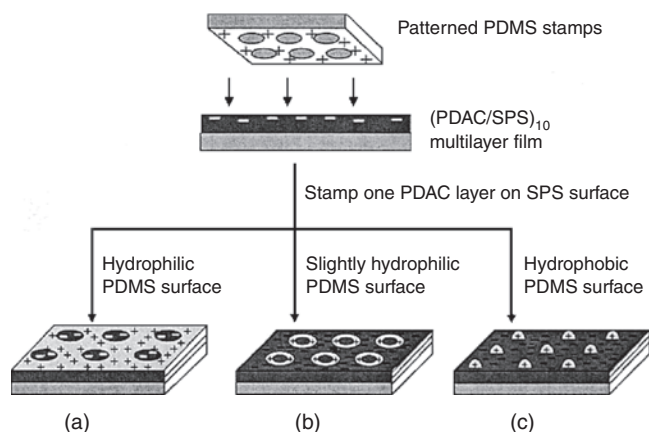

Recently, this technique was further broadened to transfer surface chemistry to different regions of a substrate using a block copolymer and a common polyelectrolyte. A broad range of substrates, including the polymeric surfaces, has been explored and the complex multiple level heterostructures via stamping atop continuous or patterned polymer thin film was created. The use of functionalized polymer, polyions, and low molar mass substituents, which can be stamped directly onto other surfaces, particularly plastic

substrates and multilayer films, has been investigated [172–176]. And the ability to create multilevel microstructures with layer-by-layer self-assembly broadens the area by allowing the construction of devices such as transistors, diodes, sensors, and other optical and electrical components. The patterning of the top surfaces of the multilayer films also brings new opportunities to incorporate other materials onto multilayer films; the use of such patterns to direct material deposition can lead to the patterning of metal electrodes, the placement of colloidal particles, or the directed deposition of other polymer films atop layer-by-layer functional thin film. The Hammond's group created patterns on a polyelectrolyte surface. By this way, any surface that can be covered with at least one surface layer of polyion is able to be modified.

Many new functional surfaces can be achieved through the use of a block copolymer or a graft copolymer, because a number of existing polymers may be used for this technique. Examination of the effectiveness and stability of polymer-on-polymer requires an understanding of the interaction between the polymer to be transferred and the underlying surface. Conditions must be achieved that allow for effective contact of the desired functional group with the chemical functional group on the surface, and both the polymer “ink” and the surface functional groups must be in a form that encourages covalent, ionic, or hydrogen bonding. The influence of factors such as temperature and pH, as well as the stability of polymer-on-polymer-stamping on model and multilayer surfaces, were investigated by this group [172]. Another important aspect of this technique is the optimization of the underlying polymer surface to achieve a high density of desired functional groups. In Hammond's group, direct stamping of polystyrene-poly (acrylic acid) block copolymer (PSS-PAA) has been utilized to create the alternating hydrophobic/hydrophilic regions and polyelectrolytes to generate positively and negatively charged regions.

By stamping onto the top polyamine surface. When a patterned polyelectrolyte film is used as the base layer or substrate, a second pattern can be stamped atop the original pattern array. Subsequent selective adsorption of a polymer yields a second level of microstructures. In addition, a chemical pattern can be achieved by the direct stamping of functional polymers onto a surface containing complementary functional groups. The resulting pattern is then used as a template for the further deposition of the materials on the surface.

Two kinds of new patterns were generated using polyelectrolyte as inks and surface-treated PDMS stamps to create a patterned “plus/minus (+/–)” polyelectrolyte surface. Before using hydrophilic materials, such as charged polymers or proteins as ink, PDMS stamps are often treated with oxygen or air plasma [172, 175–178]. Air plasma is used to make the PDMS surface hydrophilic through the introduction of charged groups, making it wettable with aqueous solutions of charged polymers. It has been indicated that when the PDMS stamp is treated with air plasma for 20 s or more, the PDMS surface becomes completely wettable by aqueous solutions (a 0–5° contact angle with water) [172]. To transfer a negative image of the original PDMS stamp's pattern

**Figure 8.** Schematic illustration of the procedure for creation of three kinds of transferred polyelectrolyte patterns in a POPS process. Reprinted with permission from [173], H. Zheng et al., *Langmuir* 18, 4505 (2002). © 2002, American Chemical Society.

(see Fig. 8a), the PDMS stamps were pretreated with air-plasma for 20 s to render them fully wettable to a 0.02 M PDAC aqueous solution with 0.1 M NaCl, which was used as ink [172].

By tuning surface properties of the PDMS stamp—the solvents of the polymer ink and controlled POPS conditions—two kinds of new patterns—ring patterns and small-dot patterns—were created from the same patterned PDMS stamps, as well as the uniform circle-grid patterns. When the PDMS stamps were plasma treated for 5–10 s and inked with 0.02 M PDAC/0.1 M NaCl aqueous solutions, PDAC ring patterns were transferred onto the SPS surface, as shown in Figure 8b. When the stamp is not plasma treated at all, and a mixed solvent polymer ink consisting of 0.01 M PDAC water/ethanol solution (50/50, v/v) is used, the transferred pattern consists of small periodic dots as shown in Figure 8c.

Two different particles on a defined array use two different approaches—ionic attractions coupled with hydrophobic and hydrogen bonding interactions, respectively. The first set of negatively charged particles were deposited on the multilayer surface primarily through electrostatic interactions, whereas the second set of colloidal particles adsorb onto a neutral SAM surface [174].

Two component colloidal arrays on a single-patterned PDAC/EG surface, were fabricated by adding surfactant, DTAB, to tune the selective deposition of the colloidal particles. When low concentrations of DTAB are added to the colloidal suspension ( $10^{-6}$ – $10^{-5}$  M), the PSS particles are deposited primarily on the multilayer surface with small changes in their packing density [179]. As more DTAB suspension ( $10^{-4}$ – $10^{-3}$  M) is added, the surfaces of the particles become increasingly hydrophobic as the negative charge density is reduced and alkyl chains are introduced. The selectivity of the particles for the PDAC surface decreases sharply at a given degree of surfactant shielding, resulting in little or no selectivity [179]. Finally, at a high degree of shielding, the selectivity is reversed, and the deposition occurs preferentially on the neutral surface.

## 6. LITHOGRAPHIC APPROACH TO PATTERN LAYER-BY-LAYER THIN FILMS

Nanoassembly of ultra-thin films through alternate adsorption of oppositely charged components (linear polyions, nanoparticles, and enzymes) allows the formation of layers with component location precision of a few nanometers in the direction perpendicular to the surface. Since its demonstration by Decher et al. [180, 181], applications have been found in electro-optical devices, biocompatible coverage, and in bioreactors [180–186]. The typical procedure of layer-by-layer self-assembly is as follows: A pretreated silicon substrate is immersed in a cationic solution for 10 min, forming a single layer of cationic polyelectrolytes on the substrate. The substrate is then rinsed. Next, it is immersed in a polyanion solution for 10 min to adsorb a layer of anionic polyelectrolyte. The process can be repeated indefinitely; the only condition is a proper alternation of positive and negative components. Linear polyions frequently used in the layer-by-layer (LbL) assembly are cationic poly(ethylenimine) (PEI), PDDA, PAH, polylysine, chitosan, and anionic sodium PSS, and poly(vinylsulfate), polyacrylic acid, and DNA. Enzymes and charged nanoparticles were also used in the LbL assembly [179]. To use LbL multilayers in devices, one has to provide film ordering not only in a vertical direction but also in the planar direction. This is critical for nanodevice production, such as nanoelectronic chips or nano electro mechanical systems (NEMS) [192–195].

There are works on applications of the layer-by-layer assembly on two-dimensional (2D) patterns [196–201]. They are based mostly on the microprinting of thiol compounds on gold and further assembly of the polyion multilayers on charged patterns, and they were developed by Hammond et al. [196–199]. This strategy is designed to produce patterns by stamping onto substrate chemicals with different functionalities, that is, polyion adhesive or resisting. The polyions were directed only to charge “attractive” regions and were repelled from the resistant regions. Whitesides et al. [200] crystallized latex particles in capillary channels produced by PDMS micromolding and made 3D ensembles of 450-nm spheres with a resolution of ca.1  $\mu\text{m}$ . In another approach [201], poly(pyrrole) and poly(styrenesulfonate) were LbL-assembled on the 2D charged micropattern produced on a fluoropolymer by plasma treatment. The three methods described were quite successful, but restricted in applications by substrate materials (gold, fluoropolymers) or by the necessity of special plastic stamps. We presented two approaches to realize 2D patterning of self-assembled multilayers by silicon-based lithographical technology, which is a well-established industrial process.

The first one is referred to as the metal mask approach. By using this method, we avoid the selective deposition, which demands strict control and consequently obtains extremely high reproducibility and a simplified process. Since layer-by-layer self-assembly and lithography techniques are mature processes, and lithography is widely applied to the modern semiconductor industry, a combinative technique will be economic and suitable for mass production. By just following the traditional process, the nanostructures comprised of nano-building bricks can be

realized. As it behaves in the semiconductor industry, the process results in such a high reproducibility that distinct patterns (in this experiment, 10  $\mu\text{m}$ ) can be created in almost all the dyes on the wafer. Commercial electronic and photonic devices, such as metal-oxide semiconductor FET (MOSFET) or solar cells with nanostructures, are expected to be fabricated by this method at a considerably lower cost and temperature. Layer-by-layer self-assembly was employed to deposit the nanoparticle-based thin film on a substrate while using a semiconductor process to pattern the thin film [202]. At first, a layer of nanoparticles is adsorbed onto a silicon wafer. Then a layer of aluminum and resist are deposited and coated on top of the nanoparticle layer. Patterns are made on resist by UV lithography and transferred to a aluminum layer by etching aluminum. As a result, nanoparticles previously covered under aluminum begin to be open to the air. Then, it is etched by oxygen plasma, and nanoparticles are removed in compliance with the designed patterns. During the etching process, metal acts as the mask over the nanoparticles. After the remaining aluminum and resist are dissolved, only the desired pattern is left on the substrate.

The second patterning approach is called a “lift-off” since lift-off acts as a critical step in the process. At the beginning, photoresist is spun on a silicon wafer and patterned. Then nanoparticles are deposited with layer-by-layer assembly on the whole wafer. Eventually, the wafer is put into acetone solution to dissolve resist and particles self-assembled on it are removed as well [202].

Both methods work well for the thin film patterning. As for the lift-off method, it can be applied to all types of nanoparticles. In the other experiments, the metal mask method succeeded in controlling the spatial position of organic polystyrene particle by oxygen plasma etching. As a matter of fact, it can also be applied to inorganic particles if the appropriate recipe is available. If not, the flexibility of the mature semiconductor process can provide a simple wet etching to deal with it as a substitute to the dry etching.

Both methods can be applied to 3D fabrication as well as functional devices. In the 3D case, some factors have to be seriously controlled such as height, surface or border roughness, and sidewall profile. Two methods can work out a 3D structure individually or both of them can be used if necessary. Table 1 shows the comparison of two methods.

In our experiment, the capacitor arrays were patterned by the “modified lift-off” as illustrated in Figure 9. These capacitors can be fabricated onto integrated circuit chips. Metal-oxide semiconductor (MOS) capacitors, with thermal  $\text{SiO}_2$  as the gate oxide, have become the prime structure to carry out digital functions in silicon-integrated circuits. However, the fabrication of a MOS capacitor, using the conventional silicon MOS technology, demands sophisticated facilities. High process temperature also needs to be balanced to avoid the damage to subsequent processes, and the growth rate of the thermal silicon dioxide is usually very low. Hereby, an approach to fabricate the basic MOS capacitor with a technique combining traditional lithographic technique and LbL self-assembly was developed because the dielectric layer consisting of silica and polyion can be self-assembled easily and rapidly. The insulating layer is made up of six layers of LbL, self-assembled silica nanoparticle thin

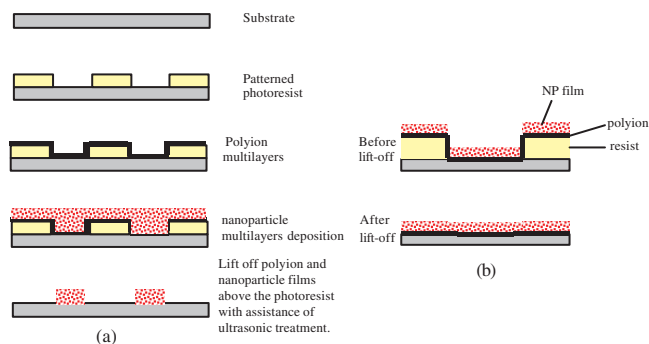

**Table 1.** Comparison of lift-off and metal mask methods.

	Metal mask	lift-off
Border sharpness		better
Surface roughness	better	
Defect in structure		more
Adhesion to substrate		better
contamination	more	
Channel cleanness		better
process		simple

film. Capacitors are fabricated on 4-inch P-type and N-type silicon wafers. The measured CV curves are in compliance with typical MOS capacitors. Compared to the traditional process, this has the advantages of low temperature, low cost, and short processing time. The simplicity and reliability of this process to fabricate the simple MOS capacitor provides a new way to fabricate other microelectronic or optoelectronic devices by traditional lithography and LbL, self-assembled building blocks.

Figure 10(a) shows an SEM image of the  $(45\text{-nm silica/PDDA})_4$  multilayer cross-section. The film has a permanent thickness of 170 nm, leading to 43 nm for every bilayer close to the silica particle diameter. A film mass from QCM and a film thickness from SEM gives a density of the  $\text{SiO}_2/\text{PDDA}$  multilayers as  $\rho = 1.43 \pm 0.05 \text{ g/cm}^3$ . To calculate the silica-packing coefficient in the films, it is reasonable to assume that the dry film consists of  $\text{SiO}_2$ , PDDA, and air-filled pores. The mass ratio of PDDA to  $\text{PDDA}/\text{SiO}_2$  bilayer obtained from QCM measurements is 0.08. Taking

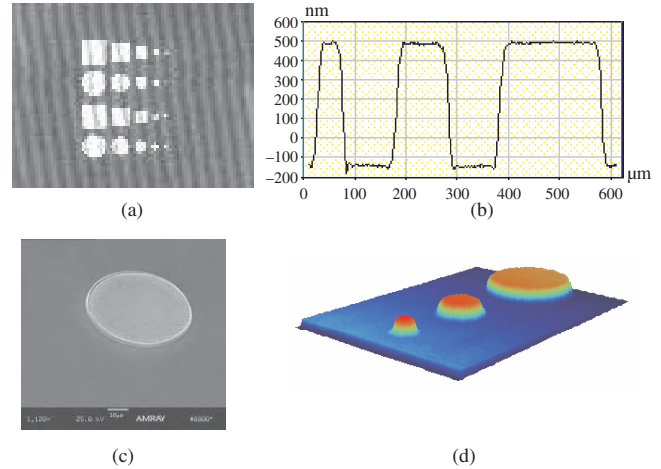

**Figure 9.** (a) Scheme of patterning nanoparticle thin films with ultrasonic treatment. (b) Scheme of patterning nanoparticle thin films without ultrasonic treatment. Hua et al., *Nanotechnology* 14, 453 (2003). © 2003, Institute of Physics.

**Figure 10.** (a) SEM image of cross-section of (45-nm silica/PDDA)<sub>4</sub> multilayer on silver electrode (b) QCM-monitored, 45-nm silica growth. Reprinted with permission from [203], F. Hua et al., *Nanotechnology* 14, 453 (2003). © 2003, Institute of Physics.

into account component densities ( $\rho = 1.43$ ,  $\rho_{\text{SiO}_2} = 2.2$ , and  $\rho_{\text{PDDA}} = 1.1 \text{ g/cm}^3$ ), the volume ratio is obtained as  $V_{\text{PDDA}}/V_{\text{bilayer}} = 0.1$ . From the equation  $\rho_{\text{PDDA}}V_{\text{PDDA}} + \rho_{\text{SiO}_2}V_{\text{SiO}_2} + \rho_{\text{air}}V_{\text{air}} = \rho V$ , where the air-term is very small,  $V_{\text{SiO}_2}/V = 0.7$ . This is very close to the theoretical dense-packing coefficient for spheres (0.63), and corresponds to details in the SEM micrographs. SiO<sub>2</sub>/PDDA film volume composition is: 70% SiO<sub>2</sub> + 10% polycation + 20% air-filled pores. These pores are formed by closely packed 45-nm SiO<sub>2</sub> and have a typical dimension of 15 nm. Therefore, the dielectric constant of our silica/PDDA multilayer is different from silica due to about 30% of inclusions, such as air, polycation layers, etc. In the analysis of the MOS devices, it is found that the dielectric constant was slightly higher than the one for thermal silica. In our group, it is possible to produce ultra-thin multilayers of silica nanoparticles in the thickness ranging from 100 nm to hundreds of nm with a precision of about 10 nm. These films have a porous structure related to the close packing of silica spheres in the layer.

As shown in Figure 11, clear patterns of the capacitor arrays with sharp borders were created on a silicon wafer. The arrays consist of round and square capacitors with various sizes. All 45 nm SiO<sub>2</sub> spheres were closely packed to form a dense structure. The surface roughness of the capacitor was 6.5 nm measured by RST. The growth step can be easily estimated by measuring the frequency shift of the quartz crystal microbalance resonator, and the monolayer thickness can be calculated accordingly by the Sauerbrey equation. Figure 10(b) gives the QCM monitoring of alternate PDDA and SiO<sub>2</sub> adsorption, where the thickness was calculated from frequency shifts with formula 2. As recorded by QCM, at every assembly step, the component

**Figure 11.** (a) Optical image of the capacitor arrays, the minimum diameter or size is 50 μm. (b) 2D profile (c) SEM image of layers of 45-nm silica particle thin film. (d) 3D plot of the capacitors. Reprinted with permission from [203], F. Hua et al., *Nanotechnology* 14, 453 (2003). © 2003, Institute of Physics.

monolayer was formed. It shows that at the sixth cycle, the thickness of the SiO<sub>2</sub> layers is 260 nm. When added to the 300 nm aluminum electrode, the height of the whole device is 567 nm, well in compliance with the 2D profile of Figure 11(b).

The fabricated device demonstrates the C-V curve of a typical MOS capacitor with distinct accumulation, depletion, and inversion regions, as shown in Figure 12. The MOS structure is basically a capacitor with the silica as the dielectric material. If the silicon were a perfect conductor, the parallel-plate capacitance would be determined by the oxide capacitance as it is in the accumulation region. However, it always deviates from the oxide capacitance due to the voltage dependence of the surface space-charge layer in silicon. The space-charge occurring at the interface of silicon and oxide acts as another capacitance in a series with the oxide capacitor, giving an overall capacitance that is smaller than the pure oxide capacitance. Since the inversion of a P-type MOS capacitor happens at a positive voltage and an N-type one at a negative voltage, the C-V curves move in opposite directions for P- and N-type MOS capacitors. If the layer of silicon dioxide was produced by conventional thermal oxidation, the dielectric constant would be 3.9. Given the size of each square device, 200 μm by 200 μm and 267 nm high, the oxide capacitance is calculated as 5.2 pF, reasonably close to the experimental data, 8 pF. The slightly larger value means a larger dielectric constant of the LbL, self-assembled insulator layer. The precursor and intermediate polyion multilayer is the root for the higher dielectric constant because the dielectric constant of the polyion film is normally 10 times higher than silica [204]. The experimental results also show that the capacitance of each device is strictly proportional to the area of the electrode, implying an extremely high reproducibility of the processes.

In our process, a conventional lithographic technique, such as lift-off, was used to pattern the capacitors on multilayer films. However, because the LbL-self-assembled nanoparticle films are unlike the conventional thin films in

**Figure 12.** Capacitance versus voltage curves of MOS P- and N-type capacitors (a) N-type square capacitor with size of  $200 \mu\text{m}$ . (b) N-type round capacitor with diameter of  $200 \mu\text{m}$ . (c) P-type square capacitor with size of  $200 \mu\text{m}$ . (d) P-type round capacitor with diameter of  $200 \mu\text{m}$ . many respects, modification and optimization of the traditional process is required.

During the lift-off, it was better to introduce ultrasonic treatment for 3 seconds when the wafer was soaked in

developer solution. Inside the structure of the nanoparticle film, polyion multilayers such as PDDA and PSS were sandwiched between the nanoparticle film and photoresist as a kind of “chemical glue.” The structure of the polyion is like a long thread that strongly links one to the other. It is hard to break them up during the lift-off, so at some areas the nanoparticle and polyion multilayer cannot be removed when the photoresist is dissolved. They just drop down and reattach to the film underneath, as shown in Figure 9(b). The ultrasonic treatment is introduced to disconnect the linkage between polyion branches and obtain a more distinct pattern with higher reproducibility.

Other dielectric materials, such as montmorillonite, has also been tested as the insulating layer. They did not perform as well as the silica nanoparticle, although the monolayer thickness can be more precisely controlled. There are many other nanoparticles suitable for LbL self-assembly that may function differently for various devices.

## 7. NANOFABRICATION FOR NANO-ELECTRONICS

The semiconductor industry has seen a remarkable miniaturization trend, driven by many scientific and technological innovations. However, if the trend is to continue and provide even faster and cheaper computers, the size of microelectronic circuit components will soon need to reach the scale of atoms or molecules [205].

Photolithography, the technology used to manufacture computer chips and virtually all other microelectronic systems, can be refined to make structures smaller than  $100$  nanometers, but doing so is very difficult, expensive, and inconvenient.

The electronics industry is deeply interested in developing new methods for nanofabrication so that it can continue its long-term trend of building even smaller, faster, and less expensive devices.

Despite enormous recent progress in the fabrication and demonstration of nanoelectronic devices, many challenges remain. For solid-state electronics, one of the most important challenges is to be able to produce reliable and uniformly in silicon the characteristic nanometer-scale features required for nanoelectronics: nanometer-scale islands, barriers, and “heterojunctions” between islands and barriers.

One leading contender is electron-beam lithography [206]. In this method, the circuitry pattern is written on a thin polymer with a beam of electrons. An electron beam does not diffract at atomic scales, so it does not cause blurring of the edges of features. Researchers have used this technique to write lines with widths of only a few nanometers in a layer of photoresist on a silicon substrate. The electron-beam instruments currently available, however, are very expensive and impractical for large-scale manufacturing.

Another contender is lithography using X-rays with wavelengths between  $0.1$  and  $10$  nanometers or extreme ultraviolet light with wavelengths between  $10$  and  $70$  nanometers. Because these forms of radiation have much shorter wavelengths than the ultraviolet light currently used in photolithography, they minimize the blurring caused by

diffraction [206]. But these technologies have their own problems: conventional lenses are not transparent to extreme ultraviolet light and do not focus X-rays.

For top-down lithography, they begin with a pattern generated on a larger scale and reduce its lateral dimensions. But no top-down method is ideal; none can conveniently, cheaply, and quickly make nanostructures of any materials. Thus researchers have shown a growing interest in bottom-up methods, which start with atoms, molecules, and nanoparticles to build up nanostructures with dimensions between 2 and 10 nanometers and do so inexpensively [207].

Bottom-up approaches to nanoelectronics [208], where the functional electronic structures are assembled from well-defined nanoscale building blocks, such as carbon nanotubes [203–208], molecules [215–217], and/or semiconductor nanowires [218–220], inorganic nanoparticles have the potential to go far beyond the limits of top-down manufacturing.

The formation of carbon nanotubes could be traced back to the discovery of the fullerene structure  $C_{60}$  (buckball) in 1985 [221]. The structure of the buckball, comprised of 60 carbon atoms arranged by 20 hexagonal and 12 pentagonal faces to form a sphere, is elongated to form a long and narrow tube with a diameter of approximately 1 nm, which is the basic form of a carbon nanotube [222]. Nanotubes have extraordinary mechanical, electrical, and thermal properties while providing strong, light, and high toughness characteristics. Since the discovery of nanotubes, extensive research in carbon, fullerene, nanosensor, nano-indentator, and nanomachine has blossomed in many different directions, and has attracted a great deal of attention to advanced composite society. It is well understood that carbon fibers or nanotubes could not be utilized alone without any supporting medium, such as a matrix to form structural components. Whereas, the investigation on the interfacial bonding properties between the nanotube and matrix system is of great interest, it ensures a good stress transfer between the nanotube and matrix of nanocomposite structures in the development of nanotube composites.

Carbon nanotubes exhibit several technologically important characteristics. Metallic(m) nanotubes can carry extremely large current densities [223, 224]. Semiconducting nanotubes can be electrically switched on and off as field-effect transistors (FETs) [225, 226]. The two types may be joined covalently [227, 228].

Carbon nanotubes [222, 229–234] are very attractive because they are capable of emitting high currents (up to 1 A/cm<sup>2</sup>) at low fields ( $\sim 5$  V/ $\mu$ m), and their potential as emitters in various devices have been amply demonstrated [235]. Furthermore, the controlled deposition of nanotubes on a substrate has become possible through the combined use of chemical vapor deposition (CVD) methods and catalyst patterning techniques.

The study of nanometer-sized semiconductor crystals has been advancing at a rapid pace. Much of the interest in these materials stems from the fact that their physical and chemical properties can be systematically tuned by variation of the size, according to increasingly well-established scaling laws. In the semiconductor quantum dot (QD), the electrons and holes are three dimensionally confined inside a nanometer scale “quantum box.” The confinement causes a discrete

atomic-like, energy-level structure for the carriers and a variety of new physical phenomenon are observed [236, 237]. Researchers have been exploring the possibility of combining quantum confinement with the introduction of extra carriers by means of doping and charging to obtain a new set of properties in these materials [238–244]. The impurity doping which is routine in bulk semiconductors is now extended to semiconductor nanocrystals. Many efforts that try to attack these problems have focused on doping II–VI semiconductor nanocrystals with metals such as Mn, 10, 11, or Cu<sup>12</sup> and rare-earth elements such as Tb.<sup>13</sup> These impurities do not affect the adsorption spectrum, but strongly modify the luminescence properties [245].

A PBG crystal (or photonic crystal) is a spatially periodic structure fabricated from materials having different dielectric material constants [246]. It can influence the propagation of electromagnetic waves in a similar way as a semiconductor does for electrons. The concept of this new class of material was first proposed independently by Yablonovich [247] and John [248] in 1987, and since then a wide variety of applications has been envisioned or demonstrated for this new class of materials. In silicon and other semiconductors, adjacent atoms are separated by about a quarter of a nanometer. Photonic bandgap materials involve similar structures but on a larger scale. A photonic crystal, for example, provides a convenient and powerful tool to confine, control, and manipulate photons in all three dimensions of space, for example, to block the propagation of photons irrespective of their polarization or direction; to localize photons to a specific area at restricted frequencies; to inhibit the spontaneous emission of an excited chromophore; to modulate or control simulated emission; and to serve as a lossless waveguide to direct the propagation of photons along a specific direction [249–254]. All of these photonic properties are technologically important because they can be exploited, in principle, to produce light-emitting diodes (LEDs) that display coherence properties, fabricate thresholdless semiconductor diode lasers, and significantly enhance the performance of many other types of optical, electro-optical, and quantum electronic devices. Patterning photonic crystal thin films into optical circuits would represent the ultimate limit of optoelectronic miniaturization.

Ultimately, it will be desirable to build ultra-dense, low-power nanoelectronics circuits made from purely nanometer-scale switching devices and wires. Molecules electronics, using individual covalently bonded molecules to act as wires and switching devices, is another longer-term alternative to build ultra-dense, low-power nanoelectronics circuits. Individual molecular switching devices could be as small as 1.5 nanometers across, with densities of approximately 10<sup>12</sup> devices per sq cm. A primary advantage of molecular electronics is that molecules are natural nanometer-scale structures that can be made absolutely identical in vast quantities. Also, synthetic organic chemistry (the chemistry of carbon-based compounds) offers more options for designing and fabricating these intrinsically nanometer-scale devices than the technology presently available for producing solid-state chips with nanometer-scale features. It has been shown that small organic molecules can conduct and control electricity [255–260] and large organic biomolecules are conductive [261].

There has been a great deal of interest in the use of both supermolecular assemblies and nanoparticle structures as components of electronic circuits [262, 263]. A machine based on molecules acting as components also requires a high level of complexity in the actual chemistry required. Switches are key components of any electronic device to be used for computational purposes, and for these uses, quantum states appear as the obvious choice to achieve this functionality. In order to construct useful switching structures based on individual molecules, the transfer function of a two-contact switching unit must involve a range of applied potentials in which the device exhibits a negative resistance.

Another approach in nanoscale electronics is based on the use of nanoparticles for the construction of electronic components of nanometer dimensions. Well-defined rules of how these materials can be organized have emerged. The vigorous recent efforts in synthesizing MPCs have resulted in the availability of functionalized nanomaterials that while retaining the properties of a metallic core can be handled like simple, stable chemical compounds. The question that needs to be addressed is would it be possible to synthesize chemically functionalized nanoscale objects that would spontaneously organize into superstructures with desirable functionalities?

Many ways have been developed for preparing nanostructures, ranging from single-atom manipulation to organic synthesis. The tremendous strength of the colloidal preparation routes is that they yield large amounts of monodisperse nanocrystals with easy size tuning. Furthermore, the presence of organic molecules on the surface of the nanocrystals enables extensive chemical manipulation after the synthesis.

The development of advanced materials from inorganic nanoparticles (NPs) is currently one of the most dynamic areas of science. Nanoparticles are attracting significantly fundamental and commercial interest, with a wide range of applications including the next generation of optics, electronics, and sensors [264]. In optical, electrical, and magnetic devices, NPs will be mostly used in the form of thin films. Currently, such films are typically made by spin-coating, spraying, or sometimes simple painting of nanoparticle-matrix mixtures.

There has recently been an intense effort to produce metal nanoparticles capped with a variety of functional groups [265]. The rapid development of this field is resulting in the availability of many different functionalized nanoparticles that can be used in much the same way as organic chemical reagents. The main synthetic strategies that have been developed are based on either the direct one-step, single-phase reduction (gas-phase synthesis) or on the two-phase reduction (sol-gel processing), and also on the use of place-exchange reactions with a target ligand. Sol-gel processing is a wet chemical synthesis approach that can be used to generate nanoparticles by gelation, precipitation, and hydrothermal treatment (Fig. 13). Size distribution of semiconductor, metal, and metal oxide nanoparticles can be manipulated by either dopant introduction or heat treatment. Better size and stability control of quantum-confined semiconductor nanoparticles can be achieved through the use of inverted micelles, polymer matrix architecture based on block copolymers or polymer blends, porous glasses,

**Figure 13.** Sol-gel technology in nanoparticle synthesis. Reprinted with permission from [267], <http://www.chemat.com/html/solgel.html>. © Chemat Technology, Inc.

and *ex-situ* particle-capping techniques. Supercritical solvents represent convenient media for synthesis because their solvation properties can be easily controlled by varying the pressure. Supercritical fluids exhibit gas-like mass transfer properties and yet have liquid-like solvation capability. Carbon dioxide is one of the mostly widely used gases for supercritical fluid applications because of its moderate critical constants, nontoxic nature, low cost, and availability in pure form. Metal ions are insoluble in supercritical  $\text{CO}_2$  because of the charge neutralization requirements and the weak solute-solvent interactions. However, when metal ions are bound to organic ligands, they may become quite soluble in supercritical  $\text{CO}_2$  [266].

Microemulsions have been extensively employed for nanoparticle synthesis because the reaction can be confined in a well-defined environment. This approach has been successfully developed for the synthesis of Ag nanoparticles in supercritical carbon dioxide ( $\text{sc-CO}_2$ ) by the reduction of  $\text{Ag}^+$  incorporated in a water-in  $\text{CO}_2$  microemulsion. In addition, phase-extraction methods, in which the aqueous colloidal metal solution is extracted into an immiscible organic phase containing the capping reagent, have been employed. Microemulsion copolymerization is shown to be a very useful method to produce stable aqueous suspensions of ultra-fine, selective metal-complexing nanoparticles with controlled size and adjustable metal-binding capacity [268].

The ability to assemble nanoparticles into highly ordered 2D or 3D arrays is very important in fabricating novel devices utilizing quantum dots and inorganic (or organic) colloidal particles. Several techniques have been demonstrated for forming such arrays: for example, 2D arrays have been fabricated using methods based on chemical vapor deposition, Langmuir-Blodgett films, molecular beam epitaxy, pulsed electrochemical deposition, and microcontact printing [269–275]; 3D arrays have been realized through self-assembly approaches that usually involve electrostatic interaction [276–281], sedimentation [282–287], and solvent evaporation [288–289].

Layer-by-layer assembly is one of the new methods of thin-film deposition, often realized as a sequentially absorbed monolayer of oppositely charged polyelectrolytes [290]. Layer-by-layer assembly has also been successfully applied to thin films of NPs and nanocolloids, that is, dispersed species with only one or two spatial dimensions in the nanoscale regime. A large number of studies on the assembly of semiconductor, metallic, magnetic, insulating, composite, and other materials have been undertaken [291–299]. The main advantages are the simplicity, universality, and high quality of the resulting coating. Based on this, LBL assembly can be a convenient method for processing NPs into thin films, both for advanced materials research and industrial production.

Soft lithography generates micropatterns of SAMs [300–305] by contact printing, and also forms microstructures in materials by embossing (imprinting) [306–315] and replica molding [316–318]. The strength of soft lithography is in replicating rather than fabricating the master, but rapid prototyping and the ability to deform the elastomeric stamp or mold gives it unique capabilities even in fabricating master patterns. Soft lithography is not subject to the limitation set by optical diffraction and optical transparency and can be usually carried out in the laboratory environment.

Researchers have recognized the utility of DNA in nanofabrication [319–323]. DNA oligonucleotides contain hybridization information encoded in their sequences. In exploiting this phenomenon of DNA hybridization, interactions can be made specific by the DNA sequence, while interparticle distance can be controlled through the selection of the oligonucleotide length. Consequently, a nanostructure much more complex than that which is possible using SAMs might be achieved by using DNA as a “linker” of the nanoparticles.

Template-directed synthesis is a convenient and versatile method for generating porous material. It is also a cost-effective and high-throughput procedure that allows the complex topology present on the surface of a template to be duplicated in a single step. In this technique, the template simply serves as a scaffold around which other kinds of materials are synthesized. By templating against supermolecular assemblies self-organized from small molecules, surfactants, and block copolymers, it has been possible to prepare various types of porous materials with pore sizes in the range of 0.3–10 nm [324–328]. With the use of mesoscale objects such as templates, the dimension of these pores can be significantly extended to cover a wide range that spans from  $\sim 10$  nm to  $10 \mu\text{m}$  [329–332]. In particular, templating against opaline arrays of colloidal spheres offers a generic route to macroporous materials which exhibit precisely controlled pore size and highly ordered 3D porous materials [333–339]. The fidelity of this procedure is mainly determined by van der Waals interactions, the wetting of the template surface, a kinetic factor such as the filling of the void spaces in the template, and the volume shrinkage of precursors during the solidification. Templating against opaline arrays of colloidal spheres has been successfully applied to the fabrication of 3D microporous structures from a wide variety of materials, including organic polymers, ceramic materials, inorganic semiconductors, and metals [333–350].

Fabrication based on this approach is remarkable for its simplicity and its fidelity in transferring the structure from the template to the replica. The size of the pores and the periodicity of the porous structures can be precisely controlled and readily tuned by changing the size of the colloidal spheres.

Although this templating procedure may lack the characteristics required for high-volume production, it does provide a simple and effective route to 3D porous materials having tightly controlled pore sizes and well-defined periodic structures. These porous structures can serve as a unique model system to study many interesting subjects such as adsorption, condensation, transport (diffusion and flow), and separation of molecules in macroporous materials, as well as mechanical, thermal, and optical properties of 3D porous materials.

## 8. POLYMER MICROELECTRONICS

Polymer microelectronics/optoelectronics is an emerging field of research and development. Nanoassembly and other nanofabrication techniques can be applied to the fabrication of polymer microelectronics/optoelectronics to improve the fabrication efficiency and reduce the cost. Here we review the recent progress in materials, current fabrication technologies, devices designs, and applications related to polymer microelectronics, including transistors and integrated circuits.

Since the 1950s, inorganic silicon and gallium arsenide semiconductors, silicon dioxide, silicon nitride, and metals such as aluminum and copper have been the backbone of the semiconductor industry. However, since the late 1980s, there has been a growing interest in polymer or organic microelectronics based on the conjugated polymers, oligomers, or other molecules. By recent research efforts through novel synthesis and process techniques, the performance as well as the stability and ability to process these active materials has been greatly improved. Although polymer microelectronic devices cannot rival the traditional, mainstream inorganic microelectronic devices due to the relatively low mobilities of the organic semiconductive materials, they can be competitive for the applications requiring structural flexibility, low temperature processing, large-area coverage on materials such as plastic and paper, batch production, and especially low cost. The applications of the polymer microelectronics include the active-matrix flat-panel displays [351] based on the OLEDs, low-end smart cards, electronic identification tags, photovoltaic cells, high bandwidth photodetectors [352], high density memory chips, sensors and actuators, and some pervasive computing needs. The main fabrication technologies include ink-jet printing, photochemical lithography [363], spin-coating, vacuum evaporation, soft lithography (contact transfer) [353], RIE, and nano self-assembly.

### 8.1. Materials and Physics

Alan MacDiarmid, Alan Heeger, and Hideki Shirakawa won the 2000 Nobel Prize in Chemistry for the discovery and development of conductive polymers. Most polymers are insulators because their electrons are localized, that is, each of the electrons is attached to its own nucleus. However, the conducting or semiconducting polymers have conjugated

double bonds. The double bond consists of a  $\sigma$  bond and a  $\pi$  bond. Due to the conjugated structure, the electrons have gained the freedom to move along the entire chain. In metals and conventional semiconductors, charge-transport occurs in delocalized states. Such a model is no longer valid in low conductivity organic semiconductors, where a simple estimate shows that the mean-free path of carriers would become lower than the mean atomic distance. In these materials, carrier-transport occurs through hopping of charges between localized states. The modeling of organic field effect transistors (OFETs) is currently hampered for several reasons. First, the charge-transport in organic semiconductors is still not well understood. Second, there are great differences between the behaviors of OFETs made from different compounds. Furthermore, the fabrication method seems to strongly affect the device performance. Nevertheless, some attempts [354–356] have been made, such as the model based on a simple trap distribution applied on the dihexylquaterthiophene (DH4T).

The charge mobility increases with temperature in most organic materials. A useful model to describe the charge-transport in organic materials is that of the small polaron, developed by Holstein [357]. Localization in conjugated organic materials occurs via the formation of polarons resulting from the deformation of the conjugated chain under the action of the charges. This mechanism of self-trapping is often described through the creation of localized states in the gap between the valence and the conduction bands.

In a multiple trapping and release (MTR) model, a narrow delocalized band is associated with a high concentration of localized levels that act as traps. During their transition through the delocalized levels, the charge carriers interact with the localized levels via trapping and thermal release. The prominent feature of OFETs is that the field-effect mobility is gate bias dependent. A general feature of charge-transport in organic materials is that the mobility becomes field dependent at high electric field (namely, at fields in excess of  $\sim 10^5$  V/cm).

Figure 14 shows the structures of the several conducting or semiconducting polymers. The conductivity of the

**Figure 14.** The chemical structures of polymers for devices. Reprinted with permission from [363], <http://www.conductivepolymers.com/#1>. © Advanced Polymer Courses.

polymer materials have been improved quickly in recent years. For example, Ormecon Chemie, Germany, which developed polyaniline, has developed grades of polyaniline with conductivity of 300 S/cm in 1998.

## 8.2. Polymer Transistors and Integrated Circuits

In 1930, Lilienfeld first proposed the principle of the field-effect transistor (FET) [358]. And in 1960, Kahng and Atalla [359] fabricated the first silicon-based MOSFET. Although first descriptions of the field effect in organic semiconductors can date back to 1970, organic FETs (OFETs) have only been identified as potential elements of electronic devices since the report by Koezuka et al., in 1987, on a structure based on electrochemically polymerized polythiophene [360]. But the first all-polymer transistor was fabricated by the team of Francis Garnier et al. after 24 years [361].

The performance of OFETs has been continuously improved since the 1980s, and some OFETs can now compete with amorphous silicon FETs. The performance of OFETs is primarily limited by the relatively low electron or hole mobility of the channel materials, either polymers or small molecules. Due to the molecular vibrations and large intermolecular distances (typically about 0.35 nm), conductivity in small molecule organic films depends on the rate of electron- or hole-hopping between the molecules. Polymers show even lower mobility than small molecules due to their less ordered structures. Figure 26 shows the highest field-effect mobilities ( $\mu$ ) reported for OTFTs fabricated from the most promising polymeric and oligomeric semiconductors versus year from 1986 to 2000 [362].

Organic FETs and integrated circuits recently reported by Philips [364], IBM, Lucent Technologies, and Pennsylvania State University [365, 366] indicate that great advances have been made.

Pentacene OTFTs have produced the highest performances with mobility as large as  $1.5 \text{ cm}^2 \text{ V}^{-1} \text{ S}^{-1}$  and an on/off ratio larger than  $10^8$  in 1997 [367, 313]. However, the operating voltage requiring such performance was too high (100 V). Using much higher dielectric constant metal oxide film, barium zirconate titanate (BZT) as a gate insulator, researchers at IBM reported a similar performance of pentacene TFT fabricated on transparent polycarbonate substrates and operated at a maximum voltage of only 4 V, with the mobility values of  $0.38 \text{ cm}^2 \text{ V}^{-1} \text{ S}^{-1}$  [362]. As most organic materials, pentacene is intolerant to exposure of various chemicals used in traditional lithography. Therefore, they are difficult to be patterned using lithography. Usually shadow masks are used during the deposition. To overcome this, researchers at Pennsylvania State University used a double-layer resist active-layer patterning technique that does not require the organic film to be exposed to process chemicals. This patterning technique also reduces the current leakage in the pentacene film outside the active device areas [365, 366]. By 2000, the maximum field-effect mobility was reported to be  $2.7 \text{ cm}^2/\text{VS}$  for holes in a pentacene single crystal by Schön et al. at Bell Laboratories [369].

Researchers at the Philips Company have also made impressive progress, developing the first all-polymer ICs

consisting of 326 transistors with a 2- $\mu\text{m}$  gate length and more than 300 vertical contacts in 1998 [364]. It involves reproducible fabrication of field-effect transistors in which the semiconducting, conducting, and insulating parts are all made of polymers. The interconnections between the transistors are also conducting polymers. The transistor structures are created by masking the polyaniline and irradiating it with UV radiation to reduce its conductivity by almost 10 orders of magnitude, from  $10^3$  Ohm/sq to more than  $10^{13}$  Ohm/sq. Philips developed a 15-bit programmable code generator with bit rates of 30 bits/sec. The circuits remain functional when the foils (substrate) are sharply bent. Recently, Philips is also working on polymer memory chips and displays.

Lucent Bell Laboratories reported the large scales of integration up to 864 transistors per circuit and operation speeds of  $\sim 1$  KHz in clocked sequential complementary circuits [370]. Bell Labs have been able to print functional circuits on flexible sheets of plastics using inexpensive screen-printing techniques in 1997 [371]. After that, Lucent Bell Laboratories and Opticom ASA have entered into an agreement to develop the plastic memory using polymer integrated circuits.

The disadvantage of using well-ordered pentacene as the active material in the TFT is that it needs the vacuum evaporator to deposit the crystalline film layer. The technologies that are believed to have the potential to produce the highest impact on polymer microelectronics are large-area stamping, ink-jet printing, screen-printing, and self-assembling using the soluble polymer semiconductors without the lithography process. Ink-jet printing deposition is a method in which the pattern can be directly printed onto the substrate, giving very high-resolution patterns and the ability to separate pixels of red, green, and blue-emitting polymers onto the substrate. Using this technology will not only lower the production cost but will also make it possible to fabricate flexible and large area devices. The University of Cambridge reported the all-polymer thin-film transistors fabricated by high-resolution ink-jet printing for the first time in 2000 [372, 373]. They realized a channel length of down to 5  $\mu\text{m}$  and fabricated the TFT with a high mobility of  $0.02 \text{ cm}^2 \text{ V}^{-1} \text{ S}^{-1}$  and an on/off ratio of more than  $10^5$  by aiding a self-aligning flow of solution.

In recent years, most studies on the solution-processable polymeric semiconductor focused on poly(3-hexylthiophene). With the treatment of  $\text{SiO}_2$  with hexamethyldisilazane (HMDS) or an alkyltrichlorosilane, the OTFTs from highly regioregular poly(3-hexylthiophene) with the mobilities of  $0.05$  to  $0.1 \text{ cm}^2 \text{ V}^{-1} \text{ S}^{-1}$  has been reported [374–376]. Other regioregular poly(3-alkylthiophene), such as poly(3-octylthiophene) and poly(3-dodecylthiophene) have also been used to fabricate the field-effect transistors [371].

More recently, mobilities in the range of  $10^{-2}$  to  $10^{-1} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  have been achieved using solution-processed, substituted oligothiophenes [377–379]. The mobility is found to strongly depend on film morphology, which can be controlled by the processing conditions. In one study,  $\alpha, \alpha'$ -dihexylhexathiophene (DH6T) and  $\alpha, \alpha'$ -dihexylquaterthiophene (DH4T) were dissolved in hot chlorobenzene or 1,2,4-trichlorobenzene, then solution-cast onto bottom-contact substrates. The solvent was evaporated

in a vacuum oven at temperatures between room temperature and  $100^\circ\text{C}$ . For DH6T films prepared in this way, the mobilities ranged from  $4 \times 10^{-3}$  to  $5 \times 10^{-2} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ , with the highest mobilities corresponding to trichlorobenzene and  $70^\circ\text{C}$  solvent evaporation. The mobilities of DH4T films ranged from  $1 \times 10^{-3}$  to  $7 \times 10^{-2} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ , slightly lower than those of DH6T films prepared under the same conditions [378]. In another study, additional solvents including 3-methylthiophene, anisole, and toluene were investigated. Chlorobenzene, 1,2,4-trichlorobenzene, and 3-methylthiophene all yielded smooth films and mobilities occasionally as high as  $0.1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  and routinely  $0.03 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  when the DH6T concentration was less than 0.1%. From a film of  $\alpha, \alpha'$ -dihexylquinquethiophene (DH5T) cast from chlorobenzene onto a  $50^\circ\text{C}$  substrate, the mobility of  $0.03 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  was obtained [379]. But a subsequent study reported a mobility of  $0.1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  from a DH5T film solution-cast from toluene [377].

Other soluble organic oligomers have also been investigated as semiconducting materials for OFETs. Anthradithiophene, a fused heterocycle compound similar to pentacene, is soluble in its dihexyl end-substituted form. Dihexylanthradithiophene (DHADT)-based transistors were fabricated by solution-casting from hot chlorobenzene, then evaporating the solvent in a vacuum oven at various temperatures. However, the electrical characteristics of the films were strongly dependent on the solvent evaporation temperature. The highest mobilities,  $0.01$  to  $0.02 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ , were obtained for a drying temperature of  $100^\circ\text{C}$  [379, 380]. In comparison, vacuum-evaporated films of DHADT gave mobilities as high as  $0.15 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  [380]. Organic FETs utilizing another thiophene-containing oligomer, trans-trans-2,5-bis-[2-{5-(2,2'-bithienyl)}ethenyl]thiophene (BTET), were fabricated by spin-coating from hot NMP. The mobility of such a device was  $1.4 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  compared to  $0.012 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for a vacuum-evaporated device [381].

Another approach to solution-processable oligomeric materials is to begin with a precursor molecule that is soluble but not semiconducting, and then convert it to its semiconducting, insoluble form. This approach has been realized for pentacene, with initial mobilities of  $0.01$  to  $0.03 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  reported [383–385]. The pentacene precursor is soluble in dichloromethane and forms continuous, amorphous films when spun onto transistor substrates. The conversion to pentacene is accomplished by heating the films to a temperature of  $140$ – $220^\circ\text{C}$  in a vacuum for several minutes to 2 hours. Tetrachlorobenzene is eliminated in the conversion process, and electron microscopy reveals microcrystallites in converted films. In a subsequent study, by treatment of the  $\text{SiO}_2$  substrate with HMDS prior to spin-coating the precursor and optimizing the conversion conditions, a mobility of  $0.2 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  was achieved [386].

The precursor approach can also be applied to polymers. In fact, one of the first reported polymer transistors with mobilities in the range of  $10^{-4}$  to  $10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  used precursor-route polyacetylene as the semiconducting layer [387, 388]. Recently, another polymeric semiconductor that has been processed from a soluble precursor polymer is polythiophenevinylene (PTV). In the study, a PTV film was spun from dimethylformamide and then coated with a layer of precursor poly(p-phenylene vinylene) (PPV). Both the

PTV and PPV were converted at 100–300 °C in a N<sub>2</sub> atmosphere, with the PPV precursor supplying protons to catalyze the PTV conversion. A mobility of  $6 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  was reported for a device prepared in this way [389]. Subsequent studies have spun the PTV precursor from chloroform and dichloromethane, and have converted the PTV at 140–160 °C in a N<sub>2</sub> atmosphere with a flow of HCl gas to catalyze the reaction [364, 383, 385]. Although the mobilities remain fairly low, one advantage of this processing approach is that organic solvents can be used in subsequent device-processing steps without disturbing the converted PTV [364].

Most polymer semiconductors, including the oligomers discussed above, are p-type semiconductors. As for the n-type semiconductor, the highest mobilities have been found with C<sub>60</sub>-based TFTs:  $0.08 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for the neat material, and a factor of 3–4 higher for devices grown on substrates pretreated with tetrakis(dimethylamino)ethylene [382]. However, a naphthalenetetracarboxylic diimide derivative with fluorinated R groups has been reported as a solution-processable, n-type organic semiconductor [377]. This compound is soluble in hot  $\alpha, \alpha, \alpha$ -trifluorotoluene. Solution-casting of this material results in morphologically nonuniform films, with some regions of the films giving mobilities greater than  $0.01 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ .

Because the field-effect mobility for the polymer TFT is relatively low and because of the large horizontal geometry of the transistors, the operating frequency of the circuits is only around 200 Hz at the working voltage of 3 V. Compared to the inorganic microelectronics, the performance and the integration level are still poor. If we can successfully fabricate the OTFTs with vertical device architecture instead of that with horizontal structure, the circuit bandwidth around several hundred MHz at the low working voltage could be expected as well as the high integration level.

### 8.3. OLEDs and Polymer Displays

OLEDs have three main advantages over its silicon counterpart: high contrast, high brightness, and low power consumption. And in addition, the OLED has fewer restrictions in terms of size. Organic light-emitting diodes were invented by Tang and Van Slyke [390], who found that p-type and n-type organic semiconductors could be combined to form diodes. This breakthrough initiated great efforts in the development of new molecular materials and device structures. In 1990, the researchers at Cambridge University, under the direction of Richard Friend, reported a similar light-emitting effect in a semiconducting organic polymer film consisting of PPV [391].

In recent years, not only polymer transistors and ICs obtain fast progress, but also polymer OLEDs and displays have impressive development. Major electronic firms such as Philips, Pioneer, Lucent Technologies, IBM, Dupont, Xerox, Mitsubishi, and Hitachi, and smaller companies such as Cambridge Display Technology (CDT), Universal Display, the Franco-German group Aventis, and UniAx, are currently working on the OLEDs and organic full-color displays. CDT Company, which was founded when luminous polymers were discovered at the University of Cambridge, owns the patent to the first luminous polymer, PPV. Cambridge Display Technology is working on flexible displays

based on poly LED and has shown a first prototype of a polymer display developed in cooperation with Seiko-Epson in 1998. In 1999, the color polymer display by ink-jet printing of emitting layers such as PPV and poly-fluorene (F8) was reported [251]. Here, control of the thickness and shape of the droplet, which eventually sets into a high-resolution pixel, remains an as-yet-unsolved problem. As the light-emitting polymer films are very thin, it is quite difficult to use the conventional photolithography technique to pattern them. In 2001, the University of Cambridge has made an agreement with Seiko-Epson and a regional Cambridge operation called Plastic Logic to manufacture full-color display from sophisticated polymers using ink-jet printing [392].

Since the late 1990s, OLEDs have entered the stage of commercialization. In November 1997, Pioneer Company in Japan commercialized a monochrome  $256 \times 64$  dot matrix OLED display for automotive applications [393]. After that, Pioneer Electronics has launched production of a car-stereo system that has an organic multicolor graphic display, while Philips is currently setting up a production line for polymer displays [394]. Organic EL was originally released by Pioneer with three models in 1999 and is now taken to the next level with the ability to download images directly to the face of the radio. Its OEL displays working at very low voltage requirements (<5 volts) have three models, including DEH-P9300, DEH-P6300, and DEH-P7300 [395]. Multi-color organic EL provides a very wide viewing angle, eliminates the need for backlighting, without loss of visibility from sunlight or a bright environment.

In September 2001, Lucent Bell Laboratories and E-Ink, a Cambridge, MA, Company, have developed a flexible electronic display prototype that is the world's first electronic paper [396, 397]. This prototype electronic paper display, holds its image when its power is shut off, so it only requires electric current when the screen changes. The display is made up of a flexible electronic circuit printed on a sheet of mylar and electronic ink made up of tiny capsules that hold white particles suspended in black dye. An electrical current moves the particles to the top or bottom of the capsules, changing the display's image. The display represents a significant scientific advance over previous works in plastic electronics and paper-like displays. The prototypes consist of a 25-square-inch display area made up of several hundred pixels. The transistors in these circuits are made of plastic materials and are fabricated with a low-cost printing process that uses high-resolution rubber stamps.

Recent advances in boosting the efficiency of OLED have also been made. By using guest-host organic material systems, where the radiative guest fluorescent or phosphorescent dye molecule is doped at a low concentration between 0.5 and 5% into the conducting host molecule, the efficiency can be increased to 10% or higher for phosphorescence or up to about 3% for fluorescence. Currently, the best efficiency of OLED has exceeded that of incandescent light bulbs. Efficiencies of 20 lumens per watt have been reported for yellow-green emitting polymer devices, and 40 lm/W attained for phosphorescent molecular OLEDs, compared to less than 20 lm/W for a typical incandescent lightbulb [390]. According to the report by Yu et al., the luminance efficiency of 3.3 lumens per watt has been reached for the red-light emitting of double-layer organic EL devices by doping the

emitting layer with the *N,N'*-bis[4-(*N,N*-dimethylamino)-benzylidene]diaminomaleonitrile (BAM) [398].

Vladimir Bulovic and co-workers at Princeton University demonstrated transparent OLEDs (or TOLEDs), which could be used in either transparent head-up or high-contrast displays [391]. But, developing reliable organic devices remains a challenge. Charge conduction requires very high electrical fields (1–5 MV/cm), so it is only the extreme thinness of OLEDs that enables them to operate at relatively low voltages. That thinness can contribute to rapid device degradation through the generation and subsequent growth of dark spots. The problem is especially acute when the devices are exposed to the atmosphere. Organic displays work reliable only when their constituent organic materials are stable. One use means to extend the lifetime of the devices by using organic phosphors. The key point of this approach is to reduce the amount of time a light-emitting molecule remains in the excited state. Through use phosphor emitters, OLEDs have the potential to achieve operational lifetimes of many hundreds of thousands of hours, easily meeting the demands on display performance. The ultimate goal of using high-efficiency, phosphorescent, flexible OLED displays in the cell phones, personal digital assistants, laptop computers, and even for home video applications may be realized no more than in a few years. However, there are still some challenges to be met, such as achieving higher efficiencies, lower power consumption, and longer device lifetime.

Princeton University developed a micro-patterning technique of organic electronic devices by the process of cold-welding of metal cathodes followed by lift-off from the organic substrate [399]. They fabricated a  $17 \times 17$  passive matrix display, with a pixel size of  $440 \mu\text{m}$  by  $320 \mu\text{m}$ .

There have been tremendous advances in polymer microelectronics and optoelectronics during the last decade. Such achievement will have huge impacts on the future of polymer microelectronics in various applications like information technology. Some kinds of polymer-integrated circuits and field-effect transistors with high mobilities have already been fabricated. The performance can even compete with the amorphous silicon device in some cases. Polymer semiconductors, such as pentacene, deposited by vacuum sublimation, have the best performances because of their very well-ordered structures. However, great improvements made in solution-processable organic semiconductors, with their mobilities only one order of magnitude lower than those of vapor-deposited TFTs, result in even lower process technologies, such as the stamping, ink-jet printing, and self-assembling without the lithography and vacuum facilities. Using the organic LEDs with high efficiencies, full color displays may eventually replace LCDs for use in laptops, PDAs, and even home video displays. Although the chemistry and physics behind the polymer or plastics are not well understood, science is close to creating a next-generation chip that can help the digital revolution mature. More and more polymer microelectronic and optoelectronic devices may enter the stage of commercialization. However, there is still much to be done for the commercialization of polymer or organic electronic devices in the market. Higher operation frequency, a higher integrated level, higher device performance, a lower power consumption, a longer device lifetime, and performance stability are all challenges to us.

Nano self-assembly and other nanofabrication techniques could be approaches in resolving the above problem and can lead to the commercialization of polymer microelectronics/optoelectronics.

## 9. POTENTIAL APPLICATIONS OF NANO SELF-ASSEMBLY

### 9.1. Current Applications

- Biocompatible coverage of eye lenses and implants.
- Precise dye casting on optical elements (film thickness 50–200 nm,  $\pm 5$  nm).
- Increase of bioreactor efficiency by deposition of enzyme/polyion multilayers.
- Formation of polyion capsules for drug delivery.

### 9.2. Potential Applications

#### 9.2.1. Surface Modifications

- Surface wettability, hardness, magnetic properties, lubrication, biocompatibility can be modified by self-assembly of ultrathin nanostructured coating (e.g., plastic hardening by coating with  $\text{Al}_2\text{O}_3$  or  $\text{ZrO}_2$  nanoparticle multilayer; precise  $\lambda/4$  dye-coating of lenses and optical fibers, and other antireflection coating, paper processing). In biomaterials the assembly is applicable directly to tissue surfaces.
- The concept of a “smart” surface may be realized by including functional proteins in biocompatible films (e.g., lipases destroying harmful lipids in contact with biological liquids).
- Filter layer with calibrated nano-pores.
- Nanoparticle catalytic multilayers.

#### 9.2.2. Sensor Layers and Bioreactors

The protein films can be made very thin and contain precisely 1, 2, 3, 4, 5, or more monolayers, which is important for biosensor elements. The deposition of enzyme/polyion multilayers onto carriers of biological reactors permits an increase in their output proportionate to the number of immobilized enzyme layers. Sequential 2–3 step catalytic reactions can be realized in multiprotein films (cascade bioreactions). Enzymes in the polyion films are stabilized and could work with nonaqueous substrate solutions. Polyions, which keep together enzyme layers in the films, can be doped by vitamins (co-factors), specific dyes, or nanoparticles of metal catalysts to mediate reaction activity.

#### 9.2.3. Nanoreactors

Construction of tiny catalytic units containing ordered multilayer shells of enzymes, nanoparticles and polymers.

#### 9.2.4. Electronics

- Conductive thin films. Electrical conductivity of up to 200 S/cm in 50-nm thick polypyrrole/poly(styrenesulfonate) film was achieved.

- Light emitting diodes and display devices of large area and low operating voltage. Light emitting diodes based on multilayer heterostructure of alternate poly(phenylene vinylene) and sulfonated polyaniline were made.
- Electrodes for lithium storage batteries based on graphite nanoplate/polycation multilayers.
- Magnetic nanoparticle mono- and multilayers, including formation of magnetic/dielectric superlattices and soft/hard magnet nanocomposites.
- Optical second harmonic generation layers.

## 10. CONCLUSIONS

- (1) Nano self-assembly has been described as an approach to design organized films that contain different polymer, protein, dye, and nanoparticle monolayers in precise locations perpendicular to the surface. The films are amorphous in plane but organized in the third direction with a precision of a few nanometers. Surfaces, porous carriers, and fibers of any dimension, curvature, or complexity may be covered by the self-assembled films. A layer-by-layer assembly is an easy and general fabrication process. It does not demand a high purity of components. It can be automated and scaled-up for mass production.
- (2) Soft lithography and conventional lithography are two approaches to realize the patterning of self-assembled thin films for device fabrication. The combination of conventional lithography and nano self-assembly has higher precision and reproducibility than soft lithography. Since layer-by-layer self-assembly and lithography techniques are mature processes and lithography is widely applied to the modern semiconductor industry, a combinative technique will be economical and suitable for mass production. By just following the traditional process, the nanostructures comprised of nano building blocks can be realized. As it reacts in semiconductor industry, the process results in such a high reproducibility that distinct patterns can be created in almost all chips on the wafer.
- (3) Polymer microelectronics/optoelectronics is an emerging field of research and development with huge potential commercialization market. Nano self-assembly and other nanofabrication techniques will open new approaches to nanoelectronics. Nano self-assembly will be one of the dominant techniques in realizing commercial polymer microelectronics/optoelectronics with high efficiency and low cost. Thus, polymer microelectronics/optoelectronics could be the revolution of solid-state microelectronics in low-end applications.

## GLOSSARY

**Bottom-up** It starts with atoms, molecules and nanoparticle to build up nanostructures with dimensions between 2 and 10 nanometers- and do so inexpensively.

**Carbon nanotube** The structure of the buckball comprised of 60 carbon atoms arranged by 20 hexagonal and 12 pentagonal faces to form a sphere, when the buckyball is elongated

to form a long and narrow tube with a diameter of approximately 1 nm, which is the basic form of a carbon nanotube.

**Conjugated polymers** Conjugated polymers are polyunsaturated compounds in which all backbone atoms are sp- or sp<sup>2</sup>-hybridized. Conjugated polymers are -in their pristine, neutral state- either insulators or wide-gap semiconductors, and some of them turn into metallic type conductors only after a process called doping.

**Lift-off** This patterning approach is called by us “lift-off” since lift-off acts as a critical step in the process. At the beginning, photoresist is spun on silicon wafer and got patterned. Then nanoparticles are deposited with layer-by-layer assembly on the whole wafer. Eventually, the wafer is put into acetone solution to dissolve resist and particles self-assembled on it are removed, too.

**Metal mask method** This patterning approach is called “metal mask”. At first, a layer of nanoparticles are adsorbed onto silicon wafer. Then a layer of aluminum and resist are deposited and coated on top of nanoparticle layer. Patterns are made on resist by UV lithography and transferred to aluminum layer by etching aluminum. As a result, nanoparticles previously covered under aluminum begins to be open to the air. Then it is etched by oxygen plasma and nanoparticles are removed in compliance with the designed patterns. During the etching process, metal acts as the mask over the nanoparticles. After remained aluminum and resist are dissolved, only the desired pattern is left on the substrate.

**Microcontact printing ( $\mu$ CP)** Microcontact printing is a flexible, non-photolithographic method that routinely forms patterned SAMs containing regions terminated by different chemical functionalities with submicron lateral dimensions.

**Microemulsions** Microemulsions are thermodynamically stable systems (usually in the size range of 5–50 nm).

**Nano self-assembly** A layer-by-layer (LbL) assembly of alternating layers of oppositely charged polyelectrolytes and nanoparticles provides the formation of 5–500 nm thick films with monolayers of various substances growing in a preset sequence on any substrates at a growth step of about 1 nm. This technique was called “molecular beaker epitaxy” meaning by this that with simple instruments (exploiting the materials self-assembly tendency) one can get molecularly organized films similar to the ones obtained with highly sophisticated and expensive molecular beam epitaxy technology for metals and semiconductors.

**PBG crystal (or photonic crystal)** A PBG crystal (or photonic crystal) is a spatially periodic structure fabricated from materials having different dielectric material constants [246]. It can influence the propagation of electromagnetic waves in a similar way as a semiconductor does for electrons.

**Poly(dimethylsiloxane) (PDMS) elastomers (or silicone rubbers)** Used in most demonstrations. Poly(dimethylsiloxanes) have a unique combination of properties resulting from the presence of an inorganic siloxane backbone and organic methyl groups attached to silicon. These liquid materials can be poured over a master having a relief structure on its surface, then easily converted into solid elastomer by curing and peeling off PDM.

**Spin assembly** Spin-assembly is a specialized application of spin coating, in which a polyelectrolyte multilayered thin film is self-assembled onto a spinning substrate.

**Top-down** Top-down lithography, they begin with pattern generated on a larger scale and reduce its lateral dimensions.

## ACKNOWLEDGMENT

We are thankful for NSF-LEQSF 0092001 and NSF-0210298 grants supporting this work. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the view of the National Science Foundation.

## 1. INTRODUCTION

Biology has entered a new era with the recent advances in nanotechnology, which have recently led to the development of biosensor devices having nanoscale dimensions that are capable of probing the inner space of single living cells. Nanosensors provide new and powerful tools for monitoring *in vivo* processes within living cells, leading to new information on the inner workings of the entire cell. Such a systems biology approach could greatly improve our understanding of cellular function, thereby revolutionizing cell biology. Fiber-optic sensors provide useful tools for remote *in-situ* monitoring. Fiber-optic sensors can be fabricated to have extremely small sizes, which makes them suitable for sensing intracellular/intercellular physiological and biological parameters in microenvironments. A wide variety of fiber-optic chemical sensors and biosensors have been developed in our laboratory for environmental and biochemical monitoring [1–8]. Submicron fibers have been developed for use in near-field optics [9, 10]. Tapered fibers with submicron tip diameters have also been developed for near-field scanning optical microscopy (NSOM). NSOM was used to achieve subwavelength 100 nm spatial resolution in Raman detection [11–13]. Tan and co-workers developed and used chemical nanosensors to perform measurements of calcium and nitric oxide, among other physicochemicals in single cells [14, 15]. Vo-Dinh and co-workers

developed nanobiosensors with antibody probes to detect biochemical targets inside living single cells [16–23]. This chapter presents an overview of the principle, development, and applications of fiber-optic nanosensors.

## 2. NEAR-FIELD OPTICS AND NANOFIBERS

Nanoscale optical fibers were first developed for use in near-field optical microscopy, which is a relatively recent technique involving light sources or detectors that are smaller than the wavelength of light [9]. The first method developed for performing these experiments was to place a pinhole in front of the detector, thus effectively reducing the detector size. In a later variation to these pinholes, an excitation probe with dimensions smaller than the wavelength of the light was used for sample interrogation. Betzig and Chichester reported the development of one such probe capable of obtaining measurements with a spatial resolution of approximately 12 nm [10]. The probe was constructed by using a micropipet puller to pull a single-mode optical fiber to a tip diameter of 20 nm, and then coating the walls of the fiber with 100 nm of aluminum to confine the excitation radiation to the tip. With this nanoprobe, images of a pattern were reconstructed from a raster scan performed in the illumination mode, with the probe acting as a localized light source.

Due to its extremely high spatial resolution (subwavelength), near-field microscopy has received great interest, and has been used in many applications [9]. For example, a relatively new technique known as near-field surface-enhanced Raman spectroscopy (NF-SERS) has been used for the measurement of single-dye and dye-labeled DNA molecules with a resolution of 100 nm [11–13]. In this work, DNA strands labeled with the dye brilliant cresyl blue (BCB) were spotted onto a SERS-active substrate that was prepared by the evaporation of silver on a nanoparticle-coated substrate. The silver-coated nanostructured substrates are capable of inducing the SERS effect, which can enhance the Raman signal of the adsorbate molecules up to  $10^8$  times [24]. NF-SERS spectra were collected by illuminating the sample using the nanoprobe, and detecting the SERS signals

using a spectrometer equipped with a charge-coupled device (CCD). Raster scanning the fiber probe over the sample and normalizing for surface topography using Rayleigh-scattered light produced a two-dimensional SERS image of the DNA on the surface of the substrate with subwavelength spatial resolution. Near-field optical microscopy promises to be an area of growing research that could potentially provide an imaging tool for monitoring individual cells, and even biological molecules. Single-molecule detection and imaging schemes using nanofibers could open new possibilities in the investigation of the complex biochemical reactions and pathways in biological and cellular systems.

### 3. BIOSENSORS

#### 3.1. Biosensor Principle

A biosensor is generally defined as a measurement system that consists of a probe with a biological recognition element, often called a bioreceptor, and a transducer [3, 18, 22]. Two fundamental operating principles of a biosensor are: (1) “biological recognition,” and (2) “sensing.” Therefore, a biosensor can be generally defined as a device that consists of two basic components connected in series: (1) a biological recognition system, often called a bioreceptor, and (2) a transducer. The basic principle of a biosensor is to detect this molecular recognition, and to transform it into another type of signal using a transducer. The main purpose of the recognition system is to provide the sensor with a high degree of selectivity for the analyte to be measured. The interaction of the analyte with the bioreceptor is designed to produce an effect measured by the transducer, which converts the information into a measurable effect, such as an electrical signal.

Biosensors can be classified based on the transduction methods they employ. Transduction can be accomplished through a large variety of methods. Most forms of transduction can be categorized in one of three main classes: (1) optical detection methods, (2) electrochemical detection methods, and (3) mass-based detection methods. Other detection methods include voltaic and magnetic methods. New types of transducers are constantly being developed for use in biosensors. Each of these three main classes contains many different subclasses, creating a large number of possible transduction methods or combinations of methods. Special emphasis will be placed on the description of optical transducing principles, which is the focus of this chapter. Figure 1 illustrates the conceptual principle of the biosensing process using an antibody as the bioreceptor probe and fluorescence as the detection method.

#### 3.2. Bioreceptors

Bioreceptors are the key to specificity for biosensor technologies. They are responsible for binding the analyte of interest to the sensor for the measurement. These bioreceptors can take many forms, and the different bioreceptors that have been used are as numerous as the different analytes that have been monitored using biosensors. However, bioreceptors can generally be classified into five different major categories: (1) antibody/antigen, (2) enzymes, (3) nucleic

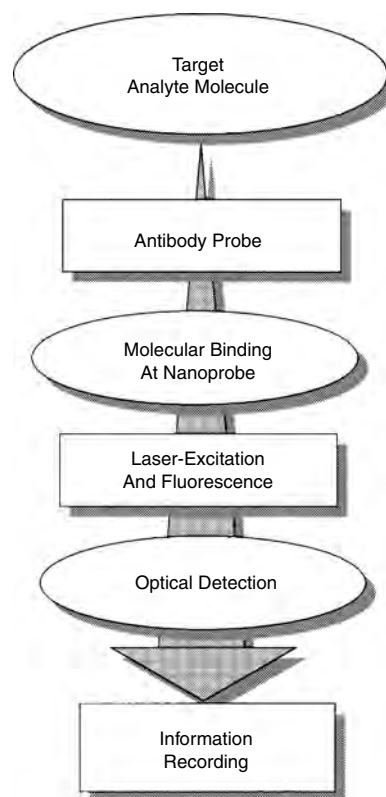

Figure 1. Operating principle of biosensor systems.

acids/DNA, (4) cellular structures/cells, and (5) biomimetic. This chapter deals with biosensor systems using antibody probes, often called immunosensors, with optical detection.

The antigen–antibody (Ag–Ab) binding reaction, which is a key mechanism by which the immune system detects and eliminates foreign matter, provides the basis for specificity of immunoassays. Antibodies are complex biomolecules, made up of hundreds of individual amino acids arranged in a highly ordered sequence. Antibodies are produced by immune system cells when such cells are exposed to substances or molecules, which are called antigens. The antibodies appearing following antigen exposure have recognition/binding sites for specific molecular structures (or substructures) of the antigen. The way in which an antigen and an antigen-specific antibody interact is analogous to a lock and key fit, in which specific configurations of a unique key enable it to open a lock. In the same way, an antigen-specific antibody fits its unique antigen in a highly specific manner, so that the three-dimensional structures of antigen and antibody molecules are complementary. Due to this three-dimensional shape fitting, and the diversity inherent in individual antibody make up, it is possible to find an antibody that can recognize and bind to any one of a large variety of molecular shapes. This unique property of antibodies is the key to their usefulness in immunosensors; this ability to recognize molecular structures allows one to develop antibodies that bind specifically to chemicals, biomolecules, microorganism components, and so on. One can then use such antibodies as specific probes to recognize and bind to an analyte of interest that is present, even in extremely small amounts, within a large number of other chemical substances.

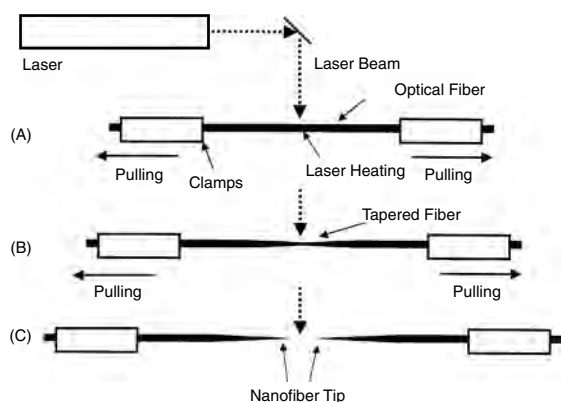

In the 1980s, advances in spectrochemical instrumentation, laser miniaturization, biotechnology, and fiber-optics research provided opportunities for novel approaches to the development of sensors for the detection of chemicals and biological materials of environmental and biomedical interest. Since the first development of a remote fiber-optics immunosensor for *in-situ* detection of the chemical carcinogen benzo[a]pyrene [1], antibodies have become common bioreceptors used in biosensors today.

## 4. NANOSENSOR FABRICATION

### 4.1. Fabrication of Nanofiber Probes

This section discusses the protocols and instrumental systems involved in the fabrication of fiber-optic nanoprobes. Two methods are generally used for preparing the nanofiber tips. The so-called “heat-and-pull” method is the most commonly used. This method consists of local heating of a glass fiber using a laser or a filament, and subsequently pulling the fiber apart. The shape of the nanofiber tips obtained depends on controllable experimental parameters such as the temperature and the timing of the procedure. The second method, often referred to as “Turner’s method,” involves the chemical etching of glass fibers. In a variation of the standard etching scheme, the taper is formed inside the polymer cladding of the glass fibers. The description of these fabrication methods is given in the following section.

The fabrication of nanosensors requires techniques capable of making reproducible optical fibers with a submicron-size diameter core. Figure 2 illustrates the experimental procedures for the fabrication of nanofibers using the heat-and-pull procedure [21]. Since these nanoprobes are not commercially available, investigators have to fabricate them in their own laboratories. Our laboratory uses the heat-and-pull procedure, which consists of pulling a larger silica optical fiber to produce the tapered nanotip fiber using a special fiber-pulling device (Sutter Instruments P-2000). This method yields fibers with submicron diameters. One end of a 600  $\mu\text{m}$  silica/silica fiber is polished to a 0.3  $\mu\text{m}$  finish with an Ultratec fiber polisher. The other end of the optical fiber is then pulled to a submicron length using a fiber puller. A scanning electron microscopy (SEM) photograph of one of the

**Figure 2.** The “heat-and-pull” method for the fabrication of nanofibers.

fiber probes fabricated for studies is shown in Figure 3. The distal end of the nanofiber is approximately 30 nm.

To prevent light leakage of the excitation light on the tapered side of the fiber, the sidewall of the tapered end is then coated with a thin layer of metal, such as silver, aluminum, or gold (100 nm thickness) using a thermal evaporation metal coating device. The coating procedure is schematically illustrated in Figure 4 [21]. The metal coating is only for the sidewall, and leaves the distal end of the fiber free for subsequent binding with bioreceptors. The fiber probe is attached on a rotating plate inside a thermal evaporation chamber [3, 19, 21]. The fiber axis and the evaporation direction formed an angle of approximately 45°. While the probe is rotated, the metal is allowed to evaporate onto the tapered side of the fiber tip to form a thin coating. The tapered end is coated with 300–400 nm of silver in a Cooke Vacuum Evaporator system using a thermal source at  $10^{-6}$  torr. Since the fiber tip is pointed away from the metal source, it remains free from any metal coating. With the metal coating, the size of the probe tip is approximately 250–300 nm (Fig. 5).

Chemical etching using HF is the basis of the second method for fabricating optical nanofibers. There are two variations of the HF etching method: one method involving the use of a mixture of HF acid and organic solvent, known as Turner etching [25], and the second using only HF, known as tube etching [26–28]. In the Turner method, a fiber is placed in the meniscus between the HF and the organic overlayer, and over time, a small tip is formed, with a smooth, large-angled taper. This large taper angle provides much more light at the tip of the fiber, which in turn greatly increases the sensitivity of the nanosensors. The reproducibility of the Turner method is strongly affected by environmental parameters such as temperature and vibration because of the dual chemical nature of the etching process. To avoid this problem, a variation of the etching method was developed, which involves a tube-etching procedure. In this procedure, an optical fiber with a silica core and an organic cladding material is paced in an HF solution. The HF slowly dissolves the silica core, producing a fiber with a large taper angle and nanometer-sized tip. The HF begins first to dissolve the fiber’s silica core, while not affecting

**Figure 3.** Scanning electron photograph of an uncoated nanofiber. The size of the fiber tip diameter is approximately 40 nm.

**Figure 4.** Procedure for coating a fiber with silver. (A) Uncoated fiber tip. (B) Fiber coating using metal evaporation over the rotating tip. (C) Coated fiber. Adapted from [21], T. Vo-Dinh et al., *Nature Biotechnol.* 18, 76 (2000). © 2000, Nature Publishing Group.

the organic cladding material. This unaffected cladding creates localized convective currents in the HF solution, which causes a tip to be formed. After some time, more of the silica core is dissolved, until it emerges above the surface of the HF solution. At this juncture, the HF is drawn up the cladding walls via capillary action, and runs down the silica core to produce a nanometer-sized tip. By varying the time of HF exposure and the depth to which the fiber is submerged in the HF solution, one can control the size of the fiber tip and the angle of the taper. Once the tip has been formed, the protruding cladding can be removed either with a suitable organic solvent or by simply burning it off. Nanotips fabricated using etching procedures, which can be designed to have sharp tips [13], have been used in NSOM studies to detect SERS-labeled DNA molecules on solid substrates at the subwavelength spatial resolution [11–13].

## 4.2. Antibody Immobilization

The next step in the preparation of the nanobiosensor probes involves the covalent immobilization of receptors onto the nanofiber tip. For antibody binding, several strategies can be used to retain the antibody at the sensing probe.

**Figure 5.** Scanning electron photograph of a nanofiber having the sidewall coated with silver.

Whatever procedure is involved, one requirement is that the antibody should retain its antigen-binding activity as much as possible. Perhaps the easiest procedure involves enclosure of the antibody in solution, within a semipermeable membrane cap, which fits over the end of the sensor [2]. However, this design is more complicated, and would increase the size of the tip of the nanosensor.

Antibodies can be immobilized onto the nanofiber probes by using a chemical immobilization method. The fiber is derivatized in 10% GOPS in H<sub>2</sub>O (v/v) at 90 °C for 3 h. The pH of the mixture is maintained below 3 with concentrated HCl (1 M). After derivatization, the fiber is washed in ethanol, and dried overnight in a vacuum oven at 105 °C. The fiber is then coated with silver as described previously. The derivatized fiber is activated in a solution of 100 mg/mL 1,1'-carbonyldiimidazole (CDI) in acetonitrile for 20 min, followed by rinsing with acetonitrile and then phosphate-buffered saline (PBS). The fiber tip is then incubated in a 1.2 mg/mL antibody solution (PBS solvent) for four days at 4 °C, and then stored overnight in PBS to hydrolyze any unreacted sites. The fibers are then stored at 4 °C, with the antibody-immobilized tips stored in PBS. This procedure has been shown to maintain over 95% antibody activity [21].

## 5. EXPERIMENTAL PROTOCOL AND INSTRUMENTAL SYSTEM

### 5.1. Experimental Procedure

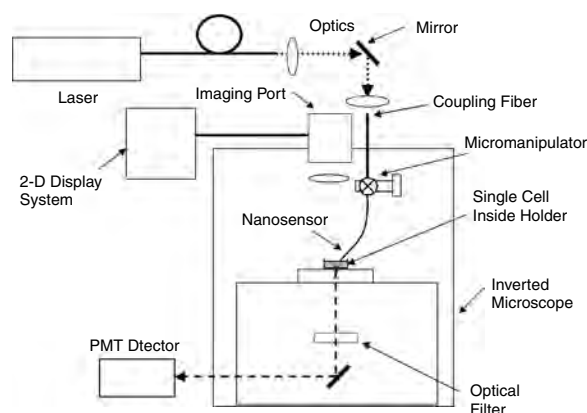

An application that is truly unique to nanosensors involves monitoring living single cells *in vivo* [18–23]. Examples of this application in molecular biology will be discussed later. This section provides a description of the procedures for growing cell cultures for analysis using the nanosensors. Cell cultures were grown in a water-jacketed cell culture incubator at 37 °C in an atmosphere of 5% CO<sub>2</sub> in air. Clone 9 cells, a rat liver epithelial cell line, were grown in Ham's F-12 medium (Gibco), supplemented with 10% fetal bovine serum and an additional 1 mM glutamine (Gibco). In preparation for an experiment,  $1 \times 10^5$  cells in 5 mL of medium were seeded into standard dishes (Corning Costar Corporation). The growth of the cells was monitored daily by microscopic observation, and when the cells reached a state of confluence of 50–60%, the analyte solution was added and left in contact with the cells for 18 h (i.e., overnight). This procedure is designed to incubate the cells with the analyte molecules for subsequent monitoring using the nanosensors. The growth conditions were chosen so that the cells would be in log-phase growth during the chemical treatment, but would not be so close to confluence that a confluent monolayer would form by the termination of the chemical exposure. The analyte solution was prepared as a 1 mM stock solution in reagent grade methanol, and further diluted in reagent grade ethanol (95%) prior to addition to the cells. Following chemical treatment, the medium containing the analyte was aspirated and replaced with standard growth medium, prior to the nanoprobe procedure.

Monitoring target analyte molecules in single cells was then performed using antibody nanoprobe in the following way. A culture dish of cells was placed on the prewarmed microscope stage, and the nanoprobe, mounted on the

micropipette holder, was moved into position (i.e., in the same plane of the cells), using bright field microscopic illumination, so that the tip was outside the cell to be probed. The total magnification was usually 400 $\times$ . Under no room light and no microscope illumination, the laser shutter was opened to illuminate the optical fiber for excitation of the analyte molecules bound on the antibodies at the fiber tip. Usually, if the silver coating on the nanoprobe was appropriate, no light leaked out of the sidewall of the tapered fiber. Only a faint glow of laser excitation at the tip could be observed on the nanoprobe. A reading was first taken with the nanoprobe outside the cell and the laser shutter closed. The nanoprobe was then moved into the cell, inside the cell membrane, and extending into the cellular compartments of interest. The laser was again opened, and readings were then taken and recorded as a function of time during which the nanoprobe was inside the cell.

## 5.2. Instrumentation

The optical measurement system used for monitoring single cells using the nanosensors is schematically illustrated in Figure 6 [18–23]. Laser excitation light, either the 325 nm line of an HeCd laser (Omnichrome, 8 mW laser power) or the 488 nm line of an argon ion laser (Coherent, 10 mW), was focused onto a 600  $\mu\text{m}$  delivery fiber, which was connected to the nanofiber through an SMA connector. The nanofiber was secured to a micromanipulator on the microscope. The experimental setup used to probe single cells was adapted for this purpose from a standard micromanipulation/microinjection apparatus. A Nikon Diaphot 300 inverted microscope (Nikon, Inc.) with a Diaphot 300/Diaphot 200 Incubator, to maintain the cell cultures at  $\sim 37^\circ\text{C}$  on the microscope stage, was used for these experiments. The micromanipulation equipment used consisted of MN-2 (Narishige Company, Ltd.) Narishige three-dimensional manipulators for coarse adjustment, and Narishige MMW-23 three-dimensional hydraulic micromanipulators for final movements. The optical-fiber nanoprobe was mounted on a micropipette holder (World Precision Instruments, Inc.). The fluorescence emitted from the cells was collected by the microscope objective, and passed through an appropriate long-pass dichroic mirror to

**Figure 6.** Instrumental system for fluorescence measurements of single cells using nanosensors.

eliminate the laser excitation scatter light. The fluorescence beam was then focused onto a photomultiplier tube (PMT) for detection. The output from the PMT was passed through a picoammeter, and recorded on a strip-chart recorder or a personal computer (PC) for further data treatment. To record the fluorescence of analyte molecules binding to antibodies at the fiber tip, a Hamamatsu PMT detector assembly (HC125-2) was mounted in the front port of the Diaphot 300 microscope, and fluorescence was collected via this optical path (80% of available light at the focal plane can be collected through the front port). A charge-coupled device mounted onto another port of the microscope could be used to record images of the nanosensor monitoring single cells.

## 6. APPLICATIONS

### 6.1. Nanofiber Probes for Intracellular Fluorescence Measurements

Optical nanofiber probes without antibody probes have been fabricated and used to monitor fluorescence emission from chemical species inside living single cells [17]. In this study, mouse epithelial cells were incubated with a fluorescent dye by incubating the cells in the dye solution and allowing membrane permeabilization to take place. Another procedure for loading cells with fluorophors involved the method called “scrape loading.” In the scrape loading procedure, a portion of the cell monolayer was removed by mechanical means, and cells along the boundary of this “scrape” were transiently permeabilized, allowing the dye to enter these cells. The dye was subsequently washed away, and only permeabilized cells retained the dye molecules, as they were not internalized by cells with intact membranes. Following incubation, the fluorescence signal of fluorescent dye molecules in single cells was detected using the optical nanofibers. A photograph of a nanosensor used to monitor clone 9 single cells is shown in Figure 7. Micromanipulators were used to move the optical fiber into contact with the cell membrane of a cell to be monitored. The fiber tip was then gently inserted just inside the cell membrane for fluorescence measurements. An argon-ion laser beam was transmitted through the optical nanofiber, and used for excitation. The dye molecules inside the cell were excited,

**Figure 7.** Photograph of single-cell sensing using a fiber-optic nanosensor.

and their fluorescence emission was collected and detected using the microscope instrumental system described previously. Background measurements were performed with cells that were not loaded with the fluorophores. Fluorescence signals were successfully detected inside the fluorophore-loaded cells, and not inside nonloaded cells. As another control, the optical-fiber probe was then moved to an area of the specimen where there were no cells, and the laser light was again passed down the fiber for excitation. No visible fluorescence (at the emission wavelength) was detected for this control measurement, thus demonstrating the successful detection of the fluorescent dye molecules inside single cells. These results demonstrated the capability of optical nanofibers for measurements of fluorophores in intracellular environments of single living cells.

## 6.2. Nanobiosensors for Monitoring Subcompartments of Single Cells

Nanosensors having antibody-based probes for use in measuring fluorescent targets inside a single cell have been demonstrated [18–23]. Since cells have very small sizes (1–10  $\mu\text{m}$ ), the success of intracellular investigations depends on several factors, including the sensitivity of the measurement system, the selectivity of the probe, and the small size of the nanofiber probes. The smallest cells to be nondestructively probed with a fiber-optic nanobiosensor were reported by Vo-Dinh and co-workers [21]. In that work, the antibody probe was targeted against benzopyrene tetrol (BPT), an important biological compound, which was used as a biomarker of human exposure to the carcinogen benzo[a]pyrene (BaP), a polycyclic aromatic hydrocarbon of great environmental and toxicological interest because of its mutagenic/carcinogenic properties and its ubiquitous presence in the environment. Benzo[a]pyrene has been identified as a chemical carcinogen in laboratory animal studies [29]. The small size of the probe allowed manipulation of the nanosensor at specific locations within the cells. The cells were first incubated with BPT prior to measurements using the experimental procedures described previously. Interrogation of single cells for the presence of BPT was then carried out using antibody nanoprobe for excitation and a photometric system for fluorescence signal detection.

Nanobiosensors for BPT were used for the measurement of intracellular concentrations of BPT in the cytoplasm of two different cell lines: (1) human mammary carcinoma cells, and (2) rat liver epithelial cells, following treatment of the culturing media with an excess of BPT. Figure 8 shows a digital image of the nanosensor actually being inserted into a single human mammary carcinoma cell. The measurements were performed on rat liver epithelial cells (Clone 9) used as the model cell system. The cells had been previously incubated with BPT molecules prior to measurements. The results demonstrated the possibility of *in-situ* measurements of BPT inside a single cell.

In this study, the nanosensors employed single-use bioprobes because the probes were used to obtain only one measurement at a specific time, and could not be reused due to the strong association constant of the antibody–antigen binding process. The antibody probes, however, could be regenerated using ultrasound methods. Our laboratory has

**Figure 8.** Digital image of a nanosensor inserted into a single human mammary carcinoma cell (the small size of the probe allowed manipulation of the nanoprobe at specific locations within a single cell).

successfully developed a method using ultrasound to non-invasively release antigen molecules from the antibodies, and therefore to regenerate antibody-based biosensors [30]. The results of the measurements with antibody against breast cancer antigen illustrate the effectiveness and potential of the regenerable immunosensor. A 65% removal of the antigens bound to the monoclonal antibodies immobilized on the fiber surface is attained after ultrasound regeneration. The ultrasound regeneration scheme is a non-destructive approach that has a great potential to be applied to nanosensors. The results demonstrate the effectiveness of this innovative ultrasound-based approach for biosensor regeneration, that is, releasing the antigen from the antibody probe.

Multiple (e.g., five) recordings of the fluorescence signals could be taken with each measurement using a specific nanoprobe. We have made a series of calibration measurements of solutions containing different BPT concentrations in order to obtain a quantitative estimation of the amount of BPT molecules detected. For these calibration measurements, the fibers were placed in petri dishes containing solutions of BPT with concentrations ranging from  $1.56 \times 10^{-10}$  to  $1.56 \times 10^{-8}$  M. By plotting the increase in fluorescence from one concentration to the next versus the concentration of BPT, and fitting these data with an exponential function in order to simulate a saturated condition, a concentration of  $(9.6 \pm 0.2) \times 10^{11}$  M was determined for BPT in the individual cell investigated [23].

Detection of BaP transport inside single cells is of great biomedical interest since it can serve as a means for monitoring BaP exposure, which can lead to DNA damage [29]. In another study, nanosensors were developed for *in-situ* measurements of the carcinogen BaP [31]. In order to perform these measurements, it was necessary to use antibodies targeted to BaP. The fluorescent BaP molecules were bound by interaction with the immobilized antibody receptor, forming a receptor–ligand complex. Following laser excitation of this complex, a fluorescence response from BaP provided a basis for the quantification of BaP concentration in the cell being monitored. The fluorescence signal generated allows for a high sensitivity of detection. The intracellular measurements of BaP depend on the reaction times involved. The reaction time established in this study for antibody–BaP complexing was 5 min. This was used as a standard

time to enable calibration from fiber to fiber. Additionally, the nanosensors were calibrated using standard analytical procedures using measurements of known concentration of reference solutions.

## 7. CONCLUSION

Dynamic information of signaling processes inside living cells is important to a fundamental biological understanding of cellular processes. Many traditional microscopy techniques involve incubation of cells with fluorescent dyes or nanoparticles, and examining the interaction of these dyes with compounds of interest. However, when a dye or nanoparticle is incubated into a cell, it is transported to certain intracellular sites that may or may not be where it is most likely to stay, and not to areas where the investigator would like to monitor. The fluorescence signals which are supposed to reflect the interaction of the dyes with chemicals of interest is generally directly related to the dye concentration as opposed to the analyte concentration. Only with optical nanosensors can excitation light be delivered to specific locations inside cells. An important feature of nanosensors is the minimal invasiveness of the monitoring process. A cell survival study was previously performed whereby an investigation was made to determine whether penetration of the cell by the nanosensor resulted in intracellular or membrane damage of such a nature as to compromise cellular viability. It was determined that the process of mitosis continued normally, and that nanosensor insertion and withdrawal did not affect the life cycle of the cell. Nanosensors are an important technology that can be used to measure biotargets in a living cell, and that does not significantly affect cell viability. Combined with the exquisite molecular recognition of antibody probes, nanosensors could serve as powerful tools capable of exploring biomolecular processes in subcompartments of living cells. They have a great potential to provide the necessary tools to investigate multiprotein molecular machines of complex living systems, and the complex network that controls the assembly and operation of these machines in a living cell. Future developments would lead to the development of nanosensors equipped with nanotool sets that enable tracking, assembly, and disassembly of multiprotein molecular machines and their individual components. These nanosensors would have multifunctional probes (antibody as well as DNA probes) that could measure the structure of biological components in single cells. Until now, scientists have been limited to investigating the workings of individual genes and proteins by breaking the cell apart and studying its individual components *in vitro*. The advent of nanosensors will hopefully permit research on entire networks of genes and proteins in an entire living cell *in vivo*.

## GLOSSARY

**Bioreceptor** A biological recognition element, such as antibody, DNA, enzyme, etc., used to bind selectively to a target analyte compound.

**Biosensor** A measurement system that consists of a probe with a bioreceptor, and a transducer.

**Nanobiosensor** Biosensor having nanoscale-dimension probe.

**Near-field scanning optical microscopy (NSOM)** Microscopy technique using scanning probe providing sub-wavelength spatial resolution.

**Surface-enhanced Raman scattering (SERS)** Enhanced Raman scattering of compounds adsorbed on nanostructures metallic materials.

## 1. INTRODUCTION

Nanostructures have unique properties due to the quantum confinement effects arising from the reduced dimensions. One-dimensional nanostructures have received more and more attention in recent years following the discovery of carbon nanotubes [1, 2] and related nanowires [3]. Carbon nanotubes are structures made by rolling up graphite sheets into seamless cylinders with diameters in nanometer scale. The structural change from graphite sheets into carbon nanotubes introduces quantum confinement along the direction of the tube circumference. This confinement allows electron transport only along the direction of tube axis, which makes carbon nanotube a good one-dimensional electron system. It is interesting to note that the combination of the quantum confinement effect and the electronic structure of graphite can change the properties of carbon nanotubes more than other materials: A single carbon nanotube can be metallic or semiconductor depending on its diameter or its chirality—a notation on how the nanotube is rolled up [4]. This property gives us great hope to realize intramolecular devices by engineering the atomic structure of carbon

nanotubes and fusing them together into one molecule. Several theoretical and experimental investigations have shown the junction of a metallic tube and a semiconducting tube could work as a Schottky diode [5–7].

Although this kind of intramolecular junction is of great interest in molecular devices, it is difficult to find a practical method to fabricate the junctions in a controllable way. Comparing with carbon nanotubes, the properties of non-carbon nanotubes and nanowires are normally easier to control because they are primarily determined by their chemical composition instead of geometry. For example, BN is insulator independent of its chirality and diameter, and silicon nanowires are always semiconductors like their bulk counterpart. Similar quantum confinement effects, however, would exist for all these different one-dimensional structures. Construction of nanoscale heterostructures by combining these one-dimensional objects will provide great potential for future quantum devices. Although a rich variety of one-dimensional nanostructures has been discovered in recent years, a general technology to build the one-dimensional heterostructure has not been well established. Unlike the two-dimensional heterostructures such as thin-film semiconductor superlattices that can be precisely engineered by techniques such as molecular beam epitaxy (MBE), phase formation in one-dimensional nanostructures is not straightforward and is hard to control by simple physical deposition. Nevertheless, some very exciting progress has been made in synthesizing heterogeneous nanotubes, nanowires, and their junctions. And some have already show promises in real applications. For example, the method of making carbon nanotube and titanium carbide junction has been used to improve the contact in nanotube field-effect transistors [8, 9].

The heterogeneous one-dimensional nanostructures composed of nanotubes and nanowires can generally be divided

into two categories according to the direction of nanowire axes relative to the interfaces that separate different materials in the heterogeneous nanostructures. In the first category, the axes of the nanowires and nanotubes are parallel to the interface planes. The phase separation is in the radial direction. Most nanotubes or nanowires in this category have homogeneous phase distribution along the whole length. The nanostructures in this category are also called composite nanotubes or nanowires (different from nanotube or nanowire composite which normally refers to a material made by dispersing nanotubes or nanowires into a matrix material). A representative structure of this category is a “nanocable” that has a core nanowire sheathed by one or more layers of different materials [10]. Composite nanotubes and carbon nanotubes with a second material filled into their hollow cores also belong to this category. In the second category, the axes of the nanotubes and nanowires are normal to the heterointerfaces. This category includes heterojunctions connecting nanotubes and solid nanowires [8, 11] or nanowire superlattices that are composed of alternating semiconductor nanowire segments of different chemical composition [12–14]. Because of the small cross section of nanotubes and nanowires, the junctions formed from them are in nanometer scale. They are therefore called “nanojunctions.” The nanojunctions represent a new kind of structure that could have great potential applications in nanoscale electronics and optoelectronics. This chapter will give a review of the progress on fabrication and characterization of the heterogeneous one-dimensional nanostructures of both categories.

## 2. COMPOSITE NANOTUBES

A composite nanotube refers to a multiwalled nanotube (MWNT) that is composed of shells with more than one kind of chemical composition. There is a big difference between a composite nanotube and compound nanotubes. A composite nanotube has distinguishable phase separation between cylindrical shells that constitute the tube, while all the shells in a compound nanotube consist of a single compound phase. Examples of compound nanotubes are nanotubes of  $W_2S$  [15],  $Mo_2S$  [15, 16], BN [17–20]. Composite nanotubes synthesized today are normally a mixture of carbon shells and shells of compound materials such as BN. B-C-N nanotubes are widely studied because theoretical calculation predicts that their electrical properties are controlled by their chemical composition instead of the subtle geometrical parameters [21, 22]. Similar to their pure carbon and compound counterpart, composite nanotubes are normally produced by arc-discharge and laser ablation method.

The main tool used for characterizing composite nanotube is a high-resolution scanning transmission electron microscope (STEM) equipped with a parallel electron energy-loss spectrometer (PEELS) [23, 24]. The STEM-PEELS system has a spatial resolution in subnanometer scale which other analytical microscopes cannot compete with and thus can be used to map the spatial distribution of elements in nanostructures. A linear scan of focused electron beam across an object and measurement of the elemental concentration at each step during scanning is called

elemental profiling, which is a powerful technique to determine the structure of one-dimensional nanostructures.

Earlier arc-discharge experiments for synthesizing B-C-N nanotubes used anodes made of a mixture of B, N, and C [25–27]. The obtained products contained a majority of carbon and only a very low concentration of boron and nitrogen. Elemental analysis of the nanotubes in the products showed inhomogeneous distribution of B, N, and C in the radial direction with normally B and N rich at outer surface layer [25, 27]. The B:N ratio was close to 1:1. The very low concentration of B and N in the sample suggests these elements are doped into the lattice of carbon nanotubes. There are several possibilities for how these elements are distributed in the tubes. One is that they form homogeneous  $B_xC_yN_z$  compound shells that wrap the carbon nanotube cores. Another scheme is that BN exists in domains in the outer carbon shells. The weak signal of the B and N in STEM-PEELS, however, failed to give a conclusive evidence of intershell phase separation.

B-C-N nanotubes produced by laser ablation using a target made of a compressed mixture of BN and C powders gave a similar result as arc-discharge [24]. The results obtained by STEM-PEELS show all nanotubes are C rich although the BN and C ratio in the target is 1:1. A lot of BN crystallites were found in co-products. The tubes with a few walls are normally composed of pure carbon. Those with more walls are normally not uniform in diameter along their axis as well as the B and N distribution. The distribution of B and N is rich at the outer surface layers similar to the B-C-N nanotubes produced by earlier arc-discharge method [25, 27]. Again, it is unable to be determined whether the B and N are homogeneously doped into graphite lattice (true ternary  $B_xC_yN_z$  phase) or they are mixed binary phases such as BN or  $BC_x$  embedded in the graphite outer layers (subcomposite tubes).

The laser ablated B-C-N nanotubes not only have similar morphologies and element distribution as those in earlier arc-discharged products, they should also share a similar growth mechanism since both methods employ a local high-temperature process to vaporize graphite and BN. From the feature that all obtained composite nanotubes have carbon cores, a two-step growth model has been proposed and is shown in Figure 1 [24]. The first step is the nucleation and growth of pure multiwalled carbon nanotubes. This step occurs in the high-temperature plasma region where B and N can easily diffuse out of the graphite lattice and form more favorable BN crystallites of planar structure. Carbon nanotubes formed in the process are all multiwalled because the presence of B and N atoms in this step could introduce defects on the graphitic wall that are preferable nucleation

**Figure 1.** Growth model of heterogeneous B-N-C composite nanotubes. Reprinted with permission from [24], Y. Zhang et al., *Chem. Phys. Lett.* 279, 264 (1997). © 1997, Elsevier Science.

sites for additional layers and the foreign atoms could also serve as the bridging atoms in lip-lip growth model [28]. The second step is partial coating of B-C-N layers. The growth of additional walls could also initiate from the defects on the carbon nanotube wall. The B and N diffusion process is reduced by lower temperature when the nanotube moves out of the plasma center. The inert gas used in the arc-discharge and laser ablation processes provides an efficient heat exchange medium for cooling down the species and works as a barrier to confine the expansion of the plasma and sustain a high density of multielement vapor for doping BN in nanotubes.

The two-step model, however, is not adequate to explain the formation of all B-C-N nanotube structures. One exception is the sandwiched C-BN-C nanotubes, where carbon is rich both in core shells and in outer shells [23]. The growth mechanism for such sandwiched nanotubes is still not clear. One possible model is a simultaneous growth of multiphase shells through a lip-lip-interaction [28]. Another possibility is that the tube flies through three zones in the discharge chamber during its layer-by-layer growth, and the three zones have different concentrations of active elements and thus form sandwiched structure.

The sandwiched C-BN-C nanotubes were produced by arc-discharge in nitrogen atmosphere using a HfB anode and a carbon cathode [23]. The use of non-carbon anode increases the B and N concentration in the product because the carbon cathode is only slightly evaporated in the arc-discharge. The high concentration of B and N enables more precise determination of local chemical composition using a STEM-PEELS. Figure 2 shows a high-resolution electron

micrograph of such a B-C-N MWNT and its elemental profile measured by scanning electron beam across the tube [23]. The high-resolution image cannot give any information about phase separation because all possible phases in B-C-N system, BN,  $BC_2N$ ,  $BC_3$ , have very similar crystal structure with graphite, and thus give the same image in the transmission electron microscope. The elemental profile, however, can give detailed phase information of all shells assuming each shell is composed of a single phase. In a cross-section elemental profile of single-phase cylindrical structure, maximum only occurs at the position that corresponds to the inner edge parallel to the probing electron beam. This is because this position has the largest equivalent thickness through which electron beam transmits and loses its energy. The elemental profile of a multiwalled nanotube can be simulated by adding up the profiles of all the shells with each shell as a single-phase cylinder. For a single-phase MWNT, there should be only two maxima in the profile because the probe size of the STEM, 0.5–1 nm, cannot resolve adjacent individual shells in a MWNT. Figure 2B shows four maxima in the C profile and two maxima in the B and N profiles. The positions of the two maxima in the B and N profiles coincide with two minima of the C profile. The result can be interpreted as a C-BN-C three-layered tubular structure as modeled in Figure 2D. Simulated elemental profiles (Fig. 2C) from the model agree with the experimental results very well. The analysis of the C-BN-C nanotubes has provided the first clear evidence of intershell phase separation (with atomic-scale sharp interfaces) in composite nanotubes.

More recently, some other composite nanotubes have been reported. One example is the  $TiO_2$ - $SiO_2$  composite nanotubes synthesized by sol-gel template method presented in [29]. The coaxial structure is made by sequential formation of amorphous  $SiO_2$  nanotubes in the pores of anodic alumina and  $TiO_2$  nanotubes within the  $SiO_2$  nanotubes. The composite nanotubes have a relatively large diameter of 200–250 nm. Another type of novel composite nanotubes are produced by growth of  $NbS_2$  nanotubes on carbon nanotube templates. High-resolution transmission electron microscopy and energy dispersive X-ray analysis revealed that the uniform well-crystallized  $NbS_2$  is nucleated and grown from an intermediate phase of  $NbO_2$  which is unevenly wrapped on the carbon nanotube templates. A multipoint nuclei site growth mechanism has been proposed to account for nanotube formation [30].

### 3. NANOCABLES

A coaxial nanocable is generally defined as a multilayered structure with a core nanowire coaxially sheathed by one or more shells of different materials. Nanocables include filled nanotubes and core-shell nanowire heterostructures.

#### 3.1. Filling Carbon Nanotubes

The discovery of carbon nanotubes has stimulated scientists for a range of potential applications [1], including the filling of hollow carbon nanotubes with chosen materials. Three main approaches have been used for filling carbon nanotubes with both crystalline and noncrystalline

**Figure 2.** Phase separation in a C-BN-C composite nanotube. Reprinted with permission from [23], K. Suenaga et al., *Science* 278, 633 (1997). © 1997, American Association for the Advancement of Science.

materials. The first approach involves inserting the selected materials, either physically or chemically, into the opened carbon nanotubes [31, 32]. The as-produced carbon nanotubes, however, normally have closed caps at their ends. Filling of nanotubes, therefore, always relies on a method to open the ends of the nanotubes. Oxidation and acid treatment are two efficient routes for opening the tips of carbon nanotubes [33–35]. Open nanotubes can be filled via capillary action using either a low melting or low surface tension material (i.e., material with a surface tension lower than the threshold value of 100–200 millinewtons per meter) [36]. The first filling experiment reported by Ajayan et al. used an oxidation method to simultaneously open and fill multi-walled carbon nanotubes (MWCNTs) [31]. Metallic Pb was first deposited onto samples containing MWCNTs produced by arc-discharge method. The samples were then heated in air to about 400 °C which is above the melting point of Pb. High-resolution electron microscopy (HREM) images taken after the heat treatment show that MWCNTs are opened at their tips and filled with solid materials (Fig. 3). Using this approach, metal (Pd, Ag, Au, Bi), metal oxides (oxides of Mo, Sn, Ni, U, Co, Fe, Nd, Sm, Eu, La, Ce, Y, Cd), metal chlorides (AuCl, UCl<sub>4</sub>), FeBiO<sub>3</sub>, HReO<sub>4</sub>, MoO<sub>2</sub>, and SnO, have all been successfully filled into carbon nanotubes [33, 37–46]. This approach is also useful for filling single-walled carbon nanotubes (SWCNTs or SWNTs) with halides, oxides, carbides, and metals [47–63]. One good example is KI filled SWCNT prepared by heating KI with SWCNT inside an evacuated silica ampoule at the temperature of 954 K for 2 hr. Figure 4 shows a phase image reconstructed from a 20-member focal series of a 1.6-nm-diameter SWCNT containing a KI single crystal [49]. In cross section, the filled crystal can be regarded as a single KI unit cell viewed along the  $\langle 110 \rangle$  direction of the parent rock salt structure, with the  $\langle 001 \rangle$  direction parallel to the tube axis. The crystal is well resolved in regions 1 and 3 of the restoration, whereas in region 2, the crystal is rotated about

**Figure 4.** Phase image showing a  $\langle 110 \rangle$  projection of KI incorporated within a 1.6-nm-diameter SWCNT, reconstructed from a focal series of 20 images. The upper left inset shows an enlargement of region 1. The lower right inset shows the surface plot of the region 1. Reprinted with permission from [49], R. R. Meyer et al., *Science* 289, 1324 (2000). © 2000, American Association for the Advancement of Science.

its axis. In the  $\langle 110 \rangle$  projection, each white spot corresponds to a column of pure I or pure K that is exactly one, two, or three atoms in thickness, as can be seen in the enlargement of region 1 (upper left inset). The different phase shifts arising from different atomic columns are visible when region 1 is displayed as a surface plot (lower right inset) [49]. SWCNT filled with polystyrene and styrene-isoprene is also reported [64].

In 1998, a new type of self-assembled hybrid structures consisting of fullerene arrays inside SWCNTs, so-called “peapods,” were reported [65, 66]. Recent progress in the high yield synthesis opens up a huge possibility for the peapod research. Various types of fullerenes and endohedral metallofullerenes, such as C<sub>60</sub>, Gd@C<sub>82</sub>, Sm@C<sub>82</sub>, La@C<sub>82</sub>, La<sub>2</sub>@C<sub>82</sub>, La<sub>2</sub>@C<sub>80</sub>, Er<sub>x</sub>Sc<sub>3-x</sub>@C<sub>80</sub>, Dy@C<sub>82</sub>, can now be fully inserted inside SWCNTs [67–80]. Potential applications of peapods range from data storage to quantum cascade laser, quantum computing [81, 82], field-effect transistor [75], and hydrogen storage [83].

The second approach is to simultaneously encapsulate the materials during the formation of carbon nanotubes.

Such encapsulation has been observed in MWCNTs synthesized by arc-discharge [84–95], electrolysis [96–98], field-anode activation [99], laser ablation [100], chemical vapor deposition [101–103], and pyrolysis [104] with metals, oxides, carbide, nitrides, chlorides, and sulfides. Among these processes, arc-discharge produces the best-graphitized sheathing MWCNTs, which is also true in synthesizing hollow carbon nanotubes. Arc-discharge is also more versatile for encapsulation of different elements. In this process, a graphite anode is drilled and filled with a mixture of graphite and the chosen element powders. One then proceeds with the conventional Krätschmer–Huffman arc deposition technique. Encapsulation abilities of more than 41 elements have been systematically investigated [39, 85, 87, 89]. This approach is also useful for filling single-walled carbon nanotubes [105, 106].

The third approach is a two-step process. First, nanowires are synthesized and then used as templates to deposit graphite layers on their surface [107, 108]. Zhang et al. deposited thick graphitic layers on the surface of Si nanowires by using a hot filament chemical vapor deposition method. When the temperature was as high as 1000 °C, Si cores tended to transform into SiC cores [107]. Han et al. reported the synthesis of GaN nanorods coated with graphitic carbon layers (usually less than 5), including single carbon layers, on preproduced GaN nanorods using a conventional thermal chemical vapor deposition method. The graphitic carbon layers conform to the shape of the GaN nanorods [108].

### 3.2. Filling Inorganic Nanotubes

Analogous to filled carbon nanotubes, inorganic nanotubes, such as BN [17],  $B_xC_yN_z$  [25], and sulfide nanotubes [15], have also been filled with different materials. This category of nanocable is usually synthesized through a simultaneous phase separation process during the synthesis of nanotubes and nanowires.

The first sophisticated coaxial nanocable structure with insulated shells was produced via laser ablation of a composite target containing BN, graphite, and a small amount of SiO and  $Li_3N$  at high temperature [10]. Figure 5 shows the transmission electron microscope (TEM) images of the fabricated coaxial nanocables. They are normally a few tens of micrometers long and 10–100 nm in their diameters. The diameters are quite uniform throughout the whole length of the nanocable (Fig. 5A). High-resolution TEM images in Figure 5B and C indicate that the core of the nanowire has a crystalline phase whose electron diffraction pattern (left bottom inset of Fig. 5B) and lattice image (right bottom inset of Fig. 5C) fit well with that of cubic SiC. The intermediate layer shows an amorphous phase. The outermost layer consists of graphite multiwalls. A detailed elemental profile analysis across the nanocable by STEM-PEELS reveals the Si:C ratio in the core wire and Si:O ratio in the intermediate layer is 1:1 and 1:2, respectively. The outer layer of the nanocable is composed of C and BN with signature of intershell phase separation similar to that of composite nanotubes described in the previous section. The solid phases in the core and intermediate layer region have been

**Figure 5.** HREM images and selected-area electron diffraction pattern of  $SiC-SiO_2-(BN)_x C_y$  coaxial nanocables. Reprinted with permission from [10], Y. Zhang et al., *Science* 281, 973 (1998). © 1998, American Association for the Advancement of Science.

further confirmed by comparing the Si L-edge fine structure with those of SiC and  $SiO_2$  reference spectra (Fig. 6). The characterization therefore gives a well-defined composite nanowire structure with  $SiC-SiO_2-(BN)_x C_y$  multilayers forming a semiconductor-insulator-(semi)conductor coaxial nanocable.

BN nanotubes filled with SiC were synthesized by using multiwall carbon nanotubes as templates [109]. This method combines both carbon nanotubes (CNTs)-substitution reaction [110] and confined reaction [111, 112]. Through the CNT-substitution reaction, CNTs react with boron oxide vapor in the presence of nitrogen gas to form BN-NTs, whose diameters and lengths are similar to those of the starting CNTs. The formation of the SiC filling proceeds by the penetration of SiO vapor into the cavity of the nanotubes. The subsequent reaction of SiO vapor with the inner carbon layers or volatile carbon mono-oxide in the interior forms SiC nanowires. The entire length of the nanotubes can be filled. SiC filled  $(BN)_x C_y$  nanotubes, which are a metal(C)-insulator(BN)-semiconductor (SiC) (MIS)

**Figure 6.** (A) A schematic illustration of a coaxial nanocable. (B) Si-L fine structure obtained from a nanocable with electron probe positions as indicated by arrows in (A). Spectrum c is obtained by subtracting a from b, representing a contribution from the core of the nanocable. Reference spectra from pure  $\text{SiO}_2$  and SiC phases are displayed for comparison. structure, also form in the product. Using the same methods, BN and  $(\text{BN})_x\text{C}_y$  nanotubes filled with boron carbide [113] and  $(\text{BN})_x\text{C}_y$  nanotubes filled with iron boride [114] have been prepared. Other similar structures, such as Fe filled C-BN [115] and BN nanotubes [116], Fe-Ni alloy filled BN nanotubes [116], Mo filled BN nanotubes [117],  $\text{Al}_2\text{O}_3$  filled BN nanotubes [118], GaN filled BN nanotubes [119], BN nanotubes filled with SiC and SiN [120], and  $\text{ZrO}_2$  filled BN nanotubes [121] have also been reported.  $\text{C}_{60}$  filled BN nanotubes have been theoretically studied and experimentally achieved [122, 123].

Hofmann et al. found  $\text{Ni}_{17}\text{S}_{18}$  filled  $\text{MoS}_2$  nanotubes combined with sulfide nanowires when they checked nanostructures on processed, sulfur contaminated Mo grids. Carbon is found both in the outer walls and in the core of the wire [124].

### 3.3. Core-Shell Nanowire Heterostructures

One-dimensional core-shell nanowire heterostructures are another kind of nanocable with radial heterostructures. After high-temperature reaction processes, many semiconductors and metal nanowires are found to have a thin oxide shell, forming a core-shell nanowire. Such configurations are Si/ $\text{SiO}_x$  [125], SiC/ $\text{SiO}_x$  [126–128], Ge/ $\text{GeO}_2$  [129], GaN/ $\text{GaO}_x$  [130], and Zn/ $\text{ZnO}$  [131]. Other similar structures, such as  $\text{Si}_3\text{N}_4$ / $\text{Si}/\text{SiO}_2$  [132], B/ $\text{SiO}_2$  [133], Ge/ $\text{SiO}_2$  [134], Ag/ $\text{SiO}_x$  [135], CdS/ $\text{SiO}_2$  [136], Zr/ $\text{ZrO}_2$  [137],  $\text{La}(\text{OH})_3$ / $\text{Ni}(\text{OH})_2$  [138], NiFe/Cu [139], Au/Ag [140], and  $\text{Cu}_2\text{S}/\text{Au}$  [141], have also been synthesized using chemical vapor deposition, laser ablation, electrodeposition, and redox deposition techniques. In addition to the inorganic core-shell nanowires, semiconductor/polymer core-shell nanowires, such as CdSe/poly(vinyl acetate), have been produced using low-temperature solution methods [142].

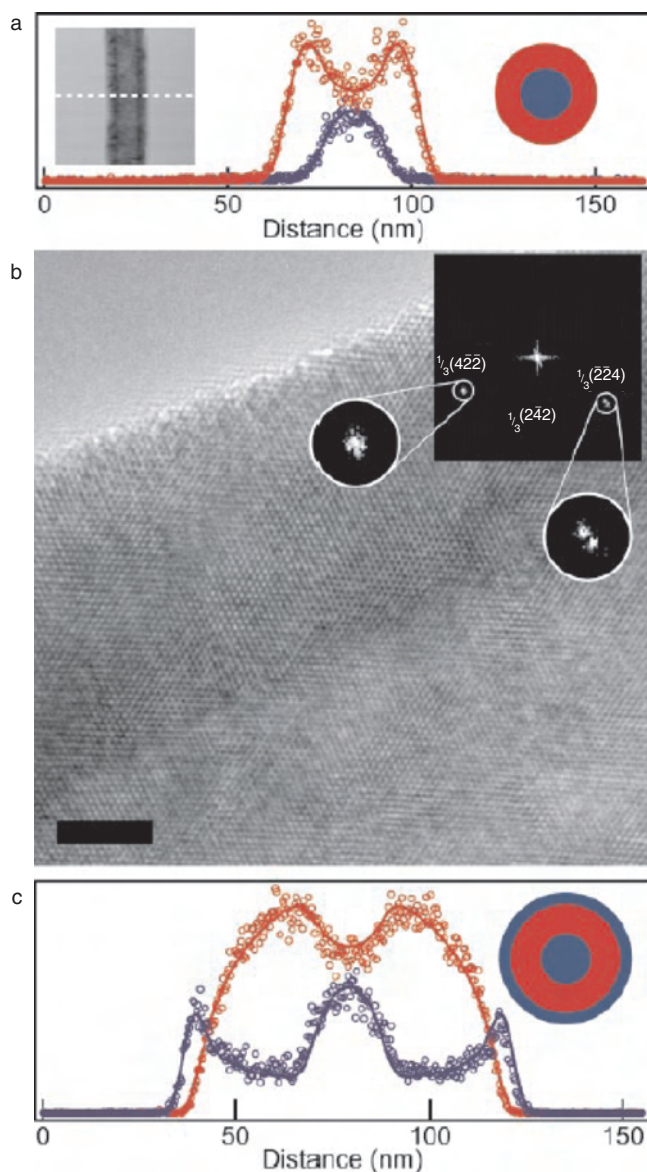

Very recently, controlled growth of core-shell and multishell heterostructures of silicon-germanium systems has been approached using a chemical vapor deposition system [143]. This work is based upon control of radial versus axis growth (Fig. 7). Metal nanoparticles could act as a catalyst to direct axis growth by a vapor-liquid-solid growth process (Fig. 7a). Axial growth proceeds when reactant activation and addition occurs at the catalyst and not on the nanowire surface (Fig. 7b). By altering conditions to favor radial growth on the nanowire surface, it is possible to drive conformal shell growth (Fig. 7c). In this work, the radial growth is turned on by moving the growth substrate downstream to favor uncatalyzed surface growth. Subsequent introduction of different reactants and/or dopants produces multiple shell structures (Fig. 7d). By this method, core-shell structures such as intrinsic silicon (i-Si)/boron doped (p-type) silicon, i-Si/ $\text{SiO}_x$ /p-Si, i-Ge/p-Si, Si-Ge, Si-Ge-Si, and p-Si/i-Ge/ $\text{SiO}_x$ /p-Ge core-multishell nanowire structures have been synthesized [143]. TEM images and elemental mapping show the Si-Ge core-shell structure with a sharp interface (Fig. 8a). Figure 8b shows that the Ge shell is fully crystallized. Figure 8c shows a cross-section elemental mapping of a Si-Ge-Si core-double-shell nanowire. Another interesting experiment in this work is to measure the  $I$ - $V$  curve of p-Si/i-Ge/ $\text{SiO}_x$ /p-Ge core-multishell nanowires, which can be used as field-effect transistors. The source, drain, and gate contacts were made by selective etching and metal deposition onto the inner i-Ge shell and outer p-Ge shell, respectively.

Another controllable example is the growth of CdSe/CdS/ZnS core-shell nanorods [144]. Short CdSe nanorods (aspect ratios range from 2:1 to 10:1) were first grown by sol-gel processes [145] and then put into the precursor solution for the growth of CdS/ZnS graded shells at low temperature (160 °C) [144]. Interfacial segregation is used to

**Figure 7.** Synthesis of core-shell nanowires by chemical vapor deposition. (a) Gaseous reactants (red) catalytically decompose on the surface of Au nanocluster leading to nucleation and direct nanowire growth. (b) One-dimensional growth is maintained as reactant decomposition on the Au catalyst is strongly preferred. (c) Synthetic conditions are altered to induce homogeneous reactant decomposition on the nanowire surface, leading to a thin, uniform shell (blue). (d) Multishells are grown by repeated modulation of reactants. Reprinted with permission from [143], L. J. Lauhon et al., *Nature* 420, 57 (2002). © 2002, Macmillan Magazines Ltd.

preferentially deposit CdS near the core since its lattice matches better to CdSe than ZnS does. This layer of CdS mediates the growth of the more highly strained ZnS. The shell growth is uniform and epitaxial, completely coating the CdSe core, although it may have defects present due to the lower growth temperature. After an irreversible photochemical annealing process, the core-shell nanorods have increased quantum efficiencies and are stable in air under visible or UV excitation [144].

#### 4. NANOWIRE SUPERLATTICES

Metallic nanoparticles have been demonstrated to play a key role for the synthesis of nanowires by a vapor-liquid-solid growth process [146, 147]. Moreover, a metallic nanoparticle could catalyze two different materials to grow nanowire heterojunctions, such as silicon/carbon nanotube nanowire heterojunctions [11]. Using the same tactic, several groups recently reported their work about the fabrication of semiconductor nanowires with segments of varying chemical- or dopant-composition superlattice nanowires. This greatly increases the versatility and power of these building blocks in the application of nanotechnology [12–14, 148–150]. All of this work focuses on semiconductors composed of modulated Group III-V [12, 14, 148], Group II-VI [149], and Group IV [13] elements. Gold nanoparticles have been used as catalysts in all this work.

In the synthesis of nanowire superlattices, a catalyst available to two or more different materials serves as the critical point for nucleation and directional growth of the nanowires. Meanwhile, the reactants are modulated during growth. Figure 9 is a schematic diagram of the process [14]. The nanoparticle catalyst (yellow) nucleates and directs the nanowire (blue) growth with the catalyst remaining at the terminus of the nanowire (Fig. 9a). To create a single junction within the nanowire, the addition of the first reactant is stopped during growth, and then a second reactant is introduced for the remainder of the synthesis (Fig. 9b). Repeated modulation of the reactants during growth produces nanowire superlattices (Fig. 9c).

Nanowire superlattices of gallium arsenide (GaAs)/gallium phosphide (GaP) were reported by Gudiksen et al. [14]. GaAs/GaP nanowire superlattices are an attractive system to explore for nanophotonic applications because GaAs is a direct-bandgap semiconductor, while GaP has an indirect gap. The GaAs/GaP nanowire superlattices were grown by laser-assisted catalytic growth using GaAs and GaP targets. Au nanoparticles were used as a catalyst to direct the growth. Solid targets of GaAs and GaP were ablated using either a pulsed ArF excimer or Nd:YAG lasers and growth was carried out at 700–850 °C in an argon flow. The number

**Figure 9.** Synthesis of nanowire superlattices. (a) Nanocluster catalyst (gold) nucleates and directs one-dimensional semiconductor nanowire (blue) growth with the catalyst remaining at the terminus of the nanowires. (b) Upon completion of the first growth step, a different material (red) can be grown from the end of the nanowire. (c) Repetition of steps a and b leads to a compositional superlattice within a single nanowire. Reprinted with permission from [14], M. S. Gudiksen et al., *Nature* 415, 617 (2002). © 2002, Macmillan Magazines Ltd.

of periods and repeat spacing of the compositionally modulated nanowire superlattices can be readily varied during growth. High-resolution TEM images show that GaAs/GaP junction regions exhibit a crystalline nanowire core without obvious defects and can be abrupt. Photoluminescence, electrical transport, and electroluminescence measurements of single nanowire superlattices suggest potential applications ranging from nano-barcodes to polarized nanoscale LEDs [14].

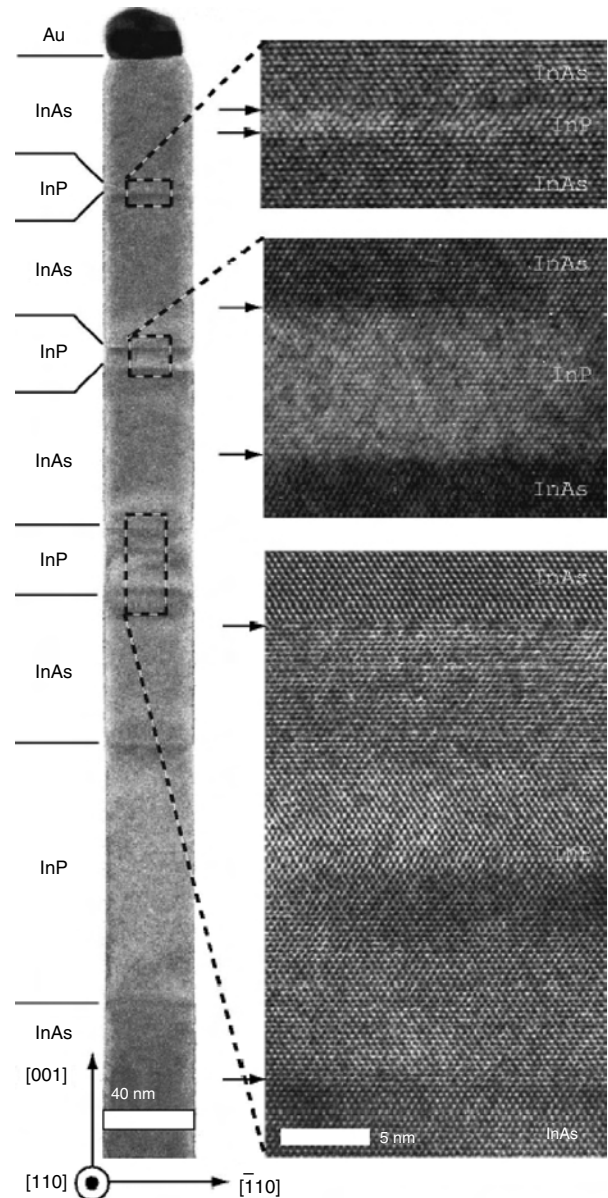

Bjork et al. reported the growth of InAs/InP nanowire superlattices in an ultrahigh vacuum chamber designed for chemical beam epitaxy (CBE) [12, 148]. The rapid switching between InAs and InP is obtained via a sequence where growth is interrupted as the indium source (TMIn) is switched off, followed by a change of As or P source. Finally, the supersaturation conditions, as a prerequisite for reinitiation of growth, are reestablished as the indium source is again injected into the growth chamber. Significantly, their lattice-resolved TEM images show that the interfaces are atomically abrupt (Fig. 10). The periods of the modulated nanowire structures range from 100 to just several nanometers. Electrical measurements of thermionic emission across an 80-nm-wide INP heterobarrier, positioned inside InAs whiskers 40 nm in diameter, yield a barrier height of 0.6 eV.

Wu et al. reported a hybrid pulsed laser ablation/chemical vapor deposition process for the synthesis of Si/SiGe<sub>x</sub> nanowire superlattices [13]. Ge vapor is generated in pulsed ablation of a pure Ge target. A gas mixture of H<sub>2</sub> and SiCl<sub>4</sub> is continuously introduced into the reaction tube. Si precursors continuously deposit onto Au to induce the Si nanowire growth. During this growth process, if the laser is turned on, Ge vapor is generated and will react with Si precursors to grow SiGe<sub>x</sub>. By periodically turning the laser on and off, Si/SiGe<sub>x</sub> nanowire superlattices form. Solanki et al. focused on the growth of ZnSe/CdSe nanowire superlattices using an atomic layer deposition (ALD) technique [149]. ALD is a monolayer stepwise growth process that proceeds by exposing the substrate surface alternately to each precursor followed by an inert gas (N<sub>2</sub>) pulse to remove the excess species and by-products of the reaction [151]. The precursors for ZnSe and CdSe are elemental Zn, Se, and Cd.

Apart from the important contributions to materials science and nanostructure formation, these results could greatly increase the versatility and power of these building blocks in nanoscale electronic and photonic applications [150]. Potential applications include nano-barcodes, quantum cryptography and computing, “engineered” one-dimensional electron waveguides [14], heterostructures integrated in scanning probe- or field-emission, 1D-0D-1D resonant tunneling devices, one-dimensional superlattice arrays of intercoupled quantum dots [12, 148], nanoscale circuits, thermoelectrics [13], and light-emitting devices [13, 14, 149].

## 5. NANOJUNCTIONS

Nanoscale devices have great potential to replace traditional silicon-based devices because they can yield higher integration density, although many technical challenges exist.

**Figure 10.** TEM image of an InAs whisker, 40 nm in diameter, containing four sequential InP barriers. The strain fields around each interface can be seen as elliptical, darker areas, having an extension of about 20 nm. In the thickest barrier the crystal is therefore completely relaxed. The magnified views prove that abruptness of the interfaces on the atomic scale is obtained. Reprinted with permission from [12], M. T. Bjork et al., *Appl. Phys. Lett.* 80, 1058 (2002). © 2002, American Institute of Physics.

Semiconductor-metal, semiconductor-semiconductor junctions are important building blocks which can be used for rectifiers, light-emitting diodes, and photodetectors. Recently, one-dimensional nanojunctions with different materials have been fabricated.

### 5.1. Silicon-Carbon Nanotube Junctions

Si nanowire-carbon nanotube junction was fabricated in Lieber's group [11] by two approaches as shown in Figure 11. The first approach is growth of silicon nanowires

**Figure 11.** Synthetic approaches to nanotube-silicon nanowires junctions. (a) Growth of Si nanowires, afterwards growth of nanotube from the same catalytic particles. (b) Growth of nanotube and attachment of Au nanoparticles, then growing nanowires. Reprinted with permission from [11], J. T. Hu et al., *Nature* 399, 48 (1999). © 1999, Macmillan Magazines Ltd.

from iron nanoparticles. Afterwards, nanotubes were grown from the same particles by chemical vapor deposition method. The second approach: catalyst nanoparticles are deposited on nanotube ends and then used to direct the growth of Si nanowires. The key point for the first approach is that both growth processes share the same catalyst particle. The interface between nanowire and nanotube for the first approach might not be clean, while the second approach yields clean interface, considering that base growth model can be applied to carbon nanotube growth and that tip growth model can be applied to silicon nanowire growth. For base growth, the catalyst particles responsible for nucleation and growth remain pinned on the support surface, while tip growth involves a metal catalyst nanoparticle at a nanowire or nanotube end that is carried away as the nanowire or nanotube grows which is responsible for supply feedstock for the growth.

It is established that Fe and Fe/Au are efficient catalysts for the growth of silicon nanowires [3]. Meanwhile, it is found that Fe is a good catalyst for the growth of carbon nanotubes. Lieber's group used a laser to ablate a  $Fe_{0.9}Au_{0.1}$  target in 20-torr 10%/90% silane/He at 450 °C. After silicon nanowire growth, the nanotubes were grown from the same catalyst particles in 300-torr ethylene at 600 °C. A transmission electron microscope (TEM) image in Figure 12a shows that a silicon nanowire and multiwalled carbon nanotube junction were obtained. There is a common catalyst particle at the junction. Electron diffraction on silicon nanowires shows that the silicon nanowire maintains its crystalline structure after tube growth.

Lieber's group also used the second approach to fabricate nanojunctions. Gold cluster was deposited on the end of nanotubes by electrodeposition. Silicon nanowire was then grown from the attached gold cluster by using silane mixed with He for 15 min at 510 °C. A scanning electron microscope image of as-grown junction is shown in Figure 12b. The Au nanoparticle is sitting at the end of silicon nanowire. A clean interface was achieved.

**Figure 12.** (a) TEM image of a nanotube-nanowire junction grown by approach a. The junction area was highlighted by a larger arrow. The small arrow indicates a metal catalyst particle. ## 5.2. SiC-Carbon Nanotube and TiC-Carbon Nanotube Junctions

Zhang et al. [8] found an easy and simple approach to fabricate single-walled carbon nanotube-carbide junctions based on solid-solid reaction at a high temperature from 800 °C to 1000 °C. This method as shown in Figure 13 is based on a direct solid-solid reaction: C (carbon nanotube) + M (solid) = MC (solid), where M could be either silicon or a transition metal. The carbide initially forms at the C/M interface once a sufficient temperature is reached for the reaction to occur [152]. They found that the self-diffusion rate through bulk SiC or transition-metal carbide is extremely slow in the temperature range of 800 °C to 1000 °C, which guarantees a clean nanoscale interface between SiC and carbon nanotube.

In the experiments, the Si, Ti, and Nb substrates were thinned with perforations by means of conventional transmission electron microscopy sample preparation techniques.

**Figure 13.** A schematic description of the method for fabricating nanotube/carbide heterostructures by a solid-solid reaction. Reprinted with permission from [8], Y. Zhang et al., *Science* 285, 1719 (1999). © 1999, American Association for the Advancement of Science.

Then single-walled carbon nanotubes were deposited on the substrates. The prepared substrates were heated in the ultrahigh-vacuum TEM column or in a side chamber either by an infrared heating lamp or by electrical current heating the substrate. They found that  $\beta$ -phase SiC was formed at the junction between silicon and single-walled carbon nanotube bundles according to high-resolution TEM as shown Figure 14. NaCl-structured TiC was obtained between Ti substrate and carbon nanotubes (Fig. 15). Improvement of the contact conductance between carbon nanotubes and Ti electrodes was demonstrated through the formation of TiC junctions (Fig. 15). This method has been used by other researchers to make ohmic contact between Ti electrode and semiconducting nanotubes by annealing devices above 700 °C in fabrication of nanotube transistors [153].

It was also found that carbon nanotube can react with Ti scanning tunneling microscope tip with solid-solid reaction after the nanotube was attached to the tip by using a nanomanipulator [8]. This kind of probe is supposed to be more robust than nanotube attached by glue or chemical vapor deposition growth [154, 155].

### 5.3. Boron Carbonitride-Carbon Nanotube Junction

Guo et al. [156] found a method to fabricate boron carbonitride nanojunctions by bias-assisted hot-filament chemical vapor deposition with a pause-reactivation two-stage process. They fabricated BCN nanotubes on polycrystalline nickel substrate by bias-assisted hot-filament chemical vapor deposition. A mixture of high-purity  $N_2$ ,  $H_2$ ,  $CH_4$ , and  $B_2H_6$  is utilized as the precursors. The composition of the BCN nanotubes is controlled simply by varying the flow rate of  $B_2H_6$ . This method results in a sharp interface structure and composition. A similar approach was used to synthesize  $CN_x$ /carbon nanotube junctions by using microwave chemical vapor deposition of  $N_2/CH_4$  and  $H_2/CH_4$  [157].

**Figure 14.** A TEM image showing a nanojunction between SiC nanorod and SWNT bundle. A clean interface was observed. Reprinted with permission from [8], Y. Zhang et al., *Science* 285, 1719 (1999). © 1999, American Association for the Advancement of Science.

**Figure 15.** TEM images showing nanojunctions between TiC nanorod and SWNT bundle (a) and a single SWNT (b). (c) shows the  $I$ - $V$  curves of SWNTs crossing two Ti pads before (dotted line) and after (solid line) vacuum annealing. The improvement of the conductivity is attributed to the formation of Ti-TiC-SWNT junctions. Reprinted with permission from [8], Y. Zhang et al., *Science* 285, 1719 (1999). © 1999, American Association for the Advancement of Science.

### 5.4. Nanotube-Nanotube Junction

Nanotubes with different diameters can form junctions. Because bandgap of a nanotube is related with its diameter, semiconductor-semiconductor and semiconductor-metal junction can be formed between nanotubes. It can be defined as physical heterojunction.

Li et al. [158] used nanostructured alumina template channels to grow individual Y-junction carbon nanotube heterostructures by the pyrolysis of acetylene with cobalt catalysis. Multiwalled carbon nanotube Y-junctions were obtained

as shown in Figure 16. Ho et al. [159] applied high electric fields on multiwalled carbon nanotube arrays to create nanotube junctions. The high electric field as well as thermal effects result in carbon-carbon bond breaking and redeposition leading to nanojunction formation.

Satishkumar and colleagues [160] used a simple pyrolysis method to prepare multiwalled carbon nanotube Y-junctions. Organometallic precursor of nickelocene, together with thiophane, was decomposed at 1273 K. Two-temperature zone furnace was used for the synthesis; nickelocene was placed at the first zone with temperature of 623 K and thiophane was placed at the second zone with temperature of 1273 K. Argon and hydrogen are used as carrier gases. Y-junction structure was verified with HRTEM.

X- and Y-junctions of single-walled carbon nanotubes were fabricated by electron beam exposure at high temperatures [161]. The experiments were carried out in a high-voltage TEM with accelerating voltage of 1.25 MV. Carbon nanotubes were heated to 800 °C by using a Gatan heating stage in the TEM chamber. It was noted that high temperature is necessary to induce the formation of junctions because electron irradiation at room temperature would rapidly lead to heavy radiation damage of the tubes. The ready-formed X-junctions can be manipulated in order to create Y- and T-like molecular connections by using careful conditions of irradiation of electron beam. Single-walled carbon nanotube Y-junctions were also synthesized by chemical vapor deposition of methane and hydrogen on  $\text{Si}_3\text{N}_4$  membrane at 950 °C [162].

Chiu et al. [163] used a chemical approach to fabricate nanotube junctions. The single-walled carbon nanotubes were sonicated in  $\text{HNO}_3$  for 20 min to produce shortened and open-ended nanotubes, meanwhile to create defects on side walls. During the treatment, oxygen-containing groups are attached to opened ends of tube and side wall of tubes. Subsequently Chiu et al. converted these oxygen-containing groups to corresponding acid chloride by reacting with  $\text{SOCl}_2$  at room temperature for 24 hr. Then the solution was decanted and the deposit was rinsed with toluene followed by immersion in tripropyltetramine.

**Figure 16.** A TEM image of Y-junction nanotube with 50 nm scale bar. Reprinted with permission from [158], J. Li et al., *Nature* 402, 253 (1999). © 1999, Macmillan Magazines Ltd.

It was supposed that the bifunctionalized amine interconnects two nanotubes via formation of acidic amide bonding. Figure 17 shows the schematic representative junction structure. They found a lot of junctions with atomic force microscope after the chemical modifications.

Single-walled carbon nanotube p-n junctions were fabricated by Zhou et al. [164] by using modulated chemical doping method. A 340-nm-thick polymethylmethacrylate layer covers a half of the nanotube, leaving the other half exposed which was doped by potassium doping in vacuum by electrical heating of a potassium source. As-grown semiconducting tubes are p-type [165, 166]. After doping with potassium, the other half of tube becomes n-type; thus p-n junction formed within the same nanotube. One disadvantage of this method is that potassium-doped tube is unstable in air. Later the same group found a way to functionalize carbon nanotube with polyethyleneimine, which makes nanotube n-type and stable in air [167].

### 5.5. Nanojunction Fabrication Using Nanoporous Oxides as Templates

Besides nanotube Y-junction [158], different nanojunctions were fabricated by using nanoporous alumina as template.  $\text{Al}/\text{Al}_2\text{O}_3/\text{Ni}$  nanowire and  $\text{Al}/\text{Al}_2\text{O}_3/\text{carbon}$  nanotube arrays were prepared by using nanoporous  $\text{Al}_2\text{O}_3$  as templates [168–171]. A nanoporous alumina film prepared by electrochemical etching of an Al thin film has an array of nanosized diameter pores located like honeycomb. The nanopores have a straight-line shape perpendicular to Al substrate with a single tunnel barrier attached to each bottom. Ni nanowires were electrochemically deposited within the pores. Alternatively, multiwalled carbon nanotubes were grown within the pores with chemical vapor deposition of  $\text{C}_2\text{H}_2$  using a thin layer of Ni as catalyst. Coulomb blockade associated with weak localization in an array of single nano-tunnel junction/multiwalled carbon nanotubes was observed. Magnetoresistance jump in Ni-nanowire array was also found. The nanoporous templates can be extensively used to fabricate other nanowire junctions, such as silicon and germanium nanowire junctions.

**Figure 17.** Schematic representation of nanotube junctions, where  $\text{R} = (\text{CH}_2)_3\text{NH}(\text{CH}_2)_3\text{NH}(\text{CH}_2)_3$ . Reprinted with permission from [163], P. W. Chiu et al., *Appl. Phys. Lett.* 80, 3811 (2002). © 2002, American Institute of Physics.

## 5.6. Nanojunction Fabrication by Scanning Probe Microscope

Due to their ultra-sharpness of scanning probe, scanning probe microscopes have been used to fabricate nanoscale p-n junction in silicon [172], and submicron bipolar transistors in CuInSe<sub>2</sub> [173, 174]. It was found that application of local, strong electric fields, at ambient temperatures, to originally electrically homogeneous crystals of doped Si and CuInSe<sub>2</sub> semiconductors induces nonequilibrium doping profiles in them. Conductive atomic force tips are used to induce a strong electric field between tip and semiconductor surface. Davidsson et al. [175] exposed thin resist layer with electrons by using atomic force microscope. Fifty nanometer long, 6-nm-thick Al lines were fabricated which can be used to define small tunnel junctions.

It is worth noting that another type of nanojunctions can be made by simply laying one nanowire or nanotube across another. Nanotube-V<sub>2</sub>O<sub>5</sub> nanofiber junction is an example [176]. Nanowire cross-junctions can be routinely obtained by microfluidic alignment method [177, 178]. However, in order to achieve high density and reliable nanojunction arrays, tremendous technical breakthroughs are necessary.

## 5.7. Electrical Properties of Nanojunctions

Use of nanojunctions for rectifiers, light-emitting diodes, and negative differential conductance have been demonstrated recently by different groups.

### 5.7.1. Negative Differential Conductance of Carbon Nanotube p-n Junctions

Negative differential conductance (NDC), discovered by Esaki in degenerately doped p-n junctions, has wide applications for high-frequency amplifiers and oscillators. Zhou et al. [164] observed negative differential conductance in single-walled carbon nanotube p-n junctions.

The method to prepare the p-n junction was introduced in Section 4.4. Device scheme with the SWNT contacted by two Ni/Au electrodes is shown in Figure 18a. A band diagram for the system is shown in Figure 18b by assuming that the tube is highly doped, therefore a p<sup>+</sup>/n<sup>+</sup> junction was formed. Zhou et al. controlled the doping level by changing gate voltage. By setting gate voltage at -9.5 V, NDC was observed at low temperatures as shown in Figure 19. Figure 19A shows negative differential conductance in an

**Figure 18.** (a) Device scheme with the SWNT contacted by two Ni/Au electrodes. The tube was partially doped with potassium. (b) A band diagram for p<sup>+</sup>/n<sup>+</sup> junction, E<sub>c</sub>, E<sub>v</sub>, E<sub>f</sub> represent the conduction, valence band, and Fermi level, respectively. **Figure 19.** (A) Current versus bias voltage with -9.5 V gating. (B through E) Band diagrams show the transport mechanisms. The symbols in B to E match the ones in A with certain bias voltages. Reprinted with permission from [164], C. W. Zhou et al., *Science* 290, 1552 (2000). © 2000, American Association for the Advancement of Science.

intra-SWNT Esaki diode. Band diagrams of Figure 19B to E are shown at different bias voltage regions. NDC due to resonant tunneling was observed. At room temperature NDC is not obvious.

### 5.7.2. Nanojunction Rectifiers

The first nanowire-junction rectifier was demonstrated by Hu et al. [11]. Nanotube-silicon nanowire junction was synthesized by chemical vapor deposition and electrically connected to a Pt-Ir tip with silver paste at the nanotube end and to Ga-In liquid metal at the silicon nanowire end. *I-V* curves were measured with scanning tunneling microscope electronics.

The current-voltage measurements on NT/SiNW junctions with only the SiNW in contact with the Ga-In liquid exhibit reproducible rectifying behavior as shown in Figure 20. By doing several control experiments, Hu et al. concluded that the rectifying behavior is due to the metal-semiconductor Schottky barrier between NT and SiNW.

Electronic transport was also performed with Y-junction carbon nanotubes [179]. In order to make the measurement,

**Figure 20.** (a) Diagram of electrical measurement setup; a SEM image of NT/SiNW is shown. (b) *I-V* curve of two independent junctions. Reprinted with permission from [11], J. T. Hu et al., *Nature* 399, 48 (1999). © 1999, Macmillan Magazines Ltd.

individual Y-junctions were chemically removed from their growth template [158] and deposited on patterned electrodes. Electrical field enhanced diffusion of gold was applied to yield an ohmic contact between nanotube and electrodes.  $I$ - $V$  data display distinct asymmetric and rectifying behavior with current flowing more easily under negative bias. Li et al. modeled the Y-junction nanotube as a p-p isotype semiconductor heterojunction with different bandgaps using standard heterostructure semiconductor physics and explained the observed results. Rectifying behavior was also observed by Chiu et al. [163] using chemical functionalized nanotube junctions, by Kim et al. [176] using  $V_2O_5$  nanofiber-carbon nanotube junction, and by Zhou et al. [164] using carbon nanotube p-n junctions.

### 5.7.3. Nanojunction Light-Emitting Devices

In 1994, Katsuyama et al. [180] fabricated GaAs p-n nanowire junction based on reduced-pressure metal-organic vapor-phase epitaxy. Intense light emission was observed during carrier injection to the p-n junction formed in the GaAs whisker. The emitted light showed strong polarization anisotropy, which was explained by the quantum confinement effect. Recently, Gudiksen et al. [14] reported a method to synthesize p-n junctions. In order to create a single junction within a nanowire, the addition of the first reactant is stopped during growth, and then a second reactant is introduced for the remainder of the synthesis. Nanojunction with different elements or different major carrier types was obtained.

Using this method, InP nanowire p-n junction was fabricated. Besides this nanojunction showing rectifier behavior, light emitted from the p-n junction was observed as shown in Figure 21. The polarization direction is found to be along that of the nanowire. The light emission was found blue-shifted due to the one-dimensional structure and radial quantum confinement. The efficiency of their intranowire LEDs is around 0.1%, which can be improved by optimizing the devices. Recently, electrically driven lasing from single n-type CdS nanowire was achieved by Duan and his colleagues [181]. More exciting demonstrations on application of nanowire junctions can be expected and are appearing.

**Figure 21.** (a) Schematic of an InP nanowire LED. (b) Polarized emission from the LED along the nanowire growth direction. Dashed lines indicate the edge of the electrodes. Scale bar is 3  $\mu$ m. Reprinted with permission from [14], M. S. Gudiksen et al., *Nature* 415, 617 (2002). © 2002, Macmillan Magazines Ltd.

## GLOSSARY

**Carbon nanotube** A tubular structure made by rolling up graphite sheets into seamless cylinders with diameters on nanometer scale. Carbon is the only element in a carbon nanotube.

**Composite nanotube** A multiwalled nanotube composed of shells of more than one kind of chemical composition.

**Composite nanowire** A nanowire composed of two or more different materials or phases homogeneously distributed along its whole length.

**Compound nanotube** A nanotube composed of a single chemical compound. Almost all noncarbon nanotubes (inorganic nanotubes) are compound nanotubes.

**Nanocable** A composite nanowire (nanotube) that has a core nanowire (nanotube) sheathed by one or more layers of different materials or phases. Some nanocables resemble the structure of a coaxial cable.

**Nanojunction** An area formed by end-to-end connection of two types of nanowires (nanotubes), or one nanowire and one nanotube. Because of the small cross section of nanotubes and nanowires, the junctions formed from them are in nanometer scale.

**Nanowire** A wire with a thickness in nanometer scale.

**Nanowire superlattice** A nanowire composed of alternating semiconductor nanowire segments of different chemical compositions.

## 1. INTRODUCTION

Everyone can understand the meaning of the word “capsules,” when one takes medicine that is in the form of capsules. We are familiar with capsules where the medicine is inside, with a shell outside, which is used for prolonging or improving the absorption of the medicine. Nanocapsules are capsules of nanometer size (i.e.,  $10^{-9}$  m), which are normally composed of a core and a shell that are made of different materials. One can understand nanocapsules, when one imagines the reduction of hen eggs to nanometer scale. The shell has a number of names depending on the research field or industry, which can be referred to as a membrane, a wall, a covering, or a coating. The internal core material also goes by a number of terms such as payload, core, encapsulant, fill, active ingredient, internal phase (IP), or internal ingredient. For the purposes of this chapter we will refer to the terms shell and core.

The word “nanocapsules,” or “nanoencapsulations,” started to appear in the literature in the middle of 1970s, most of which was related to the topics of controlled release of drugs [1–5] and new drug carriers [6–13]. The word “nanocapsules” (or “nanoencapsulations”) emerged in the literature for carbon encapsulating materials at the beginning of 1990s [14–22], after the discovery of fullerenes

[23, 24]. Indeed, the discovery of  $C_{60}$  and successful preparation of the material in macroscopic quantities initiated extensive investigations of fullerenes [23, 24], carbon nanotubes [25, 26], carbon-coated nanocapsules [14–22], and a wide range of carbon-based materials [27, 28]. Recently, there has been extensive and increasing interest in the field of nanocapsules as well as nanoencapsulation.

Actually, nanoencapsulation is a more precise derivative of a well-developed process, called “microencapsulation,” which encloses very small-sized core materials, either solids or liquids, in the coating materials. This technique has played a significant role in a variety of industries for many years. These include medical, pharmaceutical, cosmetic, food, agricultural, plastic, paper, photographic printing, paint, adhesive, and computer industries. During nano/microencapsulation, very thin coatings of inert natural or synthetic (polymeric or others) materials are deposited around nano/microsized particles of solids or droplets of liquids. Products thus formed are known as nano/microcapsules, depending on their size scales. The unique feature of nanocapsules is the diminutive size of the coated particles. The particle size usually ranges from several nanometers to 1 micrometer. The coated particles between 1 and 1000 nanometers in diameter are referred to as the nanocapsules.

Various types of physical structure of the product of nanoencapsulation, such as mononuclear spheres, multinuclear spheres, and multinuclear irregular particles, can be obtained depending on the manufacturing process. The most common structure formed is the mononuclear sphere. The spherical surface is the smallest surface among all other shapes for the condensing/nanoencapsulation process, which is usually with a minimum free energy. Thus it is the common surface for most nanocapsules. However, other shapes are still possible, since the symmetry of the crystals could become dominant in a certain case.

The most applicable nanoencapsulation procedures include: physical techniques such as arc discharge, heat evaporation, laser/electron beam heating, sputtering, etc.; chemical techniques such as chemical vapor deposition, solid-state reactions, sol-gel, precipitation, hydrothermal

process, solvent process, latex process, oxidation process, polymerization, etc.; physicochemical techniques such as coacervation-phase separation, etc.; mechanical techniques such as air suspension, pan coating, spray-drying and congealing, and multiorifice centrifugation.

It is understandable that nanocapsules can possess the same (or similar) physical properties as those of nanoparticles. The activities in the field of the nanocapsules/nanoparticles could date back to the pioneering work of Japanese scientists Kubo [29], in theory, and Uyeda et al. [30–35], in experiments. Kubo [29] predicted in his theory that the thermal behavior at low temperatures of metal particles could be evidently different than that of bulk materials, because the average energy gap  $\delta$  close to the Fermi energy could be much larger than the thermal energy  $k_B T$  (where  $k_B$  is the Boltzmann constant and  $T$  is temperature) because of the discontinuity of the energy levels in the limited systems. Using a transmission electronic microscope (TEM), Uyeda et al. investigated systematically the crystallographic structures of various metal and nonmetal ultrafine particles (or nanoparticles) prepared by evaporation and condensation technology [30–53]. Because of their high surface activity, almost all nanoparticles possess the core/shell structure with a shell of oxides and thus belong to the nanocapsule category [30–53]. The exception is nanoparticles (like pure oxides, carbon) without the core/shell structure.

Nanocapsules are matters in intermediate states between bulk and atomic materials which offer an opportunity to investigate the dimensionally confined systems in basic research areas. Various abnormal phenomena, such as magic effects, quantum size effects, surface effects, hyperfine structure etc., in the nanocapsules, alter the physical behavior of the materials. The optical absorption, thermal resistance, melting points, and magnetic properties of the nanocapsules could be quite different than the bulk counterparts. Nanoscale magnetic capsules are expected to have potential applications in various areas such as magnetic recording, magnetic fluids, superconduction, and medicine. The study of the preparation, structure, and physical properties of the nanocapsules has become very important in the field of nanoscience and nanotechnology [54]. Furthermore, as the word “nanocapsules” originated from medicine, the medical and biomedical field is the most active one studying nanocapsules, driven by the motivation of discovering new drug carriers [1–13].

In this chapter, we give a comprehensive review of the advances in the area of the nanocapsules. We outline the theoretical background on this topic in Section 2, which describes energy levels, quantum effects, magic effects, surfaces/interfaces, and metastable phases in nanocapsules. In Section 3, we represent the most applicable nanoencapsulation procedures including physical, chemical, physicochemical, and mechanical techniques. In Section 4, we show the physical properties, including optical, electronic, magnetic, and dynamic properties, of nanocapsules. In Section 5, we concentrate on the biomedical properties, including artificial cell and red blood cell substitutes, drug delivery and controlled release, etc. of nanocapsules. Section 6 is for concluding remarks.

## 2. THEORETICAL BACKGROUND

### 2.1. Introduction

Nanocapsules have physical properties that differ from those of bulk materials. One of the main origins of such differences is the discreteness of the energy levels in the limited systems. According to the energy band theory, the energy levels of a bulk metal are in general continuum (or so-called quasi-continuum) because the number of electrons in the bulk is infinite. For limited systems, like clusters, nanoparticles, and nanocapsules, the limited number of electrons leads directly to the discreteness of the energy levels. When the energy gap is larger than the thermal, magnetostatic, electrostatic, photon, or condensation energy of the superconductivity, the quantum size effect would result correspondingly in different (thermal, magnetic, electronic, photon, or superconducting) behavior of the limited systems. In bulk materials, the cyclic condition and the translation symmetry in three dimensions lead to the plane wave character of electrons. When the size of limited systems is comparable to or even less than the optical wavelength, the de Broglie wavelength, the free path length of electrons, or the coherence length of the Cooper pair, the cyclic condition and the translation symmetry would be broken down, which also affects the physical properties of the systems. The quantum interference of electrons in the confined states could become more pronounced in the nanocapsule systems. The magic number effect is a character observed in the small systems, like clusters, nanoparticles, and nanocapsules. The lack of symmetry of the atoms located at the surfaces/interfaces affects the chemical and physical properties of nanocapsules. The typical core/shell structure could also contribute to the behavior of nanocapsules. Furthermore, the metastable phases could exist in nanocapsules, which could result in different properties of nanocapsules. In this section, we introduce several concepts and topics, such energy levels, quantum effects, magic effects, surfaces/interfaces, and metastable phases, which are particular for the nanoparticles/nanocapsules. Understanding these topics and their differences from those of bulk materials is extremely important for studying the properties of nanocapsules.

### 2.2. Energy Levels

The prediction of discontinuous energy levels was a breakthrough in the area of limited systems. The limited number of electrons results in different characters of electrons in the systems with a limited size. Two basic assumptions of Kubo’s theory are [29, 55–57]: (1) the Poisson distribution of the energy levels close the Fermi surface is held, while the Fermi statistics is invalid in the nanoparticles; (2) the electronic neutral is valid, because it is extremely difficult to take (or put) one electron out from (or in) a nanoparticle because it is necessary to overcome the extremely large Coulomb energy. Considering the effects of the discreteness of the energy levels on the physical properties of metal particles, Kubo and co-workers [29, 55–57] proposed a famous relation,

$$\delta = \frac{4E_F}{3N} \propto V^{-1} \quad (1)$$

for the gap between the nearest neighboring energy levels, where  $E_F$  is Fermi energy,  $N$  is the number of the conduction electrons in the particles, and  $V$  is the volume of the particles. If the particles were in the shape of balls, from Eq. (1), one would have a relation of  $\delta \propto d^{-3}$ . Therefore, the energy gap increases rapidly with decreasing particle size. Because the average energy gap  $\delta$  close to the Fermi energy could be much larger than the thermal energy  $k_B T$  at low temperatures, the discreteness of the energy levels would affect obviously the thermodynamic properties of the materials, and thus the specific heat; the susceptibility of the particles would differ evidently from those of bulk materials. It was found that the specific heat and the susceptibility of the particles depend on the parity (i.e., odd–even) of the number of the electrons in the systems. It is evident that this kind of the quantum size effect becomes much more pronounced only if the following condition is satisfied: the gap of the discreteness of the energy levels is larger than the thermal energy  $k_B T$ , the magnetostatic energy, the magnetoelectric energy, the photon energy, etc. It was estimated that the temperature for a metallic particle of 10 nm showing the quantum size effect is about 2 K; that for a particle of 2 nm could be room temperature. Several groups tried to modify Kubo's theory in order to detect the effects of different distributions of the energy levels and to reach a better agreement between the theoretical and experimental results [58–62]. For details of this topic, readers are referred to the review article by Halperin [63].

### 2.3. Quantum Effects

It is well known that besides the quantum size effect, other quantum effects could be very pronounced in limited systems, like thin films, chains, and particles, when at least one of the dimensions of the systems could be negligible compared to others. When the size of the nanoparticles as well as nanocapsules is reduced to be less than a certain critical value, the systems could be treated as zero (or quasi-zero) dimensional ones. In these cases, the quantum effects become dominant, which originate not only from the discreteness of the energy levels but also from the quantum interference as well as the quantum tunneling in the systems. The cyclic condition and the translation symmetry are lost, when the size of the systems is comparable to the optical wavelength, the de Broglie wavelength, the free path length of electrons, or the coherence length of a Cooper pair. Actually, the breaking down of the translation symmetry leads the wavevector of electrons to not be a “good” quantum number. In the limit case of large nanocapsules, one could treat the wavevector as a “pseudo-good” quantum number and deal with the problem approximately using bulk theory and perturbation theory. In the limiting case of small nanocapsules, such a concept and the corresponding approximation are not valid anymore [64]. The limited systems could be treated as quantum wells, in which the electrons feel the energy/potential difference between different materials when they move. The energy of electrons moving in a quantum well is quantized according to quantum mechanics. If the electrons move in two or more quantum wells separated by spacers, the quantum well interference

between the wells may be either neglected when the thickness of the spacers is thick enough or very pronounced when the wells are close enough. It is easy to find the solution of the quantization of the quantum well states in a single quantum well in any textbook on quantum mechanics [65–67]. Recently, the quantum interference in double quantum wells was studied systematically within the framework of the effective mass model [68]. It has been found that several types of quantum effects (e.g., macroscopic quantum tunnel effects, Coulomb blockade, and quantum tunnelling [69]) occur in the nanoparticles.

### 2.4. Magic Effects

The main feature of magic effects is the existence of magic numbers in elements, clusters, and nanoparticles. For elements, it was found that the protons and the neutrons each form particularly stable systems in an atomic nucleus when the number of either kind of nucleon is one of the so-called magic numbers 2, 8, 20, 50, 82, and 126, which relate to the stability of nuclei and the shell structure of atoms. Nuclei with these magic numbers of protons or neutrons exhibit certain properties which are analogous to closed shell properties in atoms, including anomalously low masses, high natural abundances, and high energy first excited states [70].

Analogically, the magic number has been observed in the systems of clusters and nanoparticles, with regard to their stability. It has been observed that the clusters of some size are much more abundant than others. These clusters containing certain a special number of atoms seem to be much more stable compared to others. These numbers are also referred to as magic numbers. It is understood that factors such as bonding energy, configuration, symmetry, geometry, surface, etc. could affect the magic effects, with respect to the minimum of the total free energy of the clusters or the nanoparticles. Only the more stable clusters/nanoparticles are found to be abundant. Thus, the magic numbers indicate the stability of certain clusters/nanoparticles [71, 72].

The magic numbers seen for rare-gas clusters like argon, krypton, and neon are well understood [71–73]. These magic numbers correspond to nicely close-packed structures that can be formed by packing spheres. The special stability of rare-gas clusters is due to the geometric close-packing of atoms in the clusters. Because spheres can be packed snugly together in certain configurations, one would expect the atoms of inert gases, such as helium, to cluster together in similar tightly packed groups. The numbers of spheres or atoms in these geometrically and energetically favored clusters are termed “magic.” One would expect, for example, the number 13 to be magic because this would be the number of spheres fitting tightly into a 20-sided solid. When clusters of helium atoms are “weighed” with a mass spectrometer, the number 13 is strongly favored; so are 19, 25, 55, 71, 87, and 147. Some of these experimentally derived magic numbers can be predicted theoretically, but some theoretical magic numbers did not turn out to be magic in reality, notably 7, 33, and 43 [74].

The clusters of various metals show the magic numbers which are very different from those of rare gases. The clusters of alkali metals, like lithium, sodium, potassium, and

other metals like aluminum, are stable when the total number of free electrons in the cluster is 8, 20, 34, 40, 58, ... [75, 76]. Notice that what is important here is the total number of free electrons, not the number of atoms in a cluster. This can be understood with the help of the so-called jellium model, in which one assumes that the outer electrons of the metal atoms are loosely bound so that when a cluster is formed, they can move around everywhere in the clusters and are not bound to a particular atom [75, 76]. The atoms without their outer electrons are positively charged ions. So the free electrons "see" a jellium of positive ions in the cluster and move around in the positive jellium. If one tries to theoretically solve the problem of free electrons in a positive jellium, one indeed observes that the clusters are energetically most stable when the total number of electrons in them is 8, 20, 34, 40, 58, etc. Another example of the magic effect is related to the members of the fullerene family, among which  $C_{36}$ ,  $C_{60}$ ,  $C_{72}$ , etc. are much more abundant than others fullerenes [23, 24]. Evidently, the magic effects become less pronounced when the size of the clusters or the particles becomes larger enough. A similar effect was found to be at work on surfaces, where vapor atoms can stick in clusters of specific sizes [77, 78].

## 2.5. Surfaces/Interfaces

The surface phenomenon is one of the most common ones in nature. Everyone can see in daily life the direct consequence of surface effects: water droplets automatically tend to be in the shape of balls. Surface effects originate basically from the surface energy, which is mainly ascribed to the crystallographic asymmetry of the surface atoms bearing the noncompensated forces from other atoms. Surface effects become much more important when one system is of nanocapsule/nanoparticle size [79]. The smaller the size of the particles, the higher the surface energy because of the larger specific surface area. The specific surface area is defined as the surface area  $A$  per the unit volume  $V$  of matter,

$$A_s = \frac{A}{V} \propto d^{-1} \quad (2)$$

where  $d$  is the diameter of a particle. When the diameter of the particle decreases, the specific surface area and the number of surface atoms increase evidently. For instance, when  $d = 10$  nm, 20% of the total  $3 \times 10^4$  atoms are located on the surface; when  $d = 4$  nm, 40% of the total  $4 \times 10^3$  atoms are the surface atoms. The large number of surface atoms, the high surface energy, and the lack of atomic coordination number lead to the high chemical activity of the surface atoms. Because the surface atoms possess less stabilized chemical bonds with neighboring atoms, they are very unstable and thus can combine easily with other atoms. The tendency to be stabilized results in the high chemical activity of the surfaces of the nanoparticles. It is very common for the metal nanoparticles spontaneously to burn in air. It is also a fact that the atoms at the surface of the inorganic particles could easily absorb the atoms/molecules, like gases, water, etc., in air. However, after the formation, the shells of some nanocapsules could prevent the particles from further oxidation.

The interfaces in the nanocapsules could be distinguished as: (1) the interface between different crystal grains of one phase, (2) the interface between different crystal grains of different phases, (3) the interface between the shell and the core, etc. For the small nanocapsules, it is possible that only a single phase exists in the core and the interface of the second type does not exist. In the limited case, the interface of the first type may not exist in the very small nanocapsules. In nanoparticles without the core/shell structure, the interface of the third type cannot be observed. However, in some cases, all interfaces of the three types may be observed in a nanocapsule with a large enough size.

The surfaces/interfaces play important roles in the physical properties of the nanocapsules, because the environments of the atoms at the surface/interface are totally different than those of the atoms inside the grains [80–83]. The physical behaviors of the atoms located inside the grains could be very close to those of atoms in bulk materials. The properties of the atoms at the surfaces/interfaces could differ from those of bulk materials, which are partially due to the lack of structural symmetry of these atoms, similar to what happens in thin films [80–83].

## 2.6. Metastable Phases

It is well known that the saturation evaporation pressure  $P'$  of a small liquid droplet with a radius  $r$  is larger than  $P$  of a liquid surface with an infinite radius, which is described by the famous Kelvin equation [79]

$$\ln \frac{P'}{P} = \frac{2\sigma M}{\rho R T r} \quad (3)$$

where  $\sigma$  is the surface tension,  $M$  is the molecular weight,  $\rho$  is the density of the liquid, and  $R$  is the Avogadro constant. A similar conclusion could be derived for the crystals. Namely, the saturation evaporation pressure of a small crystallite is larger than that of a bulk crystal. The saturation evaporation pressure affects the melting point and the solubility of the crystals. The smaller the crystallite, the lower the melting point and the higher the solubility. In saturated liquid, small crystallites can be spontaneously dissolved or melted, while large ones can spontaneously grow. On the contrary, it is easy to understand that the process of solidification or crystallization can be more difficult for the smaller crystallites. It is difficult to form a new phase out of a phase, which results in different kinds of supersaturation phenomena, like the supersaturation of a gas or a solution, the superheating or the supercooling of a liquid or a solid, etc. From the thermodynamic point of view, all types of supersaturated systems are in the nonequilibrium state. The matter formed during such procedures should be in the nonequilibrium state. Of course, the phases could remain in such a state for a long period, which could be defined as metastable. A metastable phase is a phase that does not exist in equilibrium conditions. It is not the thermodynamically most stable phase but rather a temporarily stable one in a certain condition. The metastable phase forms under conditions corresponding to a local minimum of the free energy. The large energy barrier between this local energy minimum and the lowest energy minimum hinders the formation of

the equilibrium phase in the sense of the dynamics. Nanoparticles as well as nanocapsules usually form in nonequilibrium conditions and consequently the phases formed can be metastable. It was found that in rare-earth transition-metal systems, the formation and phase transformation of rare-earth metastable phases depend sensitively on the structural symmetry of the metastable phases [84]. It is understandable that the structural symmetry of the metastable phases would be one of the most important factors that govern the formation and the phase transformation of the metastable phases in nanocapsules/nanoparticles.

### 3. SYNTHETIC METHODS

#### 3.1. Introduction

Nanocapsules are nanoparticles with a core/shell structure. Nanocapsules consist of two major parts. The inner part is the core material comprised of one or more active ingredients, which may be solids, liquids, or gases. The outer part is the coating material that is usually a high molecular weight polymer (or a combination of such polymers), carbon, or oxide. The polymer can be chosen from a wide variety of natural and synthetic polymers. Normally, the coating material must be nonreactive to the core material, preferably biodegradable, and nontoxic if used for medicine. Other components, such as plasticizers and surfactants, may also be added to the nanocapsules.

Nanocapsules can be prepared by various methods with different mechanisms, including physical, chemical, physicochemical, and mechanical ones. The structural, physical, and biomedical properties of nanocapsules depend sensitively on the processes used for sample preparation. For instance, the preparation procedure could control the size of the nanocapsules, the size distribution of the particles, the thickness of the shell, the size of the grains, the morphology of the nanocapsules, etc. Different nanocapsules may need to be synthesized by different types of preparation techniques. Some methods may be suitable for synthesis of only some typical nanocapsules.

In this section, we describe the most applicable nanocapsulation procedures, including physical methods such as heat evaporation, arc discharge, laser/electron beam heating, sputtering, etc.; chemical methods such as chemical vapor deposition, solid-state reactions, sol-gel, precipitation, hydrothermal process, solvent process, latex process, oxidation process, polymerization, etc.; physicochemical methods such as coacervation-phase separation, etc.; mechanical methods such as air suspension, pan coating, spray-drying and congealing, and multiorifice centrifugation. In this section, we concentrate mainly on the preparation procedures and leave the detailed description of the physical and biomedical properties to next two sections.

#### 3.2. Physical Methods

The physical methods for synthesizing the nanocapsules could be separated into two categories: breaking down and building up. The breaking-down process means to mill mechanically the bulk materials to be particles. In general, the breaking-down process could be employed to produce

particles of about 1  $\mu\text{m}$  in size and it is difficult to prepare nanoparticles and nanocapsules with sizes below 100 nm. We shall not discuss this type of the process in detail. The building-up process synthesizes nanoparticles and nanocapsules through the nucleation and growth processes of the elementary particles, like ions and atoms. The building-up process is one of the most effective processes for the formation of nanoparticles as well as nanocapsules, which satisfies the conditions requested for the preparing nanoparticles: (1) clean surfaces; (2) controllable sizes and narrow size distribution; (3) easy collections; (4) stability of the particles; (5) high efficiency for production; etc. The basic principles for the building-up process are at first heating metals in gas atmospheres of several hundred to thousands of Pa and then condensing. Depending on the heating procedures, the build-up process could be of several different kinds, such as evaporation, arc discharge/plasma, laser heating, electron beam heating, sputtering, etc. Depending on the gas atmospheres, the final production could be different kinds of nanoparticles/nanocapsules.

##### 3.2.1. Evaporation

Evaporation in gases is a method that evaporates metals, alloys, or ceramics so that the atoms bump each other and also atoms of inert gases, or they react with active gases. Condensation in the cold gases results in the formation of nanoparticles (or ultrafine particles as defined in some literature many years ago) and nanocapsules. Heating by a resistance heater or a high frequency induction furnace is the simplest method in laboratories for evaporating the metals [29–41]. The resistance heater can be made of graphite, tungsten wire, or other kinds of metal wires. In the earliest experiments, metals were put in a tungsten basket inside a vacuum chamber and then evaporated in argon atmosphere of 1–50 Torr [30]. The metal smoke deposited on the water-cooled inner wall of the chamber. Figure 1 shows iron and copper smoke [35]. The nanoparticles were collected by a TEM mesh grid for observation by a TEM. The crystallographic properties of various nanoparticles, such as Mg, Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, Ag, Cd, Sn, Au, Pb, and Bi, were investigated systematically by TEM observations. It is a common fact that for all metals, the size of the particles is reduced with decreasing atmospheric pressure [30–35]. It is interesting to note that usually a shell of oxidations (commonly in amorphous) of several nanometers forms on the surface of the nanoparticles. The different metal nanoparticles have different crystallographic structures. For instance, Al, Bi, Sn, and Pb particles are balls, Mg particles are hexagons, and Cr particles are body-centered cubic (bcc) structures. Magnetic particles, like Fe and Co, can align as a necklace or a chain [30–35] due to the existence of stable magnetic moments and magnetostatic forces. Dipolar interaction plays an important role on such alignment of magnetic nanoparticles, which may become dominant compared to the van der Waals attraction and steric repulsion that usually lead to a close-packed arrangement [85, 86]. The magnetic domains in the particles were observed by means of Lorentz electron microscopy [87–90].

The character (i.e., the shapes and colors) of the metal smokes was found to depend on the gas pressure/density

**Figure 1.** Iron and copper smokes. The smoke looks white for all metals and no color is observed. A beautiful color, however, characteristic of each metal, is seen in the neighborhood of the heater. (a) shows iron smoke in 50 Torr of helium, which has a typical candle-flame shape with inner, intermediate, and outer zones. The bright intermediate zone implies that the smoke is denser there than in the dark inner zone. In the case of iron, red light is emitted from the neighborhood of the heater. (b) shows copper smoke in 30 Torr of argon, which is thinner, because 30 Torr of argon is denser than 50 Torr of helium. The blue color is seen near the evaporation source. Adapted with permission from [35], R. Uyeda, in “Morphology of Crystals” (I. Sunagawa, Ed.), Ch. 6, p. 367. Terra Scientific, Tokyo, 1987. © 1987, Terra Scientific.

and the temperature/velocity of evaporation [35, 39, 42, 43]. The shape of the metal smoke can be candle-fire-, ring-, tulip-, and butterfly-like. The color of the smoke can be purple (for Al, Ag), green (for Au), red (for Be, Co, Fe, Ni), blue (for Cu, Nb, W), orange (for Ti), green plus orange (for Cr, Fe), yellow plus green (for Mo), etc. [35, 43, 46, 49, 50]. Granqvist and Buhrman obtained nanoparticles with an average size of about 10 nm by evaporating Al, Mg, Zn, Sn, Cr, Fe, Co, Ni, and Ca in argon atmosphere of 0.5–4 Torr by applying a facility with a graphite heater [91–96]. Increasing one of several factors (velocity of evaporation, temperature of the evaporating materials, evaporating pressure of the materials, press of inert gases) would increase the size of the nanoparticles/nanocapsules. Evaporation by a resistance heater is usually suitable for producing a small amount of the particles in laboratories, while heating by a high frequency induction furnace could be applied for producing a large amount of materials in the industrial scale. The advantages of the latter method are the stability of evaporation temperature, the homogenous melting alloys, the high energy power supply, etc. For details of the crystal habits and crystal structures of nanoparticles, the reader is referred to Uyeda’s book [35] and other original contributions [30, 36–53, 97–101].

### 3.2.2. Arc Discharge/Plasma

The formation mechanism of nanoparticles/nanocapsules in plasma is that matter clusters with high activity exist in the plasma, which could exchange rapidly the energy with the

reacted matter clusters, beneficial to the reaction between them. When the reacted matter clusters leave the high temperature in the flame tail region of the plasma, the rapid decrease of the temperature lets the clusters be in the saturation state in dynamic equilibrium; thus they are dissociated. The rapid cooling/quenching leads to the nucleation of crystallites and the formation of nanoparticles/nanocapsules. According to the method of production, the plasma can be of two kinds: direct current arc plasma and high frequency plasma. Direct current arc plasma uses the direct current arc in inert/active gases to ionize the gases, generate the high temperature plasma, and melt the materials. The cooling, reaction, and condensation of the evaporating matters lead to the formation of nanoparticles and nanocapsules. The high frequency plasma is produced by induction coils outside the quartz tube, which can generate the magnetic field with MHz frequency. The advantages of the high frequency plasma method are: less contamination because no cathode is used, the use of reaction gases, and enough space for plasma so that the reaction and heating are sufficient for the plasma matter. The direct current arc plasma and the high frequency plasma methods can be combined in equipment for industrial purposes.

There has been great interest in the incorporation of foreign materials into fullerene structures (C<sub>60</sub>, nanotubes, nanoparticles, onions), which has been driven by the potential applications of the filled fullerenes, which lie in diverse areas such as optics, electronics, magnetic recording materials, and nuclear medicine. In particular, the onion structures of extreme strength may offer excellent protection of their encapsulated nanomaterials for applications. The arc vaporization/discharge method has been widely used for the formation of fullerenes and related materials [102]. One of the remarkable properties of fullerenes and related materials is that they have hollow structures with a cavity of nanometer-scale diameter; outer cages are made up of single or concentric multilayers of graphene sheets. When foreign materials, such as metal atom(s) or nanocrystallites, are trapped in the inner cavity, unusual physical and chemical properties are brought about.

The structures of carbon polyhedral particles stuffed with YC<sub>2</sub>, synthesized by arc discharge of carbon rods containing yttrium, were studied with a TEM [103]. The YC<sub>2</sub> crystals with typical sizes of a few tens of nanometers were wrapped by multilayered graphitic sheets and were protected against hydrolysis. It was demonstrated that a finely focused electron beam opened the graphite cage. A growth model of the carbon nanocapsules stuffed with metal carbides was proposed. Then the encapsulation of metals in multilayered graphitic capsules was studied for all the rare-earth elements (Sc, Y, and R = La, Ce, . . . , Lu) excluding Pm by using electric arc discharge [104]. Most rare-earth metals (Sc, Y, La, Ce, Pr, Nd, Gd, Tb, Dy, Ho, Er, and Lu) were encapsulated in the form of carbides, but the others, Sm, Eu, and Yb, were not. The metals in the former group that were encapsulated had vapor pressures definitely lower than those in the latter group. In the case of thulium (Tm), whose vapor pressure was intermediate between the two groups, only a trace amount of encapsulated carbide was formed. The volatility of metal played an important role in the metal encapsulation process.

Crystallites of scandium carbides, nesting in multilayered polyhedral graphitic cages, were produced by evaporating a scandium–graphite composite rod in helium gas [105]. The encapsulated scandium carbide was identified as  $\text{Sc}_{15}\text{C}_{19}$ , instead of dicarbide  $\text{RC}_2$ , the form of carbide commonly found for other rare-earth-based nanocapsules. The size of the capsules ranged from about 10 to 100 nm. Morphological features of the outer graphitic carbon, multilayered and polyhedral, were quite similar to those for the capsules protecting  $\text{RC}_2$  ( $R = \text{Y}, \text{La}, \text{Ce}, \dots, \text{Lu}$ ) [104].

Experiments aimed at the encapsulation of foreign materials within hollow graphitic cages were carried for iron group metals (Fe, Co, Ni) [106–114]. For iron group metals, particles of both a carbide phase ( $\text{M}_3\text{C}$ ,  $M = \text{Fe}, \text{Co}, \text{Ni}$ ) and also a metallic phase [ $\alpha$ -Fe,  $\gamma$ -Fe, hexagonal close-packed (hcp) Co, face-centered cubic (fcc) Co, fcc Ni] were encapsulated in graphitic carbon [106, 107]. Sometimes, metallic nanocrystals of Fe, Co, and Ni were in the fcc phase, and no trace (or a trace amount) of the bulk equilibrium phases of bcc Fe and hcp Co was found [108, 109]. Especially for Ni, exotic carbon materials with hollow structures, bamboo-shaped tubes, and nanochains as well as single-layered nanotubes were discovered [110]. Figure 2 shows high resolution TEM (HRTEM) images of the shell/core structure of Ni(C) nanocapsules [109]. The particles were nominally spherical in shape and typically 10–100 nm in diameter. The core Co metal was protected against oxidation and coalescence.

Evaporation of Fe, Ni, or Co with graphite in a hydrogen atmosphere resulted in graphite encapsulated nanoparticles. Similar experiments in helium led to nanoparticles embedded in an amorphous carbon/fullerene matrix. Comparing the experimental results in helium and hydrogen, a mechanism for the formation of encapsulated nanoparticles was proposed [113, 114]. The hydrogen arc produced polycyclic aromatic hydrocarbon molecules, which can act as a precursor to the graphitic layers around the nanoparticles. Direct evidence for this mechanism was given by using methane ( $\text{CH}_4$ ) [113] or pyrene ( $\text{C}_{16}\text{H}_{10}$ ) [114], a polycyclic aromatic hydrocarbon molecule, as the only carbon source to form encapsulated nanoparticles. Pyrolysis of hydrocarbon

**Figure 2.** HRTEM images showing the shell/core structure of Ni(C) nanocapsules. After [109], V. P. Dravid et al., *Nature* 374, 602 (1995). © 1995, Macmillan Magazines Ltd.

compounds on evaporated metal-based catalysts was used to produce carbon shells, hollow fibers, and other hollow carbon forms [115]. A kinetic model for their formation and the mechanisms for obtaining different types of hollow carbons were proposed [115], in which two competing processes, the linear growth rate of the carbon and the catalyst outlet rate relative to the growing carbon, determined the type of hollow carbon.

A process of arc discharge was developed to fabricate carbon-encapsulated magnetic nanocapsules in methane ( $\text{CH}_4$ ) atmosphere, where a carbon rod was used as the cathode and a metal or alloy block was used as the anode [113].  $\gamma$ -Fe(C),  $\alpha$ -Fe(C) and  $\text{Fe}_3\text{C}$  [113, 116], Fe–Ni(C) [117, 118], and Fe–Co(C) [119–121] nanocapsules were synthesized successfully by arc discharge in methane. Figure 3 presents a HRTEM image showing the shell/core structure of Fe–Co(C) nanocapsules with a graphite shell of about 3.4 nm thickness and a crystalline Fe–Co core [121]. The shell is characterized by curved lattice fringes of interplanar spacing 0.34 nm corresponding to the (0002) lattice plane of graphite carbon [121]. This process was employed to produce nanocapsules with different types of shells and cores only by changing the atmosphere. Fe(B) and Co(B) nanocapsules sheathed with boron oxide were prepared in diborane ( $\text{B}_2\text{H}_6$ ) atmosphere [122–124]. Figure 4a shows a TEM photograph of Co(B) nanocapsules which arrange as a chain due to the magnetostatic energy, while Figure 4b gives a HRTEM image showing the shell/core structure of Co(B) nanocapsules with an amorphous boron oxide shell of about 4.0 nm thickness and a crystalline CoB core [124]. Amorphous boron nanoparticles and BN encapsulating boron nanocapsules were prepared by arc decomposing diborane and nitriding [125].

Twenty elements were co-deposited with carbon in an arc discharge between graphite electrodes [126]. The majority of them were evaporated from composite anodes that contained the elements or their oxides stuffed into central bores in the graphite rods. The deposits, found in the soot at the

reactor walls or as slag at the cathode, were characterized. The products fall into four categories: (1) elements that can be encapsulated in the form of their carbides (B, V, Cr, Mn, Y, Zr, Nb, Mo); (2) elements that are not encapsulated but tolerate the formation of graphitic carbon cages (Cu, Zn, Pd, Ag, Pt); (3) elements that form stable carbides, competing with and preempting the carbon supply for the graphitic cage formation (Al, Si, Ti, W); and (4) the iron-group metals (Fe, Co, Ni) that stimulate the formation of single-walled tubes and strings of nanobeads in the conventional arc discharge condition and produce nanometer-size carbon-coated ferromagnetic particles in a modified arc discharge in which metals are in molten form in graphite crucible anodes exposed to a helium jet stream. The criterion determining the formation was discussed, according to one of the four categories. It was apparent that the physical properties, such as vapor pressure, melting and boiling points, the completeness of the electronic shells of the elements, and the heat of carbide formation, were not sufficient to explain the selectivity of the encapsulation without exceptions. A hypothesis was advanced that emphasizes the existence of the carbide, interfacial compatibility with the graphitic network, as well as the transport and supply parameters in the reaction space.

Encapsulation of platinum-group metals (Ru, Ph, Pd, Os, Ir, Pt) within carbon nanocapsules and synthesis of single-layered carbon nanotubes by arc evaporation of metal/carbon

composites were studied [127]. All the platinum-group metals, forming small particles (10–200 nm in diameter), were encapsulated within multilayered graphitic cages. Particles trapped in the cages were single-domain crystallites in normal metallic phases. Ph, Pd, and Pt showed catalytic activity for growing single-layered carbon tubes, but the other metals did not.

Fine crystallites of titanium and hafnium carbides encapsulated within graphite cages were formed by arc discharge between a metal/carbon composite anode and a graphite cathode [128]. Encapsulated TiC crystallites ranging from 30 to 150 nm in size were found in carbonaceous materials formed around a cathode. Short, single-walled carbon nanotubes were also observed, extruding from carbon layers with complicated structures surrounding TiC crystallites. For hafnium whose vapor pressure was lower than that of carbon at high temperatures, the formation of HfC crystallites (20 to 80 nm in diameter) was limited within a slaglike deposit, which was also encapsulated in graphite cages.

Encapsulation of Cr, Mo, and W in multilayered graphitic cages by arc evaporation of metal/carbon composites under different pressures (100, 600, and 1500 Torr) of helium gas was studied [129]. The encapsulated crystallites were carbides, that is,  $\text{Cr}_7\text{C}_3$  and  $\text{Cr}_3\text{C}_2$  for Cr;  $\text{Mo}_2\text{C}$ ,  $\delta\text{-MoC}_{1-x}$  (NaCl-type), and  $\gamma'\text{-MoC}$  (AsTi-type) for Mo;  $\text{W}_2\text{C}$  and  $\beta\text{-WC}_{1-x}$  (NaCl-type) for W. The effect of helium gas pressure on the formation of the nanocapsules was found for tungsten: Encapsulated tungsten carbides were formed at the highest pressure, but not at the lower pressures.

A dc arc discharge was generated between graphite and molybdenum electrodes at 25 kPa of He gas ambient, in order to reveal the relation between nanotube growth and arc discharge phenomena [130]. Numerous multiwall carbon nanotubes and nanocapsules were observed at the cathode spot area of the C cathode. An explanation was presented for the growth of soft-core containing nanotubes and a hard shell in the usual arc with a C-cathode and C-anode electrode system.

A form of graphitic cage in nanometer scale, rectangular parallelepiped (or cube), was produced by arc evaporation of a carbon electrode containing calcium or strontium [131]. Both empty and filled rectangular nanocapsules averaging 20–100 nm in size were formed, though the empty ones were dominant. The rectangular cages were made up of multiwalled (5–20 layers) graphitic carbon. The encapsulated materials were  $\beta\text{-CaC}_2$  (tetragonal),  $\gamma\text{-CaC}_2$  (cubic), and  $\delta\text{-CaC}_2$  (monoclinic) for C/Ca evaporation, and  $\beta\text{-SrC}_2$  (tetragonal) and metallic Sr for C/S revaporation.

The growth phenomena of different metals encapsulated into carbon cages were studied in emphasizing the effect of carbon and metal supply on the size of particles [132, 133]. Postdeposition annealing was introduced as a process that induces structural rearrangements and thus enables changes in morphologies. Particles made under the same experimental conditions of the arc discharge process were of roughly the same size. The average diameter of the particles produced by using a larger diameter of the metal pool was bigger than those of the particles produced from the smaller metal pool. The annealing provided additional thermal energy making structural rearrangement possible long after the initial deposition process was terminated.

The effects of the carbon content, chamber pressure, arc current, and blowing gas velocity on the encapsulation of nickel in graphite layers were observed by systematically varying each of these variables in a tungsten-arc encapsulation setup [134]. The properties of the arc translated into changes in the encapsulated product. A larger and hotter arc resulted in more encapsulation in the final sample. These findings, along with evidence of graphite layers forming on precrystallized particles, indicated that the graphite layers might form by two sequential formation steps. The first step was the simple phase segregation of carbon from a cooling liquid particle, resulting in surface graphite. The second step was the growth of carbon on a crystallized nickel particle, regardless of the temperature at which this occurs.

Gold, iron oxide, and germanium nanocapsules encapsulated in the boron nitride sheets were produced by arc melting in a nitrogen gas atmosphere using a tungsten electrode and a boron-based mixture powder [135, 136]. Nanoscale materials created from boron nitride by arc discharge between  $ZrB_2$  electrodes in  $N_2$  atmosphere were investigated [137]. Boron nitride nanotubes were formed together with Zr-compound nanoparticles encapsulated in boron nitride cages. Concerning the helical structures of the boron nitride tubes, a variety of chiral angles, including the zigzag and the armchair types, were observed. Weak peaks of photoluminescence spectrum were observed from the nanocapsules with germanium nanoparticles [136].

The spatial distribution of the chemical species (B, C, N, and Hf) present in multielement nanoparticles and nanotubes, which were produced by arc discharging a hafnium diboride rod with a graphite rod in a nitrogen atmosphere [138], was investigated by means of electron energy loss spectroscopy (EELS). For the hafnium-boride metallic particles coated by C/BN envelopes, a model was proposed based on the solidification from the outside to the inside of isolated liquidlike droplets: the carbon phase solidifies first according to theoretical phase diagrams and forms the outer shells.

Various boron nitride and carbon nanocage fullerene materials (clusters, metallofullerenes, onion, nanotubes, and nanocapsules) were synthesized by arc melting, electron beam irradiation, chemical reaction, and self-organization [139–141]. Boron nitride nanotubes, nanocapsules, and nanocages were fabricated by arc melting  $LaB_6$  and boron/ $LaB_6$  powder compacts in a nitrogen/argon gas atmosphere [141]. A guideline for designing the boron nitride and carbon fullerene materials was summarized. B–C–N nanotubes prepared by a flush evaporation method using a dc arc plasma were characterized by TEM and EELS [140]. The nanotubes obtained were divided into three types, such as carbon, boron nitride, or carbon nanotubes surrounded with boron nitride nanotubes. These types of nanotubes were obtained only at temperatures higher than approximately 3000 K. On the other hand, nanocapsules were formed at all the temperature regions, but the nanocapsules obtained at lower temperatures were smaller. The addition of nickel produced a bundle of single-walled carbon nanotubes and boron nitride nanocapsules surrounding nickel particles.

Ge and SiC nanoparticles and nanowires encapsulated in carbon nanocapsules and nanotubes were produced by direct current and radio frequency hybrid arc discharge of

C, Ge, and Si elements [142, 143]. HRTEM images showed the formation of Ge and SiC nanoparticles and nanowires encapsulated in carbon nanocapsules and nanotubes. The growth direction of the Ge nanowires was found to be (111) of Ge, and a structure model for Ge/C interface was proposed. Silicon–fullerene compounds  $Si@C_n$  ( $n = 74, 86$ , etc.) and carbon nanocapsules filled with SiC were produced in a modified fullerene generator, where a direct current or radio frequency discharge was superimposed in the periphery region of an arc-discharge plasma [144].

HRTEM images of  $C_3N_{3.6-4.5}O_{1.1-1.2}H_{4.1-4.2}$  showed nanocage- and nanotube-like structures, which have cage and tube sizes in the range of 10–500 nm [145]. Electron diffraction of the cage structures indicated a disordered  $CN_x$  structure, and carbon and nitrogen were detected. Nanocrystalline grains encapsulated in  $CN_x$  nanotubes and nanocapsules were also observed, and carbon, oxygen, and a little nitrogen were detected.

### 3.2.3. Laser/Electron Beam Heating

Electron beam heating has been used widely in the fields of melting, welding, sputtering, and micromanufacturing. The electrons emit from the cathode of the electron gun where the temperature is very high due to the application of the high voltage that is necessary for the emission of electrons. Thus the high vacuum must be kept in the electron gun. Actually, the electron gun inside a TEM can be conveniently used for electron beam heating and irradiating of the materials. Another efficient method is laser heating, which has several advantages: the heating source is outside the evaporation system; any materials, including metals, compounds, ceramics, etc., can be evaporated; there is no contamination from/for the heating source. Both the laser and the electron beam heatings are efficient for evaporation of materials with high melting points.

A method was developed for formation of carbon nanotubes, carbon nanocapsules, and carbon nanoparticles in which polyyne-containing carbons were heated and irradiated by an electron beam in a TEM [146–149]. The technique was applied to carry out *in-situ* observation of those formation processes. Though carbon nanoparticles were formed accompanied by carbon nanotubes, carbon nanoparticles and nanocapsules were formed independently of the carbon nanotubes [146]. The carbon nanotubes were preferentially inside of the polyyne-containing carbon films, while the carbon nanoparticles/nanocapsules were outside of the films. The differences on the inside and the outside were discussed to understand the formation process of the carbon nanoparticles/nanocapsules. From *in-situ* observation, the existence of metal particles, the high surface energy, the high wettability, and the high viscosity of the polyyne-containing carbons were assumed to be relevant to the preferential formation of the carbon nanoparticles/nanocapsules to the carbon nanotubes.

Carbon onions were produced in a TEM by electron irradiation of amorphous carbon in the presence of Pd clusters [147]. HRTEM revealed the structural changes of the onion surface, and the atom clouds were observed at the pentagonal vertices. In some onions, Pd atoms were intercalated between the graphite onion sheets, and a structural model

for the intercalation was proposed. Electron beam irradiation of amorphous carbon in the presence of Pd clusters was shown to be an effective method for the formation of intercalated onions.

Metallic nanocrystals, such as cobalt or gold, were encapsulated by spherical graphitic shells under high-temperature electron irradiation [148]. The irradiation promoted a heavy contraction of carbon onions. The contraction forced the metal atoms to migrate outward through the shells, even without further irradiation. This led to a gradual but complete displacement of the encapsulated crystals. *In-situ* observation in a TEM allowed shrinkage of the encapsulated crystals and migration of the atoms through the shells to be monitored. The spherically curved graphene layers were permeable to metal atoms.

Copper substrates were implanted with carbon ions at temperatures ranging from 570 to 973 K [149]. Carbon onions and nanocapsules were observed together with amorphous carbon layers. Most of the nanocapsules were found to be hollow and rarely included copper nanoparticles. The encapsulating of Cu nanoparticles with graphene layers, the gradual shrinkage of the encapsulated clusters, and finally the disappearance of the clusters (leaving behind hollow nanocapsules) were observed under electron irradiation at 783 K. Statistics of cluster size as a function of ion fluence, implantation temperature, and substrate crystallinity gave insights into the nucleation processes of onions and nanocapsules. One process involved the formation of graphene layers on grain boundaries to encapsulate copper particles. Another process was the nucleation of graphene cages, probably fullerenes, due to a high concentration of carbon atoms and a high amount of radiation damage.

Nanocapsules of crystalline boron nitride with diameters ranging from 50 to 300 nm were synthesized by pulsed-laser vaporization of BN, where the laser plume was controlled by the modulated plasma jet flow field [150]. Their shapes varied from polyhedrons to cocoons and the interlayer spacings along the *c* axis were enlarged according to their size and shape (curvature). Without the synchronization of the laser pulses with the plasma modulation, sootlike BN was obtained.

Magnetic Fe<sub>3</sub>C and  $\alpha$ -Fe nanoparticles were prepared by laser-induced pyrolysis of Fe(CO)<sub>5</sub> and C<sub>2</sub>H<sub>4</sub> [151]. It was found that not only was oxygen content of the  $\alpha$ -Fe particles much higher than that of the Fe<sub>3</sub>C particles, but the oxygen was in different states for the two nanoparticles. The oxygen present on the Fe<sub>3</sub>C particles was primarily in absorbed form, compared to chemically combined oxygen as in the  $\alpha$ -Fe particles. Iron carbonitride nanoparticles (20–80 nm in size) were synthesized by laser-induced pyrolysis of a Fe(CO)<sub>5</sub>-NH<sub>3</sub>-C<sub>2</sub>H<sub>4</sub> mixture [152]. Surface morphology, structural characteristics, oxidation behavior, and magnetic properties of the iron carbonitride particles were reported. The unilateral lattice expansion of the iron carbonitride compound was interpreted in terms of the structural and chemical bonding features of the iron carbonitride compound.

$\alpha$ -Fe (bcc) and  $\gamma$ -Fe (fcc) nanoparticles were prepared by laser-induced pyrolysis [153]. The structures, morphologies, and magnetic properties of the oxide layers covering the iron

nanoparticles were investigated. The iron oxide layers consisted of very fine crystallites of 2–5 nm in diameter, and the layers were nonferromagnetic or superparamagnetic. The iron oxide layer formed on iron nanoparticles at room temperature was Fe<sub>3</sub>O<sub>4</sub>, rather than a mixture of Fe<sub>3</sub>O<sub>4</sub> and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>.

$\gamma$ -Fe(N) nanoparticles (containing 5.9% N, atomic fraction) were prepared by laser induced pyrolysis [154]. The martensitic transformation temperature of the nanoparticles was much lower than that of the bulk materials with the same composition. The effect of particle size on the transformation temperature was discussed. It was suggested that the hydrostatic pressure resulting from surface tension of the nanoparticles was responsible for the decrease of the transformation temperature. In order to verify the plastic deformation induced martensitic transformation of the  $\gamma$ -Fe(N) nanoparticles, the effects of pressurization (0.5–4.0 GPa) on the martensitic transformation and microstructures of the particles were presented.

### 3.2.4. Sputtering

Sputtering is a convenient method for preparing films, by which different elementary materials are ionized or heated to form the plasma before depositing on substrates. Sputtering can be employed for preparing the nanoparticles embedded in the thin films, or so-called granular films. The mechanism of the sputtering is as follows: the direct current of hundreds of voltages applied between the cathode and the anode in atmosphere of inert and active gases leads to glow discharge. The ions during the process of discharge bump the target that serves as the cathode, so that the atoms of the target materials could evaporate from the surface. The cooling and the condensation in inert gases and/or the reaction in active gases of the evaporation atoms result in the formation of nanoparticles and nanocapsules, or thin films. The advantages of sputtering are as follows: no crucible is needed; particles of metals with a high melting point can be prepared; the evaporation surface can be large; particles of alloys can be synthesized using active gases; granular thin films can be prepared; the narrow size distribution of the particles can be controlled well; nanocomposite materials can be produced if several different materials are used as targets; etc. The voltage, current, gas pressure, and target are the most important factors which affect the formation of nanoparticles/nanocapsules.

A method was reported for fabricating thin films of carbon nanocapsules and onionlike graphitic particles [155], which consisted of cosputtering Ni and graphite and subsequent thermal annealing in vacuum. The films were composed of Ni-filled carbon nanocapsules with graphitic coatings several nanometers in thickness. Ni particles were removed by acid etching, resulting in the formation of thin films composed of onionlike graphitic particles. Electron field emission properties of the onionlike graphitic-particle films were studied.

C-Ag thin films were synthesized by cosputtering of a silver-graphite target [156]. The deposition temperature ranged from 77 to 773 K, while the silver concentration varied from 10 to 71 at%. The homogeneously distributed silver nanoparticles, having an elongated shape along the

direction of the thin film growth, formed within a more or less graphitized carbon matrix. A graphitization led to the encapsulation of the silver nanoparticles in graphite-like carbon when the depositions were performed at 773 K for lower silver concentrations without ion-beam assistance and below 573 K for upper silver concentrations with ion-beam assistance.

$(\text{Ni}_{66}\text{Fe}_{22}\text{Co}_{12})_x\text{C}_{1-x}$  nanocomposite films with  $x = 10\text{--}75$  at% were prepared by dc magnetron cosputtering [157]. Subsequent thermal annealing was performed in a vacuum ( $<2 \times 10^{-3}$  Pa) furnace for 1 h at various temperatures. The phase transition with increase of annealing temperature was closely dependent on the composition. Films with NiFeCo less than 20 at% showed an amorphous structure in the as-deposited samples and ones annealed up to 400 °C. After being annealed at 500 °C, a small amount of fcc crystalline NiFeCo precipitated while carbon remained amorphous. For the films with NiFeCo concentration of 30–55 at%, the as-deposited films consist of very small NiFeCo nanocrystals encapsulated in amorphous carbon. After being annealed, the crystal grain size of the alloys increased with increasing annealing temperature while carbon was graphitized. For the films with more than 62 at% NiFeCo, the as-deposited films went through a metastable stage at which a rhombohedral  $\text{Ni}_3\text{C}$  phase and fcc NiFeCo coexisted upon annealing to a temperature between approximately 300 and 400 °C (dependent on composition). Upon further annealing to a sufficiently high temperature between approximately 350 and 500 °C, the carbide phase decomposed and only the fcc NiFeCo nanocrystals encapsulated in graphite existed in the films.

### 3.3. Chemical Methods

The chemical methods are useful fabrication methods for the mass production of the nanoparticles and the nanocapsules, compared to the physical methods. It is very typical that during the chemical methods, some chemical reactions occur, accompanying the formation of nanoparticles/nanocapsules. Chemical methods for preparation of nanoparticles and nanocapsules include chemical gas reaction [i.e., the chemical vapor deposition (CVD)], chemical vapor condensation (CVC), solid-state reaction, sol-gel, precipitation, hydrothermal process, solvent process, latex process, oxidation process, polymerization, etc. Different chemical methods have different procedures with different chemical reactions at various steps of the synthesis of nanoparticles/nanocapsules. Thus the abundance of chemical methods could be employed to synthesize many kinds of nanoparticles/nanocapsules with various shapes, morphologies, phases, structures, sizes, etc., for different kinds of materials, varying from metals, to oxides, ceramics, organics, etc. The advantages of these chemical methods are high purity, high uniformity, small particle size, narrow size distribution, good dispersal, good chemical homogeneity, high chemical reaction activity, and structural/composition uniformity. The chemical methods are also convenient, inexpensive, and effective for preparation of nanoparticles/nanocapsules in high yield.

#### 3.3.1. Chemical Vapor Deposition

The CVD process is a method of chemical vapor reaction which utilizes the evaporation of volatile metal compounds and chemical reactions to form the compounds desired and the rapid cooling in gas atmospheres to result in the formation of nanoparticles/nanocapsules. The nanoparticles/nanocapsules produced by CVD have several advantages, like high purity, high uniformity, small particle size, narrow size distribution, good dispersal, and high chemical reaction activity. CVD is suitable for synthesizing not only nanoparticles/nanocapsules but also fibers/nanotubes of metals, metal compounds, for instance, nitrides, carbides, borides, etc. In accordance with the types of the reactions, CVD can be divided into two kinds of methods: vapor decomposition and vapor synthesis. According to the type of reaction precursor, the CVD can be classified to be the gas-gas reaction one, the gas-solid reaction one, and the gas-liquid reaction one. For the occurrence of the chemical reactions, it is used to utilize the heating and radiation activating the molecules in the reaction systems. The methods for the activation of the molecules include resistant heating, chemical flame heating, laser heating [158–160], plasma heating [161], X-ray radiation, etc.

The vapor decomposition method is a so-called single compound heat decomposition method. The compound is heated to evaporate and decompose, as in the following reaction:

The materials used for the vapor decomposition method are usually the volatile metal compounds,  $\text{Fe}(\text{CO})_5$ ,  $\text{Si}(\text{NH})_2$ ,  $\text{SiH}_4$ ,  $\text{Si}(\text{OH})_4$ ,  $(\text{CH}_3)_4\text{Si}$ , etc., which have high evaporation pressure and high reaction activity. The reaction equations are as follows:

The vapor synthesis method usually utilizes the vapor reactions between two (or more than two) different materials to form the nanoparticles/nanocapsules of the new compounds. The common reaction equation is

The materials used for the vapor synthesis method can be  $\text{SiH}_4$ ,  $\text{CH}_3\text{SiCl}$ ,  $(\text{CH}_3)_4\text{Si}$ ,  $\text{SiCl}_4$ ,  $\text{BCl}_3$ ,  $\text{TiCl}$ ,  $\text{TiCl}_4$ ,  $\text{TiI}$ ,  $\text{TiI}_4$ ,  $\text{ZrCl}_4$ ,  $\text{MCl}_3$ ,  $\text{MoO}_3$ ,  $\text{WCl}_6$ ,  $\text{H}_2$ ,  $\text{NH}_3$ ,  $\text{CH}_4$ ,  $\text{C}_2\text{H}_4$ , etc. The vapor synthesis method is highly flexible because of the combination and the exchange of the different precursors. The following reactions are listed as examples:

The heating by a resistant furnace is a traditional procedure for chemical vapor reaction, which consists of precursor treatment, the parameter control of the reaction, nucleation and growth, cooling, and condensation. For both the vapor decomposition method and the vapor synthesis method, when the laser heating is used, one needs to choose the materials with high absorption ability of the laser beam as the reaction precursors [158–160]. The mechanism of laser induced chemical vapor reaction for synthesis of nanoparticles is that the gases strongly absorb the high energy of the laser beam so that the gas atoms/molecules are heated and activated instantly. The gases reach the high temperature needed for the chemical reactions and accomplish the reactions, nucleation, and growth in a very short time. The nanoparticles of metals Fe, Ni, Al, Ti, Cr, Zr, Mo, and Ta, their oxides, and nitrides have been synthesized [151–154, 158–160].

The different preparation methods of ultrafine powders of high melting point compounds (carbides, borides, nitrides, and oxides) were reviewed [161]. The consolidation behavior of these compounds in the nanocrystalline state was described in detail. Compaction by hot pressing, including high pressure and high temperature, sintering, and high-energy consolidation methods, was analyzed. The microstructure, recrystallization, and mechanical and physical properties of the nanocrystalline carbides, nitrides, and oxides were characterized [161].

Nanoparticles of uranium dicarbide encapsulated in carbon smaller than 100 nm were obtained by chemical reactions at high temperatures [162]. Two types of nanocapsules were identified and characterized. The majority of them had small diffuse kernel surfaces, with dimensions between 5 and 15 nm, surrounded by thick spherical carbon cover. Others, in minor quantity and ranging from 15 to 40 nm, were polyhedral and surrounded by several perfect graphite layers oriented parallel to their external surface. The nanocapsules are as chemically inert as graphite.

Pyrolysis of acetylene over quartz plates coated with various metal catalysts resulted in the formation of all-carbon nanostructures [163]. The nanotubes appear to grow as ultrathin tubes with a central hollow core and considerable thickening due to secondary pyrolytic deposition. In some cases, catalytic particles were entrapped within the tubes to form the nanocapsules. The efficiency of the catalysts was evaluated semiquantitatively.

Carbon nanocapsules with SiC and Au nanoparticles were produced by thermal decomposition of polyvinyl alcohol at about 500 °C in Ar gas atmosphere [164]. The formation mechanism of nanocapsules was discussed and a structural model for the nanocapsule/SiC interface was proposed. In addition, carbon clusters were formed at the surface of carbon nanocapsules, and carbon onions were produced by electron irradiation of amorphous carbon produced from polyvinyl alcohol. Silver nanoparticles encapsulated within boron nitride nanocages were produced from mixtures of

boric acid, urea, and silver nitrate upon reduction at 700 °C in hydrogen [165]. Multilayered polymer nanocapsules were fabricated via sequential adsorption of oppositely charged polyelectrolytes onto gold nanoparticles followed by dissolution of the gold core in cyanide solution [166]. A gold nanoparticle was coated with eight polyelectrolyte layers.

Preparation and layer-by-layer self-assembly of silver nanoparticles capped by graphite oxide nanosheets were carried out [167]. Sodium borohydride reduction of silver ions in aqueous dispersions of exfoliated graphite oxide (GO) resulted in the formation of remarkably monodisperse 10 nm diameter oblate Ag particles that are effectively protected by 0.5 nm thick GO sheets, Ag–GO. Ag–GO could be self-assembled onto poly(diallyldimethylammonium) chloride (PDDA) coated substrate, and subsequent layer-by-layer self-assembly of Ag–GO and PDDA led to well-ordered ultrathin films of S-(PDDA/Ag–GO)<sub>n</sub>.

The specific features of the catalytic reduction of methylviologen by dihydrogen in water in the presence of platinum colloids synthesized by various methods were studied [168]. The colloids prepared by the radiation-chemical reduction of PtCl<sub>4</sub><sup>2-</sup> in the presence of polyacrylate or polyphosphate as stabilizers and those prepared by the reduction with dihydrogen efficiently catalyzed the reaction. The “citrate” colloids synthesized by the reduction of PtCl<sub>6</sub><sup>2-</sup> with citric acid were characterized by a prolonged induction period after which these colloids also gained catalytic activity.

A technique for the formation of carbon-encapsulated metal nanoparticles on silicon was developed [169]. Carbon encapsulated NiFe nanoparticles were prepared by high-temperature methane encapsulation of the bare bimetallic particles on alumina [170]. About 6-nm-thick carbon layers encapsulated 10–20 nm diameter NiFe nanoparticles. The NiFe nanoparticles were single crystalline and no carbide was found at the NiFe–C interface. Metallic Pd nanoparticles with a diameter of 1–2 nm were anchored on the carbon layers, which created a Pd/NiFeC&C type of catalyst that could be used for liquid phase reactions.

Carbon-encapsulated cobalt nanoparticles were prepared over a range of temperatures and partial pressures by CVD from cyclohexane on prepared substrates consisting of ground powders of SiO<sub>2</sub> impregnated with Co(NO<sub>3</sub>)<sub>2</sub> and (NH<sub>4</sub>)<sub>2</sub>Mo<sub>2</sub>O<sub>7</sub> [171]. The encapsulated cobalt nanoparticles were freed from the incorporated SiO<sub>2</sub> and molybdenum by treating the deposition product with aqueous hydrofluoric acid.

Carbon-coated cobalt nanocapsules were synthesized by CVD with cobalt carbonyl [Co<sub>2</sub>(CO)<sub>8</sub>] used as precursor and carbon monoxide (CO) as carrier gas [172]. The characterization and magnetic properties of carbon-coated cobalt nanocapsules were investigated systematically. Figure 5 shows a TEM image and a selected area diffraction (SAD) pattern of the Co(C) nanocapsules synthesized by the CVD process [172]. The decomposition of Co<sub>2</sub>(CO)<sub>8</sub> and CO gas can decrease efficiently the content of the oxygen in nanocapsules. The metal Co nanoparticles completely coated by carbon can resist the dilute acid erosion as well as the oxidation.

An *in-situ* process was developed to create a dispersed phase of lubricant MoS<sub>2</sub> nanoparticles in a matrix of a hard TiN coating [173]. The particle formation at different

(a)

(b)

**Figure 5.** (a) TEM image and (b) selected area diffraction (SAD) pattern of Co(C) nanocapsules with core-shell structure, which are synthesized by chemical vapor condensation process with the cobalt carbonyl ( $\text{Co}_2(\text{CO})_8$ ) used as precursor and the carbon monoxide (CO) as carrier gas. After [172], Z. H. Wang et al., *Carbon*, in press. © Elsevier Science.

total and partial pressures was investigated. High yields of particles with diameters of 30–50 nm were obtained thermally at temperatures  $> 300$  °C and pressures  $> 5$  hPa with  $\text{MoCl}_5/\text{H}_2\text{S}$  as precursors. In the low pressure range, particles were formed by a plasma CVD process using the reaction of elementary sulphur or  $\text{H}_2\text{S}$  with  $\text{MoCl}_5$ .

Plasma enhanced CVD was used to synthesize Fe nanoparticles in an amorphous boron carbide matrix [174]. The nanoparticles ranged in size from approximately 0.7 to 4.5 nm. The size of the nanoparticles was proportional to the density of the Fe precursor (ferrocene) in the vapor.

Anatase titania nanoparticles were prepared using pyrolysis of titanium tetrabutoxide in oxygen-free and oxygen containing atmospheres by metal organic chemical vapor deposition (MOCVD) [175]. Influence of oxygen on the properties of titania nanoparticles was investigated. With increasing oxygen flow rates, the average grain sizes of the nanoparticles decreased and the particle size distributions became uniform. Oxygen exerted great influence on the

nucleation rate of the nanoparticles and reaction kinetics occurred in the reactor. The formation of titania nanoparticles by MOCVD was not a growth controlled process but was a nucleation rate controlled process.

Cobalt nanoparticles encapsulated in carbon shells were synthesized by catalytic CVD in high yield by reducing with a  $\text{H}_2/\text{CH}_4$  gas mixture a  $\text{Mg}_{0.9}\text{Co}_{0.1}\text{O}$  solid solution impregnated MgO catalyst [176]. The carbon encapsulated Co nanoparticles had a narrow distribution of diameters within the range of 5–15 nm. They were made of fcc Co which is very stable to air oxidation and the magnetic properties confirmed that Co was present in the metallic state.

A modification of the conventional inert gas condensation apparatus was developed for making nanostructured powders, wherein an evaporative source was replaced by a chemical source [177]. CVC combines CVD together with cooling condensation in evaporation. This process was used to synthesize loosely agglomerated amorphous nanoparticles of  $\text{SiC}_x\text{N}_y\text{O}_z$ , starting from hexamethyldisilazane as precursor compound [177]. The density, surface area, particle size, and composition of as-synthesized nanoparticles of  $\text{SiC}_x\text{N}_y\text{O}_z$  were modified by changing the synthesis temperature and carrier gas. The phase and morphology of as-synthesized powders were modified by heat treatment.

A concept was introduced of synthesis of nonagglomerated nanoparticles by rapid condensation from the vapor phase in a reduced pressure environment [45]. The source of the material was an evaporative source, which is ideally suited for low vapor pressure and low melting point metals. A variation in this process was developed, in which the source of the nanophase material was a metalorganic precursor [178–180]. The process, called combustion flame chemical vapor condensation (CF-CVC), is a modification of the original CVC process which involves pyrolysis of chemical precursors in the gas phase. The key parameters are gas phase residence time, temperature of the hot-wall reactor, and precursor concentration in the carrier gas. Careful selection of flow parameters resulted in powders that were only loosely agglomerated, significantly enhancing their usefulness in commercial applications. The nanopowders had a narrow particle size distribution with a mean particle size controllable between 5 and 50 nm. The CVC processing unit is an effective nanoparticle generator that is suitable for many different types of materials, like SiC,  $\text{Si}_3\text{N}_4$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$ ,  $\text{ZrO}_2$ , and other refractory compounds. They extended the processing capabilities to include a flat flame combustor unit which is particularly suited to synthesis of oxide phases either as powders, films, coatings, or freestanding forms.

The ductile behavior of nanophase yttria doped zirconia ceramics was investigated during low-temperature deformation experiments [181]. Ceramics were produced by following a standard processing route of mechanical compaction of the dispersion mixed nanoparticles synthesized by inert gas condensation or CVC and pressureless sintering. The influence of initial grain size and porosity on strain and strain rate was a topic of interest as well as the microstructural evolution during deformation.

The effect of the ratio of  $\text{O}_2/\text{He}$  flow rate in the reactor on the characteristics of nanosized  $\text{TiO}_2$  powder synthesized

by CVC was investigated under fixed conditions of supersaturation ratio, collision rate, and residence time [182]. As the ratio of O<sub>2</sub>/He flow rate increased, the particle size of TiO<sub>2</sub> powder almost remained unchanged but the agglomeration of nanoparticles enlarged in which the degree of agglomeration was defined as the ratio of particle size to crystallite size.

A vapor phase synthesis process was developed, in which vapors of chemical precursors were pyrolyzed in a low pressure flat flame [183, 184]. By controlling the time-temperature history of the particles in the hot zone of the flame, high surface area nanopowders of oxides that have primary and secondary (aggregate) nanoscale particle sizes were produced. The synthesis process, scalability issues, powder properties, and areas of application were described.

Magnetic nanoparticles of Fe and Co were synthesized by CVC using the precursors of iron carbonyl [Fe(CO)<sub>5</sub>] and cobalt carbonyl as the sources under a flowing helium atmosphere [185–187]. Typical particle sizes were on the order of 5 to 13 nm with uniform dispersion. A correlation between the process parameters of CVC and the resulting microstructure of the nanoparticles was investigated. Average particle size increased with increasing the decomposition temperature of the precursor.

A series of iron-cobalt alloyed (Fe<sub>1-x</sub>Co<sub>x</sub>,  $x \leq 50$  wt%) nanoparticles with core/shell structure was prepared by CVC [188, 189]. The relation between the process parameters and the resulting characterization and microstructure and the crystalline structure after oxidation at different temperatures were studied. The particles had a mean size of 5–25 nm, which consisted of metallic cores and oxide shells. The nanoparticle size increased with increasing gas flow rate and decomposition temperature.

### 3.3.2. Solid-State Reactions

Solid-state reactions offer the possibility of generating nanoparticles by controlled phase transformations or reactions of solid materials. The advantage of this technology is its simple production route. The solid-state reaction technique is a convenient, inexpensive, and effective preparation method of monodisperse oxide nanoparticles/nanocapsules in high yield. Controlled growth of nanoparticles and their self-assembly into one-, two-, three-dimensional arrays by chemical methods are currently attracting considerable attention for potential applications in nanodevices.

An overview of the low-temperature heterogeneous and solid reactions was presented as a result of synthesis dispersed and nanophased powders of carbides based on molybdenum, tungsten, or titanium [190]. In known methods of synthesis of nanophased powders by physical and chemical vapor deposition, solution chemistry materials are assembled from atoms (or molecules) to nanoparticles in a bottom-up approach. Such methods have a long history of use in catalysis and colloid chemistry. Among known methods of low-temperature synthesis of nanophased powders, the catalytic reduction and following carbidization, activation of gas phase, and mechanical attrition were discussed. Primary attention was paid to the questions of dispersion and coalescence under topochemical reactions [190].

The different methods for encapsulating crystalline materials inside fullerene related structures were reviewed

[191]. The relationships between the mode of encapsulation and the crystallization behavior obtained in each case were described. The mechanisms of morphological and orientational control of crystallite growth inside carbon nanotubes and the comparative encapsulation behavior of materials encapsulated by physical and catalytic methods were discussed. The encapsulation of defect tungsten oxide structures within inorganic fullerene-like structures was described.

Preparation methods of zeolite molecular sieve membranes and films with and without support were reviewed [192]. Unsupported films were prepared by *in-situ* synthesis, casting of zeolite nanoparticles, and solid-state transformation, and supported films were obtained by *in-situ* synthesis, vapor-phase synthesis, secondary growth, casting of nanoparticles, and their combinations or modifications.

Core-shell nanoparticles of metal oxides ([Fe<sub>2</sub>O<sub>3</sub>]MgO, [Fe<sub>2</sub>O<sub>3</sub>]CaO, [V<sub>2</sub>O<sub>3</sub>]MgO, and the other first-row transition metal shell materials coated on nanoparticles of MgO or CaO) were studied as destructive adsorbents for CCl<sub>4</sub>, CHCl=CCl<sub>2</sub>, C<sub>5</sub>H<sub>4</sub>Cl<sub>2</sub>, CN<sub>3</sub>P(O)(OCH<sub>3</sub>)<sub>2</sub>, and SO<sub>2</sub> [193]. A catalytic effect due to the transition metal shell material was observed, where solid-state ion-ion exchange took place, thus allowing penetration into the MgO or CaO particles and thereby regenerating the transition metal oxide for additional catalytic action. Due to this catalytic effect, the destructive adsorption reaction became nearly stoichiometric, and therefore much higher capacities for destruction/immobilization of the adsorbate under study were realized. The catalytic effects were due to the intermediacy of transition metal chlorides, phosphates, or sulfites, which were mobile and sought out reactive sites on the MgO or CaO nanoparticles.

High yields of nanocrystals at ambient temperature were attained for several inorganic salts such as ZnS and CuO [194]. Edone-step, solid-state reactions between easily obtained starting materials such as CuCl<sub>2</sub> · 2H<sub>2</sub>O and NaOH were reported to give nanoparticles with narrow size distribution. The process was carried out in air and required no complex apparatus, reagents, or techniques and thus it showed potential for mass production of nanocrystals. All of the reactions involved hydrated salts, and the role of the water in the reaction mechanism was discussed.

Carbon-coated  $\alpha$ -iron particles were prepared through a simple heat treatment of mixtures of Fe<sub>3</sub>O<sub>4</sub> and polyvinylchloride at 1000 °C in an Ar flow [195]. Hollow carbon particles were obtained after HCl treatment of the particles to remove iron and iron compounds. According to thermogravimetric analysis of the Fe<sub>3</sub>O<sub>4</sub>-polyvinylchloride mixture, the formation of carbon-coated  $\alpha$ -iron particles proceeds in four steps with weight loss, the first two steps being due to the pyrolysis and carbonization of polyvinylchloride, and the last two to the reduction of Fe<sub>3</sub>O<sub>4</sub> to  $\alpha$ -Fe. Using the other transition metal oxides, NiO, CoO, and Cu<sub>2</sub>O, carbon-coated respective metal particles were also prepared using the same procedure.

Nano-oxides (SiO<sub>2</sub>, CeO<sub>2</sub>, SnO<sub>2</sub>) were successfully synthesized by solid-state reactions at ambient temperature [196–198]. For instance, tin oxide (SnO<sub>2</sub>) nanocrystals were synthesized by two-step solid-state reactions [198]. In the first step, the SnO fine particles were synthesized from the

reaction of  $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$  precursor with KOH in the size range of 500 nm. Then the fine particles were oxidized into nanosized  $\text{SnO}_2$  crystals with  $\text{O}_2$ . It is an environment friendly, convenient, inexpensive, and efficient preparation of  $\text{SnO}$  nanocrystals with grain size of 20 nm. Effects of calcination on the nanoparticles were studied. The mechanisms of the formation of nanomaterials by solid-state reactions at ambient temperature were primarily investigated. The shape and size control of nanoparticles with organic stabilizers were studied, which had one (or more) coordination group and long alkyl chain [199]. The organic stabilizers were used as the templates of nanoparticle self-assembly.

A simple one-step solid-state reaction in the presence of a suitable surfactant was developed for synthesizing PbS nanoparticles with diameters of 10–15 nm [200]. The surfactant  $\text{C}_{18}\text{H}_{37}\text{O}(\text{CH}_2\text{CH}_2\text{O})_{10}\text{H}$  in the formation of PbS nanoparticles was discussed, which played an important role in the preparation of PbS nanoparticles.

Barium hexaferrite particles between 1  $\mu\text{m}$  and 100 nm in diameter were prepared by solid-state reaction from different iron oxide precursors [201]. The characteristics of the iron oxide precursor in terms of particle size and its distribution were essential to prepare the hexaferrite at a significantly reduced temperature as well as to obtain particles with reduced size. When a goethite sample consisting of uniform particles of 200 nm length was used as iron oxide precursor, pure and uniform hexaferrite particles of around 100 nm diameter were obtained by heating up to 675 °C for 1 h the mixture of iron oxide and barium carbonate.

A form of fullerene-type carbon, named carbon nanoflask, was synthesized, using  $\text{CO}(\text{CO})_3\text{NO}$ , as a special precursor [202]. Upon its decomposition, the  $\text{CO}(\text{CO})_3\text{NO}$  was not only a source of carbon but also gave rise to fcc cobalt particles. After a careful purification process, the percentage of cobalt-filled carbon flasks was as high as 30%. The graphitic layers of the flask walls were over 100 nm thick, and much thicker than the flask cap. After an acid treatment of the sample, opened and empty carbon flasks were easily obtained.

Gold nanoparticles and nanowires encapsulated in carbon nanocapsules and nanotubes were spontaneously formed from one-dimensional self-organized gold nanoparticles on carbon thin films by annealing at 200–400 °C [203]. The one-dimensional arrangement of gold nanoparticles was strongly dependent on the adhesive force at the atomic step edges of amorphous carbon thin films. The gold crystals inside the nanotubes were distorted by the crystal growth of the nanowires. The result was expected as a fabrication technique for self-assembled ultra-large-scale-integration nanowires and cluster-protected quantum dots protected by nanocapsules and nanotubes at scales beyond the limits of current photolithography.

Stepwise adsorption of polyelectrolytes was used for the fabrication of micro- and nanocapsules with determined size, capsule wall composition, and thickness [204]. The capsule walls made of polyelectrolyte multilayers exclude high molecular weight compounds. Assembly of lipid layers onto these polyelectrolyte capsules prevented the permeation of small dyes. Encapsulation of magnetite nanoparticles and the features of these capsules were discussed.

Co-filled carbon nanocapsules, formed by a heat treatment of the mixture of Co and diamond nanoparticles, were studied [205]. The heat treatment reduced the surface native oxide ( $\text{Co}_3\text{O}_4$ ) of Co nanoparticles. The reduction was accompanied by graphitization of diamond nanoparticles, indicating that diamond nanoparticles in contact with the metallic Co were transformed into graphitic coating. *In-situ* TEM studies showed that the graphitic coating was formed in the heating process, not in the cooling process. Once the coating was completed, the number of the graphitic layers was almost constant on further heating and cooling. It was concluded that metallic Co particles simply acted as templates for graphitic coating.

Controlling the surface properties of nanoparticulate materials is necessary if they are exploited in applications such as colloidal crystals or biolabeling [206]. By tailoring the polymer flexibility and the electrostatic forces involved in polyelectrolyte adsorption onto highly curved gold surfaces, through variation of the total salt concentrations suspending the chains and spheres, the irreversible polyelectrolyte wrapping of gold nanoparticles can be affected. By consecutively exposing the nanoparticles to polyelectrolyte solutions of opposite charge, polyelectrolytes can be deposited in a layer-by-layer sequence, yielding gold nanoparticles coated with uniform polyelectrolyte multilayers. Self-supporting polyelectrolyte multilayered nanocapsules were formed after dissolution of the metallic core. The gold nanoparticle surface charge, created by the adsorption of anions, was insufficient to overcome the ionic and hydrophobic polyanion/polycation interactions, resulting in polymer desorption from the highly curved nanoparticle surface. One successful method to immobilize the charge on the gold nanoparticle surface was to covalently attach an anionic thiol before polyelectrolyte modification.

Formation of carbon nanocapsules with various clusters ( $\text{SiC}$ , Au, Fe, Co, Ge, and  $\text{GeO}_2$ ) by polymer pyrolysis was investigated [207], and nanocapsules with  $\text{SiC}$  and Au nanoparticles were produced by thermal decomposition of polyvinyl alcohol at around 500 °C in Ar gas atmosphere [164, 165, 207].

Preparation of polycyclodextrin hollow spheres by templating gold nanoparticles was reported [208]. Oxidation of gold nanoparticles protected by thiolated  $\beta$ -cyclodextrin molecules led to formation of water-soluble polycyclodextrin nanocapsules held together by S–S bonds.

$\beta$ - $\text{SiC}$  nanorods were synthesized by the reaction of  $\text{SiO}$  and carbon nanocapsules [209]. For the synthesis of  $\text{SiC}$  nanorods, the reaction temperature and the ratio of  $\text{SiO}$  to carbon nanocapsules were important and the most appropriate temperature and ratio were around 1380 °C and 5:2, respectively. Most of the  $\text{SiC}$  nanorods were straight and had diameters of 30–150 nm while the  $\text{SiC}$  tips of the  $\text{SiC}$  nanorods were 100–400 nm in size. Each  $\text{SiC}$  nanorod had one kind of preferential axis direction, which was either parallel or normal to the [111] direction. A possible growth mechanism of the  $\text{SiC}$  nanorods was proposed.

Dispersed  $\text{Eu}^{3+}$  cations in an aqueous  $\text{EuCl}_3$  solution easily incorporated in pores in a hydrogenated porous  $\text{AlO}(\text{OH}) \cdot \alpha\text{H}_2\text{O}$  boehmite powder [210].  $\text{H}_2$  gas in pores and  $\text{OH}^-$  anions from energized boehmite with pores converted  $\text{EuCl}_3$  into  $\text{Eu}_2\text{O}_3$  in pores as per the reaction 2

$\text{EuCl}_3 + 3/2\text{H}_2 + 3 \text{OH} \rightarrow \text{Eu}_2\text{O}_3 + 6 \text{HCl}$ , in a closed reactor at room temperature. The obtained  $\text{Eu}^{3+}:\text{Al}_2\text{O}_3$  product consisted of dispersed  $\text{Eu}_2\text{O}_3$  nanoparticles (crystallite size was about 30 nm) in an amorphous  $\text{Al}_2\text{O}_3$  in a mesoporous structure. On heating,  $\text{Eu}_2\text{O}_3$  nanoparticles dissolved in high surface energy pores and resulted in a complete amorphous structure of  $\text{Eu}^{3+}:\text{Al}_2\text{O}_3$  at about 700 K. A controlled reconstructive nucleation and growth into  $\gamma\text{-Al}_2\text{O}_3$  nanoparticles (crystallite size was about 6.5 nm) occurred from the amorphous state at about 1000 K.

### 3.3.3. Sol–Gel

The sol–gel method is a process, consisting of solution, sol, gel, solidification, and heat treatment of metal organic or inorganic compounds, which is applicable to preparation of metal oxides and other compounds [211, 212]. The processing parameters can be controlled well at the beginning step so that the uniformity can be achieved at the scale of micrometers, nanometers, and even at the level of molecules, and the micro/nanostructures of the materials can be controlled/designed. The advantages of the sol–gel method are high purity due to no need for mechanical mixing; good chemical homogeneity and structural/composition uniformity; small particle size and narrow size distribution; low process temperature; simple technology and equipment; etc. The mechanisms for the formation of the sol–gel are traditional colloid type, inorganic polymer type, and complex type. The sol–gel method can be used for producing nanoparticles, nanocapsules, thin films, fibres, nanocomposites, and bulk materials. The sol–gel procedure allows coating of templates with complex shapes on the micrometer to nanometer scale, which some commonly used coating procedures cannot achieve. In addition, sol–gel coating techniques can be applied to delicate systems without disruption of their structure or functionality, for example, the coating of bio-complexes or organic aggregates, such as organogelators. Three-dimensional structures with elaborate pore architectures, such as polymer membranes and gels, can also be infiltrated with sol–gel solutions to achieve nanocoatings.

Carbon nanocapsules and nanotubes were formed by one-dimensional self-organization of gold nanoparticles, caused by the adhesive force at the step edge of amorphous carbon thin films [213]. The technique used was expected to be promising for self-assembly of nanowires and cluster-protected quantum dots at scales beyond the limits of current photolithography.

Investigation of encapsulation and solvatochromism of fullerenes in binary solvent mixtures was reported [214]. Fullerenes, when dissolved in certain binary solvent mixtures, were found to exhibit strong solvatochromism and an unusual chemical inertness. From ultraviolet-visible (UV-vis) optical absorption measurements, dynamic light scattering size measurements, and chemical tests on  $\text{C}_{60}$ /pyridine/water mixtures, the origin of these unusual effects was the formation of monodisperse, spherical, and chemically inert  $\text{C}_{60}$  nanocapsules. Pyridine acted as a surfactant around fullerene molecules protecting them from chemical reagents. The hydrophobic surfactant interactions were thought to act in stabilizing the structures into chemically inert, uniformly sized particles.

Using vesicular polymerization, water-soluble polyelectrolyte nanocapsules were prepared which were able to undergo a reversible swelling transition upon changing the pH and/or salt concentration [215]. The solvation of Nafion oligomer in equimolar water–methanol solution was studied by means of molecular dynamics simulations [216]. Star-shaped patterns, which were composed of rodlike nanoparticles with diameters of 4–7 nm and lengths ranging from 150 to 200  $\mu\text{m}$ , were prepared by a convenient microemulsion technique at room temperature [217]. The hydrophobic carbon chain of surfactant played an important role in controlling the morphology of the product. This microemulsion method was relatively mild and of low toxicity, which provided a route to the production of other metal sulfide patterns at room temperature.

A type of supramolecular compound, molybdenum-oxide-based composite was formed, consisting of magnetic nanocapsules with encapsulated keggion electron reservoirs cross-linked to a two-dimensional network [218].

Ag colloid-containing coatings on soda lime glass and fused silica were prepared via the sol–gel process [219]. To incorporate  $\text{Ag}^+$  ions in the coatings homogeneously, they are stabilized by a functionalised silane (aminosilane) and then mixed with the basic sol prepared from 3-glycidoxypropyl trimethoxysilane and tetraethoxysilane. Crack-free and transparent coatings with thickness of 0.5 to 1.2  $\mu\text{m}$  were obtained by heat treatment between 120 and 600  $^\circ\text{C}$ . The Ag-colloid formation was monitored by UV-vis spectroscopy as a function of temperature. The substrate had a deciding influence on the Ag-colloid formation caused by alkali diffusion from the substrate into the coating. Polycrystalline  $\text{Ag}_x\text{O}_y$  nanoparticles formed during thermal densification in the coatings, which was accompanied by a vanishing of the yellow color of the coatings.

One-dimensional composite nanostructures (i.e., a  $\beta\text{-SiC}$  nanorod within a  $\text{SiO}_2$  nanorod) were synthesized by the combination of a carbothermal reduction at 1650  $^\circ\text{C}$  and a heating at 1800  $^\circ\text{C}$  of sol–gel derived silica xerogels containing carbon nanoparticles [220, 221]. The composite nanostructures were more than 20  $\mu\text{m}$  in length. The diameters of the center thinner  $\beta\text{-SiC}$  nanorods were typically in the range of 10–30 nm, while the outside diameters of the corresponding thicker amorphous  $\text{SiO}_2$  nanorods were between 20 and 70 nm. Large quantities of SiC rod nuclei and the nanometer-sized nucleus sites on carbon nanoparticles were both favorable to the formation of much thinner  $\beta\text{-SiC}$  nanorods. The formation of the outer coaxial thicker amorphous  $\text{SiO}_2$  nanorod was from the combination reaction of decomposed SiO vapor and  $\text{O}_2$  during cooling.

Two sol–gel fabrication processes were investigated to make silica spheres containing Ag nanoparticles: (1) a modified Stober method for silica spheres below 1  $\mu\text{m}$  size, and (2) a  $\text{SiO}_2$  film formation method on spheres of 3–7  $\mu\text{m}$  size [222]. The spheres were designed to incorporate silver nanoparticles in a spherical optical cavity structure for the resonance effect. For the incorporation, interaction between  $[\text{Ag}(\text{NH}_3)_2]^+$  ion and SiOH was important. In the Stober method, the size of the silica spheres was determined by a charge balance of plus and minus ions on the silica surface. In the film formation method, the capture of Ag complex ion on the silica surface depended on whether the surface

was covered with OH groups. After doping  $[\text{Ag}(\text{NH}_3)_2]^+$  into silica particles or  $\text{SiO}_2$  films on the spheres, these ions were reduced by  $\text{NaBH}_4$  to form silver nanoparticles. From plasma absorption at around 420 nm wavelength and TEM photographs of nanometer-sized silver particles, their formation inside the spherical cavity structures was confirmed.

Poly(*N*-vinyl 2-pyrrolidone)-protected gold clusters, incorporated into silica ( $\text{SiO}_2$ ) glass by a sol-gel process, were reported [223]. A sol-gel process was developed for fabricating inherently homogeneous nanocomposites involving precipitation of nanoparticles, coating the nanoparticles with a film of matrix phase, and powder formation and sintering [224].

Injectable and sprayable nanometer size hydrated silica particles encapsulating high molecular weight compounds such as [I-125]tyraminylinulin (mol wt 5 kD), fluorescein isothiocyanate-dextran (mol wt 19.6 kD), and horseradish peroxidase (mol wt 40 kD) were prepared [225]. The size of these particles was below 100 nm in diameter and the entrapment efficiency was found to be as high as 80%. Enzymes entrapped in these particles show Michaelis-Menten kinetics and the catalytic reaction took place only after the diffusion of substrate molecules into the particles through the pores of the silica matrix. Peroxidase entrapped into silica nanoparticles showed higher stability toward temperature and pH changes compared to free enzyme molecules.

A chemically bound  $\text{TiO}_2$  layer was created on silica using a grafting method of chemical surface coating [226].  $\text{TiCl}_4$  and  $\text{H}_2\text{O}$  were used as reagents in successive cycles. The  $\text{TiO}_x$  layer is constituted of nanoparticles of anatase homogeneously spread over the surface. Calcination of the  $\text{TiO}_2$ - $\text{SiO}_2$  materials led to a particle size increase. An extensive pore size analysis was undertaken to investigate the morphological changes as a function of the number of reaction cycles.

Nanosized Ce-doped silica particles (without and with Al addition) dispersed within pores of mesoporous silica host were synthesized by soaking and sol-gel techniques [227]. The dispersed phosphor particles were mainly located within the pores that were less than 4 nm in diameter. There existed two luminescence peaks at about 350 and 700 nm, respectively, for this phosphor in the dispersed or aggregated state. For the dispersed system, the luminescence intensities of both peaks are more than 14 times higher than those of the aggregated one, and the shoulders on the lower sides of the luminescence peaks disappear.

Ellipsoidal mesoscale “eggshells” were prepared by a template-directed synthesis using a sol-gel precursor [228].  $\text{TiO}_2$  shells of micrometer sizes would have great potential as containers in microencapsulation and their ellipsoidal shape would provide them with a range of interesting optical, mechanical, and hydrodynamic properties.

Nanohybrids containing nonstoichiometric zinc ferrite of spinel structure in an amorphous silica matrix exhibited a fundamentally different structure to that formed by stoichiometric zinc ferrite [229]. A unique cluster glass structure, where nanocrystallites of zinc ferrite existed in amorphous Fe-rich pockets, occurred at the significantly high Fe/Zn molar ratio of 10. The occurrence of zinc ferrite crystallites due to the  $\text{Zn}^{2+}$  deficiency, together with the confinement of

the silica matrix, suppressed the nucleation and crystallization of  $\alpha\text{-Fe}_2\text{O}_3$  to a temperature above 900 °C, preserving the cluster glass structure.

A route was described for the synthesis of nanometric Ni particles embedded in a mesoporous silica material with excellent potential for catalytic applications [230]. Mesoporous silica with a surface area in the range of 202–280  $\text{m}^2/\text{g}$  with narrow pore size distribution and Ni nanoparticles (particles in the range of 3–41 nm) were obtained in a direct process. A different approach was adopted to process such a nanocomposite, which was based on the formation of a polymer with the silicon oxianion and nickel cation chelated to the macromolecule structure and on the control of the pyrolysis step. The  $\text{CO}/\text{CO}_2$  atmosphere resulting from the pyrolysis of the organic material promoted the reduction of the Ni citrate.

The hybrid materials were investigated, consisting of nonagglomerated iron oxide particles hosted in silica aerogels [231]. The composite material can be produced as a monolith, in any shape, and with different dilutions of the iron oxide phase. Two sol-gel chemistry routes followed: a solution of  $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  was added either to the silica gel or to the initial sol, and the iron salt provided the water required for the gel polymerisation. To obtain monolithic aerogels, the gels were dried by hypercritical solvent evacuation. On the other hand, some gels were dried by slow and controlled evaporation of the solvent, resulting in xerogels. Several heat treatments were performed and the iron oxide particle phase, growth mechanism, and crystallinity were analyzed.

Mesoporous nanocrystalline titanium dioxide with narrow pore size distribution was prepared by a sol-gel technique, when butanediol mixed with tetrapropylthotitanate was used as precursor [232]. The aging time for the synthesis had an evident influence on the phase transition of  $\text{TiO}_2$  and the nucleation process. A very fine network texture made from uniform nanoparticles was revealed. The mesoporous structure of as-prepared titania was maintained after a heat treatment at 350 and 400 °C for 1 h, exhibiting a significant thermal stability. Four titania crystal phases (amorphous, anatase, anatase-rutile, rutile) were observed at different calcination temperatures.

$\gamma\text{-Fe}_2\text{O}_3/\text{SiO}_2$  nanocomposites were prepared using a sol-gel procedure, starting from iron nitrate and triethyl orthosilicate [233]. The addition of acids to the sols resulted in a way to increase particle size, keep iron concentrations low, and narrow the particle size distribution of  $\gamma\text{-Fe}_2\text{O}_3$  in the glass composite. The addition of 0.56 mmol HCl (approximate to 0.1 M) to a solution having an Fe/Si molar ratio of 18% led to an increase of  $\gamma\text{-Fe}_2\text{O}_3$  particle size from 6 to 13 nm together with a remarkable decrease in the polydispersity degree of the particle size from 66% to 15%. The iron oxide crystalline phase, the particle size and shape, and the homogeneity of the resulting nanocomposites were studied. The influence of acid addition on the size of the magnetic particles was found to depend on the matrix microstructure, the charge environment, and the presence of counteranions of the acids.

A study was reported of the formation of particles of Ni-Zn ferrites embedded in a xerogel  $\text{SiO}_2$  matrix [234]. Initial solutions were prepared mixing tetraethyl

orthosilicate, distilled water, ethanol, and three different nitrates: iron, nickel, and zinc. Formation of  $\text{Ni}_{0.5}\text{Zn}_{0.5}\text{Fe}_2\text{O}_4$  as well as structural modifications of the  $\text{SiO}_2$  matrix induced by these particles were discussed. The composites of  $\gamma\text{-Fe}_2\text{O}_3/\text{SiO}_2$  and  $\alpha\text{-Fe}_2\text{O}_3/\text{SiO}_2$  were reported, starting from three different iron precursors: iron nitrate, iron chloride, and nanometric Fe particles prepared by aqueous chemical reduction [235].

Nanocoating, the covering of materials with a layer on the nanometer scale or covering of a nanoscale entity, to form nanocomposites and structured materials using the sol-gel process was reviewed [236]. Templates from spherical nanoparticles to complex bicontinuous networks were discussed, where either the coated material or the structured inorganic hollow frame resulting after removal of the template were of interest in fields of application ranging from information storage to catalysis.

### 3.3.4. Precipitation

The precipitation method is a convenient and powerful technique for synthesizing nanoparticles and nanocapsules. Dissolvable salt solution consisting of one type or multitypes of ions could be hydrolyzed at a certain temperature when precipitator, like  $\text{OH}^-$ ,  $\text{C}_2\text{O}_4^{2-}$ ,  $\text{CO}_3^{2-}$ , etc., is added. The hydrates, hydrate oxides, or salt would form and separate out from solution. The oxide powders can be obtained by washing the anions in the solution and the solvent, and subsequently by pyrogenation or dehydration. When the precipitator is added in the solution consisting of multitypes of cations, the complete precipitation of all the ions is the so-called co-precipitation method. The co-precipitation method consists of single-phase co-precipitation and mixture co-precipitation. Only a single compound or solid solution is the sediment in the former process, whereas the mixture deposits in the latter one. If one of the sediments were grown on the surface of others and the powders were in nanoscale, nanocapsules would form by employing the co-precipitation method. The advantages of the precipitation method are: high purity, high uniformity, small particle size, narrow size distribution, and structural/composition uniformity. Precipitation is a promising method for the economical production of commercial amounts of nanoparticles/nanocapsules because it is fast and operable at ambient temperature.

ZnO nanoparticles in the size range from 2 to 7 nm were prepared by addition of LiOH to an ethanolic zinc acetate solution [237]. Nanoparticles of a model drug, viz. cholesteryl acetate, were prepared [238]. The cholesteryl acetate was dissolved in cyclohexane containing lecithin. The organic solution was emulsified in an aqueous solution containing a cosurfactant and a stable oil/water (o/w) emulsion resulted. The solvent was evaporated from the emulsion and cholesteryl acetate precipitated in the emulsion droplets. The size of the particles was almost unaffected by the concentration of cholesteryl acetate in cyclohexane.

A methodological description of heterogeneous polymerization processes, including suspension, emulsion, dispersion, and precipitation polymerization, was presented [239]. The discussion focused on the initial state of the polymerization mixture, the mechanism of particle formation, and

the shape and size of polymer particles produced in different heterogeneous polymerization systems. The dependence of particle size and morphology on manufacturing parameters such as emulsifier, stabilizer, reactor design, and stirring speed was discussed. Special topics, including emulsifier-free (soapless) emulsion polymerization, seeded polymerization, and the formation of core-shell particles were covered.

Nanoparticles of barium ferrite ( $\text{BaFe}_{12}\text{O}_{19}$ ) were synthesized using a method called microemulsion processing [240]. The aqueous cores (typically 5–25 nm in size) of water-cetyltrimethylammonium bromide-*n*-butanol-octane microemulsions were used as constrained microreactors for the co-precipitation of precursor carbonates (typically 5–15 nm in size). The carbonates formed were separated, dried, and calcined to form nanoparticles (less than 100 nm) of barium ferrite.

Cubic structured CdS, CdSe, and CdTe, II-VI semiconductor nanoparticles were synthesized using aqueous solution precipitation at room temperature [241]. Thermal annealing caused an increase in particle size, a structural transition from the cubic to the bulk hexagonal structure for CdS and CdSe, and no structural transition for CdTe.

Well defined spherical particles of  $\gamma\text{-Fe}_2\text{O}_3$  were synthesized in the pores of a polymer matrix in the form of beads by an ion exchange and precipitation reaction [242]. The particle size distribution was Gaussian with an average diameter of 8 nm. The particles were superparamagnetic with a blocking temperature  $T_b$  of about 55 K. The optical absorption edge of the mesoscopic system was redshifted with respect to single crystal films of  $\gamma\text{-Fe}_2\text{O}_3$  with an absorption tail extended deeply in the gap.

A kind of fullerene, a carbon nanoparticle encapsulating  $\beta\text{-SiC}$  grain, was precipitated during cooling  $\text{Al}_2\text{O}_3\text{-Y}_2\text{O}_3\text{-CaO}$  oxide melt containing SiC and C from 2023 K [243]. The SiC grains with a diameter of 5–20 nm were covered with 2–4 graphitic carbon layers with spacings of 0.34 nm.

Polyacrylamide-silver nanocomposites with silver nanoparticles well dispersed in polyacrylamide matrix were synthesized by  $\gamma$ -irradiation at ambient conditions in alcohol solvent [244]. The nanocomposites consisted of Mo phases, metallic silver, and polyacrylamide. The amount of silver present as metallic species in polyacrylamide matrix was measured by precipitation titration. The infrared (IR) spectrum confirmed the polymerization of acrylamide monomer and the formation of polyacrylamide in ethanol upon  $\gamma$ -irradiation.

The biocatalytic systems from nanocapsules containing  $\alpha$ -chymotrypsin in the inner aqueous cavities were prepared [245], which acted in both the organic solvent and the aqueous medium. For such encapsulation, the reversed hydrated micelles from *N,N*-diallyl-*N,N*-didodecyl ammonium bromide (DDAB) in cyclohexane ( $w_0 = 22$ ), including  $\alpha$ -chymotrypsin, were polymerized by UV initiation. After precipitation by acetone, these nanocapsules were moved into the aqueous medium with the aid of ionic or non-ionic surfactants. In this case, unilamellar liposomes were formed. They had the inner monolayer from the poly-DDAB network and the outer one predominantly from surfactant molecules. According to the light-scattering data, the average outer diameter of nanocapsules equals 20 nm. The

vesicular “coated”  $\alpha$ -chymotrypsin was used for study of enzymatic activity.

The lattice dynamics of nanoparticles of Co embedded in Ag, created by ion implantation and subsequent annealing, were investigated [246]. A type of material that was able to produce giant strain in a nonhomogeneous magnetic field was developed [247]. In these magnetic-field-sensitive gels (ferrogels) fine colloidal particles having superparamagnetic behavior were incorporated into a highly swollen elastic polymer network. Magnetic properties were interpreted on the basis of a core-shell model.

Mössbauer spectroscopy in combination with atomic scale modeling was used in order to gather a comprehensive understanding of the growth and the dynamics of cobalt nanoprecipitates in silver [248]. The modeling made use of classical molecular dynamics in the canonical ensemble by means of the Rahman-Parinello technique.

Organic nanoparticles of cholesterol, Rhovanil, and Rhodiarome were synthesized in different microemulsions [AOT/heptane/water; tritonidecanol/water; cetyltrimethylammonium bromide (CTABr)/hexanol/water] by direct precipitation of the active compound in aqueous core under continuous ultrasound treatment [249]. The size of the nanoparticles depended on different parameters such as the concentration of the organic molecules and the diameter of the water cores, which was related to the ratio  $R = [H_2O]/[surfactant]$ .

Polyvinyl alcohol coated magnetic particles (PVA ferrofluids) were synthesized by chemical co-precipitation of  $Fe^{2+}/Fe^{3+}$  salts in 1.5 mol/L  $NH_4OH$  solution at 70 °C in the presence of PVA [250]. The resultant colloidal particles had core-shell structures, in which the iron oxide crystallites formed the cores and PVA chains formed the shells. The hydrodynamic diameter of the colloidal particles was in the range of 108 to 155 nm, which increased with increasing PVA concentration from 5 to 20 wt%. The size of the magnetic cores was relatively independent of PVA concentration.

Nanoparticles of various compositions were fabricated by chemical processes [251], like sol-gel processes and precipitation processes, and surface modifiers acted as vehicles to tailor surface chemistry, to tailor the  $\zeta$  potential, and to avoid agglomeration.

A line was drawn from the controlled preparation and understanding of Langmuir monolayers to the fabrication of hollow capsules [252]. Polymeric ultrathin films were permeable to small molecules, which could be used to prepare capsules after coating depolymerizable colloids. The inside of the capsule was designed such that it was distinguished by inner walls and pH in the interior in order to perform a specific chemistry. As an application example, selective precipitation of a dye molecule as a model for drug loading was presented.

Precipitation in the nanostructured  $Cr_3C_2/NiCr$  coatings was investigated [253].  $Cr_2O_3$  particles with an average size of 8.3 nm were observed in the nanostructured  $Cr_3C_2/NiCr$  coatings exposed to elevated temperatures. In addition to the precipitation of oxide particles, the phase transformations in the original NiCr amorphous phase were always observed in the as-sprayed nanostructured  $Cr_3C_2/NiCr$  coatings. The increases in microhardness and scratch resistance

and decrease in coefficient of friction of the nanostructured coatings were attributed to a high density of oxide nanoparticles precipitating within the coating as the exposure temperature increased.

A composite film of titanium dioxide ( $TiO_2$ ) nanoparticles and hydrolyzed styrene-maleic anhydride alternating copolymer (HSMA) was obtained on a substrate when a  $TiCl_4$  solution was heated at 80 °C with a spin-cast thin HSMA film present in the solution [254]. The  $TiO_2$  nanoparticles discretely dispersed on the polymer layer, which were dominantly rutile phase, of a spherical shape and 18–20 nm in diameter. In contrast, mainly amorphous  $TiO_2$  powders were obtained from the identical  $TiCl_4$  solution by drying the solution with the absence of the HSMA film. The  $TiO_2$  nanoparticles deposited on the polymer layer were regarded to contain polymer chains, and a multilayered core-shell model was suggested for the formation of these composite nanoparticles.

Nanostructured coatings on metals, plastics, and textiles have numerous applications, for example, as antifogging and self-cleaning coatings as well as protective coatings against corrosion, heat, or wear. The preparation at low temperature of dense nanostructured tetragonal  $ZrO_2$  coatings via a modified emulsion precipitation method was presented [255]. The method, which involved the controlled preparation, crystallization, and densification of nonagglomerated  $ZrO_2$  nanoparticles, opened up the possibility of applying nanocoatings of high-melting oxides to steel or plastic, where low temperatures were required.

Spontaneous core-shell and shell-shell reactivities of thiolate-capped nanoparticles were exploited for assembling nanoparticle network thin films via an exchange-cross-linking-precipitation route [256]. Gold nanoparticles of two different core sizes (2 and 5 nm) capped with decanethiolates and alkylthiols of two different functionalities, 1,9-nonanedithiol (NDT) and 11-mercaptoundecanoic acids (MUA), were studied as the assembly components. The film formation and growth involved intercore covalent Au-thiolate bonding at both ends of NDT, or intershell non-covalent hydrogen bonding at carboxylic acid terminals of MUA shells.

Synthesis and coating of superparamagnetic monodispersed iron oxide nanoparticles were carried out by a chemical solution method [257]. A controlled coprecipitation technique was used to prevent undesirable critical oxidation of  $Fe^{2+}$ . The obtained  $Fe_3O_4$  nanoparticles were coated with sodium oleate.

Doped ZnS nanoparticles were synthesized using a chemical coprecipitation of  $Zn^{2+}$ ,  $Mn^{2+}$ ,  $Cu^{2+}$ , and  $Cd^{2+}$  with sulfur ions in aqueous solution [258]. The diameter of the particles was close to 2–3 nm. The unique luminescence properties, such as the strength (its intensity is about 12 times that of ZnS nanoparticles) and stability of the visible-light emission, were observed from ZnS nanoparticles codoped with  $Cu^{2+}$  and  $Mn^{2+}$ .

A method of preparing CdS nanoparticles inside MCM-41 was described [259]. This method made use of the unique interfacial properties of selectively functionalized ordered mesoporous materials to deliver cadmium ions inside the mesopores of MCM-41 via an ion-exchange reaction, thereby minimizing uncontrolled precipitation reactions of

cadmium ions outside the mesopores. The general methodology can also be used to prepare other sulfide, telluride, and oxide nanoparticles.

$\text{Co}_3(\text{BO}_3)_2$ /surfactant composites were prepared by the controlled precipitation of aqueous cobalt cations together with surfactant [260]. The composite showed a layered structure, in which the  $\text{Co}_3(\text{BO}_3)_2$  layers of about 6 Å in thickness were in alternation with surfactant bilayers. There was a freezing temperature at low temperature (<6 K) and the temperature was weakly frequency dependent. All the experimental observations suggested that the multilayers were spin glass in nature.

Thermoresponsive, core-shell poly-*N*-isopropylacrylamide (*p*-NIPAm) nanoparticles (microgels) were synthesized by seed and feed precipitation polymerization, and the influence of chemical differentiation between the core and shell polymers on the phase transition kinetics and thermodynamics was examined [261]. The core-shell architecture was a powerful one for the design of colloidal “smart gels” with tunable properties. The addition of small concentrations of a hydrophobic monomer (butyl methacrylate, BMA) into the particle shell produced large decreases in the rate of thermally induced particle collapse.

BN tassellike and treelike nanostructures were synthesized through a CVD method [262]. The tassellike morphology was made up of a BN bamboo-shaped nanotube and numerous polyhedral particles attached onto it. The tree consisted of a BN main stem and many BN nanotube branches growing outward from it. The attachments, either particles or nanotube branches, remained adhered to the primary stems even after 15 min sonication treatment, indicating the high stability of these nanostructures. The formation of these unusual structures was proposed to arise from a two-stage deposition process: First, primary BN stems were formed, followed by subsequent precipitation of amorphous clusters onto the rough outer surfaces. Second, polyhedral particles or BN nanotubes nucleated and grew on the outer surface as a result of further deposition from the vapor phase.

An approach to incorporate different polymers into micro- and nanocapsules fabricated by means of layer-by-layer adsorption of oppositely charged polyelectrolytes on colloidal particles was proposed [263]. This method comprised two stages. At first, the polymers, which were supposed to be incorporated, precipitated on the surface of colloidal particles. This can be done either by complexation of polyelectrolytes with multivalent ions or by adding miscible nonsolvents. Then stable layer-by-layer assembled polyelectrolyte shells were formed. After core decomposition, the inner polymer molecules were released from the wall but were captured by the outer shell and floated in the capsule interior. The possibilities to encapsulate a wide class of charged and noncharged polymers were demonstrated on such examples as sodium poly(styrene sulfonate) as a polyanion, poly(allylamine hydrochloride) as a polycation, and Dextrane as noncharged water soluble polymer.

A method for the preparation of composite nanoparticles  $\text{SiO}_2/\text{ZnO}$  by the controlled double-jet precipitation technique was described [264]. On the silica ( $\text{SiO}_2$ ) surface, the ZnO nanoparticles were coated as thin layers or nanoclusters, depending on the reaction conditions.

Various  $\text{Au}/\text{Fe}_2\text{O}_3$  catalysts were prepared by the coprecipitation method, and CO oxidation was studied at ambient temperature and in the presence of water vapor in the feed [265]. The precipitation method and the calcination temperatures had a significant effect on the catalytic performance of CO oxidation. The stability was related to the particle size of metallic gold and  $\alpha\text{-Fe}_2\text{O}_3$  and the oxidation state of gold and the iron crystalline phase. The sintering of the gold particles, the reduction of oxide gold to metallic gold, the accumulation of carbonate, and a decrease in the specific surface area were observed during the reaction.

The process control of precipitation, due to the rapidity of the involved processes of mixing, nucleation, growth and agglomeration, and the stabilization against agglomeration represented challenges to this method. Schwarzer et al. showed how these challenges can be successfully handled [266]. The focus was set on how to tailor the particle-size distribution in continuous precipitation [266]. Precipitation experiments with barium sulfate in a T-mixer were presented. It was found that the size of the precipitated primary particles was strongly dependent on the mixing intensity. On increasing the mixing intensity, it was possible to generate particles of approximately 50 nm in diameter. The second challenge, to stabilize the particles against agglomeration, was successfully met by adsorbing potential-determining ions on the particle surfaces (i.e., by increasing repulsive particle interactions). Thus, stable suspensions of barium sulfate nanoparticles were obtained.

Strontium ferrite nanoparticles were prepared by coprecipitation in a polyacrylic acid (PAA) aqueous solution [267]. The average diameter of the mixed hydroxide precipitates was 3.1 nm. The average diameters of the strontium ferrite nanoparticles calcined at 700 and 800 °C were 34 and 41 nm, respectively.

The effects of the interactions of metal ions with lipoic acid-capped Ag and Au nanoparticles were studied [268], which were dependent on the metal ion concentration. First, in the dilute regime, there was reversible chelation of the metal ions, causing a marked dampening of the plasmon resonance band of the nanoparticles, but there was no aggregation. The magnitude of plasmon dampening depended on the nature as well as the concentration of the metal ions. In the intermediate concentration regime, aggregation occurs, but in the high concentration regime, there was precipitation.

Nanoparticles of a series of magnetic ferrites ( $\text{MFe}_2\text{O}_4$ ,  $\text{M} = \text{Zn}, \text{Ni}, \text{Co}, \text{Cu}, \text{Mn}$ ) were fabricated by hydrothermal precipitation [269]. The results on the mechanochemical synthesis of  $\text{CaCO}_3$ ,  $\text{Cr}_2\text{O}_3$ , and  $\text{Nb}_2\text{O}_5$  nanopowders were reported [270]. The volume fraction of the matrix phase was crucial to the formation of separate, unagglomerated particles. With  $\text{Cr}_2\text{O}_3$  and  $\text{Nb}_2\text{O}_5$ , amorphous particles were formed by mechanochemical reaction and a low temperature heat treatment was required for crystallization.

A heterogeneous precipitation method was described for obtaining nanocomposite powders consisting of Ni nanoparticles homogeneously dispersed within  $\gamma\text{-Al}_2\text{O}_3$  [271]. The amorphous  $\text{Al}(\text{OH})_3$  was nucleated on the surfaces of NiO nanoparticles and crystallized to  $\gamma\text{-Al}_2\text{O}_3$  at 900 °C. The porosity of  $\gamma\text{-Al}_2\text{O}_3$  allowed the growth of NiO

nanoparticles during calcinations. After the calcined nanocomposite powders were selectively reduced at 700 °C in a hydrogen atmosphere, NiO nanoparticles were converted to Ni with the size of 25–35 nm, which were uniformly dispersed in the  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> matrix.

Nanosized nickel aluminate spinel particles were synthesized with the aid of ultrasound radiation by a precursor approach [272]. Sonicating an aqueous solution of nickel nitrate, aluminum nitrate, and urea yielded a precursor that on heating at 950 °C for 14 h yielded nanosized NiAl<sub>2</sub>O<sub>4</sub> particles with a size of 13 nm and a surface area of about 108 m<sup>2</sup> g<sup>-1</sup>.

The precipitation and condensation of submicrometer organic particles were reviewed [273]. The importance of physical state effects was discussed, and the role of compartmentalization in controlling particle size was introduced. The thermodynamic driving forces for precipitation and phase transformation were briefly reviewed. The use of emulsification as a primary step in producing small particle dispersions was described with photographic and pharmaceutical applications. Precipitation driven by solvent shifting was illustrated and applications in preparing organic–inorganic composites and protein coacervation were described. Miscible solvent–nonsolvent induced precipitation was outlined and followed by related applications using supercritical fluid technology. The applications of organic particle precipitation in reverse microemulsion systems were described. The applicability of gas condensation methods and of precipitation in submicrometer hollow spheres and dye entrapment in submicrometer polymer gel networks were discussed.

### 3.3.5. Hydrothermal Methods

Hydrothermal methods include all chemical reactions in water in high temperatures and high pressures. The hydrothermal methods consist of hydrothermal oxidation, hydrothermal precipitation, precipitation synthesis, hydrothermal deoxidization, hydrothermal decomposition, hydrothermal crystallization, etc. The hydrothermal reactions can be used to prepare nanoparticles as well as nanocapsules. The typical chemical reactions are listed as follows:

- (1) the hydrothermal oxidation:  $mM + nH_2O \rightarrow M_mO_n + H_2$ , where M = Cr, Fe, and their alloys,
- (2) the hydrothermal precipitation:  $KF + MnCl_2 \rightarrow KMnF_2$ ,
- (3) the precipitation synthesis:  $FeTiO_3 + KOH \rightarrow K_2O \cdot nTiO_2$ ,
- (4) the hydrothermal deoxidization:  $Me_xO_y + yH_2 \rightarrow xMe + yH_2O$ , where Me = Cu, Ag, etc.,
- (5) the hydrothermal decomposition:  $ZrSiO_4 + NaOH \rightarrow ZrO_2 + Na_2SiO_3$ ,
- (6) the hydrothermal crystallite:  $Al(OH)_3 \rightarrow Al_2O_3 \cdot H_2O$ .

The hydrothermal methods are convenient, lower temperature, and environmentally friendly solution processing routes for synthesis of advanced ceramic materials with desired shapes, sizes, and form, compared with other ceramic materials processing methods such as solid-state reactions, CVD, MOCVD, and physical vapor deposition (PVD) involved using higher temperatures or toxic organometallic precursors, or complicated reaction and post-treatment systems.

Hydrothermal/solvothermal processing of advanced ceramic materials was reviewed [274]. The review focused on the development of the hydrothermal process, its integration with other activation methods such as electrochemistry, microwaves, and its counterpart the solvothermal process for fabrication of ceramic thin films, nanoparticles, and single crystals. The solvothermal process proved to play a significant role in synthesis of advanced nonoxide ceramic materials by using reactions in nonaqueous solutions, which will be an exciting and promising field for preparation of ceramic materials. Shapes, sizes, and phases of the synthesized ceramics can be well controlled by employing different solution processes, which will play a key role in tailoring the properties of ceramic materials.

A series of layered magnesium organosilicate nanocomposites containing covalently linked organic functionalities was prepared by a one-step, direct synthesis procedure [275]. The *in-situ* reactivity of organic moieties (e.g., phenyl, thiol) within the layered inorganic–organic nanocomposites, as well as the potential use of thiol-containing materials as host matrixes for the organized deposition of gold nanoparticles, was described.

Semiconductor nanoparticles assembled within a zeolite are an example to create a quantum confined system. Molecular sieves were prepared under hydrothermal conditions from Catapal alumina, aluminosilicate, silicate, and ethylsilicate gels, respectively, under carefully chosen conditions of pH, temperature, and crystallization time [276]. Coadded alkali metal cations, quaternary alkylammonium cation, and surfactant species functioned as charge balancing spacing-filling, and structure-directing agents to obtain an ultralarge pore molecular sieve.

Nanocrystalline titanium dioxide colloids were synthesized using a sol–gel technique followed by growth under hydrothermal conditions at temperatures between 190 and 270 °C [277]. Thin films were made from aqueous suspensions of these colloids. The rodlike particles self-organized into regular cubic arrays with the long axis of the rods aligned perpendicular to the film surface. This self-organization was dependent upon the base used in colloidal synthesis and also upon the dielectric constant of the medium used during film formation.

Colloidal solutions and redispersible powders of nanocrystalline, lanthanide-doped YVO<sub>4</sub> were prepared via a hydrothermal method at 200 °C [278]. The crystalline particles ranged in size from about 10 to 30 nm. The particles exhibit the tetragonal zircon structure known for bulk material.

A variety of synthetic methods of metal sulfide particles were reviewed [279]. Some research work via hydrothermal and solvothermal routes was summarized, concerning the synthesis of metal sulfide nanoparticles and the control of particle size, size distribution, as well as morphology. Nanocrystalline Co<sub>9</sub>S<sub>8</sub> was successfully prepared by a hydrothermal-reduction method at 120 °C [280]. The reducing agents were produced from disproportionation of white phosphorus in alkaline medium.

CeO<sub>2</sub> nanoparticles coated by sodium bis(2-ethylhexyl) sulfosuccinate were prepared by using the microemulsion method [281]. ZnGa<sub>2</sub>O<sub>4</sub> fine particles with a single phase of spinel were synthesized from a mixed solution of gallium

sulfate and zinc sulfate in the presence of aqueous ammonia under hydrothermal conditions above 180 °C [282]. The effects of treatment temperature and ZnO/Ga<sub>2</sub>O<sub>3</sub> molar ratio in the starting solution on the crystallite size, morphology, lattice parameter, and chemical composition of the ZnGa<sub>2</sub>O<sub>4</sub> spinel particles were examined. Spinel particles with different morphologies, cubic nanoparticles, and elongated rodlike particles were thought to be formed based on the structure of amorphous gallium hydroxide and needlelike GaO(OH) particles, respectively.

A hydrothermal CVD process was reported which produced self-assembled patterns of iron oxide nanoparticles [283]. By exposing a planar silica substrate to a prevaporized mixture of water, ferrocene [Fe(C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>], and xylene (C<sub>8</sub>H<sub>10</sub>), at temperatures around 1000 °C, Fe<sub>2</sub>O<sub>3</sub> nanoparticles were deposited on the substrate surface, in regular circular patterns.

Nanosized TiO<sub>2</sub> particles coated with dodecylbenzenesulfonic acid (DBS) and stearic acid (St) were prepared using the hydrothermal procedure [284, 285]. The average size of the DBS/TiO<sub>2</sub> and St/TiO<sub>2</sub> particles was about 8 nm. Raman spectra from DBS/TiO<sub>2</sub> and St/TiO<sub>2</sub> were measured, and scattering signals from both TiO<sub>2</sub> and the coating were observed. In contrast to the redshift of Raman peaks in the nanoparticles with decreasing particle size, a blueshift, namely the Raman peak shift to the higher wavenumber side, in the coated particles was recorded. It was also found that different coatings show different extents of Raman shifts.

Organic monolayer-stabilized copper nanocrystals were synthesized in supercritical water [286]. When water was heated and pressurized above the critical point, it became a suitable solvent to employ organic capping ligands to control and stabilize the synthesis of nanocrystals. Without alkanethiol ligands, Cu(NO<sub>3</sub>)<sub>2</sub> hydrolyzed to form polydisperse Cu<sup>2+</sup> oxide particles with diameters from 10 to 35 nm. The use of a different precursor, Cu(CH<sub>3</sub>COO)<sub>2</sub>, led to particles with significantly different morphologies. A mechanism was proposed for sterically stabilized nanocrystal growth in supercritical water that described competing pathways of hydrolysis to large oxidized copper particles versus ligand exchange and arrested growth by thiols to produce small monodisperse Cu nanoparticles.

CdS and ZnO-capped CdS semiconductor nanoparticles were synthesized via a hydrothermal method by thermal decomposition of the cysteine-cadmium complex precursor [287]. Compared to CdS nanoparticles, the bandgap emission of CdS/ZnO was greatly improved, meaning that the shell of ZnO modified the surface of the CdS core and reduced the surface defect.

The increasing awareness of the need to create green and sustainable production processes in all fields of chemistry has stimulated materials scientists to search for innovative catalyst supports. These new catalytic supports should allow the heterogenization of most catalytic processes, increasing the efficiency and selectivity of the synthesis and reducing waste. A hexagonal material with large pore diameters and thick walls (4 nm), containing internal microporous silica nanocapsules, was developed [288]. These plugged hexagonal templated silicas had two types of micropores (originating from the walls and the nanocapsules respectively)

and a tunable amount of both open and encapsulated mesopores. The micropore volumes had a high value (up to 0.3 cm<sup>3</sup>/g) and the total pore volume exceeded 1 cm<sup>3</sup>/g. The obtained materials were much more stable than the conventional micellar templated structures and can easily withstand severe hydrothermal treatments and mechanical pressures.

The methods were investigated for preparation of Au/TiO<sub>2</sub> catalysts to obtain small gold metal particles (2–3 nm) and a higher Au loading [289]. The possible mechanisms of deposition of gold on the TiO<sub>2</sub> support by the different preparation methods were discussed.

In Mn<sub>1-x</sub>Zn<sub>x</sub>Fe<sub>2</sub>O<sub>4</sub> (x = 0 to 1) nanosize particles prepared through hydrothermal precipitation, a decrease in particle size was observed from 13 to 4 nm with increasing Zn concentration from 0 to 1 [290].

Hematite nanocrystals modified with surface layers of amorphous hydrous iron oxides (Fe<sub>2</sub>O<sub>3</sub>·1.64H<sub>2</sub>O) were prepared by hydrothermal conditions at 130 °C in the absence of alkali [291]. When the temperature was lower than 130 °C, no product was formed, while above this temperature, the amount of amorphous hydrous iron oxides at the surface of hematite nanocrystals was drastically decreased.

Rutile or anatase nanocrystals were prepared by a low temperature dissolution–reprecipitation process in HCl or H<sub>2</sub>SO<sub>4</sub> solutions around room temperature [292]. The reprecipitation temperature and organic solvent addition in the solution system greatly affected the phase composition of the final powders.

Semiconductor selenides of MSe (M = Cd, Hg) nanocrystalline powders were synthesized through the reactions between metal chlorides and sodium selenosulfate in the ammoniacal aqueous solution at room temperature for 6–10 h [293]. The average diameters of CdSe and HgSe nanocrystallites were 4 and 8 nm, respectively. The storage and an interesting phase transition under hydrothermal conditions were presented. The absorption spectrum of the as-prepared samples exhibited an obvious blueshift due to the size confinement.

Cerium oxide nanoparticles coated by cetyltrimethylammonium bromide were prepared using reverse micelles and the microemulsion method [294]. A chemical transformation from an amorphous Ce<sup>3+</sup> component to a crystalline Ce<sup>4+</sup> component was found in the temperature range of 200 to 400 °C. For the as-prepared nanoparticles without annealing (25 °C), a single shell (10 × 2.59 Å) was sufficient to describe its local structures, while two shells had to be used for the nanoparticles annealed at 200 and 350 °C. One shell corresponded to the Ce<sup>3+</sup> component. Another corresponded to the Ce<sup>4+</sup> component. A core–shell model was used to explain the structural parameters around cerium for the two samples annealed at 200 and 350 °C.

The covalent binding of yeast alcohol dehydrogenase to magnetic nanoparticles via carbodiimide activation was studied [295]. The magnetic nanoparticles Fe<sub>3</sub>O<sub>4</sub> were prepared by coprecipitating Fe<sup>2+</sup> and Fe<sup>3+</sup> ions in an ammonia solution and treating under hydrothermal conditions. The resultant magnetic nanoparticles were superparamagnetic characteristics, and their saturation magnetization was reduced only slightly after enzyme binding. The kinetic measurements indicated the bound yeast alcohol dehydrogenase

retained 62% of its original activity and exhibited a 10-fold improved stability than did the free enzyme.

Cerium oxide ( $\text{CeO}_2$ ) nanoparticles were prepared sonochemically, by using cerium nitrate and azodicarbonamide as starting materials, and ethylenediamine or tetraalkylammonium hydroxide as additives [296]. The additives had a strong effect on the particle size and particle size distribution.  $\text{CeO}_2$  nanoparticles with small particle size and narrow particle size distribution were obtained with the addition of additives, while highly agglomerated  $\text{CeO}_2$  nanoparticles were obtained in the absence of additives. Blueshifts of the absorption peak and the absorption edges of the products were observed in the UV-vis absorption spectra as a result of the quantum size effect.

Millerite NiS nanocrystals were prepared through the solvent (hydro)thermal method [297]. Using ethylenediamine and hydrazine hydrate as solvent resulted in the formation of rodlike nanocrystalline NiS, whereas spherical nanoparticles were obtained using aqueous ammonia as solvent.

The hydrolyze process consists of hydrolyzing compounds in water to form precipitates, which can be used to prepare nanoparticles/nanocapsules. Usually, the starting materials of the hydrolyze process are water and metal inorganic salts like chlorates, sulphates, nitrates, ammonium salts, etc. The metal organic salts, like metal alcoholic salts, which can be solved in organic solvents, can be used for the starting materials of the hydrolyze process. The products of the hydrolyze reactions are hydroxids and hydrates. The difference between the hydrolyze process and the hydrothermal process is that high temperature and pressure are not needed in the former. The following are several examples for the hydrolyze process. Pseudolatexes of the biodegradable polyesters poly(D,L-lactide) (PLA) and poly( $\epsilon$ -caprolactone) (PCL) were developed as potential aqueous coatings for sustained release [298]. The influence of the surfactant system, temperature, pH, and particle size on the chemical stability of the polymers as aqueous colloidal dispersions was investigated. The room-temperature reactions of the chemical warfare agents VX [*O*-ethyl S-2-(diisopropylamino) ethyl methylphosphonothioate], GD (3,3-dimethyl-2-butyl methylphosphonofluoridate, or Soman), and HD (2,2'-dichloroethyl sulfide, or mustard) with nanosize MgO were studied [299]. All three agents hydrolyzed on the surface of the very reactive MgO nanoparticles. Procedures for the preparation at low temperature (80 °C) of uniform colloids consisting of  $\text{Mn}_3\text{O}_4$  nanoparticles (about 20 nm) or elongated  $\alpha$ -MnOOH particles with length less than 2  $\mu\text{m}$  and width 0.4  $\mu\text{m}$  or less, based on the forced hydrolysis of aqueous  $\text{Mn}^{2+}$  acetate solutions in the absence ( $\text{Mn}_3\text{O}_4$ ) or the presence ( $\alpha$ -MnOOH) of HCl, were described [300]. The role that the acetate anions played in the precipitation of these solids was analyzed.

### 3.3.6. Solvent Process

The solvent process utilizes solvable salts or compounds that can be dissolved by acids as the raw materials; they are then mixed in water or other solvents to be uniform solutions. Then the solvents are evaporated by heating evaporation, spraying dryness, flaming dryness, or cooling dryness. Finally, the heat decomposition reactions result in the

nanoparticles/nanocapsules or nanocomposites. Besides the solvent evaporation method, the emulsion techniques, such as partial-microemulsion, double-microemulsion, pressure homogenization-emulsification, or modified spontaneous emulsification solvent diffusion methods, can be categorized as solvent methods. The solvents used vary from water, to organic solvents, like acetone, ethanol, chloroform, benzene, 2-propanol, 2-methoxyethanol, 1,2-dimethoxyethane, *N,N*-diethylaniline, *N,N'*-dimethylformamide, trihexylamine, ammonium carbonate, ammonia solution, etc. The polymers, like poly(D,L-lactic acid), poly(*N*-vinyl-2-pyrrolidone), poly(lactide-co-glycolide), poly- $\Sigma$ -caprolactone, poly( $\gamma$ -benzyl L-glutamate), poly(ethylene oxide), poly(ethylene glycol), etc., can be employed for this purpose, especially for coating the biomaterials. The solvent process has been used for encapsulation of not only metal nanoparticles, but also biomedical materials, such proteins, cyclosporin A, triptorelin, Rolipram, insulin, vitamin E, and so on. The solvent process is a simple and cheap method which is suitable for industrial production of uniform nanoparticles/nanocapsules in large batches.

Entirely biodegradable poly(D,L-lactic acid) nanoparticles coated with albumin were prepared by the solvent evaporation technique [301]. Their degradative properties were investigated in simulated gastric and intestinal fluids.

A synthetic route was developed for the preparation of clay intercalated palladium catalysts [302]. A toluene-rich bulk liquid phase was equilibrated with a swollen, ethanol-rich interlamellar phase having a volume of about 0.9  $\text{cm}^3/\text{g}$  organoclay. Introduction of  $\text{Pd}^{2+}$  acetate into the organoclay suspension led to the generation and deposition of a metallic palladium dispersion in the interlamellar space. This system behaved as a versatile nanophase reactor, wherein the ethanol functioned as both solvent and reducing agent. The mean diameter of monodispersed Pd nanoparticles could be controlled from 17 to 30 Å in a one-step reaction by changing the amount of protective polymer, poly(*N*-vinyl-2-pyrrolidone), and the kind and/or the concentration of alcohol in the solvent [303]. The Pd nanoparticles had fcc structures like that of bulk Pd, although the lattice constant increased with a decrease in the particle size.

The preparation and use of iron-based catalysts having performances very similar to those of NiMo/KB-based catalysts were described [304]. The iron-based catalysts were prepared by impregnating soluble iron salts onto KB.

The poly(lactide-co-glycolide) nanospheres were designed to deliver proteins for extended periods of time [305]. A water-in-oil-in-water (w/o/w) emulsion technique was modified. A study was performed to evaluate how the solvent elimination procedure, the copolymer type (different molecular weight and containing either free or esterified carboxyls), and the surfactant Poloxamer 188 affected the properties of the nanoparticles.

The long-term stability of cyclosporin A-loaded nanoparticle suspensions, stored at 8 and 25 °C, was evaluated [306]. The stability of freeze-dried samples was investigated. Nanoparticles of poly- $\Sigma$ -caprolactone, a biodegradable polymer, were obtained by a modified nanoprecipitation method. A central composite experimental design was used to investigate the simultaneous effect of technological factors (temperature of the aqueous phase and needle gauge) and

formulation variables (volume of acetone and the amount of polymer and surfactant). The effect of these variables on the stability of the 100–220 nm particles was evaluated.

Silica–copper composite powders with high surface areas of about 200–400 m<sup>2</sup>/g were synthesized by the controlled hydrolysis/polymerization of sodium metasilicate (Na<sub>2</sub>SiO<sub>3</sub>) and copper nitrate [Cu(NO<sub>3</sub>)<sub>2</sub> · 3H<sub>2</sub>O] via partial-microemulsion and double-microemulsion processes at 28 °C [307]. Each microemulsion system consisted of sodium 1,4-bis(2-ethylhexyl) sulfosuccinate and sodium dodecyl sulfate, cyclohexane, and an aqueous solution of sodium metasilicate or copper nitrate. The partial-microemulsion method produced silica–copper oxide composites consisting of nanoparticles ranging from 20 to 50 nm with a uniform elemental distribution.

The preparation and the characterization of poly(lactic acid) nanoparticles containing protein C, a plasma inhibitor, were reported. nanoparticles were prepared by the double-emulsion method (w/o/w), using methylene chloride as an organic solvent and polyvinyl alcohol or human serum albumin as a surfactant [308, 309]. The influence of experimental constraints such as sonication and organic solvent on protein C activity was evaluated.

Diblock copolymers composed of poly( $\gamma$ -benzyl L-glutamate) as the hydrophobic component and poly(ethylene oxide) as the hydrophilic component were obtained by the polymerization of  $\gamma$ -benzyl L-glutamate *N*-carboxyanhydride, initiated by the primary amino end group of the  $\alpha$ -methoxy-omega-amino poly(ethylene oxide) [310, 311]. Nanoparticles were formed from an organic solution of the block copolymers by the diafiltration method.

An oligonucleotide drug was encapsulated within poly(lactide) microparticles with high encapsulation efficiencies at high theoretical drug loadings by the solvent evaporation method [312]. With the conventional w/o/w method, the encapsulation efficiency decreased with increasing internal water content, increasing stirring time prior to filtration of the microparticles, and increasing drug loading. The encapsulation was improved by replacing methylene chloride with ethyl acetate, by using micronized drug powder instead of an internal aqueous phase or by adding electrolytes or non-electrolytes to the external phase.

The imaging of ultrafine Au, Pd, CdS, and ZnS particles prepared in reverse micelles was studied by atomic force microscopy [313]. Mica substrates, derivatized with a monolayer of amine or thiol-terminated silanes, were used to immobilize the particles. The incorporation of CdS nanoparticles, as prepared in reverse micellar systems, into silica matrices, via a sol–gel process, was investigated [314]. The silica colloids containing CdS nanoparticles were prepared via the surface modification of CdS nanoparticles using 3-mercaptopropyltrimethoxysilane in reverse micelles. The recovery and dispersion of the nanoparticles was performed in an appropriate organic solvent, followed by a sol–gel process, using tetramethyl orthosilicate or tetraethyl orthosilicate in MeOH or EtOH solution. The size and morphology of the resulting silica colloids containing CdS nanoparticles was controlled by changes in the silica source and the organic solvents.

An electrochemical procedure, based on the dissolution of a metallic anode in an aprotic solvent, was used to obtain

silver nanoparticles ranging from 2 to 7 nm [315]. The influence of the different electrochemical parameters on the final size of silver particles was studied by using different kinds of counterelectrodes. The effect of oxygen presence in the reaction medium and the type of particle stabilizer employed were investigated.

The first step toward hydrophobic, polymer-based nanospheres for gene delivery is to encapsulate and release plasmid DNA. However, encapsulating large hydrophilic molecules in very small nanospheres is difficult. For example, maximizing protein and peptide as well as small molecule encapsulation requires adjustments in pH or addition of excipients to charge neutralize, and make less hydrophilic, the compound to be encapsulated. A cationic lipid was used to load and release plasmid DNA from nanospheres made by the phase inversion/solvent diffusion method [316].

The structural and magnetic properties of two Fe<sub>2</sub>O<sub>3</sub>–SiO<sub>2</sub> nanocomposites, containing respectively 16.9 and 28.5 wt% Fe<sub>2</sub>O<sub>3</sub>, were investigated [317]. The nanocomposites were synthesized by a sol–gel method, using ethylene glycol as a solvent, and heating the gels gradually to 900 °C. The procedure allows one to obtain  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticles homogeneously dispersed in the amorphous silica matrix.

Triptorelin is a decapeptide analog of luteinizing hormone releasing hormone, currently used for the treatment of sex-hormones-dependent diseases. The triptorelin-loaded nanospheres were prepared, which were useful for transdermal iontophoretic administration [318]. Nanospheres were prepared with the double-emulsion/solvent evaporation technique. The effect of three parameters on the encapsulation efficiency was determined: the role of the pH on the internal acid external aqueous phases.

The preparation of well-size-controlled colloidal gold nanoparticles in organic solvent was presented [319]. After the preparation of well-size-controlled aqueous colloidal gold particles, the solvent was changed to an organic one. This technique was required to enable a chemical reaction between gold particles and hydrophobic molecules, since a colloidal gold solution was typically prepared in water using a reduction process. The stability of the gold particle suspension was investigated, and it was found that the stability decreased in the sequence of water, ethanol, chloroform, and benzene solution.

Composite materials containing amorphous Cu nanoparticles and nanocrystalline Cu<sub>2</sub>O embedded in polyaniline matrices were prepared by a sonochemical method [320]. These composite materials were obtained from the sonication of Cu<sup>2+</sup> acetate when aniline or 1% v/v aniline–water was used as solvent. Mechanisms for the formation of these products were proposed. The physical and thermal properties of the as-prepared composite materials were presented.

The preparation of nanoparticles as a potential drug carrier and targeting system for the treatment of inflammatory bowel disease was investigated [321]. Rolipram was chosen as the model drug to be incorporated within nanoparticles. Pressure homogenization–emulsification with a microfluidizer or a modified spontaneous emulsification solvent diffusion method was used.

Di-*n*-hexadecyldithiophosphate (DDP)-coated ZnS nanoparticles and noncoated ZnS nanoparticles were chemically synthesized [322]. The antiwear ability of the DDP-coated ZnS nanoparticles and noncoated ZnS nanoparticles as additives in liquid paraffin were evaluated on a four-ball machine; the morphologies of the worn surfaces were examined.

Nanoparticles of tin disulfide were prepared by the solvent-thermal synthesis method using different precursors [323]. The products were of hexagonal SnS<sub>2</sub> phase, which were laminar particles with the average size of about 150 nm.

Pd Nanoparticles were synthesized by reduction of palladium acetate by ethanol in systems containing tetrahydrofuran (THF) as dispersion medium and tetradodecylammonium bromide (TDARr) surfactant as stabilizer [324]. The polar phase (ethanol) acted at the same time as the reducing agent. THF/TDABr/H<sub>2</sub>O inverse microemulsions containing micelles of various sizes were prepared, and the structure of complex liquids was studied by density measurements.

Nickel colloids were prepared by codeposition of the metal with several organic solvents: acetone, ethanol, 2-propanol, 2-methoxyethanol, and 1,2-dimethoxyethane at 77 K [325]. The stabilities of the colloids and fine powders were measured. The metallic films and active solids were obtained by evaporation under vacuum at room temperature.

A type of composite particle consisting of a zinc sulfide (ZnS) core and a silica (SiO<sub>2</sub>) shell or vice versa was reported [326]. Both kinds of morphologies were created using a seeded growth procedure using monodisperse seeds on which homogeneous layers with a well-defined thickness were grown.

Size-monodisperse metal nanoparticles were prepared via hydrogen-free spray pyrolysis [327]. Size-monodisperse pure copper particles are formed from metal salt precursors in a spray pyrolysis process using ethanol as cosolvent, thus avoiding the addition of hydrogen or other reducing gases.

Calix[4]resorcinarene-derived surfactants were highly effective at stabilizing metal nanoparticles of different sizes, creating opportunities to fabricate well-defined nanostructures with size-tunable materials properties [328]. The resorcinarenes had a critical role in the dispersion of nanoparticles under various solvent conditions and in the robustness of the protective surfactant layer. Magnetic cobalt particles stabilized by resorcinarenes self-assemble into nanostructured “bracelets” in toluene. Resorcinarene surfactants can promote the self-organization of gold nanoparticles as large as 170 nm into two-dimensional arrays.

The hybrid materials consisting of nonagglomerated iron oxide particles hosted in silica aerogels were investigated [329]. The composite material can be produced as a monolith, in any shape, and with different dilutions of the iron oxide phase. Two sol-gel chemistry routes were followed: a solution of Fe(NO<sub>3</sub>)<sub>3</sub>·9H<sub>2</sub>O was added either to the silica gel or to the initial sol; the iron salt provided the water required for the gel polymerization. To obtain monolithic aerogels, the gels were dried by hypercritical solvent evacuation.

Silver and gold nanocrystals, sterically stabilized with dodecanethiol ligands, were dispersed in supercritical ethane [330]. Nanocrystal dispersibility was measured as a function

of solvent density—with pressures and temperatures ranging from 138 to 414 bar and 25 to 65 °C, respectively. Dispersibility depended strongly on the nanocrystal size and solvent density.

Iron oxide aerogels were synthesized from tetraethoxysilicon(IV) or tetraethoxysilicon(IV) and iron nitrate using an acid-catalyzed solution sol-gel method combined with subsequent extraction of the alcoholic solvent with supercritical CO<sub>2</sub> [331]. The main parameters varied in the sol-gel synthesis were the type of *N*-base used as the gelation agent (*N*, *N*-diethylaniline, trihexylamine, ammonium carbonate, ammonia), the concentration of the iron precursor, and the water content. The silicon precursor was prehydrolyzed to improve its reactivity.

Insulin and insulin/poly(ethylene glycol)-loaded poly(L-lactide) nanoparticles were produced by gas antisolvent CO<sub>2</sub> precipitation starting from homogeneous polymer/protein organic solvent solutions [332]. Nanospheres with smooth surface and compact internal structure were observed by scanning electron microscopy. The nanospheres presented a mean particle diameter in the range 400–600 nm and narrow distribution profiles.

Biodegradable polymer nanocapsules containing the lipophilic sunscreen, Parsol MCX, as the oil core were prepared by solvent displacement [333]. The influence of polysorbate 85 (P-85) and poloxamer 188 (P-188) as stabilizing agents, the Parsol MCX loading capacity, and the photoprotective potential of the formulations were investigated. The formation of nanocapsules was due to an interfacial instability arising from rapid diffusion of the solvent across the interface.

In<sub>2</sub>S<sub>3</sub> nanoparticles, short nanowhiskers, nanorods, and finger-structure nanocrystals with stoichiometric composition and high quality were prepared by a solvent-reduction route [334]. The reagent concentrations, solvent, and reaction temperature played important roles in the shape control.

Polygonal (mainly triangular) silver nanoprisms were synthesized by boiling AgNO<sub>3</sub> in *N*, *N*-dimethyl formamide, in the presence of poly(vinylpyrrolidone) [335]. Although during the synthesis a mixture of nanoprisms and nanospheroids was formed, the latter can be removed through careful centrifugation. The UV-vis spectra of the nanoprisms displayed an intense in-plane dipolar plasmon resonance band, as well as weak bands for in-plane and out-of-plane quadrupolar resonances. The nanoprisms were also stable in other solvents, such as ethanol and water, and solvent exchange led to strong shifts of the in-plane dipole plasmon band.

An understanding of the mixing and characterization of nanosized powders was gained [336]. Three different nanosized material systems were selected based on their physical and chemical properties. Mixing experiments of the selected nanopowders were performed using a variety of environmentally friendly dry powder processing devices and the rapid expansion of supercritical CO<sub>2</sub> suspensions, compared with solvent-based methods coupled with ultrasonic agitation.

The formation of silver nanoparticles in the presence of various macrocyclic thiol compounds in *N*, *N*'-dimethylformamide solution was investigated *in-situ* through visible spectrophotometric and photon correlation spectroscopic measurements [337]. While temperature, solvent

nature, and concentration of thiol compounds were important parameters in the process of metal cluster and particle generation, the chemical structure of the thiol capping molecules also played a crucial role in determining the average particle size. The existence of a macrocyclic effect was reported on silver particle formation by using two types of thiol macrocyclic compounds, thiolated  $\beta$ -cyclodextrins and thiolated cavitands [337]. Perthiolated  $\beta$ -cyclodextrins were found to be more efficient as a capping ligand than monothiolated  $\beta$ -cyclodextrins.

Core-shell type nanoparticles of poly(L-lactide)/poly(ethylene glycol) diblock copolymer were prepared by a dialysis technique [338]. Their size was confirmed as 40–70 nm using photon correlation spectroscopy. The H-1-nuclear magnetic resonance (NMR) analysis confirmed the formation of core-shell type nanoparticles and drug loading. The particle size, drug loading, and drug release rate of the poly(ethylene glycol) nanoparticles were slightly changed by the initial solvents that were used.

A chemical reduction route at room temperature was described to synthesize nanocrystalline CdS, ZnS, and  $\text{Cd}_x\text{Zn}_{1-x}\text{S}$  [339]. Anhydrous  $\text{CdCl}_2$ , or  $\text{ZnCl}_2$ , S, and  $\text{KBH}_4$  powders reacted at room temperature in various organic solvents, and the effect of the solvent on the quality of the nanoparticle product was investigated. Among the solvents used, tetrahydrofuran was shown to produce the highest quality single-phase nanoparticles.

The D- $\alpha$ -tocopheryl polyethylene glycol 1000 succinate (vitamin E TPGS) was applied as surfactant stabilizer to fabricate paclitaxel-loaded poly(lactide-co-glycolide) nanospheres in the solvent evaporation/extraction technique [340]. Encapsulation efficiency and *in vitro* release were measured by the high-performance liquid chromatography.

The preparation of capped metal oxide nanoparticles through the hydrolysis of metal salts was made arduous by the difficulty of dissolving long organic chain capping agents in water. By performing the reaction in propylene glycol under reflux, instead of water, one can hydrolyze  $\text{FeCl}_3$  in the presence of *n*-octylamine to obtain (repeatedly) soluble, monodisperse (around 5 nm)  $\gamma\text{-Fe}_2\text{O}_3$  particles displaying a tendency to aggregate into superlattices [341].

A liquid-crystal system was used for the fabrication of a highly ordered composite material from genetically engineered  $M_{13}$  bacteriophage and ZnS nanocrystals [342]. The bacteriophage, which formed the basis of the self-ordering system, was selected to have a specific recognition moiety for ZnS crystal surfaces.

Surface interaction of gold nanoparticles with solvents and functionalized organic molecules was probed using the changes in the surface plasmon absorption band [343]. A redshift in the surface plasmon band was observed with an increase in solvent dielectric constant for solvents that do not complex with the metal surface. A plot of the square of the observed position of the surface plasmon bands of Au nanoparticles in these solvents as a function of medium dielectric function showed a linear dependence.

### 3.3.7. Latex Process

The latex process utilizes two different solvents that are not soluble each other to form a uniform and homogeneous microemulsion with the help of surfactants and dispersions.

Microemulsion is usually a transparent and isotropic thermodynamic system composed of surfactants, dispersions (polymers, alcoholic, etc.), oil (hydrocarbons), and water (or electrolytical water solutions). Polymer dispersions made of a variety of monomers, including styrene, butyl acrylate, and methyl methacrylate, surround the latex droplet. The solid phase could be from the emulsion, so that the processes of nucleation, growth, assembly, aggregation, etc. could be limited inside a micro/nanoemulsion droplet to form the micro/nanoparticles in the shape of spheres. The formation of micro/nanospheres avoids further aggregation of the nanoparticles. The key to this process is to form a system that every water solution droplet with precursors must be surrounded by a continuous oil phase and the precursors are not soluble in this oil phase. Namely, it is necessary to form a w/o-type latex so that the water phase cannot be formed, but instead a pseudo phase forms. In the latex, the latex beads serve as micro/nanoreactors, because each bead of several to hundreds of nanometers in size is separated by the layer of monomers. In some cases, the latex process using polymer dispersions can be combined with the polymerization process. The shape and the structure of the nanoparticles can be controlled by processes of layer-by-layer deposition, covering, coating, assembly, etc. The spherical latex can also serve as a template for the preparation of the nanomaterials, like porous materials, networks, etc. Thus the latex process can be used for synthesizing different types of nanomaterials, including nanoparticles, nanocapsules, nanoshells, etc. The creation of core-shell particles by the latex process has been attracting a great deal of interest because of the diverse applicability of these colloidal particles (e.g., as building blocks for photonic crystals, in magnetic storage, in multienzyme biocatalysis, and in drug delivery). The advantages of the latex process are narrow size distribution, easy control of size and shape, various synthesizable nanostructures, etc.

The processing, microstructure, and optical properties of CdS semiconductor nanoparticles sequestered in spin-coated polymer films were investigated [344]. A simple processing protocol was developed to form thin film structures consisting of CdS nanoparticles dispersed in the interstices created by a close-packed stacking of polystyrene spheres.

Poloxamer 407 and poloxamine 908 were used to modify the surface of both model latex and biodegradable nanospheres showing reduced protein adsorption *in vitro* and extended circulation times *in vivo* [345].

Model polymeric nanoparticles [aqueous colloidal polymer dispersions: Eudragit(R) RL 30D, L 30D, NE 30D, or Aquacoat(R)] with different physicochemical properties were incorporated into various solid dosage forms (granules, tablets, pellets, or films) [346]. The compatibility of the nanoparticles with commonly used tableting excipients and the redispersibility of the nanoparticles after contact of the solid dosage forms with aqueous media were investigated.

The core-shell latex morphology was used to produce three-dimensionally ordered arrays of fluorescent nanoparticles in polymer composite materials [347]. With their soft, inert shells, the particles were easily ordered into an array, after which heat treatment melted the soft shells to

give an array of nanoparticles in a transparent polymer matrix.

Colloidal particles with magnetic properties are attractive due to their tunable anisotropic interactions. A class of polystyrene-core magnetite-shell particles was produced by the sequential adsorption of nanoparticles and polyelectrolyte, a process that allowed the shell thickness and composition to be controlled with nanometer precision [348–350]. The nanocomposite particles were aligned in the presence of a magnetic field. Mesoscale hollow spheres of ceramic materials were prepared by templating an appropriate sol-gel precursor against a crystalline array of monodisperse polystyrene beads [351]. An array of TiO<sub>2</sub> hollow spheres of well-controlled, uniform size, and homogeneous wall thickness resulted.

Functional core-shell particles were prepared by assembling a composite multilayer shell of charged polyelectrolytes and luminescent CdTe(S) nanocrystals (cadmium telluride with a certain content of sulfide) via their consecutive electrostatic adsorption from solution onto micrometer-sized latex particles [352]. Variation of the size and surface chemistry of the semiconductor nanoparticles, the size and shape of the colloid templates, and the nature of the polyelectrolyte opened avenues for the production of a variety of core-shell materials.

Submicrometer core-shell polymer particles, with molecularly imprinted shells, were prepared by a two-stage polymerization process [353]. Particles, prepared with a cholesterol-imprinted ethyleneglycol dimethacrylate shell and in the absence of porogen, were found to be 76 nm in diameter with a surface area of 82 m<sup>2</sup> g<sup>-1</sup>. Imprinted shells were also prepared over superparamagnetic polymer cores and over magnetite ferrocolloid alone. The cholesterol binding to magnetic particles was very similar to that of equivalent nonmagnetic materials. Magnetic particles could be sedimented in as little as 30 s in a magnetic field.

Hierarchical assembly of zeolite nanoparticles into ordered macroporous monoliths was studied using core-shell building blocks [354]. Latex beads were used as a combined template and porogen in the fabrication of monolithic silica containing a hierarchy of pores. Prefabricated core/shell particles, prepared by the layer-by-layer assembly of zeolite (silicalite) nanoparticles onto spherical latex templates, were assembled into macroscopic close-packed structures. Calcination removed all organic components and caused densification of the inorganic structure producing a macroporous zeolite in which both the pore size and wall thickness can be varied.

Spherical polystyrene latex beads of about 2.0 μm diameter were coated with islands of silver or gold metal, about 5–200 nm in diameter, by reduction of aqueous silver or gold ions in the presence of sugar-coated polystyrene latex beads [355]. The metal islands were held on the bead surface by a polymeric sugar derivative, aminodextran, covalently bound to the polystyrene aldehyde/sulfate bead.

A review presented the state-of-the-art strategies for engineering particle surfaces, such as the layer-by-layer deposition process, which allows fine control over shell thickness and composition [356]. Nanocoating, the covering of materials with a layer on the nanometer scale, or covering of a nanoscale entity, to form nanocomposites and structured

materials using the sol-gel process was reviewed [357]. Templates from spherical nanoparticles to complex bicontinuous networks were discussed where either the coated material or the structured inorganic hollow frame resulting from removal of the template were of interest in fields of application ranging from information storage to catalysis.

The ultrasonic induced encapsulating emulsion polymerization technique was used to prepare polymer/inorganic nanoparticle composites [358]. The main factors affecting ultrasonic induced encapsulating emulsion polymerization were studied. The pH value, the type of monomers, the type, content, and surface properties of nanoparticles, and the type and concentration of surfactant had great influence on the ultrasonic induced encapsulating emulsion polymerization and the obtained latex stability. The mechanism of ultrasonic induced encapsulating emulsion polymerization and the composite latex stabilization were proposed.

Mesoscopic hollow spheres of ceramic materials with functionalized interior surfaces were synthesized [359]. Amphiphilic colloidal particles with hydrophobic cores and hydrophilic shells were prepared via a two-step method [360]. First, polystyrene cores were obtained through the concentrated emulsion polymerization. In the second step, the polystyrene particles were dispersed in water, after which acrylamide, *N*, *N*'-methylenebisacrylamide, and ferrous sulfate were added.

A procedure was developed to coat colloidal polystyrene spheres with a smooth and well-defined layer of amorphous titanium dioxide [361]. The thickness of the coating was easily varied from a few nanometers upward and increased further by seeded growth. The resulting composite particles were very monodisperse. The core-shell particles were turned into spherical hollow titania shells by dissolution of the polystyrene cores in suspension or by calcination of the dried particles in a furnace.

Polymer dispersions made of a variety of monomers, including styrene, butyl acrylate, and methyl methacrylate, were generated by the miniemulsion process in the presence of a coupling comonomer, a hydrophobe, and silica nanoparticles [362]. Depending on the reaction conditions and the surfactants employed, different hybrid morphologies were obtained, comprising a “hedgehog” structure where the silica surrounded the latex droplet and provided stabilization even without any low molecular weight surfactant.

The preparation of biocolloids with organized enzyme-containing multilayer shells for exploitation as colloidal enzymatic nanoreactors was described [363]. Urease multilayers were assembled onto submicrometer-sized polystyrene spheres by the sequential adsorption of urease and polyelectrolyte, in a predetermined order, utilizing electrostatic interactions for layer growth.

Fluorescently labeled core-shell latex particles composed mainly of the thermoresponsive polymer poly-*N*-isopropylacrylamide, were synthesized such that an energy transfer donor (phenanthrene) and an energy transfer acceptor (anthracene) were covalently localized in the core and shell, respectively [364]. Core-shell particles with different shell thicknesses displayed identical phase transition temperatures, with a clear increase in collapse temperature as the shell thickness was increased.

Encapsulation of silica nanoparticles was performed by dispersion polymerization of styrene, butyl acrylate, and butyl methacrylate in aqueous alcoholic media [365]. The silica beads were modified by reacting on their surface the 3-trimethoxysilyl propyl methacrylate coupling agent.

Core-shell composite materials, consisting of a silica core and a polystyrene shell, were prepared by colloidal assembly of polystyrene nanospheres onto silica microspheres [366]. The assembly process was controlled by specific chemical (amine-aldehyde) or biochemical (avidin-biotin) interactions between the nanospheres and microspheres. Colloidal assembly was performed using polymer nanoparticles and silica particles (3–10  $\mu\text{m}$  diameter). Heating the assembled materials to temperatures above the glass transition ( $T_g$ ) of the polymer nanoparticles allowed the polymer to flow over the microsphere surfaces, resulting in uniform core-shell materials. Nanosphere packing density on the microsphere surfaces influenced the uniformity of the resulting polymer shell.

A type of micrometer-sized entity containing silver was introduced [367]. Three different approaches were employed to modify the colloidal particles with silver. According to the first technique, the particles were first coated with layers of poly(styrenesulfonate) and silver ions followed by the reduction of silver by photoirradiation. The second technique involved coating the colloidal particles with a shell capable of reduction, and sequential addition of silver salt resulted in the reduction of metal in the shell matrix. The last approach utilized the reaction of a silver mirror to silver particles.

Acrylic/nanosilica composite latexes were prepared by blending via high shear stirring or ball milling and *in-situ* polymerization [368]. For comparison, composites filled with microsilica were also prepared. The mechanical and optical properties of the polymers formed by the composite latex filled with nano- or microsilica were investigated.

Raspberrylite hybrid organic-inorganic materials consisting of spherical silica beads supporting smaller polystyrene particles were prepared through a heterophase polymerization process [369]. In a first step, micrometer-sized silica particles were synthesized according to procedures inspired from the literature. In a second step, a poly(ethylene glycol) macromonomer was adsorbed on the surface of the silica beads. Finally, polymerization of styrene was achieved in water with a nonionic surfactant as an emulsifying agent and sodium persulfate as an initiator.

Nanoparticles of polystyrene ( $M_w = 1.0\text{--}3.0 \times 10^6$  g/mol) latexes were prepared from their respective dilute polystyrene (commercial) solutions in cyclohexane, toluene/methanol, or cyclohexane/toluene at each temperature [370]. The cationic surfactant cetyltrimethylammonium bromide was used to stabilize the formed PS latex particles. By varying different concentrations of cetyltrimethylammonium bromide and polystyrene solution of various  $M_w$ , stable bluish-transparent latex particles ranging from about 10 to 30 nm in diameter were produced.

Magnetically controllable photonic crystals were formed through the self-assembly of highly charged, monodisperse superparamagnetic colloidal spheres [371]. These superparamagnetic monodisperse charged polystyrene particles

containing nanoscale iron oxide nanoparticles were synthesized through emulsion polymerization.

Polystyrene latex particles containing silanol groups were synthesized in emulsion polymerization using 3-(trimethoxysilyl)propyl methacrylate as a functional comonomer [372]. The surface properties of the functionalized polymer latexes were investigated using electrophoretic measurements and the soap titration method. This work illustrated the determining role of interfaces in the structuration of organic-inorganic colloids.

Figure 6 shows a scanning electron microscope (SEM) photograph of the conducting polymer deposited as an ultrathin overlayer onto preformed polystyrene latex particles [373]. A series of sterically stabilized polystyrene latex particles in the size range 0.1–5.0  $\mu\text{m}$  was coated with ultrathin (<50 nm) overlayers of either polypyrrole, polyaniline, or poly(3,4-ethylenedioxythiophene) [373]. In each case the conducting polymer overlayer allowed the latex particles to acquire surface charge and hence be accelerated up to hypervelocities ( $> 1 \text{ km s}^{-1}$ ) using a Van de Graaff accelerator. These coated latexes had two main advantages. First, a wider particle size range can be accessed. Second, the particle size distributions of the coated latexes are much narrower than those of the pure polypyrrole particles.

Polyaddition reactions in miniemulsions were performed by miniemulsification of mixtures of di-, tri-, and tetraepoxides with varying diamines, dithiols, or bisphenols and subsequent heating to 60  $^\circ\text{C}$  [374]. Figure 7 shows a TEM micrograph of polyaddition latex comprised of Epikote E828 and 4,4'-diaminobiphenyl. Depending on the chemical nature of the monomer, the amount of surfactant, and the pH of the reaction mixture, latex particles with diameters between 30 and 600 nm and narrow size distributions were obtained [374].

### 3.3.8. Oxidation Process

The oxidation process oxidizes and deoxidizes directly the raw materials in the liquid phase or quasi-liquid phase state. The oxidation process can be used to prepare the nanoparticles

**Figure 6.** Scanning electron microscopy (SEM) photographs of preformed polystyrene latex particles coated with the conducting polymer (poly(3,4-ethylenedioxythiophene)) as an ultrathin overlayer. After [373], M. J. Burchell et al., *J. Phys. D* 32, 1719 (1999). © 1999, IOP Publishing.

**Figure 7.** TEM micrograph of polyaddition latex comprised of Epikote E828 and 4,4'-Diaminobenzyl. After [374], K. Landfester et al., *Macromol. Chem. Phys.* 201, 1 (2000). © 2000, Wiley-VCH.

of metals, alloys, oxides, etc., in either water solutions or organic solutions. For water solutions, solutions of metal salts with different pH values can be deoxidized by the reducers in gases or liquids. Almost all the metal ions in the solutions can be deoxidized by H reduction to form nanoparticles. Usually, surfactants are needed in order to avoid aggregation of the nanoparticles. Nanoparticles can also be synthesized by thermal decomposition or reduction of the organic or metal organic solutions. On the other hand, the oxidation process can be employed for coating the cover layer of the nanoparticles to form the nanocapsules and for studying directly the oxidation behavior of the nanomaterials. The oxidation process is one of the most simple, cheap, and easily controlled processes for preparation of nanoparticles/nanocapsules.

A method was proposed for  $\text{Si}_3\text{N}_4$  ceramics by forming a nanocomposite grain-boundary phase of SiC nanoparticles in the weak grain-boundary phase [375]. The SiC nanoparticles were formed by *in-situ* reaction between an oxide phase on the surface of  $\text{Si}_3\text{N}_4$  powder and carbon, which was coated on  $\text{Si}_3\text{N}_4$  powder by thermal decomposition of methane ( $\text{CH}_4$ ) gas. The surface oxygen content increased by an oxidation process or decreased by a washing process. The precipitated SiC content depended on the coated carbon and surface oxygen content on the  $\text{Si}_3\text{N}_4$  powder surface. A surface oxidized  $\text{Si}_3\text{N}_4$  powder was regarded as an inferior powder and the oxidized powder was used to produce high quality  $\text{Si}_3\text{N}_4$  ceramics by applying the carbon coating method.

The oxidation behavior of silver (Ag) nanometer particles (about 3 nm in diameter) within pores of a silica host in ambient air (298 K) was investigated [376]. Exposure to air resulted in a blueshift of the absorption edge with time, which was attributed to the surface oxidation of Ag nanoparticles. In air at room temperature, oxidation occurred in surface layers of Ag particles in the form of a dense  $\text{Ag}_2\text{O}$  film. Once the dense film was formed, further oxidation was restrained.

$\text{TeO}_2/\text{ZnO}$  and  $\text{ZnS}/\text{ZnO}$  coated nanoparticles of a few nm in diameter were created using an oxidation process of ZnTe and ZnS particles produced by a gas evaporation technique [377]. In the case of  $\text{TeO}_2/\text{ZnO}$  production, the first phase formed on the ZnTe particle was a ZnO layer on the particle surface, and a part of the ZnTe particles was changed to Te. On further oxidation for a few hours in air at 300 °C, the Te region gradually changed to  $\text{TeO}_2$  with increasing ZnO layer. In the case of ZnS particles, the surface of the particles was gradually changed to ZnO by heat treatment above 700 °C.

Biferrocene-modified Au clusters, comprising a  $2.2 \pm 0.3$  nm diameter Au core covered with 20 biferrocene-terminated thiolates and 75 octyl thiolates on average, were synthesized by a substitution reaction of octanethiol-modified clusters with biferrocene-terminated alkanethiol,  $(\eta(5)\text{-C}_5\text{H}_5)\text{Fe}(\text{C}_{10}\text{H}_8)\text{Fe}(\eta(5)\text{-C}_5\text{H}_4\text{CO}(\text{CH}_2)_7\text{SH})$  [378]. The biferrocene-modified cluster underwent two-step oxidation reactions in  $\text{NBU}_4\text{ClO}_4 + \text{CH}_2\text{Cl}_2$  and the second oxidation process led to the formation of a uniform redox-active Au cluster film on electrode.

The electrocatalytic activities of two kinds of iridium oxide electrodes were studied for their ability to evolve hydrogen and oxygen in 1 M  $\text{H}_2\text{SO}_4$  at room temperature [379]. The first kind of electrode was made of anodic iridium oxide nanoparticles prepared by cycling well-defined iridium metal nanoparticles supported on carbon between  $\text{O}_2$  and  $\text{H}_2$  evolution potentials. The oxidation process was followed by cyclic voltammetry and CO oxidation experiments. The mechanism for the two evolution reactions and for the two different electrodes was discussed.

Anodes of SnO were charged reversibly with Li to capacities greater than 600 mAh/g. The anode materials were characterized by  $\text{Sn}^{119}$  Mossbauer spectrometry at 11 and 300 K [380]. Trends in the valence of Sn were as expected when the Sn oxides were reduced in the presence of Li. The oxidation process of Sn was very much the reverse of the Sn reduction during the Li insertion.

Weblike aggregates of coalesced Si nanocrystals were produced by a laser vaporization-controlled condensation technique, showing luminescence properties that were similar to those of porous Si [381]. The oxidized Si nanoparticles did not exhibit the red photoluminescence that was characteristic of the surface-oxidized Si nanocrystals. A significant blueshift in the red photoluminescence peak was observed as a result of the slow oxidation process. As the nanoparticles oxidize, the radius of the crystalline core decreased in size, which gave rise to a larger bandgap and consequently to the observed blueshift in the photoluminescence band.

The function of oxide film during the thermal oxidation process of Zn nanoparticles was reported [382]. A study was reported concerning oxidation of SiC and amorphous silicon ( $\alpha\text{-Si}$ ) nanoparticles obtained by plasma-enhanced CVD [383, 384]. The oxidation behavior of the as-grown powder was understood in view of its polymeric structure containing a large amount of hydrogen, allowing rapid diffusion of oxygen.

An X-ray photon spectroscopy method was used to investigate nanosize particles which worked as catalytical active surface probes for oxidation of benzene, toluene, and CO [385]. Active components in the process of benzene, toluene,

and CO oxidation were Co and B compounds with oxygen featuring dangling bonds at the surface of nanoparticles. The nanosize dimensions of the synthesized boride particles played a substantial role in the oxidation process.

SO easily reduced  $\text{Au}^{3+}$  ions (1 : 1 equiv.) to monovalent  $\text{Au}^+$  species [386]. A salt composed of oxidized dye/ $\text{Au}^+$  was isolated. This salt was further reduced by another SO (2 : 1 equiv.) leading to gold atoms that coalesce into gold powder.

Pure  $\gamma\text{-Fe}_2\text{O}_3$  particles were continuously prepared by a continuous wave  $\text{CO}_2$  laser-induced pyrolysis of iron pentacarbonyl vapor in an oxidizing atmosphere [387]. Two different oxidation procedures were investigated: (1) air-argon mixtures were employed to fill the apparatus; (2) air-ethylene mixtures were employed as carrier gas.

Electrooxidation of methanol in sulfuric acid solution was studied using Pt, Pt/Ni (1:1 and 3:1), Pt/Ru/Ni (5: 4:1 and 6:3.5:0.5), and Pt/Ru (1:1) alloy nanoparticle catalysts, in relation to methanol oxidation processes in the direct oxidation methanol fuel cell [388]. Pt/Ni and Pt/Ru/Ni alloys showed excellent catalytic activities compared to those of pure Pt and Pt/Ru. The role of Ni as a catalytically enhancing agent in the oxidation process was investigated. The presence of metallic Ni, NiO,  $\text{Ni}(\text{OH})_2$ , NiOOH, metallic Ru,  $\text{RuO}_2$ , and  $\text{RuO}_3$  was confirmed.

Supramolecular polymer structures were assembled using the layer-by-layer, polyionic deposition technique [389]. Depositing alternating layers of a polycation, poly(diallyldimethylammonium chloride), and a polyanion, poly(styrenesulfonate), formed the thin films. The nucleation of nickel hydroxide nanoparticles was achieved using a cyclical absorption-oxidation process in which nickel ions were absorbed into the polymer matrix (which bind to the sulfonate groups) and then oxidized in an alkali solution.

### 3.3.9. Polymerization

Polymerization is a very common method for preparation of nanomaterials. During polymerization, usually, the formation of microemulsion is a very important factor which has been the focus of extensive research worldwide due to its importance in a variety of technological applications. These applications include enhanced oil recovery, combustion, cosmetics, pharmaceuticals, agriculture, metal cutting, lubrication, food, enzymatic catalysis, organic and bio-organic reactions, chemical synthesis of nanoparticles and nanocapsules, etc. In particular, nanocapsules consisting of an inorganic core and a polymer shell offer interesting prospects in various applications. Miniemulsions are specially formulated heterophase systems where stable nanodroplets of one phase are dispersed in a second, continuous phase. It is delineated that miniemulsions rely on the appropriate combination of saturated high shear treatment, surfactants, and the presence of an osmotic pressure agent insoluble in the continuous phase. The droplet diameter is adjusted by the type and amount of surfactant, the volume fraction of disperse phase, and the general dispersion problem and lies between 30 and 500 nm. Since each of those droplets can be regarded as an individual batch reactor, a whole variety of polymerization reactions can be performed starting from miniemulsions, clearly extending the profile of classical emulsion polymerization. Actually, polymerization could be the only process or one of the multisteps

of a whole preparation procedure. The polymerization process varies, depending on the kinds of the polymers used and the reactions. There are different polymerization processes, such as polymerization, co-polymerization, tri-polymerization, etc., depending on how many kinds of polymers are used. The polymerization process could be enhanced or adjusted by ultrasonic, plasma, microwave, etc. methods. The polymerization could be used with combination of other synthesization processes. As shown previously, during the chemical vapor deposition, solid-state reaction, sol-gel, precipitation, hydrothermal, solvent, latex, or oxidation process, the polymers could be used as the starting materials, such as precursors, surfactants, dispersions, etc. The polymerization could occur in all these kinds of processes for synthesis of nanoparticles and nanocapsules. Furthermore, it is easy to control the preparation parameters during the polymerization so that lot of different nanomaterials, like nanoparticles, nanocapsules, nanoporous, hollow, nanowires, nanospheres, etc., can be synthesised. Figure 8 represents the design of water-soluble nanocapsules.

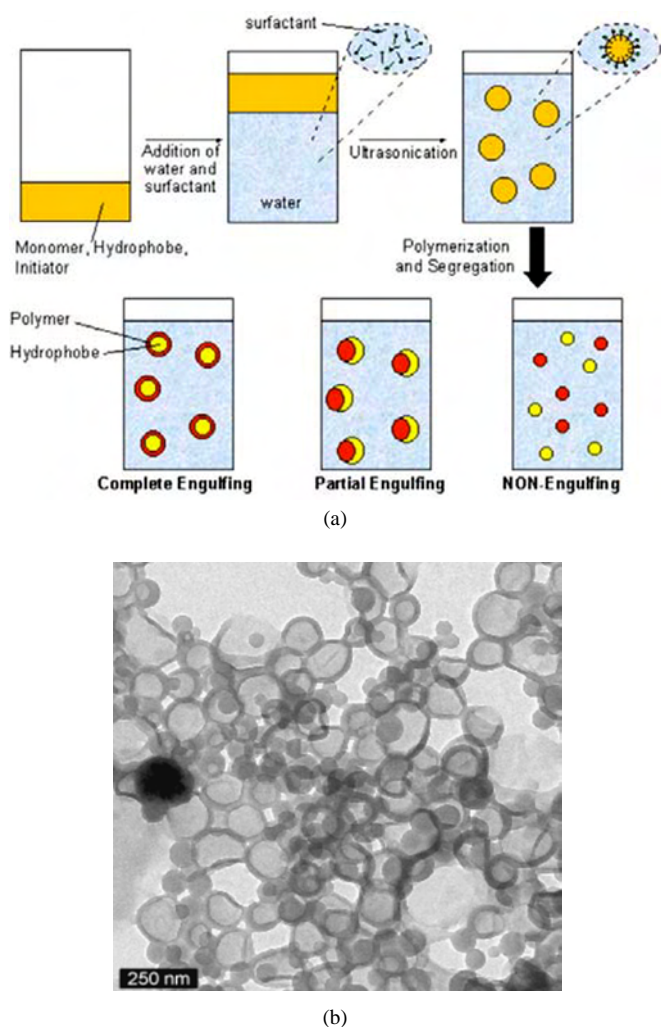

A review provided the features of microemulsions and their applications [390], which started with a brief introduction and focused on definition, structure, type, formation characteristics, stability, phase behavior, and the effect of additives, pressure, and temperature on the phase behavior of microemulsion. The physicochemical properties, state of water in the micropool, transport (electrical and hydrodynamic) behaviors, thermodynamics of formation, solubilization parameters, and uses and applications of microemulsions were presented.

Figure 9a represents the scheme of the formation of nanocapsules by miniemulsion polymerization and Figure 9b shows a TEM micrograph of nanocapsules of poly(styrene-co-acrylic acid) obtained by miniemulsion polymerization [391]. One major part of the work was concerned with the development of a convenient one-step synthesis of hollow polymer nanocapsules by the miniemulsion polymerization of different monomers in the presence of larger amounts of a hydrophobe. The idea was that hydrophobe and monomer formed a common miniemulsion, whereas the polymer was immiscible with the hydrophobe and demixed throughout polymerization to form a hollow structure surrounding the hydrophobe. It was found that the structure can be adjusted to cover the whole range from independent particles over partially engulfed structures to structurally integer nanocapsules of high uniformity [391].

An approach was presented for the identification of factors to permit the development of nanoparticle growth hormone

**Figure 8.** The design of water-soluble nanocapsules. Appropriately sized capsules are synthesised using dynamic combinatorial chemistry in an aim to develop efficient drug targeting systems. Image courtesy of S. Otto, Department of Chemistry, University of Cambridge, UK.

**Figure 9.** (a) Scheme of formation of nanocapsules by miniemulsion polymerization and (b) TEM micrograph of nanocapsules of poly(styrene-co-acrylic acid) obtained by miniemulsion polymerization. After [391], F. Tiarks et al., *Langmuir* 17, 908 (2001). © 2001, American Chemical Society.

releasing factor (GRF) formulation [392]. GRF can be associated with biodegradable poly(alkylcyanoacrylate) nanoparticles. Among other parameters, the moment at which GRF was incorporated in the polymerization medium was found to be a critical factor in avoiding the degradation of GRF and the covalent bonding of the peptide with the polymer.

Biodegradable colloids suitable for use as drug delivery systems can be formed by *in-situ* polymerization of isobutylcyanoacrylate monomers. The mechanisms of formation of colloidal systems of polyisobutylcyanoacrylate (PIBCA) obtained in the presence of oil and ethanol were studied [393]. A polymerization system, a Winsor I-like system, was used for polymerization of styrene at room temperature [394]. The system consisted of a microemulsion (lower) phase that was topped off with styrene. The factors affecting the polymerization were discussed.

Plasma polymer thin films with encapsulated dye molecules (rhodamine 6G) and silver nanoparticles were

deposited by alternating plasma polymerization, dye sublimation, and metal evaporation [395]. The interference between the optical absorption of the plasma polymer, the dye molecule absorption, and the plasma resonance absorption of the silver particles was measured in the UV-vis-near-infrared red spectral region. Fluorescence measurements demonstrated plasma polymer matrix effects on fluorescence of the dye molecules. Polymer thin films with embedded silver nanoparticles were deposited by simultaneous plasma polymerization and metal evaporation [396].

Silica (Aerosil A200 V) was functionalized by reaction with methacryloylpropyltrimethoxysilane (MPTMS) in toluene [397]. The grafting yield first increased with the ratio MPTMS/SiOH and then leveled off after full monolayer coverage, each molecule of MPTMS covering 7.1 nm. Silicone membranes with silica nanoparticles were prepared [398].

Inorganic  $\text{Fe}_2\text{O}_3$  nanoparticles of 3–5 nm diameter were assembled with polymer microspheres and then encapsulated in copolymer of St/BA/AA by a polymerization process [399].  $\text{Fe}_2\text{O}_3$  encapsulated microspheres were obtained through interaction between surface groups of the two component particles and by adjusting the pH value in the emulsion. Pretreatment of the composite particles using a certain amount of surfactant before polymerization gave a good encapsulation.

Enzyme superoxide dismutase incorporation parameters were evaluated after immobilization in polyisobutylcyanoacrylate nanoparticles [400]. After initialization of the anionic mechanism of polymerization, pH was increased and its effect on the characteristics of polyisobutylcyanoacrylate nanoparticles was analyzed. Optimization of enzyme activity during incorporation into nanoparticles and the influence on size distribution were studied.

Aiming at the preparation of nanometer-size polydiacetylene microcrystals, the crystallization process during the reprecipitation method was investigated. An amorphous nanoparticle was formed initially and subsequently crystallized [401].

AB diblock copolymers consisting of poly( $\gamma$ -benzyl-L-glutamate) (PBLG) as the hydrophobic part and poly(*N*-isopropylacrylamide) (PNIPAAm) as the hydrophilic one were prepared by polymerization of  $\gamma$ -benzyl-L-glutamate-*N*-carboxyanhydride (BLG-NCA) with semitelechelic PNIPAAm with amino end group as initiator [402]. The core-shell type nanoparticles of the block copolymers were obtained by the diafiltration method. The sizes of the nanoparticles were from about 73 to 359 nm and the shapes of them were spherical.

Low-water-content reverse micelles were formed in cyclohexane employing Triton X-100 or AOT (bis(2-ethylhexyl) sulfosuccinate sodium (salt) as the surfactant [403]. At low water content, reverse micelles cannot properly solubilize polar species but the surfactant molecules tended to reorganize themselves around the polar molecules forming structures depending on the nature of the surfactant and the charge. Solid and hollow, magnetic and nonmagnetic, organic-inorganic monodispersed hybrid microspheres were synthesized [404].

Amphiphilic block copolymers are important in interface and particle stabilization. Mesophases and micelles of block copolymers and the solubilization and adhesion of

amphiphilic block copolymers were considered [405]. AB-type amphiphilic copolymers composed of poly(L-leucine) as the A component and poly(ethylene oxide) as the B component were synthesized by the ring-opening polymerization of L-leucine *N*-carboxy-anhydride initiated by methoxy polyoxyethylene amine [406]. Core-shell type nanoparticles were prepared by the diafiltration method. Micelles were formed also by a polystyrene/poly(vinylpyridine) copolymer. Nanosized copper oxide particles dispersed in nylon 11 thin films were prepared by a thermal relaxation technique [407].

Conducting polymers and their processability problem were introduced, and the synthesis of an economically attractive and environmentally stable conducting polymer, viz., polyaniline in dispersion form, was discussed [408]. Nanoparticles of less than 20 nm in diameter were obtained from the particles in the dispersion by way of disintegrating them with the help of ultrasound. Nanoparticles produced inside of solutions of various matrix polymers underwent fractal aggregation.

An approach to prepare magnetic polymeric nanoparticles with narrow size distribution by synthesis of the magnetite core and polymeric shell in a single inverse microemulsion was reported [409]. The microemulsion seed copolymerization of methacrylic acid, hydroxyethyl methacrylate, and cross-linker resulted in a stable hydrophilic polymeric shell of the nanoparticles. The importance of three main parameters was emphasized in the nanostructured systems: the mechanical coupling between the two phases, the possible cross-linking of the macromolecules by the nanoparticles, and the connectivity between reinforcing particles [410].

Stable suspensions of superparamagnetic cobalt nanoparticles were prepared in poly(dimethylsiloxane) carrier fluids in the presence of poly[bis(dimethylsiloxane)-*b*-(3-cyanopropyl) methylsiloxane-*b*-dimethylsiloxane] triblock copolymers as steric stabilizers [411]. A series of polysiloxane triblock copolymers with systematically varied molecular weights were prepared via anionic polymerization using LiOH as an initiator. These copolymers formed micelles in toluene and served as "nanoreactors" for thermal decomposition of the  $\text{Co}_2(\text{CO})_8$  precursor.

Latexes with a poly(dimethyl siloxane) core and a poly(styrene-methyl methacrylate-acrylic acid) shell were prepared in two steps in order to generate particles that have a core with a very low glass transition temperature [412]. In the first step, poly(dimethyl siloxane) particles were obtained via the ring-opening emulsion polymerization of octamethyl tetracyclosiloxane (D-4). The polymerization was carried out using either an anionic or a cationic catalyst. Using a PD4 latex as seed, a seeded emulsion polymerization of poly(styrene-methyl methacrylate-acrylic acid) was conducted to obtain core-shell particles.

Core-shell particles consisting of a polystyrene latex colloidal core and  $\text{Fe}^{2+}$  metallosupramolecular polyelectrolyte/poly(styrenesulfonate) multilayer shells were fabricated by the consecutive assembly of these polymers on polystyrene particles [413]. Structurally well-defined metallosupramolecular polyelectrolyte-colloid assemblies were studied, which combined the functional units from supramolecular chemistry with the restricted dimensionality of colloids.

The encapsulation of seed polymer particles coated by anionic iron oxide nanoparticles was investigated using *N*-isopropylacrylamide as a main monomer, *N,N*-methylene bisacrylamide as a cross-linking agent, itaconic acid as a functional monomer, and potassium persulfate as an anionic initiator [414].

Dispersion copolymerization of styrene and a poly(*N*-isopropylacrylamide) macromonomer in ethanol water media was carried out in the presence of  $\text{AgNO}_3$  [415]. Nanoscopic silver particles were generated on their surfaces via *in-situ* reduction of  $\text{Ag}^+$  by radicals generated from the initiator, 2,2'-azobisisobutyronitrile. The particle sizes of both polystyrene microspheres and silver nanoparticles were affected by the initial 2,2'-azobisisobutyronitrile,  $\text{AgNO}_3$ , and macromonomer concentrations.

Monodisperse poly(4- and poly(2-vinylpyridine) nanoparticles in the 500 nm diameter range were prepared by emulsifier-free emulsion polymerization techniques under free radical initiation of the respective monomers with 4 wt% divinylbenzene as the cross-linking agent [416]. The size, integrity, and nature of the Pd-coated nanospheres were investigated.

The core-shell  $\text{Y}_2\text{O}_3\cdot\text{Eu}^{3+}$ /polystyrene particles were prepared by surface modification with citric acid and emulsion polymerization method with styrene [417]. The DTA curve of coated particles exhibits a small and wide exothermic peak of organic compound around 387 °C. The carbonyl stretching vibration band was shifted to low wavenumber in the Fourier transform IR (FTIR) spectrum and the binding energy of  $\text{Y}3d^{5/2}$  was shifted to the high-energy band in the X-ray photoelectron spectroscopy (XPS) spectrum.

Nanoporous carbons with extremely high mesopore volumes and surface areas were produced using silica nanoparticles as templates [418]. The polymerization of resorcinol and formaldehyde (RF) in the presence of silica sol particles generated RF gel-silica nanocomposites.

Uniform Ag nanowires were synthesized within nanoscale channels of mesoporous silica SBA-15 by a chemical approach, which involved  $\text{AgNO}_3$  impregnation followed by thermal decomposition [419].

The preparation, luminescent properties, and bioimaging applications of a novel zinc sulfide (core)-two-photon dye-silica (shell) multilayered heterostructure were reported [420]. The method utilized reverse micelle synthesis involving multistep reactions as a result of which composite nanoparticles having different sizes (typically 15–30 nm) and morphology were obtained. An increase in the luminescence intensity (similar to 70 times higher) and in fluorescence lifetime was observed for the dye encapsulated within the silica nanobubble.

Polymethyl methacrylate-based stealth and functional nanospheres, specifically designed for the reversible adsorption of oligonucleotides, were prepared by emulsion polymerization of methyl methacrylate in the presence of an ionic comonomer, namely a quaternary ammonium salt of 2-(dimethylamino)ethyl methacrylate, and a nonionic comonomer, namely a poly(ethylene glycol) methacrylate [421]. The nanosphere size was substantially affected by the amount of both the nonionic and ionic comonomers.

Silaferrocenophanes  $\text{fcSiMe}_2$  and  $\text{fcSi}(\text{CH}_2)_3$  [ $\text{fc} = \text{Fe}(\eta_5\text{-C}_5\text{H}_4)_2$ ] were incorporated into the well-ordered, hexagonal

channels of mesoporous silica (MCM-41) [422]. Characterization of the composite materials indicated the presence of ring-opened monomer, oligomer, and polymer. From the magnetization data, the two phases were best described as Fe nanoparticles with diameters of 5.0–6.4 nm coated with a thin (ca. 0.4–0.6 nm) oxide layer.

A tripodal alkythiolate ligand was assembled on gold nanoparticles, which upon metathesis polymerization and particle etching yielded cross-linked spherical hollow polymer capsules [423]. Silver nanoparticles coated with a uniform, thin shell of titanium dioxide were synthesized via a one-pot route, where the reduction of  $\text{Ag}^+$  to  $\text{Ag}^0$  and the controlled polymerization of  $\text{TiO}_2$  on the surface of silver crystallites took place simultaneously [424]. High quality ultrathin films of the core-shell clusters were prepared via layer-by-layer assembly. The nanoparticles were arranged in closely packed layers interlaced with polyelectrolyte producing a stratified core-shell hybrid material with unique structure and catalytic and electron-transport properties.

Two polymethylmethacrylate functional nanosphere series, specifically designed for the reversible adsorption of oligonucleotides, were prepared by emulsion polymerization in the presence of two structurally different ionic comonomers, namely two quaternary ammonium salts of 2-(dimethylamino)ethyl methacrylate [425]. The nanosphere size was substantially affected by the ionic comonomer structure and amount. The width of the size distribution tended to decrease with increasing comonomer amount in solution, and monosized nanosphere samples were obtained at a high comonomer amount.

Copolymers of  $\epsilon$ -caprolactone and L-lactide with different monomer ratios were synthesized by ring-opening polymerization, and drug-loaded nanoparticles of poly- $\epsilon$ -caprolactone, poly-L-lactide, and their copolymers were prepared by a precipitation method, respectively [426]. End-functionalized three-dimensional (3D) self-assembled monolayers on gold nanoparticles were used to initiate the living cationic ring-opening polymerization reaction directly on gold nanoparticle surfaces [427]. In this manner, dense polymer brushes were prepared in a “one-pot multistep” reaction.

Ultrasonic induced encapsulating emulsion polymerization was used to prepare the polymer/inorganic nanoparticle composites [428, 429]. The behaviors of several inorganic nanoparticles ( $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$ ) under ultrasonic irradiation, such as dispersion, crushing, and activation, were studied. The dispersion stability, morphology, and structure of the ultrasonic irradiated nanoparticles were characterized. The inorganic nanoparticles in the aqueous solution can redisperse more effectively by ultrasonic irradiation than by conventional stirring. The well-dispersed nanoparticles were encapsulated by the formed polymer with thickness in the range of 5–65 nm.

Core-shell CdS/ $\text{SiO}_2$  nanoparticles were prepared and modified with the atom transfer radical polymerization initiator 3-(2-bromopropionyloxy) propyl dimethylethoxysilane [430]. The initiator-modified nanoparticles were then used as macroinitiators for the polymerization of methyl methacrylate catalyzed by  $\text{NiBr}_2(\text{PPh}_3)_2$ .

The precipitation and condensation of submicrometer organic particles and the thermodynamic driving forces for

precipitation and phase transformation were reviewed [431]. The importance of physical state effects was discussed, and the role of compartmentalization in controlling particle size was introduced. The use of emulsification as a primary step in producing small particle dispersions was illustrated with photographic and pharmaceutical applications.

Static and dynamic magnetic experiments were conducted on polymer-coated Fe nanoparticles of 15–20 nm synthesized by a microwave plasma method [432]. The field-dependent magnetization data showed the presence of sharp switching at low fields (about 60 Oe) followed by a gradual approach to a saturation magnetization of about 80 emu/g.

The effect of composition on the dispersion of  $\text{Au}_x\text{Cu}_{1-x}$  bimetallic nanoparticles into nylon 11 matrix was investigated [433]. The changes in the composition of the bimetallic particles and in the depth distribution of the particles in the nylon 11 layer caused by heat treatment in  $\text{N}_2$  atmosphere were characterized. Islandlike bimetallic particles were found to be formed on the nylon 11 surface before heat treatment. By the heat treatment, the  $\text{Au}_x\text{Cu}_{1-x}$  bimetallic particles with  $x \leq 0.55$  were not dispersed into the nylon 11 layer while those with  $x \geq 0.70$  were homogeneously dispersed in the films.

The preparation of hybrid organic/inorganic nanocomposites comprised of well-defined polymers was reviewed [434]. Synthetic methods using controlled/“living” radical polymerization techniques, such as stable free radical/nitroxide-mediated polymerizations, atom transfer radical polymerization, and reversible addition-fragmentation chain-transfer polymerization, were described. The various approaches taken to prepare hybrid copolymers, nanoparticles, polymer brushes, dispersed silicate nanocomposites, and nanoporous materials were discussed.

Polymer dispersions made of a variety of monomers, including styrene, butyl acrylate, and methyl methacrylate, were generated by the miniemulsion process in the presence of a coupling comonomer, a hydrophobe, and silica nanoparticles [435]. Depending on the reaction conditions and the surfactants employed, different hybrid morphologies were obtained, comprising a “hedgehog” structure where the silica surrounds the latex droplet and provides stabilization even without any low molecular weight surfactant.

Thermoresponsive, core-shell poly-N-isopropylacrylamide nanoparticles (microgels) were synthesized by seed and feed precipitation polymerization, and the influence of chemical differentiation between the core and shell polymers on the phase transition kinetics and thermodynamics was examined [436]. The results suggested that the core-shell architecture is a powerful one for the design of colloidal “smart gels” with tunable properties. The addition of small concentrations of a hydrophobic monomer (butyl methacrylate) into the particle shell produced large decreases in the rate of thermoinduced particle collapse.

Silver nanoclusters in poly(methyl methacrylate) were prepared by bulk polymerization of methyl methacrylate with radical initiators (AIBN or BPO) in the presence of  $\text{Ag}^+$  trifluoroacetate, followed by a period of UV irradiation [437].

A versatile method for the generation of nanoparticulate metals, ceramics, and polymers based on synthesis in miniemulsions—highly stable small droplets in a continuous

phase—was presented [438]. In addition to nanoparticles, encapsulated materials, polymer capsules, and hollow particles can also be obtained by careful selection of the starting materials.

Melt mixing of nanoparticles with high performance polymers is not feasible due to severe shear heating and formation of particle aggregates. An alternative scheme was investigated involving the use of low molecular weight reactive solvents as processing aids and dispersion agents [439]. Dispersion of nanosize fumed silica particles in polyethersulphone matrix was studied with the aid of small amounts of low molecular weight epoxy. Viscosity and processing temperatures of polyethersulphone were significantly reduced and fumed silica particles were dispersed to nanoscales.

A method was developed for the controlled release of the hydrophobic polymer chains from the core of the shell of cross-linked nanoparticles by selective cleavage of labile C–ON bonds present at the core–shell interface [440]. This represented a methodology to probe the permeability of nanoscopic membranes and a means for applications in the controlled release of macromolecular species.

A water-in-oil microemulsion method was applied for the preparation of silica-coated iron oxide nanoparticles [441]. Three different nonionic surfactants (Triton X-100, Igepal CO-520, and Brij-97) and pure water were used for the preparation of microemulsions, and their effects on the particle size, crystallinity, and the magnetic properties were studied.

The incorporation of CdS nanoparticles, prepared in reverse micellar systems, into thiol-modified mesoporous silica, such as functionalized MCM-41 and MCM-48, was investigated [442]. The nanoparticles were immobilized in the mesopores via the incorporation of water droplets of the reverse micelles.

An irradiation grafting method was applied for the modification of nanoparticles so that the latter can be added to polymeric materials for improving their mechanical performance, using existing compounding techniques. The following items were discussed: (a) chemical interaction between the grafting monomers and the nanoparticles during irradiation; (b) properties including modulus, yield strength, impact strength, and fracture toughness of the resultant nanocomposites; and (c) possible morphological changes induced by the addition of nanoparticles [443].

The coating of different materials with conducting electroactive polymers (i.e. polyaniline, polypyrrole, polythiophene, and their derivatives), provided by means of chemical polymerization, was reviewed [444]. The topics covered included the deposition of conducting electroactive polymers (i) by bulk oxidative chemical polymerization, (ii) by surface-located polymerization, and (iii) by coating of micro- and nanoparticles. The coating of different materials like polymers, polymer particles, ion-exchange membranes, glass, fiber, textile, soluble matrices, and inorganic materials was reviewed.

Chitosan–poly(acrylic acid) complex nanoparticles, which were well dispersed and stable in aqueous solution, were prepared by template polymerization of acrylic acid in chitosan solution [445]. The molecular weight of poly(acrylic acid) in nanoparticles increased with increasing molecular weight of chitosan, indicating that the polymerization of

acrylic acid in the chitosan solution was a template polymerization. The prepared nanoparticles carried a positive charge and showed a size in the range from 50 to 400 nm. The surface structure and  $\zeta$  potential of nanoparticles were controlled by different preparation processes. The potential of chitosan as an emulsion stabilizer was combined with the miniemulsion technique to generate oil droplets, hollow capsules, and latex particles in the diameter range of 100–300 nm carrying a functional biopolymer surface [446]. Facile fabrication of hollow polystyrene nanocapsules was done by microemulsion polymerization [447].

Liquid nanodroplets within a size range of 50 to 500 nm were prepared by shearing a system containing oil, water, and a surfactant [448]. The growth of the nanodroplets can effectively be suppressed by using a strong hydrophobe as an additive to the oil and an effective surfactant. The hydrophobe acted as an osmotic agent which stabilized the system against Ostwald ripening. The growth of the droplets by collision was controlled by the density of the surfactant layer. Freshly prepared miniemulsions were “critically stabilized” and show a slow but pronounced growth, whereas a miniemulsion in “equilibrium” exhibited constant droplet size on longer time scales.

Surface-initiated living free radical polymerization was employed in a multistep procedure to prepare hollow polymeric nanocapsules [449]. Initially, trichlorosilyl-substituted alkoxyamine initiating groups were attached to the surface silanol groups of silica nanoparticles. This surface layer of initiating groups was then used to grow functionalized linear chains leading to a core–shell morphology. Under either chemical or thermal conditions, the reaction of these functionalities gave a cross-linked polymeric shell that was covalently attached to, and surrounded, the central silica core. Removal of the silica core then gave the hollow polymeric nanocapsules, which were stable under solvent dissolution and thermal treatment because of their cross-linked structure.

Electron affinities of methyl-2-cyanoacrylate and ethyl-2-cyanoacrylate were predicted using four different density functional or hybrid Hartree–Fock/density functional methods [450]. Equilibrium structures and harmonic vibrational frequencies were computed for the neutral and anionic species of each system.

The protective antioxidant role of idebenone both as free drug and drug-loaded Tween 80-coated polyethyl-2-cyanoacrylate nanocapsules was reported [451]. The relationship between oxidative damage and apoptotic or nonapoptotic cell death was evaluated *in vitro*.

A synthetic process for producing aromatic polycarbonate nanoparticles using supercritical CO<sub>2</sub> was developed [452]. High molecular weight polycarbonate nanoparticles were synthesized using transesterification between bisphenol-A and diphenyl carbonate in supercritical CO<sub>2</sub> which was an excellent plasticizing agent and a good solvent for phenol, a by-product of the reaction. Poly(propylene oxide)–poly(ethylene oxide)–poly(propylene oxide) tri-block copolymer with CO<sub>2</sub>-phobic anchor and CO<sub>2</sub>-philic tail group was used as a stabilizer for the preparation of stable dispersions of bisphenol-A–diphenyl carbonate mixture in a CO<sub>2</sub> continuous phase. The resulting polycarbonate particles with

a nanosize of 30–140 nm had a high molecular weight of  $3.1 \times 10^5$  (g/mol).

Functional arborescent graft polystyrenes prepared by a technique involving the iterative grafting of end functional polymer chains onto reactive polymer backbones were synthesized [453]. The zero-generation comb polymers and then the first generation hyperbranched structures were obtained by the coupling reaction of living (*x*-acetal polystyryllithium) onto linear or comb chains of poly(chloro ethyl vinyl ether) of controlled (DP) over bar (*n*) and structure.

A type of narrowly dispersed fluorescent cross-linked polystyrene nanoparticle (20–50 nm) was synthesized via a modified microemulsion copolymerization of styrene, cross-linker divinyl benzene, and a hydrophilic comonomer amino ethyl methacrylate hydrochloride, in the presence of pyrene [454]. Characterized by steady-state fluorescence spectra, these nanoparticles showed high luminescent intensity and the embedded pyrene had a negligible desorption from the nanoparticles.

Core-shell polymeric nanoparticles were prepared by self-assembly and step-growth polymerization [455]. An approach was presented for the controlled intramolecular collapse of linear polymer chains to give well-defined single-molecule nanoparticles whose structure was directly related to the original linear polymer [456]. By employing a combination of living free radical polymerization and benzocyclobutene chemistry, nanoparticles can be routinely prepared in multigram quantities with the size being accurately controlled by either the initial degree of polymerization of the linear chain or the level of incorporation of the benzocyclobutene coupling groups. The latter allowed the cross-link density of the final nanoparticles to be manipulated.

Stable colloidal solutions of gold nanoparticles surface-derivatized with a thiol monolayer were prepared using two-phase (water–nitrobenzene) reduction of  $\text{AuCl}_4^-$  by sodium borohydride in the presence of 2-mercapto-3-*n*-octylthiophene [457]. This kind of surface-functionalized gold nanoparticle was incorporated into the poly(3-octylthiophene) films on electrode in the process of electrochemical polymerization leading to poly(3-octyl thiophene)–gold nanoparticle composite films.

Polyphenylpyrrole coated silver nanoparticles at the liquid/liquid interface were produced [458]. In the electrochemical step of the reaction, *N*-phenylpyrrole facilitated the transfer of the silver ion from an aqueous to an organic phase. This step was followed by a slow homogeneous electron transfer reaction from the *N*-phenylpyrrole to the silver ion followed by polymerization and metal cluster growth.

Inorganic silica nanoparticles were encapsulated with an epoxy resin to give waterborne nanocomposite dispersions, using the phase-inversion emulsification technique [459]. Submicrometer-sized waterborne particles with narrow size distribution were prepared. All the silica nanoparticles were encapsulated within the composites and uniformly dispersed therein. Curing of the nanocomposite dispersions proceeded in a controlled manner.

A ternary microemulsion polymerization was used to prepare nanosized hollow polystyrene microlatexes with triblock copolymers of poly(oxyethylene)–poly(oxypropylene)–poly(oxyethylene)  $[(\text{EO})_x(\text{PO})_y(\text{EO})_x]$  [460]. Micelle formation

using triblock copolymers was a useful nanoreactor in order to make polymer nanoparticles in o/w microemulsions. Poly(methyl methacrylate)/cross-linked polystyrene core/shell nanospheres were fabricated by o/w microemulsion. Polystyrene hollow nanospheres were obtained using the polymer core etching technique. The size of the hollow nanoparticle was dependent on the surfactant concentration and the weight ratio of [surfactant]/[monomer].

Drug delivery systems had a great impetus to deliver a drug to diseased lesions. A suitable carrier was needed to deliver a suitable and sufficient amount of the drug to a targeted point; hence various kinds of formulations were developed. The state of the art was reviewed regarding the synthetic methods and characterization of nanoparticles, the suitability of polymeric systems for various drugs, drug loading, and drug release properties of various systems such as nanoparticles, hydrogels, microspheres, film and membranes, tablets, etc. [461].

An overview was given on the mechanisms of formation of polymerization in miniemulsions, the synthesis of new polymers, and dispersive hybrid systems from heterophase situations [462].

The *in-situ* formation of Au/Pt bimetallic nanoparticles on the surface of polystyrene microspheres was reported [463]. This was accomplished by dispersion copolymerization of styrene and a poly(*N*-isopropylacrylamide) macromonomer in ethanol–water media in the presence of  $\text{HAuCl}_4$  and  $\text{H}_2\text{PtCl}_6$ . The particle size and morphology of the polystyrene microspheres were changed by varying the molar ratio of Au/Pt. The propagation of oligomer radicals and nucleation of polystyrene microspheres were controlled by the Au/Pt molar ratio.

Nanometer-sized CoPt particles dispersed in a poly(methyl methacrylate) matrix were prepared, as a novel nanostructured magnetic plastic, through a soft chemical processing route [464]. CoPt nanoparticles were synthesized from a solution phase reduction system in the presence of capping ligands and stabilizing agents at high temperature. The CoPt nanoparticles were annealed at 400 °C for 3 h and were subsequently redispersed in methylmethacrylate (monomer).

To study interfacial particle-to-particle bonding mechanisms, an ultrathin film of pyrrole was deposited on alumina nanoparticles using a plasma polymerization treatment [465]. A thin film of the pyrrole layer (2 nm) was uniformly deposited on the surfaces of the nanoparticles. Particles of all sizes (10–150 nm) exhibited equally uniform ultrathin films indicating well-dispersed nanoparticles in the fluidized bed during the plasma treatment. The pyrrole-coated nanoparticles were consolidated at a temperature range (approximately 250 °C).

The synthesis and characterization of well-dispersed,  $\text{CoFe}_2\text{O}_4$  nanoparticles within a polymer matrix at room temperature were reported [466]. Comparable inorganic synthetic methods required heating at high temperatures in order to produce this particular mixed-metal oxide composition. The modification of templating schemes using block copolymers consisted of introducing a mixture of metal salts to a polymer solution before any microphase separation of the block copolymer constituents can occur, thus allowing fast diffusion of metals to the functional polymer

backbone. The diblock copolymer matrix was synthesized using ring-opening metathesis polymerization of norbornene derivatives.

The preparation and evaluation were reported of cyclophosphamide loaded-polyalkylcyanoacrylate nanospheres obtained by emulsion polymerization [467]. Nanoparticles of improved stability against long-term aggregation were prepared using poly(styrene)-*b*-poly(2-vinylpyridine) star-block copolymer architectures [468]. The star-block copolymers, physically resembling diblock copolymer micelles, were synthesized by anionic polymerization and coupling with ethylene glycol dimethacrylate.

Catalytic sites can be placed at the core, at interior positions, or at the periphery of a dendrimer. There are many examples of the use of peripherally functionalized dendrimers in catalysis. A review was concerned with dendrimer-based catalysis involving catalytic sites at the core of a dendrimer and within the interior voids [469]. Key features were positive and/or negative catalytic activity.

The synthesis and applications of organic-inorganic nanostructured colloids and colloidal-based materials were reviewed [470]. Emphasis was placed on the strategies and synthetic methods developed to organize organic-inorganic architectures. A description and a general hierarchical classification of different systems were given from inorganic particle synthesis and surface modification to more elaborate nanostructured colloids obtained through *in-situ* encapsulation and/or self-assembly techniques. Ordering of colloids into two- and three-dimensional arrays and their use as templates was considered. Some properties and applicability of organic-inorganic colloids in catalysis, medicine, and coating technologies were cited.

The photoinduced flocculation of a nonaqueous dispersion of core-shell nanoparticles (diameter = 50 nm) was described [471]. The particles consist of a tightly cross-linked core composed of poly(butyl methacrylate-co-ethylene glycol dimethacrylate) and a lightly cross-linked shell of poly(butyl methacrylate-co-ethylene glycol dimethacrylate-co-methacrylic acid). The process of particle aggregation kinetics was studied in the absence of long-range electrostatic interaction by using a combination of static and dynamic laser light scattering.

### 3.4. Physical-Chemical Methods

Physical-chemical methods are the processes that combine both the physical and chemical methods during the synthesis of the materials. As shown previously, there are many different methods based on the physical or chemical principles from which lot of the physical-chemical methods could be developed. For instance, it has been shown that, as a "bottom up" process, mechanochemical processing enables the build up of nanoparticles through solid-state chemical reaction in a microscopically uniform environment, leading to the formation of nanoparticles with narrow size distributions. The physical fields, like electric fields, magnetic fields, lights, etc., could be used to affect the chemical reactions and the processes. Coacervation-phase separation has been proved to be one powerful technique for preparation of the nanocapsules. In the following, we only introduce in detail the coacervation-phase separation and briefly other physical-chemical processes.

#### 3.4.1. Coacervation-Phase Separation

Coacervation-phase separation is a method to use a coacervation-inducing agent to reach the coacervation-phase separation during/after the solvent evaporation to form the microcapsules or the nanocapsules. The coating can be controlled by changing the parameters during the process, so that the drug content, particle size distribution, biomedical properties, etc. of the microcapsules/nanocapsules can be controlled. This procedure has been employed widely for preparation of microcapsules/nanocapsules for drug release.

Terbutaline sulphate microcapsules were prepared by coacervation-phase separation induced by the solvent evaporation technique [472–474]. The cellulose acetate phthalate was employed as coating material alone and in combination with ethyl cellulose. The prepared microcapsules were evaluated for their drug content, particle size distribution (microscopic method), flow properties, bulk density, and *in vitro* dissolution. Propranolol hydrochloride microcapsules were prepared by the coacervation-phase separation induced by the solvent evaporation technique [475].

Microcapsules of phenylpropanolamine HCl were prepared by three techniques, viz. coacervation-phase separation, air suspension, and pan coating, using different polymers and/or waxes as wall-forming materials [476].

Microcapsules were prepared from naproxen and ethylcellulose by coacervation phase separation, using polyisobutylene as a coacervation-inducing agent [477]. The micrometric properties of the microcapsules and dissolution behavior were examined. Using polyisobutylene at different concentrations, the release of naproxen during an *in vitro* dissolution test from 60 to 90% was regulated. The microcapsules were aggregates of individually coated naproxen crystals clustered together.

Using ethylcellulose and cellulose triacetate as co-wall materials, sustained release microcapsules of theophylline were prepared. The solid drug dispersed in the cellulose triacetate matrices was first prepared by solvent evaporation; then the matrices were microencapsulated by means of coacervation-phase separation of ethylcellulose from toluene solution on addition of petroleum ether [478].

Phenytoin sodium was microencapsulated with ethylcellulose by a coacervation-phase separation method from ethyl acetate solution to develop a prolonged release dosage form of phenytoin [479].

Microcapsules of phenylpropanolamine (PPA) hydrochloride with core:wall ratios of 1:1, 2:1, and 1:2 were prepared by the coacervation-phase separation method, using ethylcellulose as the coating material [480]. Two batches of PPA · HCl powder with different particle sizes were used as the core material. The different sizes of microcapsules were separated using a range of standard sieves. The effects of drug particle size, the media pH, and the core:wall ratio on the dissolution kinetics were evaluated kinetically.

The preparation of lipid vesicles using simple coacervation was described [481]. The optimal coacervation conditions for the formation of lipid vesicles by the triangular phase diagram of the lipid-alcohol-water system were examined. Four different alcohols (methanol, ethanol, *n*-propanol, and 2-propanol) were used as a lipid solvent, and deionized, distilled water was used as a poor solvent for the lipids. The lamellarity and size homogeneity of the resulting lipid vesicles were observed using a specific fixation

technique with malachite green. The majority of vesicles formed by methanol as a lipid solvent appeared to be large and unilamellar, ranging from 100 to 1000 nm in diameter.

Surfactant precipitation is one method of separating and concentrating surfactant for reuse from a subsurface surfactant-based remediation process. The dialkyldiphenylether disulfonates was shown to be very effective in this application as one class of surfactant [482]. The precipitation and coacervation phase boundaries for a surfactant mixture, which was primarily dicycldiphenylether disulfonate as a function of concentration of added NaCl and KCl, were reported [482].

Nicardipine hydrochloride (N.HCl) microcapsules were prepared by means of the coacervation phase separation technique using ethylcellulose as a coating material [483, 484]. Micromeritic investigations were carried out on nicardipine hydrochloride, ethylcellulose, and nicardipine hydrochloride microcapsules in order to standardize the microcapsule product and to optimize the pilot production of dosage forms prepared with these microcapsules.

Ketorolac tromethamine is a nonsteroidal drug with potent analgesic and anti-inflammatory activity and is absorbed rapidly [T-max (1.0 h) with an efficiency >87%] following oral and intramuscular administration. Microcapsules of the ketorolac tromethamine were prepared by means of the coacervation-phase separation technique induced by the addition of nonsolvent, and release rates from microcapsules were studied [485]. Eudragit S100 was used as the coating material.

Nitrofurantoin, a synthetic bactericidal drug, was encapsulated with Eudragit RS 100 polymer by a coacervation phase separation technique using variable proportions of polyisobutylene (0% to 3%) as a protective colloid [486]. The *in vitro* release experiments were carried out over the entire pH range of the gastrointestinal tract, the data obtained from the dissolution profiles were compared in light of different kinetic models, and the regression coefficients were compared. The *in vivo* studies were performed on female human volunteers.

Rhizobacteria-containing polymer microparticles were prepared using either a complex coacervation-phase separation method or a spray-drying technique [487]. The microparticles obtained were characterized with regard to their particle size distribution, morphology, and bacterial content. Long-term bacterial survival within the microparticles stored under controlled conditions (relative humidity and temperature) was investigated.

The aspirin-impregnated microspheres of chitosan/poly (acrylic acid) copolymer were produced in order to evaluate the release characteristics as a function of pH, simulating the fluids in the gastrointestinal tract [488]. Chitosan microspheres were obtained by the coacervation-phase separation method, induced by the addition of a nonsolvent (NaOH 2.0 M solution). The microspheres were cross-linked with glutaraldehyde, reduced with sodium cyanoborohydride, and grafted with poly(acrylic acid).

### 3.4.2. Other Methods

There are many other types of the physical-chemical methods for preparing the nanocapsules, among which emulsification evaporation, solvent displacement, salting

out, emulsification diffusion, pyrolysis of polymer materials, nitridation of nanoparticles, and various self-assembly and templating approaches are very convenient tools. Exposing the nanoparticles to polyelectrolyte solutions of opposite charge, the polyelectrolytes are deposited in a layer-by-layer sequence to form nanocapsules. The  $\gamma$  radiolysis method can be applied by optimizing various conditions like metal ion concentration, polymer or surfactant concentration, and pH. Some physical-chemical methods utilize the applied electric and magnetic fields and microwave plasma to affect the chemical process, like growth of colloid nanoparticles, etc. Photochemical generation, the electrochemical procedure, the pulsed laser vaporization-controlled condensation technique, controlled chemical passivation of extremely active particles, and the explosion method are all applicable for synthesizing nanomaterials such as clusters, onions, intercalations, nanopolyhedra, nanotubes and nanocapsules, etc.

The techniques available to prepare biodegradable nanoparticles, nanospheres, and nanocapsules from preformed polymers were reviewed [489]. Four techniques were discussed in terms of their technological advantages and drawbacks: emulsification evaporation, solvent displacement, salting-out, and emulsification diffusion. The mechanism of nanoparticle formation for each technique was proposed from a physicochemical perspective.

General aspects of nanocapsules used in drug delivery systems were reviewed from both a physicochemical and a therapeutic point of view [490]. The preparation methods and ways to characterize the size, surface, density, release, and stability of this o/w system were described, and the influence of encapsulation within nanocapsules on the biological activity of numerous drugs was discussed.

Carbon nanocapsules with SiC nanoparticles were produced by thermal decomposition of polyvinyl alcohol with SiC clusters at 500 °C in Ar gas atmosphere [491]. Carbon hollow structures such as nanoparticles, polyhedra, and clusters formed. The work indicated that the pyrolysis of polymer materials with clusters is a useful fabrication method for the mass production of carbon nanocapsules at low temperatures compared to the ordinary arc discharge method.

SiC nanorods were synthesized through carbothermal reduction of SiO by C nanocapsules or amorphous activated C [492]. The nanorods formed during a reaction between SiO and C nanocapsules were straight. The nanorods formed during reaction between SiO and amorphous activated C consisted of straight and curled parts or chains of SiC nanoparticles. A surface of the rod tip was covered with a thin amorphous layer of 3 nm thickness.

Encapsulation of cobalt oxide nanoparticles and Ar in boron nitride nanocapsules was reported [493]. A large quantity of boron nitride nanocapsules with cobalt nanoparticles was fabricated by nitridation of boron and cobalt nanoparticles with a H<sub>2</sub>/NH<sub>3</sub> gas mixture [494]. Cobalt nanoparticles were encapsulated by boron nitride layers with thickness of 5 nm. Ferromagnetism and luminescence at 3.8 eV were due to separation of Co nanoparticles by the BN layers. The nitridation of boron particles with catalytic metal is a useful fabrication method for mass production of BN nanocapsules at low temperatures.

Carbon and boron nitride fullerene materials (clusters, onions, intercalations, nanopolyhedra, nanotubes, and nanocapsules) were synthesized by polymer pyrolysis, chemical reaction, arc melting, and electron-beam irradiation [495]. Fullerene clusters and atomic clouds (atom hopping) were formed on the surface of the C and BN fullerene materials. They provided angular and spherical nanocage structures, consisting of four-, five-, six-, and seven-membered ring bondings. A guideline for designing the C and BN fullerene materials, which may have various atomic structures and properties, was summarized.

A selection of graphitic materials of both scientific as well as commercial importance was modified by deposition of various metals at very low coverages under overpotential or underpotential conditions [496].

A thermodynamic theory for the deliquescence behavior of soluble crystals in an atmosphere of solvent vapor was developed [497]. The free energy barriers that could impede deliquescence were studied [497]. The integral equation theory was applied to study the solvent-induced potential of mean force between two passivated nanoparticles in dilute solution [498]. This approach explicitly accounted for the molecular structure of the solvent and the anisotropy of its density profile induced by the pair of nanoparticles.

Controlling the surface properties of nanoparticulate materials is necessary if they are to be exploited in applications such as colloidal crystals or biolabeling. By tailoring the polymer flexibility and the electrostatic forces involved in polyelectrolyte adsorption onto highly curved gold surfaces, through variation of the total salt concentrations suspending the chains and spheres, irreversible polyelectrolyte wrapping of gold nanoparticles was affected [499]. By consecutively exposing the nanoparticles to polyelectrolyte solutions of opposite charge, polyelectrolytes were deposited in a layer-by-layer sequence, yielding gold nanoparticles coated with uniform polyelectrolyte multilayers. Self-supporting polyelectrolyte multilayered nanocapsules were formed after dissolution of the metallic core.

Polymer nanocapsules were reviewed [500]. Hollow polymer particles with dimensions in the submicrometer region possess great potential for encapsulation of large quantities of large sized guest molecules into their empty core domains. Various self-assembly and templating approaches were introduced.

Whiskers of iron carbide encased in carbon shells were prepared from  $\text{Fe}^{2+}$  phthalocyanine [501]. Solid FePc was oxygenated and then thermally treated under  $\text{H}_2$  flow. With proper control of conditions,  $\text{Fe}_3\text{C}$  free from metallic iron was synthesized. The iron carbide whiskers ranged in length from 300 to 500 nm, and their widths were approximately 100 nm. The carbon coating was uniform and about 2.7 nm wide.

The immobilization of nanometer-sized and cluster metal particles in polymeric matrices was systematized for both macroligands and the matrices formed *in-situ* [502]. Special attention was paid to the controlled chemical passivation (stabilisation) of extremely active particles of colloidal size using high-molecular-weight compounds. The routes of formation of polymer-immobilized nanoparticles directly in the polymer medium were analyzed. Studies in the field of

polymer-analogous transformations, which offered a promising approach to the binding of mono- and heterometallic clusters as a new direction in the physicochemistry of nanoparticles, were discussed.

Three different examples were presented of nanocrystals prepared by the pulsed laser vaporization-controlled condensation technique [503]. The photoluminescence properties of the Si nanocrystals were represented. A photoreduction of the white  $\text{WO}_3$  nanoparticles into the blue  $\text{W}_2\text{O}_5$  followed the irradiation of the particles with the second harmonic of the Nd:YAG laser at 532 nm.

Capped copper nanoclusters were synthesized by the  $\gamma$  radiolysis method by optimizing various conditions like metal ion concentration, polymer or surfactant concentration, and pH [504]. The increasing amount of capping agent was responsible for the decrease in size as small as 17 nm of the metal clusters.

An electrochemical procedure, based on the dissolution of a metallic anode in an aprotic solvent, was used to obtain silver nanoparticles ranging from 2 to 7 nm [505]. The influence of the different electrochemical parameters on the final size was studied by using different kinds of counterelectrodes.

Gold sol, photochemically prepared in aqueous Triton X-100 (TX-100) medium, was discolored by photoirradiation in the presence of  $\text{KBrO}_3$  and any one of the following bromine containing trihalomethanes, such as bromoform ( $\text{CHBr}_3$ ) chlorodibromomethane ( $\text{CHClBr}_2$ ), and bromodichloromethane ( $\text{CHCl}_2\text{Br}$ ) owing to the dissolution of colloidal gold nanoparticles [506]. Pt nanoparticles supported in nanoporous  $\text{Al}_2\text{O}_3$  catalyst were prepared by reduction of  $\text{K}_2\text{PtCl}_4$  solution using 112 solution in the presence of  $\text{Al}_2\text{O}_3$  and poly(acrylic acid) as capping material [507].

Effects of applied electric and magnetic fields on the 2D growth of colloid nanoparticles were studied. Two-dimensional photochemical generation of amorphous iron-containing magnetic nanoparticles was carried out via ultraviolet decomposition of a volatile organometallic compound, iron pentacarbonyl, in a mixed Langmuir monolayer at the gas/water interface with stearic acid as a surfactant matrix [508]. During the formation of nanoparticles, the monolayer was in the 2D gas phase state (at very low or no surface pressure). Controlling morphology of nanostructures by synthesis under applied fields could be a promising approach for nanophase engineering and nanotechnology.

The arc-discharge method was modified to produce nanoparticle Ni encapsulated in graphite shells [509, 510]. The carbon-encapsulated metal or metal carbide was prepared based on high-temperature ( $\sim 1800^\circ\text{C}$ ) treatment of microporous carbon materials impregnated with metal precursors. The microwave plasma enhanced CVD system was used to synthesize carbon-encapsulated metal nanoparticles on silicon wafer. An explosion method was developed to prepare the nanocapsules [513–515].

### 3.5. Mechanical Techniques

Mechanical techniques utilize mechanical forces and mechanical energies for preparation of nanomaterials, like nanoparticles and nanocapsules. Milling and vibrating are two typical methods using mechanical energies. Some

mechanical techniques could be categorized as physical methods.

Drug delivery systems improve the therapeutic efficacy and safety of drugs by delivering them at a controlled rate depending on the body requirements and the site of action. These systems aid in reducing the amount of drug required, the number of doses, side effects, and bioinactivation. Currently, delivery systems for drug targeting and controlled release are being developed using drug nanoparticles. Several techniques, such as air suspension, pan coating, spray drying, and milling have been used for the manufacture of drug nanoparticles. In this section, several mechanical techniques (i.e., air suspension, pan coating, spray-drying, and congealing) which are applicable for biomedicine and drug delivery are introduced briefly. For detailed biomedical properties of the nanocapsules, refer to Section 5.

### 3.5.1. Air Suspension

Air suspension is a common technique to utilize fluidized bed systems for selecting the particle materials, which can be developed for coating the nanoparticles to realizing the micro/nanoencapsulation of drug products and food particles. This technique has been used widely in the pharmaceutical/food industry for production of core material and for film coating.

A review examined advances in the commercial production of microencapsulated drug products [516]. Factors influencing drug selection were considered with particular reference to the design of controlled drug delivery systems. The formulation of both aqueous and nonaqueous coating materials was discussed with examples of common problems encountered in applied coatings. Methods of core production were considered with emphasis on spheronization procedures. Pan and air suspension techniques, together with modification, were discussed. Local average velocity of a particle cloud in an air suspension by cross-correlation of two attenuated laser beams was measured [517].

The characterization of microcapsules containing drugs was reviewed with particular emphasis on sustained-release products produced commercially by pan or air-suspension coating and intended for oral administration [518]. After considering aspects of the core and coating, various technologies used to assess microcapsules were discussed such as optical and spectroscopic evaluation, particle size analysis, filling into hard gelatin capsules, and disintegration, dispersion, and dissolution testing. The *in vivo* testing of microcapsules and correlation with *in vitro* data was considered.

Fluidized bed systems were used in the pharmaceutical industry for production of core material and for film coating [519]. Top spray coaters produced batches of fine, coated particles in excess of 500 kg. Wurster bottom spray equipment was used to manufacture pellets as well as to coat products ranging from powders to tablets.

Within the framework of the mechanics of heterogeneous media undergoing phase transformations, a mathematical model was proposed for describing a mixture of gas and liquid (solid) metal particles. The differences between the velocities and temperatures of the phases and the nonequilibrium nature of the phase transition were considered [520]. The problem of the structure of a shock wave in an air suspension of melting particles was solved.

A controlled release preparation of salbutamol may improve patient compliance, minimize side effects, and be valuable in the treatment of nocturnal asthma by extending drug action throughout the night. A controlled release pellet preparation of salbutamol via the air suspension technique was formulated [521].

The influence of spatial nonuniformity in the distribution of chemically inert particles in a screening layer on the process of interrupting the propagation of a heterogeneous-detonation wave was studied numerically within the framework of the equations of motion of a three-velocity, three-temperature, unipressure continuum [522]. The distribution of flame-quenching particles in the layer can affect significantly the extinguishing of combustion waves in a monofuel-air suspension.

Nonpareil cores were spray-coated with a chlorpheniramine maleate (an alkylamine antihistamine) layer and a Eudragit(R) NE30D overcoat in a Wurster air-suspension apparatus [523]. *In vitro* dissolution drug release was a function of polymer membrane thickness.

A varied description was presented of the fluid bed process for coating or air-suspension coating with emphasis on the most efficient batch fluid bed apparatus (the Wurster system) and the ideal continuous fluid bed [524]. Phenomena involved in the process of coating fluidized solid particles were studied. The problem of the application of this technology to coat food particles, in terms of feasibility and profitability, was discussed.

### 3.5.2. Pan Coating

Pan coating is a technique using a polymer or different mixtures of polymers as film coating agents. The method can be based on the simultaneous spraying of aqueous solutions of a film-forming polymer and an appropriate cross-linking agent. Cross-linking of the polymer is achieved *in-situ* in the film during coating of the pellets in a fluidized bed. The pan coating can be used for preparing the nanoparticle and the nanocapsules. The differences of the different types of pan coaters were discussed from the pharmaceutical and technological points of view [525]. Besides a classification by different criteria, aspects of automation, maintenance, scale-up, etc. were discussed.

Different series of Diltiazem pellets with slow release of the active substance were prepared, by the pan coating technique, using different mixtures of acrylic polymers (Eudragit E, L, RL, and RS) as film coating agents [526–530]. The thicknesses of the coatings were varied by different amounts of Eudragit. The propranolol-HCL sustained release coated beads were prepared [527] using Eudragit RS100 as release controlling materials [527, 529]. Granules containing indomethacin crystals were coated with Eudragit solutions of different RL/RS ratios [528]. Diclofenac sodium enteric-coated beads were prepared using Eudragit L-100 as a pH-dependent release-controlling polymer [530]. Overcoating of the beads with beeswax was investigated [526–530]. The beads were characterized for their particle size distribution, drug loading efficiency, and dissolution behavior in 0.1N HCl. The process was reproducible with regard to drug content and inexpensive, and the formed granules were directly compressed into tablets. *In vitro* release of

indomethacin from coated granules, tablets, and capsules was studied as a function of different ratios of Eudragit RL/RS in the coating solution. The coating level of the polymer, the particle size of the beads, and overcoating with beeswax played a major role in determining the release rate of the drug from the coated beads.

A technique for the manufacture of water-insoluble film coatings on drug-loaded saccharose pellets was described [531]. The method was based on the simultaneous spraying of aqueous solutions of a film-forming polymer and an appropriate cross-linking agent. Cross-linking of the polymer was achieved *in-situ* in the film during coating of the pellets in a fluidized bed. Uniform film coatings were formed without additives.

Aminophylline was formulated as small spherical cores for subsequent coating, to develop a competitor microencapsulated product to the commercially available sustained-release tablet Phyllocontin [532]. Optimum spherical crystallization conditions yielded cores of loosely adhering crystals of active, highly irregular surface morphology and poor mechanical strength during pan coating. Aqueous spheronization yielded satisfactory cores in high yield when microcrystalline cellulose and liquid paraffin were used.

The dissolution profile of various weight fractions of dipyrindamole:hydroxypropylmethylcellulose acetate succinate and dipyrindamole:hydroxypropylmethylcellulose phthalate coprecipitates lead to the choice of 1:2 dipyrindamole:hydroxypropylmethylcellulose acetate succinate as the controlled-release component [533]. It was deposited to form two-thirds of the total dose as an inner layer on inert sucrose cores by air suspension coating for release mainly in the small intestine.

The electrochemical deposition of copper was studied in polyaniline layers with different redox states before the onset of metal deposition [534].

### 3.5.3. Spray-Drying

Spray-drying is the process of spraying a solution into a warm drying medium to produce nearly spherical powder granules that are relatively homogeneous. There are four stages in the spray-drying: (1) rotary atomization of the liquid feed to generate a fine spray; (2) injection of the hot gas stream into the radially distributed spray; (3) rapid vaporization of the solvent to yield the powder product; (4) centrifugal separation of the spherical particles from the gas stream. Spray-drying is also suitable for synthesis of the nanoparticles and the nanocapsules.

Poly(L-lactic acid)-coated polyisobutylcyanoacrylate microcapsules containing protein molecules were prepared by a single-step procedure based on either a double-emulsion-solvent evaporation method or a spray-drying method [535]. First, an aqueous protein solution was emulsified in an organic phase of methylene chloride containing a wall-forming monomer (isobutylcyanoacrylate), various kinds of poly(L-lactic acid), and a surfactant. An immediate polymerization process of isobutylcyanoacrylate took place at the w/o interface upon contact with hydroxide ion in the aqueous phase, leading to the formation of a polyisobutylcyanoacrylate wall around the aqueous droplets. This w/o emulsion was reemulsified in an aqueous

solution to promote the solvent removal and, consequently, the precipitation of poly(L-lactic acid) onto polyisobutylcyanoacrylate microcapsules or was spray-dried to directly deposit the poly(L-lactic acid) on the wall. Three proteins, bovine serum albumin, horseradish peroxidase, and tetanus toxoid, were encapsulated in these poly(L-lactic acid)-coated polyisobutylcyanoacrylate microcapsules.

A synthesis method was developed for hydroxyapatite particles with different morphologies [536]. The process involved chemical precipitation and spray-drying, which produced spherical, agglomerated hydroxyapatite granules with controlled particle sizes and structures. These granules contained nanoparticles with an average crystalline size of about 10 nm. The morphologies of the granules were controlled by adjusting the spray-drying conditions, such as the volume fraction of feed slurry and the atomization pressure.

Fine powder of single and binary mixed oxides was produced by decomposition of the respective metal nitrates and polyvinyl alcohol or a mixture of polyvinyl alcohol and polyacrylic acids [537]. The nanoparticles of the oxide system studied are: spinels ( $MFe_2O_4$  where  $M = Ni^{2+}$ ,  $Co^{2+}$ ,  $Zn^{2+}$ ,  $Mg^{2+}$ ); orthoferrites ( $MFeO_3$  where  $M = Gd^{3+}$ ,  $Sm^{3+}$ );  $LaAlO_3$ ,  $NdGaO_3$ ,  $CaO/MgO/Y_2O_3$  stabilized zirconia ( $ZrO_2$ ); lead zirconate titanate, lanthanum modified lead zirconate titanate, and  $BaTiO_3$ .

Solid lipid nanoparticles possess a solid matrix composed of physiological lipids or lipoids with a mean diameter in the range of approximately 50 to 1000 nm. Solid lipid nanoparticles are an alternative particulate drug carrier to polymeric nanoparticles, emulsions, and liposomes [538–540]. They combine advantages of emulsions, liposomes, and polymeric particles. Similar to emulsions and liposomes, they are composed of physiological and well-tolerated substances and can be produced on an industrial scale [541–543]. The general features of solid lipid nanoparticles and their production techniques were presented [541]. The incorporation of lipophilic, hydrophilic and insoluble drugs was presented, and incorporation rates and loading capacity were discussed [542]. Long-term stability, lyophilization, spray-drying, and possible applications in cosmetics and pharmaceuticals were dealt with [543].

A sol-gel method was employed to produce a zinc oxide colloid consisting of ZnO nanocrystalline particles with an average diameter of around 3 nm and subsequently mixed with a silica colloid [544]. The mixture was spray-dried to form a powder nanocomposite. The green photoluminescence exhibited by the composite was very stable.

A technique was proposed to produce drug particles in the nanometer range as small as 125 nm with a narrow size distribution [545], which involved the use of a vibrating surface that atomizes the jet into microdroplets. The ultrasonic field generated by the vibrating surface enhanced mass transfer through increased mixings. Particle sizes were easily controlled using this technique by changing the vibrational intensity of the vibrating surface.

Porous titania granules (1–20  $\mu m$ ) were made by spray-drying titania solutions with and without peptization. An unpeptized titania slurry was prepared by hydrolyzing titanium tetraisopropoxide, while a peptized sol was prepared by adding nitric acid to the slurry [546]. The characteristics of the granules depended on the feed solution properties.

In particular, granules from the unpeptized slurry showed a bimodal pore size distribution, with a rough surface attributed to hard aggregates; granules from the peptized sol showed a monomodal bimodal pore size distribution, with a smooth surface of well-packed nanoparticles. The effect of dopants (alumina and zirconia) was investigated.

A spray-drying method was used to produce a silica powder that contained ordered mesopores [547, 548]. A colloidal mixture of silica nanoparticles and polystyrene latex nanoparticles was mixed and sprayed as droplets into a vertical reactor that contained two temperature zones. The solvent in the droplets was evaporated at the front part of the reactor to produce a powder composite consisting of silica and polystyrene nanoparticles. The polystyrene nanoparticles in the powder were evaporated in the back portion of the reactor to produce a silica powder consisting of mesopores.

### 3.5.4. Congealing

Rapidly cooled materials are often unstable as a result of changes in their physical properties due to imperfect crystallization. In the process of congealing, melted material is atomized into droplets that are very quickly solidified. This increases the possibility of the material crystallizing in different metastable forms. Congealing is applicable to formation of nanostructured materials, like nanoparticles and nanocapsules. Nanostructured materials have a relatively large proportion of their atoms associated with the grain boundary and the method used to develop the nanograins has a strong influence on the resulting grain boundary structure.

Isothermal microcalorimetry was used to observe the change in the thermodynamic state of spray-congealed carnauba wax during storage [549]. In order to accelerate the thermodynamic change in the spray-congealed wax, three annealing procedures were developed using isothermal microcalorimetry. By means of annealing, a spray-congealed product closer to a thermodynamically stable state was achieved.

Hard shell capsules containing four theophylline compounds of different solubilities (theophylline, etofylline, diprophylline, and proxiphylline) were prepared with saturated polyglycolized glycerides (Gelucires) [550]. A polyvalent formulation was obtained after granulation by melting and congealing and use of glyceryl behenate (Compritol) as a lubricant of the solidified suspensions.

Pseudoephedrine HCl–carnauba wax microparticles were prepared by a multiple emulsion–melt dispersion technique [551]. A heated aqueous drug solution was emulsified into the wax melt (w/o emulsion), followed by emulsification of this primary emulsion into a heated external aqueous phase (w/o/w emulsion). The drug-containing microparticles were formed after cooling and congealing of the wax phase. The encapsulation efficiencies were above 80% and actual drug loadings close to 50% were achieved.

An emulsion–congealing technique was used to prepare prolonged release lipid micropellets containing ketoprofen [552]. The lipid matrix consisted of cottonseed oil/beeswax mixture and was emulsified at 70 °C into 0.1 N HCl containing Tween 60 and gelatin.

The progress toward the development of a single dose tetanus vaccine is limited by the poor stability of the protein antigen, tetanus toroid, during its encapsulation in, and release from, biodegradable polymer microspheres. To investigate alternative microencapsulation approaches for improving the stability of the tetanus toroid under these conditions, a two-step microencapsulation method was devised to form microcapsules which consisted of forming microcores of the tetanus toroid in a hydrophilic support matrix by spray-congealing, followed by coating the microcores with poly(lactide-co-glycolide) by an oil-in-oil solvent extraction method [553]. Several protein stabilizers including gelatin (with or without poloxamer 188), dextran, sodium glutamate, and polyethylene glycol were examined as potential core materials.

The effects of operating conditions in the spray-congealing process on the release and the micromeritic properties of clarithromycin wax matrix were evaluated [554]. An atomizer that operates with ultrasonic energy was described which obtained microparticulate drug delivery systems through spray-congealing or spray-drying technologies [555]. The formulations under examination contained theophylline and fenbufen as model drugs and stearic acid, carnauba wax, Cutina HR, and Compritol 888 ATO as low melting excipients. Nonaggregate and spherical-shaped microparticles were obtained with all the materials tested.

The attrition milling iron powders and blends of iron powders produced micrometer-size particles composed of nanosize grains [556]. Mechanical cold-working powder resulted in dislocation generation, multiplication, and congealing that produced grain refinement. Mechanical alloying of substitutional aluminium atoms into iron powder resulted in the aluminium atoms substituting for iron atoms in the grain boundary cells. Attrition milling iron powder in nitrogen gas resulted in nitrogen atoms being adsorbed onto the particle surface.

Marking on a silicon wafer with a small dot matrix was performed using a diode-pumped second-harmonic generation laser of yttrium aluminum garnet, liquid-crystal-display mask, and projection optics [557].

As a novel alternative to the incorporation into hard gelatin capsules or tablets, extended-release (Aquacoat- or Eudragit RS-coated) or enteric (Eudragit L-coated) pellets were embedded into congealed tablet-shaped polyethylene glycol (PEG) plugs of different molecular weights, which rapidly released the pellets upon contact with aqueous fluids [558]. The lower-molecular-weight PEGs (600 and 1000) were not suitable carrier materials, since they dissolved the coatings or significantly increased their permeability. The release characteristics of the original pellets were maintained after embedding the pellets into the higher-molecular-weight PEG 4000 or 10,000.

The degree of bitterness of clarithromycin dry syrup was evaluated using several methods [559]. Using the inversion method, shaking method, and paddle method, a reasonable correlation between the bitter taste and the amount dissolved was not observed. A minicolumn packed with clarithromycin dry syrup was used for the release test.

The methods were used in ink application and combining ink-labeled biopsy specimens into fewer containers with the goal of maintaining information regarding location while

minimizing expense [560]. The ink adhered well to dry cores, but these cores exhibited dehydration artifacts. Placing the cores on a wet sponge avoided dehydration but caused ink spread. With protocol, all biopsy specimens were placed on separate moistened gauze sponges. Specimens from the right side of the prostate were marked with green ink, and those from the left side were marked with black ink using a cotton swab. After applying 1% acetic acid to each core, the left and right cores from each location were placed in a single container. This method curbed pathology expenses and maintained tumor location information.

The utilization of a spray-congealing technique using an ultrasonic atomizer to prepare enhanced-release, solvent-free microspheres of carbamazepine-Gelucire 50/13 in different drug-to-polymer ratios was considered [561]. The spherically shaped and nonaggregated microparticles were obtained and the microspheres had a good encapsulation efficiency (>90% in the prevalent size fraction).

## 4. SPECTROSCOPIC CHARACTERIZATION

### 4.1. Introduction

The structure and properties of the nanocapsules can be characterized by various spectroscopic techniques that we used to study the bulk materials. In this section, we shall introduce briefly the following techniques: X-ray diffraction and transmission electron microscope for characterizing the structures, Raman scattering spectroscopy for obtaining information on vibration and rotation of molecules, XPS for revealing binding energy of electrons, Mössbauer spectroscopy for detecting hyperfine fields, and vibrating sample magnetometer or superconducting quantum interference devices for measuring magnetic properties of the materials. We shall also give a brief description of several novel microscopies, including scanning tunneling microscopy, atomic force microscopy, and magnetic force microscopy, which has been used to solve processing and materials problems in a wide range of technologies affecting electronics, telecommunications, biological, chemical, automotive, aerospace, and energy industries. The materials being investigated by these microscopies include thin and thick film coatings, ceramics, composites, glasses, synthetic and biological membranes, metals, polymers, and semiconductors. It is evident that these novel techniques can be applicable for characterization of the nanocapsules. In this section, we shall describe the common use of each technique and then its characteristics for investigation of the nanocapsules.

### 4.2. X-Ray Diffraction

X-ray diffraction (XRD) is one of the most commonly used spectroscopic techniques which utilizes the diffraction of a light through the crystalline lattice serving as a diffraction grating. When X-ray radiation passes through matter, the radiation interacts with the electrons in the atoms, resulting in scattering of the radiation. If the atoms are organized in planes (i.e., the matter is crystalline) and the distances between the atoms are of the same magnitude as the wavelength of the X-rays, constructive and destructive interference will occur. This results in diffraction where X-rays are

emitted at characteristic angles based on the spaces between the atoms organized in crystalline structures called planes. Most crystals can have many sets of planes passed through their atoms. Each set of planes has a specific interplanar distance and gives rise to a characteristic angle of diffracted X-rays. The relationship between wavelength, atomic spacing  $d$ , and angle  $\theta$  is described geometrically by the Bragg equation as  $n\lambda = 2d \sin \theta$ . If the wavelength  $\lambda$  is known depending on the type of X-ray tube used and the angle  $\theta$  is measured with a camera or diffractometer, then the interplanar distance can be calculated from the Bragg equation.  $n$  is an integer and represents the order of reflection, as in the case of light diffracted from an optical grating. But whereas diffraction from an optical grating takes place essentially at a single plane, X-rays penetrate through many planes of atoms and diffraction takes within a certain volume of the crystal, which acts as a kind of three-dimensional diffraction grating. A set of  $d$ -spaces obtained from a single compound represents the set of planes that can be passed through the atoms and can be used for comparison with sets of  $d$ -spaces obtained from standard compounds.

There are many X-ray diffractometers made by different companies with different radiations, among which  $\text{CuK}\alpha$  or  $\text{CoK}\alpha$  radiation is the most common one. As an example, a Rigaku D/Max- $rA$  rotation target diffractometer is normally equipped with a graphite crystal monochromator for calibration. XRD can be used for analysis of the formation of the phases and their structures, not only for bulk materials but also for nanoparticles and nanocapsules. Since X-rays penetrate through many planes of atoms, XRD usually gives the information of a comparatively large (or macroscopic) amount of the materials, namely, that of the whole system. Detailed structural information, like space group, characteristic interplanar spacings, lattice parameters, atomic site coordinate, atomic occupation, etc., can be derived for the phases in the materials. It is easier to detect a bulk material with a single phase, or better a single crystal, for a quantitative characterization.

Due to advances in XRD technology, XRD data can be analyzed quantitatively for the relative amount of different phases in a bulk material, when the diffraction factors of each kind of atom or phase in the material are known. However, it is hard to derive the relative amount of different phases and to obtain detailed structural information on the nanocapsules from XRD observation. The difficulties are mainly due to the fact that too many XRD peaks of different phases mix each other and that the different mechanisms and/or factors for the contribution to the XRD peak strengths come from the nanoparticles, the bulk materials, and the interfaces/surfaces. The average grain sizes of the materials can be deduced from Scherrer's method of XRD, in which slow scans are performed around the properly selected reflections and each scan is corrected for  $K\alpha$  spectral and instrument broadening by a computer implementation of Stokes's procedure.

Fig. 10 shows the XRD spectrum of Fe(B) nanocapsules showing diffraction peaks associated with the existence of  $\alpha$ -Fe [ $\alpha$ -Fe(B) solid solution], FeB,  $\gamma$ -Fe, and  $\text{Fe}_3\text{B}$  phases in the cores [122]. There are some weak peaks corresponding to the  $\text{Fe}_3\text{O}_4$  [and/or  $\text{Fe}_3\text{O}_4(\text{B})$ ] phase. Almost all diffraction peaks in the XRD spectrum of the nanocapsules come

**Figure 10.** XRD spectrum of Fe(B) nanocapsules showing diffraction peaks associated with the existence of  $\alpha$ -Fe ( $\alpha$ -Fe(B) solid solution), FeB,  $\gamma$ -Fe and  $\text{Fe}_3\text{B}$  phases in the cores. There are some weak peaks corresponding to the  $\text{Fe}_3\text{O}_4$  (and/or  $\text{Fe}_3\text{O}_4(\text{B})$ ) phase. For comparison, the corresponding theoretical XRD patterns for the different phases are represented below the experimental data. After [122], Z. D. Zhang et al., *Phys. Rev. B* 64, 024404 (2001). © 2001, American Physical Society.

from the cores. It is understandable that, usually, there is no sharp peak corresponding to the shells in the XRD spectrum of the nanocapsules, because of the breakdown of the cyclic condition (the translation invariance) and the incompleteness of the crystal structure of the phases in the shells of the nanocapsules.

### 4.3. TEM

The basic mechanism of the transmission electron microscope is similar to that of XRD, but using the electron beams instead of the X-rays. The successful application of the TEM is beneficial to the discovery of the de Broglie (matter) wave. In this case, the crystalline lattice serves as a grating to lead to the diffraction of the electrons. With the TEM, essentially all incoming electrons are transmitted through a specimen that is suitably thin. Rather than being absorbed, electrons may be scattered (i.e., deflected in their path) by the atoms of the specimen. The fast electrons used in a TEM are capable of penetrating many atomic planes and so are diffracted by crystalline regions of material just like X-rays. Their wavelength ( $\sim 0.04$  nm for  $E_0 \sim 100$  keV) is much less than a typical atomic-plane spacing ( $\sim 0.3$  nm) so that, according to the Bragg equation of  $n\lambda = 2d \sin \theta$ , Bragg angles  $\theta$  are small. In addition, the integer  $n$  is usually taken as unity, since  $n$ 'th order diffraction from planes of spacing  $d$  can be regarded as first-order diffraction from planes of spacing  $d/n$ .

Diffraction represents elastic scattering of electrons (i.e., deflection by the Coulomb field of each atomic nucleus) in a crystal. The regularity of the spacing of these nuclei results in a redistribution of the angular distribution of scattered intensity. Instead of a continuous distribution over scattering angle, there are sharp peaks centered around certain scattering angles, each twice the corresponding Bragg angle  $\theta$ . In

the TEM, this angular distribution can be displayed by magnifying the diffraction pattern first formed at the back focal plane of the objective lens. Examination of the TEM image of a polycrystalline specimen shows that there is a variation of electron intensity within each crystallite. This diffraction contrast arises either from atomic defects (including point defects, dislocation, planar defects) within the crystal or from the crystalline nature of the material itself, combined with the wave nature of the transmitted electrons. In addition to diffraction (or amplitude) contrast, image contrast features can result from the phases of the electron waves after they have traversed the specimen. Although this phase cannot be detected directly, it can give rise to interference between electron waves that have passed through different regions of a specimen, and these electrons are brought together if the specimen image is defocused by changing the objective-lens current slightly. Phase contrast also occurs as a result of the regular spacing of atoms in a crystal, particularly if the specimen is oriented so that its atomic columns are parallel to the electron beam. The contrast seen in high magnification ( $>500,000$ ) images is of this type and allows the lattice of atoms to be seen directly (in projection). The atoms may appear as either bright or dark spots, depending on the amount of objective-lens defocus. A more complete interpretation of the atomic-scale structure may require recording of a through-focus series of images.

The nanoparticle/nanocapsule samples for TEM observation can be prepared in two steps: (a) the nanocapsules are first dispersed in ethyl alcohol by an ultrasonic field and (b) a drop of the suspension is then allowed to evaporate onto a carbon coated TEM mesh grid. At present, most commercial TEMs are Philips, Hitachi, JEOL, etc. A TEM can be used to obtain the detailed structural information, such as space group, characteristic interplanar spacings, lattice parameters, atomic site coordinate, atomic occupation, etc., for the phases in the materials. Figure 11 shows TEM photographs of Fe and Ni nanoparticles prepared by arc discharge. The size distribution of the nanoparticles can be seen and/or analyzed from the TEM image.

The resolution of the TEM could be improved by special arrangements of the magnetic fields serving as focuses

**Figure 11.** TEM photographs of (a) Fe and (b) Ni nanoparticles. After [604], X. L. Dong et al., *J. Mater. Res.* 14, 398 (1999). © 1999, Materials Research Society.

of the electron beams, by enhancing the energy of the electrons, and so on. The main advantages of the HRTEM are the direct observations of the detailed nanostructures, such as the core/shell structure, the interfaces, and the surfaces, the atomic defects (including point defects, dislocation, planar defects), the twin structures, etc. of the nanocapsules. Because the electron beam can be focused in a narrow range, the detailed structural information of the core and also the shell of the nanocapsules can be illustrated clearly. The most advanced HRTEMs can show the images of the arrangement of the atoms. Figure 12 represents a HRTEM image showing the shell/core structure of Fe(B) nanocapsules with an amorphous boron oxide shell of about 4.0 nm thick and a crystalline Fe core with  $d = 2.0268 \text{ \AA}$  [122]. Figure 13 shows a HRTEM image for the shell/core structure of Gd(C) nanocapsules with a graphite shell and crystalline Gd core. The shell is characterized by curved lattice fringes of interplanar spacing 0.34 nm corresponding to the (0002) lattice plane of graphite carbon. HRTEM observation can indicate whether different types of the core/shell structures form, whether the interface between the shell and the core is sharp, whether the intermediate phase exists between the shell and the core, and whether different phases coexist in the cores. Furthermore, energy dispersive X-ray (EDX) microanalysis and parallel electron energy-loss spectroscopy (PEELS) data equipped in a HRTEM can indicate the composition and its distribution in nanoscale of the phases in both the core and the shell of the nanocapsules. However, it is difficult to derive the relative amount of different phases in the nanocapsules from the HRTEM observation because only limited numbers of the particles can be observed.

#### 4.4. Raman

Raman scattering spectra are recorded for the inelastic scattering of a light on the materials. When light is scattered from a molecule, most photons are elastically scattered. The

**Figure 12.** HRTEM image showing the shell/core structure of Fe(B) nanocapsules with an amorphous boron oxide shell of about 4.0 nm thick and a crystalline Fe core with  $d = 2.0268 \text{ \AA}$ . **Figure 13.** HRTEM image showing the shell/core structure of Gd(C) nanocapsules with a graphite shell and crystalline Gd core. The shell is characterized by curved lattice fringes of interplanar spacing 0.34 nm corresponding to the (0002) lattice plane of graphite carbon.

scattered photons have the same energy (frequency) and, therefore, wavelength, as the incident photons. However, a small fraction of light (approximately 1 in  $10^7$  photons) is scattered at optical frequencies different from, and usually lower than, the frequency of the incident photons. The process leading to this inelastic scatter is termed the Raman effect. Raman scattering can occur with a change in vibrational, rotational, or electronic energy of a molecule. The difference in energy between the incident photon and the Raman scattered photon is equal to the energy of a vibration or a rotation of the scattering molecule. A plot of intensity of scattered light versus the energy difference is a Raman spectrum.

The Raman effect arises when a photon is incident on a molecule and interacts with the electric dipole of the molecule. In classical terms, the interaction can be viewed as a perturbation of the molecule's electric field. In quantum mechanics, the scattering is described as an excitation to a virtual state lower in energy than a real electronic transition with nearly coincident deexcitation and a change in vibrational (or rotational) energy. The scattering event occurs in  $10^{-14}$  seconds or less. Numerically, the energy difference between the initial and final vibrational (or rotational) levels,  $\bar{\nu}$ , or Raman shift in wave numbers ( $\text{cm}^{-1}$ ), is calculated through

$$\bar{\nu} = \frac{1}{\lambda_{\text{incident}}} - \frac{1}{\lambda_{\text{scattered}}}$$

in which  $\lambda_{\text{incident}}$  and  $\lambda_{\text{scattered}}$  are the wavelengths (in cm) of the incident and Raman scattered photons, respectively.

At room temperature, the thermal population of vibrationally (or rotationally) excited states is low, although not zero. Therefore, the initial state is the ground state, and the scattered photon will have lower energy (longer wavelength) than the exciting photon. This Stokes shifted scatter is what is usually observed in Raman spectroscopy. A small fraction of the molecules are in vibrationally (or rotationally) excited states. Raman scattering from vibrationally (or rotationally) excited molecules leaves the molecule in the ground state. The scattered photon appears at higher energy. This

anti-Stokes-shifted Raman spectrum is always weaker than the Stokes-shifted spectrum, but at room temperature it is strong enough to be useful for frequencies less than about  $1500\text{ cm}^{-1}$ . The Stokes and anti-Stokes spectra contain the same frequency information. The ratio of anti-Stokes to Stokes intensity at any vibrational (or rotational) frequency is a measure of temperature. Anti-Stokes Raman scattering is used for contactless thermometry. The anti-Stokes spectrum is also used when the Stokes spectrum is not directly observable, for example because of poor detector response or spectrograph efficiency.

The frequency shifts in both the Stokes and the anti-Stokes spectra are characters for a bulk material. However, reducing the size of the material could change the frequency shifts in Raman scattering spectra. As discussed above, the limited systems could have different energy levels with those of the bulk materials. The energy levels for the vibrations and the rotations of the molecules can be different than those of the bulk materials. Thus the frequency shifts in Raman scattering spectra of the nanocapsules, which are responsible for the information of these energy levels, can be different with the bulk materials. Another reason for the change of the frequency shifts in Raman scattering spectra is the formation of the core/shell structures of the nanocapsules. The shape of the shell, the connection with the core materials, etc., could alter the vibration and the rotation of the molecules in the shell. Furthermore, usually, the peaks of the Raman scattering spectra become broad in the nanoparticles/nanocapsules. The broadening of the Raman peaks of the nanocapsules is ascribed to the decrease of the size of the material, the wide distribution of the size of the particles, the formation of the core/shell structure, etc. Figure 14 gives the Raman spectra of the B@BN nanocapsules [125].

#### 4.5. XPS

X-ray photoelectron spectroscopy is an electron spectroscopic method that uses X-rays to eject electrons from inner-shell orbitals. The kinetic energy,  $E_k$ , of these photoelectrons is determined by the energy of the X-ray radiation,  $h\nu$ , and the electron binding energy,  $E_b$ , as given by

$E_k = h\nu - E_b$ . The experimentally measured energies of the photoelectrons are given by  $E_k = h\nu - E_b - E_w$ , where  $E_w$  is the work function of the spectrometer. The electron binding energies are dependent on the chemical environment of the atom, making XPS useful to identify the oxidation state and ligands of an atom. XPS instruments consist of an X-ray source such as Al or Mg  $K_\alpha$ , an energy analyzer for the photoelectrons, and an electron detector. The analysis and detection of photoelectrons require that the sample be placed in a high-vacuum chamber. Since the photoelectron energy depends on X-ray energy, the excitation source must be monochromatic. The energy of the photoelectrons is analyzed by an electrostatic analyzer, and the photoelectrons are detected by an electron multiplier tube or a multichannel detector such as a microchannel plate. Surface spectroscopy serves to get information about the chemical nature of sample surfaces or surface near regions. XPS allows one to analyze the elemental surface composition quantitatively. Different binding states of the detected elements may be distinguished. Angle resolved XPS is a nondestructive method to investigate the distribution of elements or functional groups in the depth of the sample surface. The knowledge of the chemical surface composition and the kind of functional surface group is fundamental to evaluate surface reactivity and apply chemical and physico-chemical methods to modify the solid surface.

XPS is a very sensitive surface analysis technique providing elemental quantification and chemical information of the nanocapsules. The XPS detection therefore provides the information on the electrons and thus the materials the electrons belong to. Figure 15 shows XPS spectra of Fe(C) nanocapsules produced in methane at 13.3 kPa [113]. Figure 16 represents Fe $2p_{3/2}$ , Co $2p_{3/2}$ , and O $1s$  XPS spectra of as-prepared Fe-Co(C) nanocapsules and their surface cleaned samples [120]. XPS provides direct evidence for the existence of elements in the shells of the nanocapsules, and also for the formation of the core/shell structures. The binding energies of electrons can indicate well whether the atoms are free metal or oxides or ceramics, from which one can

find whether the atoms in the core are oxidized, whether all particles are coated completely by the shells, and whether moisture absorbs on the surface of the nanocapsules.

#### 4.6. Mössbauer

The Mössbauer effect, a physical phenomenon discovered by Rudolf Mössbauer in 1957, refers to the resonant and recoil-free emission and absorption of  $\gamma$ -rays by atoms

bound in a solid. In general,  $\gamma$ -rays are a kind of electromagnetic wave with very short wavelengths less than  $10^{-8}$  cm, which are produced by nuclear transitions from an unstable high-energy state to a low-energy state. The energy of the emitted  $\gamma$ -ray corresponds to the energy of the nuclear transition minus an amount of energy that is lost as recoil to the emitting atom. If the lost recoil energy is small compared with the energy linewidth of the nuclear transition, then the  $\gamma$ -ray energy still corresponds to the energy of the nuclear transition and the  $\gamma$ -ray can be absorbed by another atom of the same type as the first. Such emission and subsequent absorption is called resonance. Additional recoil energy is also lost during absorption, so in order for resonance to occur the recoil energy must actually be less than half the linewidth for the corresponding nuclear transition. The amount of lost energy is described by the equation  $E_R = E_{\text{gamma}}^2/2Mc^2$ , where  $E_R$  is the energy lost as recoil,  $E_{\text{gamma}}$  is the energy of the  $\gamma$ -ray,  $M$  is the mass of the emitting or absorbing body, and  $c$  is the velocity of light. In the case of a gas the emitting and absorbing bodies are atoms, so the mass is quite small, resulting in a large recoil energy, which prevents resonance.

Due to the fundamental quantum nature of solids, atoms bound in solids are restricted to a specific set of vibrational energies called phonon energies. If the recoil energy is smaller than the phonon energy, there is insufficient energy to excite the lattice to the next vibrational state, and a fraction of the nuclear events, called the recoil-free fraction, occurs such that the entire crystal, rather than just the atom, acts as the recoiling body. Since the mass of the crystal is very large compared to that of a single atom, these events are essentially recoil-free. In these cases, since the recoil energy is negligible, the emitted  $\gamma$ -rays have the appropriate energy and resonance can occur. In general, the  $\gamma$ -rays have very narrow linewidths. This means they are very sensitive to small changes in the energies of nuclear transitions. In fact, the  $\gamma$ -rays can be used as a probe to observe the effects of interactions between a nucleus and its electrons and those of its neighbors. This is the basis for Mössbauer spectroscopy, which combines the Mössbauer effect with the Doppler effect to monitor such interactions.

Mössbauer spectroscopy is a spectroscopic technique based on the Mössbauer effect. In its most common form, Mössbauer absorption spectroscopy, a solid sample is exposed to a beam of  $\gamma$ -radiation, and a detector measures the intensity of the beam that is transmitted through the sample. The  $\gamma$ -ray energy is varied by accelerating the  $\gamma$ -ray source through a range of velocities with a linear motor. The relative motion between the source and sample results in an energy shift due to the Doppler effect. In the resulting spectra,  $\gamma$ -ray intensity is plotted as a function of the source velocity. At velocities corresponding to the resonant energy levels of the sample, some of the  $\gamma$ -rays are absorbed, resulting in a drop in the measured intensity and a corresponding dip in the spectrum. The number, positions, and intensities of the dips (also called peaks) provide information about the chemical environment of the absorbing nuclei and can be used to characterize the sample. In order for Mössbauer absorption of  $\gamma$ -rays to occur, the  $\gamma$ -ray must be of the appropriate energy for the nuclear transitions of the atoms being probed. Also,

the  $\gamma$ -ray energy should be relatively low; otherwise the system will have a low recoil-free fraction, resulting in a poor signal-to-noise ratio. Only a handful of elemental isotopes exist for which these criteria are met, so Mössbauer spectroscopy can only be applied to a relatively small group of atoms. The sources commonly used for the Mössbauer spectra are  $^{57}\text{Co}$ ,  $^{119\text{m}}\text{Sn}$ ,  $^{125}\text{Sb}$ ,  $^{133}\text{Ba}$ ,  $^{195}\text{Au}$ , and  $^{182}\text{Ta}$ . The most important source is  $^{57}\text{Co}$  and the Mössbauer leap of 14.4 keV of  $^{57}\text{Fe}$  is generated from the disintegration of  $^{57}\text{Co}$ . Thus  $^{57}\text{Fe}$  is by far the most common element studied using the technique.

The Mössbauer spectra provide the information of the inner magnetic fields in the nuclei and the hyperfine fields. The Mössbauer effects can be used to study the properties of nanoparticles/nanocapsules. Figure 17 gives the  $^{57}\text{Fe}$  Mössbauer spectrum at room temperature of the Fe(B) nanocapsules [122]. The relative amounts of different phases and the hyperfine fields in the phases can be obtained for the nanocapsules. The hyperfine fields of the phases in the nanocapsules may slightly differ with those in their bulk counterparts, due to the size effect. The disadvantage of the Mössbauer study is the limitation that it can detect information on the materials with elements the same as after disintegration of the source.

#### 4.7. Scanning Tunneling, Atomic Force, and Magnetic Force Microscopies

The scanning tunneling microscope (STM) is an analytical technique based on the quantum mechanical phenomenon called tunneling, by which a high potential barrier does not eliminate the possibility of finding a particle in a region of high potential or even beyond a region of high potential. A probe tip typically made out of tungsten is attached to a piezodriven system, which is a system of very sensitive piezocrystals that expand or contract in reaction to an applied voltage. By using the piezo to position the tip within a few angstroms

of the sample, the electron wavefunctions in the tip and the sample overlap, leading to a tunneling current flow when a bias voltage is applied between the tip and the sample. A computer in the STM measures the current flow between the metal tip and the sample, which are very close together. The tunneling current is amplified and fed into the computer while processing a negative feedback loop to keep the current constant. The potential barrier is a function of distance between the two surfaces and so is the current. If the current increases, the computer can move the tip farther away from the sample, thus increasing the potential barrier, decreasing the probability of an electron jumping from the tip to the sample, and thus decreasing the current. If the current is too low, the computer will do just the opposite, moving the tip closer to the sample. By keeping track of the movements of the tip, a realistic picture of the electron density of a surface can be created. The STM can resolve local electronic structure at an atomic scale on every kind of conducting solid surface. This electron density plot can then be interpreted as the general arrangement or positioning of atoms on a conductive surface. By tunneling current out of a single atom on the tip, the sensitivity of the instrument can be such that single atom layers on a surface can be measured. One major area of STM research currently is to study self-assembled monolayers, which is a single layer of molecules aggregating on a surface.

The atomic force microscope (AFM), also termed scanning force microscope (SFM), is a newly developed for observing nanoscale topography and other properties of a surface soon after the discovery of the STM. The principles on how the AFM works are very simple. An atomically sharp tip is scanned over a surface with feedback mechanisms that enable the piezoelectric scanners to maintain the tip at a constant force (to obtain height information) or height (to obtain force information) above the sample surface. Tips are typically made from  $\text{Si}_3\text{N}_4$  or Si and extended down from the end of a cantilever. The nanoscope AFM head employs an optical detection system in which the tip is attached to the underside of a reflective cantilever. A diode laser is focused onto the back of a reflective cantilever. As the tip scans the surface of the sample, moving up and down with the contour of the surface, the laser beam is deflected off the attached cantilever into a dual element photodiode. The photodetector measures the difference in light intensities between the upper and lower photodetectors and then converts to voltage. Feedback from the photodiode difference signal, through software control from the computer, enables the tip to maintain either a constant force or constant height above the sample. In the constant force mode, the piezoelectric transducer monitors real time height deviation. In the constant height mode, the deflection force on the sample is recorded. The latter mode of operation requires calibration parameters of the scanning tip to be inserted in the sensitivity of the AFM head during force calibration of the microscope. By using an AFM one can not only image the surface in atomic resolution but also measure the force at nano-Newton scale. The force between the tip and the sample surface is very small, usually less than  $10^{-9}$  N. The detection system does not measure force directly, which senses the deflection of the microcantilever. The detecting systems for monitoring the deflection fall into several categories, such as

**Figure 17.**  $^{57}\text{Fe}$  Mössbauer spectrum at room temperature of the Fe(B) nanocapsules. The solid squares are the experimental data. The solid line is for the fitting results. The sub-spectra for  $\text{Fe}_3\text{O}_4(\text{B})$ ,  $\text{Fe}_3\text{B}$ ,  $\text{FeB}$ ,  $\alpha\text{-Fe}$  (and/or  $\alpha\text{-Fe}(\text{B})$  solid solution) and  $\gamma\text{-Fe}$  phases are represented as different lines, respectively. After [122], Z. D. Zhang et al., *Phys. Rev. B* 64, 024404 (2001). © 2001, American Physical Society.

the tunneling current, interferometer, beam bounce, diode laser, etc. According to the interaction of the tip and the sample surface, an AFM can be classified as repulsive contact mode and attractive noncontact mode. In its repulsive contact mode, the instrument lightly touches a tip at the end of a cantilever to the sample. As a raster scan drags the tip over the sample, some sort of detection apparatus measures the vertical deflection of the cantilever, which indicates the local sample height. Thus, in the contact mode the AFM measures hard-sphere repulsion forces between the tip and sample. In the noncontact mode, the AFM derives topographic images from measurements of attractive forces and the tip does not touch the sample. The AFM can achieve a resolution of 10 pm and can image samples in air and under liquids. The AFM is being applied to studies of phenomena such as abrasion, adhesion, cleaning, corrosion, etching, friction, lubrication, plating, and polishing. Figure 18 shows an AFM image of a layer-by-layer polyelectrolyte assembled capsule [562].

A magnetic force microscope (MFM) images the spatial variation of magnetic forces on a sample surface. The mechanism of the MFM is similar to that of the AFM, but for the MFM, the tip is coated with a ferromagnetic thin film. The alternating voltage on the probe tip of the AFM is replaced with an alternating magnetic field. The tip is used to probe the magnetic stray field above the sample surface, which is mounted on a small cantilever, translating the force into a deflection that can be measured. The system operates in noncontact mode, detecting changes in the resonant frequency of the cantilever induced by the magnetic field's dependence on tip-to-sample separation. The MFM can be used to image naturally occurring and deliberately written domain structures in magnetic materials. An image taken with a magnetic tip contains information about both the topography and the magnetic properties of a surface. Which effect dominates depends upon the distance of the tip from the surface, because the interatomic magnetic force

**Figure 18.** AFM image of a layer-by-layer polyelectrolyte assembled capsule. Reprinted with permission from [562], S. Loporatti et al., *Langmuir* 16, 4059 (2000). © 2000, American Chemical Society.

persists for greater tip-to-sample separations than the van der Waals force. If the tip is close to the surface, in the region where a standard noncontact AFM is operated, the image will be predominantly topographic. If the separation between the tip and the sample increases, magnetic effects become apparent. Collecting a series of images at different tip heights is one way to separate magnetic from topographic effects.

#### 4.8. Vibrating Sample Magnetometer/Superconducting Quantum Interference Device

Magnetic properties of a magnetic material could be measured by various types of facilities, among which a vibrating sample magnetometer (VSM) or a superconducting quantum interference device (SQUID) magnetometer is one of the most commonly used tools for purposes of the magnetic measurements. A VSM is a magnetometer based on the mechanism of the electromagnetic induction. A sample is vibrated in the vicinity of a set of pick-up coils. The flux change caused by the moving magnetic sample causes an induction voltage across the terminals of the pick-up coils that is proportional to the magnetization of the sample. The VSMs have a comparatively high sensitivity for measuring the magnetic moment, which can be up to  $5 \times 10^{-5}$ – $2 \times 10^{-9}$  Am<sup>2</sup>.

SQUID is a highly sensitive detector of the flux designed based on the concept of the flux quantization and the superconducting Josephson effect. The so-called Josephson junction is a junction at which a thin insulator is connected with two superconductors. When the magnetic field is applied to a superconducting ring with a Josephson junction, a stable current may pass the thin insulator between the two superconductors due to the tunneling. The sum of the flux due to the Josephson current density  $j_s$  and that of the external field, namely, the total flux of the superconducting ring, is the integer times the flux quanta  $\phi_0 = \hbar/2|e|$ . The Josephson current density  $j_s$  is the periodicity function of the external magnetic flux  $\phi$  as described as  $j_s = -j_c \sin(2\pi\phi/\phi_0)$ , where  $j_c$  is the critical current density. SQUID can measure not only the extremely weak magnetic fields with a resolution of  $10^{-19}$  Wb, but also susceptibilities, magnetic moments, magnetization curves, hysteresis loops, and their temperature dependences. SQUID can be used to measure very weak voltages and currents, to establish the voltage benchmark, and to measure directly the elementally physical constant  $|e|/\hbar$ , where  $e$  is electronic charge and  $\hbar$  is the Planck constant. SQUID is a powerful tool for validating in macroscopic range the basic principles of quantum mechanics. Figure 19 shows zero-field-cooled (ZFC) and field-cooled (FC) (in a field of 100 mT) magnetization curves of the Fe(B) nanocapsules [122].

## 5. PHYSICAL PROPERTIES

### 5.1. Introduction

The microworld is governed by atoms and molecules, while the macroworld consists of materials which contain a mind-boggling (or infinite) number of atoms or molecules. For

**Figure 19.** Zero-field-cooled (ZFC) and field-cooled (FC) (in a field of 100 mT) magnetization curves of the Fe(B) nanocapsules. After [122], Z. D. Zhang et al., *Phys. Rev. B* 64, 024404 (2001). © 2001, American Physical Society.

atoms and molecules, we face directly a world that can be described only by quantum mechanics, in which chemical bonds, reactivity of a molecule, electronic orbitals and spins, the energy band of the electrons, etc. are most important factors. In the macroworld, we see distinct phases of materials—liquid, solid, and gas—and talk of physical properties like magnetization, electrical resistance, thermal conductivity, internal energy, specific heat, stiffness, and so on. The bulk consists of atoms and molecules, so the properties of the atoms and molecules should decide the properties of the bulk materials. The physical properties of bulk materials can be described well either by quantum mechanics or by theories based on classical mechanics. According to the energy band theory, the energy levels of a bulk metal are in general continuum (or so-called quasi-continuum) because the number of electrons in the bulk is infinite. The cyclic condition and the translation symmetry in three dimensions of bulk materials lead to the plane wave character of electrons. The physical properties of bulk are the thermodynamical averages of the properties of an infinite number of electrons. Classical mechanics can be treated as an approximation of quantum mechanics in a continuous media or in a continuum limit for the macroworld.

One would like to see how things change as one goes from atoms and molecules to small assemblies of them, to large assemblies, to larger assemblies, and finally to the bulk. One would like to see how various atoms, which do not appear very different individually, work together to form bulk materials with abundance properties, like metals, insulators, and semiconductors. One would like to see whether the properties of the assemblies of atoms and molecules differ with those of bulk and how the assemblies of atoms and molecules behave. The world between atoms, molecules, and the bulk is so-called mesoworld. This is a challenging problem for scientists and only a little progress has been made in the area of the mesoscopic world.

It is clear that the physical properties of the mesoworld are quite different than those of the atoms, the molecules, and the bulk. The mesoworld is a bridge connecting with two ends: one is the microworld with the discreteness of the energy levels; another is the macroworld with the continuum

of the energy band. As a limited system, the discreteness of the energy levels is still held in the mesoworld because of the limited number of electrons. The small is different in an essential way when one (or more) of the physical dimensions of the material approaches a length-scale characteristic to a physical phenomenon (with different phenomena being characterized by different length scales), and similarly in the time domain. If the energy gap were larger than the thermal energy, the magnetostatic energy, the electrostatic energy, the photon energy, or the condensation energy of the superconductivity, the physical properties of the system would differ with those of bulk due to the quantum size effect. The cyclic condition and the translation symmetry would be broken down in the mesoworld, altering the physical properties of the systems. The quantum interference of electrons in the confined states could become more pronounced in the mesoscopic systems. The properties of the mesoscopic systems could be affected also by the magic number effect, the breakdown of the symmetry at the surfaces/interfaces, the formation of core/shell structure, the presence of metastable phases, etc. The classical mechanism can be used for description of the properties of the mesoscopic systems.

The properties of the mesoscopic systems depend sensitively on size, shape, structure, surface, etc. The sensitivity of sufficiently small materials aggregating to various shapes could change the properties of the materials. Most importantly, spontaneous shape selection occurs in the mesoscopic systems, originating from the ability of finite systems to adjust their shape and the structure in order to minimize the free energy of the systems. Small is beautiful not only since the limited systems could show the fascinating phenomena that do not exist in either the macroworld or the microworld, but also since the mesoscopic systems could be designed and constructed artificially, which could be so different from those formed naturally. For instance, the superlattices or multilayers could be grown artificially which show exchange coupling and the giant magnetoresistance effect that have been successfully applied in the reading head of the hard disk of a computer. The quantum dots could be designed to be applicable for high-density magnetic recording. Nanotubes and nanowires could be used as elementary parts of an apparatus like a quantum computer. Basic research of the structure and properties of the nanostructured materials and related issues underlies future technologies, from nanoscale machines, nanotribological systems, cellular injections, and nanocatalysis, to miniaturization of electronic circuitry and novel information storage and retrieval systems.

There is no doubt that nanocapsules are classified to the mesoscopic systems because nanocapsules are in nanoscales, having nanostructures. Indeed, nanocapsules are matter in intermediate states between bulk and atomic materials, which offer an opportunity to investigate dimensionally confined systems in basic research areas. Indeed, understanding the differences of the mesoworld to those of the bulk is extremely important for studying the properties of nanocapsules. The optical absorption, electric resistance, magnetic, and dynamic properties of nanocapsules are very different from the bulk counterparts, which would be applicable in various fields. For instance, nanocapsules could show strong band-edge photoluminescence shifting. Magnetic nanocapsules could show superparamagnetism or the

exchange bias. Graphite encapsulated nanocapsules have numerous possible applications due to their novel properties and their ability to survive rugged environments. In Sections 5.2–5.5 we shall represent the optical, electronic, magnetic, and dynamic properties of the nanocapsules (and also the nanoparticles for some materials), respectively. The biomedical properties of the nanocapsules will be introduced in the next section.

## 5.2. Optical Properties

Clusters of semiconducting materials are interesting considering their application as a photocathode. The silver chloride/silver cluster phase boundary plays a decisive role in the photocatalytic silver chloride electrode system. This system was studied by means of quantum chemical calculations [563]. The synthesis and properties of luminescent quantum-sized silver sulfide clusters in the cavities of zeolite A were reported. The color of the silver sulfide zeolite A composites ranged from colorless (low loading) to yellow–green (medium loading) to brown (high loading). A low silver sulfide content was characterized by a blue–green luminescence and distinct absorption bands, while samples with medium or high silver sulfide content showed an orange or red colored emission and a continuous absorption.

Linear (visible photoluminescence) and nonlinear (third-order susceptibility) optical properties were measured for laser-synthesized crystalline Si nanoparticles [564]. The observed luminescence was compared to that of nanocomposite aerogels prepared integrating the Si nanoparticles into a continuous silica phase by sol–gel processing. The incorporation of the Si nanoparticles into a silica matrix by sol–gel technology was not detrimental to the photoluminescence emission intensity.

Two methods for the preparation of semiconductor doped sol–gel films, for applications in nonlinear optics, were studied [565]. Porous films were spun from sols containing the cation precursor, reacted with H<sub>2</sub>S gas, and then the cation was adsorbed onto the pore surfaces of passive films from aqueous solution before the gas reaction. Preliminary results were reported for CdS doping and for other semiconductor species. The effects of heat treatment of doped films and the limitation of crystallite growth by pore size were described.

C nanoparticles embedded in  $x\text{Al}_2\text{O}_3 \cdot x\text{P}_2\text{O}_5 \cdot 100\text{SiO}_2$  ( $x = 0.25$  or  $0.5$ ) gel–glasses were prepared by a sol–gel process [566]. The gels synthesized through hydrolysis of  $\text{PO}(\text{OC}_2\text{H}_5)_3$ ,  $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  and  $\text{Si}(\text{OC}_2\text{H}_5)_4$ , were heated at 600 °C for 10 h, in which  $-\text{OC}_2\text{H}_5$  was carbonized to precipitate nanosized C particles. Glasses doped with C nanoparticles showed a strong room-temperature photoluminescence with a peak at 630 nm under 532 nm Nd:YAG laser excitation. The photoluminescence spectra were caused by C nanoparticle embedded gel–glasses.

Structural, optical, electro-, and photoelectrochemical properties of amorphous and crystalline sol–gel Nb<sub>2</sub>O<sub>5</sub> coatings were determined [567]. The coatings were *n*-type semiconductor with indirect allowed transition and present an overall low quantum efficiency ( $\phi < 4\%$ ) for UV light to electric conversion. The photoconducting behavior of the coatings was discussed within the framework of the Gartner and Sodergren models. Improvement can be foreseen if Nb<sub>2</sub>O<sub>5</sub> coatings can be made of 10–20 nm size nanoparticles.

Nanocrystalline titanium and indium oxides and TiO<sub>2</sub>–In<sub>2</sub>O<sub>3</sub> composites were prepared by the sol–gel technique using concentrated hydrous titanium dioxide and indium hydroxide sols [568]. Structural, optical, and photoelectrochemical properties of the composites with different molar ratios of TiO<sub>2</sub> to In<sub>2</sub>O<sub>3</sub> were studied. Highly transparent TiO<sub>2</sub>–In<sub>2</sub>O<sub>3</sub> films fabricated by the spin-coating technique exhibited extreme dependencies of the various optical and photoelectrochemical properties on the film composition. The bandgap edge of the composite films was blueshifted, as compared with that of single-component films. The conductivity of TiO<sub>2</sub>–In<sub>2</sub>O<sub>3</sub> films changed by six orders of magnitude in the range of compositions near the calculated value for percolation threshold associated with the formation of 3D infinite clusters of interconnected In<sub>2</sub>O<sub>3</sub> nanoparticles.

A sol–gel method was employed to produce a zinc oxide colloid consisting of ZnO nanocrystalline particles with an average diameter of 3 nm subsequently mixed with a silica colloid [569]. The mixture was finally spray dried to form a powder nanocomposite. The green photoluminescence exhibited by the composite was very stable.

ZnS nanoparticles were prepared by chemical precipitation of Zn<sup>2+</sup> with sulfur ions in aqueous solution [570]. The ultraviolet-excited samples revealed detailed structure in the luminescence spectra. A doublet pattern observed in the long wavelength region was attributed to the coexistence of the two crystalline forms in ZnS particles.

Composite particles consisting of a zinc sulfide core and a silica shell or vice versa were reported [571]. These particles were optimized for photonic applications, because ZnS had a large refractive index and did not absorb light in the visible and both ZnS and SiO<sub>2</sub> can be easily doped with fluorophores. Both kinds of morphologies were created using a seeded growth procedure using monodisperse seeds on which homogeneous layers with a well-defined thickness were grown. The ZnS and SiO<sub>2</sub> cores could be completely dissolved leaving SiO<sub>2</sub> and ZnS shells, respectively, filled with solvent or air after drying.

Zinc sulphide nanoparticles were synthesized in silica matrix using a sol–gel method [572]. Silica could be loaded with zinc sulphide over a very wide range of concentration without changing the nanoparticle size. A strongly luminescent zinc sulphide–silica composite, thermally stable even up to around 700 °C, was obtained.

Synthesis and characterization of undoped and Mn<sup>2+</sup> doped ZnS nanocrystallites (radius 2–3 nm) embedded in a partially densified silica gel matrix were presented [573, 574]. Optical transmittance, photoluminescence, ellipsometric, and electron spin resonance measurements revealed manifestation of the quantum size effect [573]. A dramatic increase in cathodoluminescence emission was observed [574]. Photoluminescence spectra recorded at room temperature revealed a broad blue emission signal centered at around 420 nm and a Mn<sup>2+</sup> related yellow–orange band centered at around 590 nm, while electron spin resonance measurements indicated that Mn in ZnS was present as dispersed impurity rather than Mn clusters [573].

The influence of the particle size on the luminescence of nanocrystalline ZnS:Pb<sup>2+</sup> synthesised via a precipitation method was studied [575]. Depending on the excitation wavelength, nanocrystalline ZnS:Pb<sup>2+</sup> showed a very broad

white ( $\lambda_{\text{exc}} = 380 \text{ nm}$ ) or red emission ( $\lambda_{\text{exc}} = 480 \text{ nm}$ ). The decay kinetics of both emissions was typical for  $\text{Pb}^{2+}$ , independent of the particle size. The quenching of luminescence with increasing temperature was explained by photoionization. The lower quenching temperature for the luminescence of larger nanoparticles was explained by quantum size effects.

ZnS nanoparticles doped with  $\text{Ni}^{2+}$  [576],  $\text{Ti}^{3+}$  and  $\text{Ti}^{4+}$  [577],  $\text{Cu}^+$  and  $\text{Cu}^{2+}$  [578],  $\text{Co}^{2+}$  [579], and  $\text{Co}^{3+}$  [580], were obtained by chemical coprecipitation from homogeneous solutions of zinc and nickel (or titanium, copper, or cobalt) salt compounds, with  $\text{S}^{2-}$  as precipitating anion, formed by decomposition of thioacetamide. The average size of particles doped with different mole ratios, was about 2–3 nm [576–580]. The absorption spectra showed that the excitation spectra of Ni-doped ZnS nanocrystallites were almost the same as those of pure ZnS nanocrystallites ( $\lambda_{\text{exc}} = 308\text{--}310 \text{ nm}$ ) [576]. Because a  $\text{Ni}^{2+}$ ,  $\text{Ti}^{3+}$ , or  $\text{Co}^{2+}$  luminescent center was formed in ZnS nanocrystallites, the photoluminescence intensity increased with the amount of ZnS nanoparticles doped with these ions [576, 577, 579]. Stronger and stable green-light emission was observed from ZnS nanoparticles doped with  $\text{Ni}^{2+}$  [576],  $\text{Ti}^{3+}$  [577], and  $\text{Co}^{2+}$  [579]. The fluorescence intensity of the ZnS nanocrystallites doped with  $\text{Ti}^{4+}$  was almost the same as that of the undoped ZnS nanoparticles [577]. The fluorescence intensity of  $\text{Co}^{3+}$ -doped ZnS nanoparticles was much weaker than that of ZnS nanoparticles [580]. The emission spectrum of ZnS nanocrystallites doped with  $\text{Cu}^+$  and  $\text{Cu}^{2+}$  consisted of two emission peaks at 450 and 530 nm [578].

Monodispersed ZnS and  $\text{Eu}^{3+}$ -doped ZnS nanocrystals were prepared through the coprecipitation reaction of inorganic precursors  $\text{ZnCl}_2$ ,  $\text{EuCl}_3$ , and  $\text{Na}_2\text{S}$  in a water/methanol binary solution [581, 582]. The mean particle sizes were about 3–5 nm with cubic (zinc blende) structure [582]. Photoluminescence studies showed stable room temperature emission in the visible spectrum region, with a broadening in the emission band and, in particular, a partially overlapped twin peak in the  $\text{Eu}^{3+}$ -doped ZnS nanocrystals.

The processing, microstructure, and optical properties of CdS semiconductor nanoparticles sequestered in spin-coated polymer films were investigated [583]. A simple processing protocol was developed to form thin film structures consisting of CdS nanoparticles dispersed in the interstices created by a close-packed stacking of polystyrene spheres. Absorption, emission, and excitation spectra of CdS nanoparticles embedded in sol-gel silica glasses were reported [584]. The effects of temperature on emission behavior were investigated.

Spherical CdS particles similar to 100 nm were synthesized by a hydrothermal process [585]. The particle formation and growth depended on the rate of sulfide-ion generation and diffusion-controlled aggregation of nanoparticles. Photoluminescence studies on CdS particles showed two emission bands at room temperature. The red emission at 680 nm was due to sulfur vacancies, and an infrared red emission at 760 nm was attributed to self-activated centers. A redshift of the infrared red band with the decrease of temperature was explained with a configurational coordinate model.

Highly luminescent CdTe nanocrystals were synthesized by reacting dimethylcadmium with different tellurium

sources in mixtures of dodecylamine and trioctylphosphine as the coordinating and size-regulating solvent [586]. Colloids of crystalline CdTe nanoparticles with zinc blende lattice displaying mean particle sizes between 2.5 and 7 nm were prepared at temperatures from 150 to 220 °C. The particles showed strong band-edge photoluminescence shifting from green to red with increasing particle size. The photoluminescence quantum yield strongly depended on the tellurium source employed in the synthesis. The highest quantum yields were observed by using a suspension of tellurium powder in a mixture of dodecylamine and trioctylphosphine. These CdTe samples showed a photoluminescence quantum yield up to 65% at room temperature without covering the surface of the nanoparticles with a passivating inorganic shell.

A convenient and safe one-pot route was presented to capped 3 nm CdSe nanoparticles with a narrow size distribution making use of common starting materials and inexpensive, low-boiling solvents under solvothermal conditions [587].  $\text{H}_2\text{Se}$  required for the reaction is generated *in-situ* through the aromatization of tetralin by Se. Figure 20 represents the powder XRD pattern of CdSe and UV-vis absorption spectrum of the nanoparticles in toluene [587].

The synthesis, characterization, and purification of GaSe nanoparticles in the size range of 2–6 nm were described [588]. These particles had a two-dimensional single tetralayer type structure. The particles had absorption onsets in the 360 to 450 nm region, with the smallest particles absorbing furthest to the blue. The particles were emissive, with emission quantum yields of about 10%.

**Figure 20.** (a) (i) Powder XRD pattern of CdSe compared with (ii) the background-subtracted Rietveld fit, (iii) DIFFaX simulation of 3 nm cubic zinc blende stacking of CdSe, and (iv) DIFFaX simulation of a 3 nm hexagonal wurtzite stacking of CdSe. The vertical lines at the top are expected peak positions for the cubic zinc blende structure. (b) UV-Vis absorption spectrum of the nanoparticles in toluene. Luminescence spectra—emission (em) following excitation at 400 nm, and excitation (ex) following emission at 540 nm are also shown. After [587], U. K. Gautam et al., *Chem. Commun.* 7, 629 (2001). © 2001, Royal Society of Chemistry.

Uniformly dispersed transparent zinc ferrite nanoparticles were synthesized in a silica matrix with both the magnetic properties and optical transparency designed in the visible wavelength region [589]. The phases and morphologies of these zinc ferrite particles were examined. A much lower formation temperature of  $\text{ZnFe}_2\text{O}_4$  in nanocomposites was observed, compared to conventional ceramic processing. The particle size of zinc ferrite varied with the initial drying temperature, suggesting that a well-established silica network provided more confinement to the growth of  $\text{ZnFe}_2\text{O}_4$  particles. The optical properties of the nanocomposites were adjusted by varying the concentration of the zinc ferrite nanoparticles. The absorption edge at around 600 nm was blueshifted by 0.65 eV when the loading of  $\text{ZnFe}_2\text{O}_4$  particles was decreased from 30 to 5 wt%, while the absorption coefficient remained below  $400\text{ cm}^{-1}$  in the red visible region.

High-pressure optical absorption spectroscopic measurements of both erbium-doped and undoped Si nanoparticles were carried out in a diamond anvil cell up to pressures of 180 kbar [590]. The emphasis was with respect to the effect of particle size on the pressure dependence of the bandgap as well as the indirect examination of the structural impact of the erbium dopant on the pressure-induced phase transitions. In terms of electronic structure, these Er-doped Si nanocrystals acted very much like indirect gap silicon, with an observed bandgap pressure dependence of  $-1.4 \times 10^{-6}$  eV/bar. Measurements of the optical spectra in terms of integrated area as a function of pressure of these doped nanoparticles revealed that the first-order phase transition must lie above 180 kbar, substantially elevated from the bulk value of 120 kbar.

Two procedures were presented which allowed the homogeneous incorporation of silica-coated gold nanoparticles within transparent silica gels [591]. There was no aggregation of the metal particles during sol-gel transition. The optical properties of the gels were compared with those of the starting sols and interpreted on the basis of the porous structure of the gels and standard optical theories.

### 5.3. Electronic Properties

$\text{Co}_x\text{C}_{1-x}$  ( $x = 0.18, 0.25, 0.39$ ) nanogranular films were prepared by pulsed filtered vacuum arc deposition [592]. The as-deposited films with various Co concentrations were amorphous. Upon annealing, nanocrystalline Co grains were formed, while the carbon content remained amorphous. The electrical resistance of the films was measured as a function of temperature between 20 and 300 K. While the as-deposited films were metallic in the measured temperature range, annealed films showed complicated transport properties, depending on both the Co concentration and the annealing temperature. Experimental results were compared to the general predictions of theories of weak localization and/or electron-electron interaction on the metallic side of the metal-insulator transition and thermally assisted hopping or tunneling on the insulating side of the transition.

Composites of silica glass and metal nanoparticles of copper or nickel were synthesized by the hot compaction of sol-gel-derived glass-metal powders [593]. The metal particle sizes ranged from 5.1 to 7.2 nm. The electrical resistivity

of the composites was characterized by semiconductor-like behavior in the temperature range 235–340 K. This was believed to arise due to electron hopping between localized states within the bandgap of amorphous silica formed by the dispersed metal atoms.

Electrically conducting films of thickness approximately  $2\ \mu\text{m}$  were prepared on ordinary glass slides by growing nanoparticles of iron and copper, respectively, from a suitable precursor sol [594, 595]. The diameters of metal particles varied from 3 to 13 nm by controlling the heat-treatment schedule of the sol coating. The resistivity values in the range  $0.0001\text{--}0.0039\ \Omega/\text{cm}$  over the temperature range 80–300 K were obtained depending on the particle diameter and the type of metal used. The effective Debye temperature  $\theta_D$  for the different nanoparticle systems was estimated by fitting the experimental data to the Ziman equation.  $\theta_D$  varied from 346 to 408 K for iron with the particle size in the range 3.4–9.5 nm. The values obtained for copper are 243–307 K with particle diameters covering a range of 5.9–12.6 nm.

### 5.4. Magnetic Properties

The magnetic properties of carbon-coated iron and iron carbide nanocapsules, synthesized by arc discharge of carbon rods, were studied [596]. These nanocapsules consist of  $\alpha\text{-Fe}$ ,  $\gamma\text{-Fe}$ , and  $\text{Fe}_3\text{C}$ . Their coercive force was larger than that of bulk  $\alpha\text{-iron}$ , being ascribed to the small particle size.

Iron particles encaged in carbon nanocapsules were produced by the carbon arc-discharge method [597]. Soot, collarette, and cathode samples were characterized by Mössbauer spectroscopy and magnetic measurements in the temperature range 4.2–300 K. Different iron phases and iron-carbon solid solutions were detected. The Einstein model was used to evaluate the coupling constant between the particles and their environment, yielding values of the order 1–10 N/m. The superparamagnetism presented only if the particles presented a blocking temperature above 300 K.

Synthesis, crystal structures, and magnetic properties of Co particles encapsulated in carbon nanocapsules were studied [598]. Cobalt particles grown were in an fcc phase, with a trace amount of hcp Co. Thickness and structure of outer carbon layers could be controlled by varying the relative area of a Co-packed hole drilled in the graphite rod. Temperature dependence of the measured  $M_s$  was consistent with that for fcc Co. The highest value of  $M_s$  of  $160\ \text{Am}^2/\text{kg}$  at room temperature, nearly the same value for bulk fcc Co, was obtained for Co particles covered with thin carbon layers.

Magnetic properties of graphitically encapsulated nickel nanocrystals synthesized via a modified tungsten arc-discharge method were investigated [599]. By virtue of the protective graphitic coating, these nanocrystals were stable against environmental degradation, including extended exposure to strong acids. The magnetic properties of the encapsulated particles were characterized with regard to the nanoscale nature of the particles and the influence of the graphitic coating. The Curie temperature of graphitically encapsulated Ni nanocrystals was the same as that of microcrystalline Ni. The saturation magnetization, remanent magnetization, and coercivity of these particles were reduced, for a range of temperatures. The unique features were

compared with those of unencapsulated nanocrystalline and coarse microcrystalline nickel particles.

The structure and magnetic properties of carbon coated nickel and cobalt nanocrystals synthesized in a special low carbon to metal ratio arc chamber were reported [600, 601]. Magnetization measurements as a function of temperature in the range 20–900 °C gave a Curie temperature equal to that of bulk metal within experimental error. Upon heating and recooling of the particles, a large magnetization as high as 57% of bulk Co and 53% of bulk Ni was obtained. The dependence of room temperature saturation magnetization, remanent magnetization, and coercive field of the particles on annealing temperature was reported. These data were described by transition of particles from single domain to multidomain as a result of particle growth due to annealing. The particle size distribution measurements showed a log-normal behavior, indicating substantial particle size growth due to annealing.

Carbon-coated cobalt nanocrystals were prepared by a modified method of arc discharge under a He gas blow around a graphite rod cathode [602]. The magnetic properties of these particles after acid treatment were measured. Large shifts of Raman peaks were observed upon acid treatment, reflecting the structural change of the carbon shell induced by the acid treatment. The blocking temperature of the sample was estimated to be 373 °C.

Shell-core structures of Fe(C), Co(C), and Fe–Co(C) nanocapsules, prepared by an arc-discharge process in a mixture of methane and helium, were demonstrated by means of HRTEM [119–121, 123]. These nanoscale magnetic cores are protected by graphite shells. The ZFC magnetization of Fe–Co(C) nanocapsules, displaying different characteristics in three temperature ranges, can be well interpreted in terms of the unblocking of magnetization of small single-domain particles and the depinning of large multidomain particles. The saturation magnetization of these nanocapsules decreased monotonically, while the coercivity decreased significantly with increasing temperature. Figure 21 represents magnetization curves at room temperature of Fe–Co(C) nanocapsules [120]. Figure 22 shows ZFC and ( $B = 0.01$  T)

**Figure 21.** Magnetization curves at room temperature of Fe–Co(C) nanocapsules. Samples a–f correspond to 10 wt%, 20 wt%, 30 wt%, 45 wt%, 60 wt%, and 80 wt% Co content in master alloys, respectively. After [120], X. L. Dong et al., *J. Appl. Phys.* 86, 6701 (1999). © 1999, American Institute of Physics.

**Figure 22.** Zero-field-cooled (ZFC) and ( $B = 0.01$  T) field-cooled (FC) magnetization curves of Fe–Co(C) nanocapsules. After [121], Z. D. Zhang et al., *J. Phys. Cond. Matter* 13, 1921 (2001). © 2001, IOP Publishing.

FC magnetization curves of Fe–Co(C) nanocapsules [121]. The results could be used to compare with those of ultrafine Ni [603], Fe–Ni [604], and Fe–Co particles [605].

Carbon-encapsulated Ni nanoparticles were synthesized using a modified arc-discharge reactor under methane atmosphere [118, 606, 607]. The average particle size was revealed to be typically 10.5 nm with a spherical shape. Superparamagnetic property studies indicated that the blocking temperature ( $T_B$ ) was around 115 K at an applied field of 0.1 T. Below  $T_B$ , the temperature dependence of the coercivity was given by  $H_c = H_{ci}[1 - (T/T_B)^{1/2}]$ , with  $H_{ci}$  approximate to 500 Oe. Above  $T_B$ , the magnetization  $M(H, T)$  can be described by the classical Langevin function  $L$  using the relationship  $M/M_s(T = 0) = \coth(\mu H/k_B T) - k_B T/\mu H$ . The particle size can be inferred from the Langevin fit (particle moment  $\mu$ ) and the blocking temperature theory ( $T_B$ ), with values slightly larger than the HRTEM observations. It was suggested that these assemblies of carbon-encapsulated Ni nanoparticles had typical single-domain, field-dependent superparamagnetic relaxation properties.

The magnetic properties of boron-oxide-encapsulated magnetic nanocapsules fabricated by arc discharge in diborane ( $B_2H_6$ ) atmosphere were investigated in the temperature range from 4.2 to 300 K [122–124]. The saturation magnetizations of Fe(B) and Co(B) nanocapsules decreased monotonically with increasing temperature. The coercivities of the Fe(B) nanocapsules are almost two orders of magnitude higher than that of bulk Fe. The loop shift in the hysteresis loop the Fe(B) and Co(B) nanocapsules indicated the existence of the exchange bias between ferromagnetic and antiferromagnetic components. The  $Fe_3O_4$  or  $Co_3O_4$  phase in the shells contributed to the exchange bias as antiferromagnetic components. The very wide energy barrier distribution existed in these boron-oxide-encapsulated nanocapsules.

After passivation, the  $Fe_3C$  particles prepared by laser-induced pyrolysis of  $Fe(CO)_5$  and  $C_2H_4$  exhibited a high saturation magnetization of 132  $Am^2/kg$  compared to that of the  $\alpha$ -Fe particles, 95  $Am^2/kg$  [151]. Thin amorphous carbon layers, formed on the surfaces of the  $Fe_3C$  particles, inhibited oxidation of the  $Fe_3C$ , resulting in the high saturation

magnetization achieved by  $\text{Fe}_3\text{C}$  particles. The role the thin carbon layer formed on the iron carbonitride particle surface played in the oxidation behavior and in the enhancement of the magnetic properties was studied [152]. A carbon layer (1–2 nm) protected the particles effectively from reaction of the iron carbonitride with oxygen, and the iron carbonitride particles exhibited a high saturation magnetization of  $142 \text{ Am}^2/\text{kg}$ .

Ferromagnetic nanocrystallites of carbon- and  $\text{C}_x\text{N}$ -coated iron and its compounds were synthesized by a modified arc method in  $\text{N}_2$  buffer gas [608, 609]. The metal to carbon ratio of the particles, ranging from 73.5 to 80.5 wt%, was controlled by the pressure of the buffer gas charging from 0.06 to 0.01 MPa. Typical sizes of these particles were 10–30 nm. The magnetic properties of these particles were measured.

Glass–metal nanocomposite powders in the  $\text{Fe}/\text{SiO}_2$  and  $\text{Ni}/\text{SiO}_2$  systems were prepared by the sol–gel technique followed by reduction treatment [610]. Bulk nanocomposites were then fabricated by hot pressing these powders. The metal particle diameters ranged from 8.9 to 14.8 nm. The materials showed enhanced coercivities. The Mössbauer spectra of  $\text{Fe}/\text{SiO}_2$  samples were comprised of a ferromagnetic component superposed on a superparamagnetic doublet.

Nanocomposites of  $\gamma\text{-Fe}_2\text{O}_3$  in a silica matrix were prepared by the sol–gel method using tetramethylorthosilicate as a precursor of silica and introducing iron as  $\text{Fe}(\text{NO}_3)_3$  with  $\text{Fe}/\text{Si}$  ratios of 2, 5, 10, and 20% [611, 612]. Superparamagnetic  $\text{Fe}^{3+}$  oxide nanoparticles with a narrow size distribution, dispersed over the amorphous silica matrix, were present in  $\text{Fe}_2\text{O}_3\text{-SiO}_2$  nanocomposites (9–33 wt%  $\text{Fe}_2\text{O}_3$ ), prepared by a sol–gel method [613, 614]. Superparamagnetic magnetization curves were fitted by a Langevin function considering a log-normal particle size distribution. The specific Faraday rotation spectrum in a magnetic nanocomposite of  $\gamma\text{-Fe}_2\text{O}_3/\text{SiO}_2$  exhibited a narrow peak centered around 765 nm, reaching a value of 110 degrees/cm and an absorption coefficient of  $64 \text{ cm}^{-1}$  [612].

Iron particles having diameters around 8 nm and loosely packed with nanosized copper particles were prepared by a sol–gel route [615]. The samples exhibited coercivities in the range 200 to 500 Oe that were typical of single-domain iron grains. The Mössbauer spectrum was consistent with the presence of  $\alpha\text{-Fe}$  particles in the system. A finite value of the isomer shift was obtained, which was ascribed to possible electron transfer between the iron atoms and the surrounding copper matrix.

$\text{Mn}_{0.5}\text{Zn}_{0.5}\text{Fe}_2\text{O}_4$  ferrite nanoparticles (<100 nm) in  $\text{SiO}_2$  matrix were prepared by the sol–gel method [616]. The nanoparticles showed superparamagnetic behavior when the particle size was below 20 nm, which was confirmed by Mössbauer spectroscopy. The average particle size in the superparamagnetic state was also estimated from the low-field magnetization measurement by considering the samples as consisting of noninteracting single domain particles.

The phase formation of nanocrystalline  $\text{NiFe}_2\text{O}_4$  particles involved the nucleation of  $\text{Fe}_3\text{O}_4$  in amorphous silica at the initial stage of mechanical activation, followed by the growth of nickel ferrite by incorporation of  $\text{Ni}^{2+}$  cations into  $\text{Fe}_3\text{O}_4$  [617]. Their magnetic anisotropy, surface spin disorder, and

cation distribution were investigated by considering both the strain imposed by silica matrix and the buffer effect during mechanical activation.

The room temperature magnetic properties of Ir–Co and La–Zn substituted Ba-ferrite powders, prepared for the sol–gel method, were investigated [618]. Saturation magnetization increased with La–Zn substitution in contrast to Ir–Co substitution. La–Zn mixtures were the least effective in reducing coercivity, while Ir–Co led to a fast reduction at low levels of substitution.

$\text{Co}_{65}\text{C}_{35}$  nanocomposite film was prepared by pulsed filtered vacuum arc deposition [619]. The as-deposited film was found to be amorphous and ferromagnetically soft. No obvious magnetic domain structures can be observed in the MFM image, indicating the low anisotropy in the amorphous film. After annealing at a temperature between about 300 and 350 °C, the as-deposited amorphous films went through a metastable stage in which a cobalt carbide phase and hcp crystalline cobalt coexisted. Upon increasing the annealing temperature to 400 °C, the carbide phase decomposed into hcp crystalline cobalt nanograins and graphitelike carbon.

Polyelectrolyte multilayer capsules were introduced as versatile magnetic carrier systems [620]. Superparamagnetic magnetite was mounted to the multilayer shell itself or was a component of the capsule interior. The polyelectrolyte multilayer was formed at different (decomposable) colloidal templates (e.g., melamine formaldehyde resin, glutaraldehyde fixed red blood cells, emulsion oil droplets).

The catalytic synthesis of carbon nanotubes filled with long continuous cobalt nanowires by a simple chemical process and a following treatment with HCl were reported [621]. The average diameter of the multiwalled nanotubes was about 40 nm. The nanowires were a few micrometers long with a diameter of 20 nm. The cobalt nanowires, encapsulated in the carbon nanotubes, had a fcc structure. The filled nanotubes can be separated by using a permanent magnet.

The magnetic properties of boron nitride nanocapsules with iron oxide nanoparticles, fabricated by an arc-discharge method, were investigated [622]. The iron oxide nanoparticles of 20 nm size were encapsulated by boron nitride sheets of 4 nm width. Magnetization of the BN nanocapsules showed paramagnetism and the initial iron oxides showed ferromagnetism, suggesting the transformation into superparamagnetism by separating the iron oxide nanoparticles with BN sheets.

Efficient synthetic strategies were developed for single molecular magnets (i.e., the design of new magnetic polyoxometalate clusters) [623–637]. Polyoxometalate chemistry served as an inexhaustible source for molecular models for different reasons, especially due to their versatile redox chemistry. Referring to molecular magnets, paramagnetic centers can be embedded in a structure-determining diamagnetic polyoxometalate (linker) framework giving rise to properties which were intermediate between simple paramagnetism and bulk magnetism. For example, in  $\{\text{Mo}_5\text{M}_6\}$ -type cluster systems, it was even possible to place (or exchange) stepwise different (para)magnetic centers M like  $\text{Fe}^{2+/3+}$  and  $\text{V}^{4+}\text{O}^{2-}$  in the respective linker positions, thus allowing some control over the cluster's magnetic properties or even the tuning of these.

## 5.5. Dynamic Properties

Carbon nanocapsules containing nanometer-size particles of molybdenum carbide were irradiated by neutrons of flux  $10^{14} \text{ N cm}^{-2} \text{ s}^{-1}$  for 6 days [638]. The  $\gamma$ -ray spectrometry showed  $10^{10} \text{ Bqg}^{-1}$  of Mo-99 transformed from Mo-89 and decayed into Tc-99. The TEM investigation indicated that the nanocapsule was robust against the neutron irradiation and was used as a container for radioactive materials and tracer elements. The contents of the capsule in the nanometer scale were activated and transformed into other nuclei.

A reactor chamber was developed for the secure handling of radioactive materials [639]. Using the arc-discharge method for fullerene synthesis, the carbon encapsulation capability of uranium was tested. The uranium was encapsulated as a dicarbide with two types of carbon covers: graphene sheets parallel to the external surface and randomly oriented carbon crystallites. The covers with parallel sheets of graphite were present with two different interlayer spacings. One corresponded to polyhedral particles with an interior gap between the kernel and capsule. The other consisted of rounded-vertex particles with no gap and with interlayer spacing between that of graphite and that corresponding to polyhedral nanocapsules. Extensive studies were described for the resolution of carbon structures and a transformation mechanism was proposed for the interpretation of rounded-vertex onionlike structures. Closed carbon covers chemically protected the actinide kernel and provided safer handling and processing of toxic materials for medical and nuclear purposes.

*In-situ* and *ex-situ* TEM observation was performed in copper implanted with carbon ions at temperatures from 570 to 973 K [640]. Carbon onions (concentric graphitic spheres) and nanocapsules (concentric graphitic spheres with cavities) were observed together with amorphous carbon layers. Statistics of cluster size as a function of ion fluence, implantation temperature, and substrate crystallinity gave insights into the nucleation processes of onions and nanocapsules. One was the formation of graphitic layers on grain boundaries to encapsulate copper particles. The other was the nucleation of graphitic cages, probably fullerenes, due to both a high concentration of carbon atoms and a high amount of radiation damage. Simultaneous observation of microstructural evolution under implantation revealed that onions were formed inside the substrate, not the surface, and that they segregate at the surface due to radiation-enhanced evaporation.

A scanning tunneling microscopy study of carbon nanocapsules (onions) was reported [641]. Spherulitic graphite was shown to be purely crystalline graphite based on XRD and TEM studies. Carbon nanocapsules grown on pitch-based carbon fibers were investigated by HRTEM [642]. Two types of nanocapsules were formed during heating up to 2000 °C in 1 atm  $\text{N}_2$  gas: one was a capsule enclosing a CaS single crystal and the other was a cubic hollow capsule. The growth mechanism of these carbon nanocapsules was discussed by comparing the structures of particles formed at several temperatures.

## 6. BIOMEDICAL PROPERTIES

### 6.1. Introduction

Recently, much interest has been generated by colloidal drug delivery systems such as nanocapsules because of the possibilities for controlled release, increased drug efficacy, and reduced toxicity after parenteral administration. Nanocapsules can be formulated into a variety of useful dosage forms including oral liquid suspensions, lotions, creams, ointments, powders, capsules, tablets, and injections. Nanoencapsulation has been applied to solve problems in the development of pharmaceutical dosage forms as well as in cosmetics for several purposes. These include conversion of liquids to solids, separation of incompatible components in a dosage form, taste masking, reduction of gastrointestinal irritation, protection of the core materials against atmospheric deterioration, enhancement of stability, and controlled release of active ingredients.

Nanoparticles used in drug delivery are solid, colloidal particles consisting of macromolecular substances that vary in size from 10 to 1000 nm. The drug is dissolved, entrapped, adsorbed, attached, or encapsulated in the macromolecular materials. Nanoparticles, also called nanopellets or nanocapsules, can have a shell-like wall, called a nanosphere, or a polymer lattice. However, it is often difficult to determine whether nanoparticles have a shell-like wall or a continuous matrix. Nanocapsules present a liquid core surrounded by a polymeric shell, while so-called nanospheres consist of a dense polymeric matrix, in which the drug can be dispersed. Compared to other colloidal carriers, polymeric nanocapsules present a higher stability when in contact with biological fluids, and their polymeric nature allows one to obtain the desired controlled and sustained drug release. Nanocapsules represent drug delivery systems suitable for most of the administration routes, even if rapid recognition by the immune system limits their use as injectable carriers.

Different approaches to preparing biodegradable nanocapsules, consisting of biodegradable polymers, have been described, as well as the methods for preparing surface-modified sterically stabilized particles [643–654]. Nanocapsules can be prepared either from preformed polymers, such as polyesters (i.e., polylactic acid), or from a monomer during its polymerization, as in the case of alkylcyanoacrylates. Most of the methods based on the polymerization of monomers (i.e., alkylcyanoacrylates) consist of adding a monomer into the dispersed phase of an emulsion or an inverse microemulsion or dissolving it in a nonsolvent of the polymer. Starting from preformed polymers, nanoparticles are formed by the precipitation of synthetic polymers or by denaturation or gelification of natural macromolecules. Two main approaches have been proposed for the preparation of nanocapsules of synthetic polymers. The first one is based on the emulsification of the water-immiscible organic solution of the polymer by an aqueous phase containing the surfactant, followed by solvent evaporation. The second approach is based on the precipitation of a polymer after addition of a nonsolvent of the polymer. Concerning nanocapsules formed of natural macromolecules, the nanocapsules can be obtained by thermal denaturation of proteins (such as albumin) or by a gelification process, as in the case of alginates. The attachment of certain hydrophilic

polymers on the surface of the carriers reduces the uptake by the immune system, therefore prolonging the blood half-life of the nanospheres and thus allowing their intravenous administration. Characterization of sterically stabilized nanospheres allows the establishment of parameters that govern the *in vivo* behavior. In particular particle size and surface properties, such as chemical composition, charge, and hydrophobic, etc., are directly correlated with the nanoparticle fate. A drug or any biologically active compound can be dissolved, entrapped, or encapsulated into the nanocapsules or simply adsorbed onto its surface. It has been well known that polymeric particulate nanocarriers, able to deliver drugs or other compounds to specific sites of action for a prolonged time, represent a potential therapeutic approach for several diseases [643–654].

The pioneers in this field discovered that the nanocapsules could be used as new type of lysosomotropic carrier [6, 7], as new dosage forms [2, 655], or for controlled release of drugs [1]. Early work also focused on the preparation and characterization of hemolysate-loaded poly(N- $\alpha$ , N- $\epsilon$ -L-lysinediylterephthaloyl) [3], gelatin [4], and polyisobutyrylcyanoacrylate nanocapsules [8–10, 656]. It was found that the polyalkylcyanoacrylate nanocapsules increased the intestinal absorption of a lipophilic drug [5, 11]. Since the mid 1980s, many different active molecules, such as anti-inflammatory agents, anticancer drugs, immunostimulating compounds, anti-infectious agents, antiglaucomatous drugs, and even peptides have been encapsulated and as a result their pharmacological effect has been improved or their secondary effects reduced compared with free drugs after administration by oral, parenteral, or ocular routes. The nanocapsules have been found also to be suitable as a biodegradable drug carrier for the administration and controlled release of drugs, like insulin, indomethacin, calcitonin, doxorubicine, gangliosides, oligonucleotides, etc.

One of the major obstacles to the targeted delivery of colloidal carriers (nanocapsules) is the body's own defense mechanism in capturing foreign particles by the reticuloendothelial system. Following intravenous administration, practically all nanometer size particles are captured by the reticuloendothelial system (mainly the liver). The design of "macromolecular homing devices" seems to disguise nonparticles from the reticuloendothelial system, which is of potential interest for the targeted delivery of nanocapsular carriers [657]. The idea is based on a graft copolymer model embodying a link site for attachment (binding) to the carrier, a floating pad for maintaining the particles afloat in the bloodstream, an affinity ligand for site-specific delivery, and a structural tune for balancing the overall structure of the homing device.

Although the oral route is preferred route for drug delivery, numerous drugs remain poorly available when administered by the oral route. In order to circumvent this problem, some drugs are associated with colloidal polymeric particle systems. Orally administered nano and microparticles can follow at least three different pathways: (i) capture by gut-associated lymphoid tissue; (ii) mucoadhesion; and (iii) direct fecal elimination. Mucoadhesion of colloidal particulate systems in the gastrointestinal tract was emphasized [658]. On the one hand, *in vitro* adsorption and desorption

studies showed that particles could be captured to a considerable extent by the mucous gel layer lining the gastrointestinal tract through a mucoadhesion mechanism. On the other hand, the *in vivo* behavior of the particle in the intestinal lumen was accurately investigated by means of radiolabelled particles.

Recently a major breakthrough has been achieved in the formulation of polymeric artificial nanocapsules, which can be made in a reproducible manner having a specific size and shape and in reasonable quantities. This opens a new field of intelligent material with possible sophisticated applications. To achieve the goal to bring this research field from the level of basic science to possible application, the necessary techniques have been developed and expertise from different fields and laboratories has been combined [659–674]. The first step to allow specific applications is to functionalize the nanocapsules by coating the surface with active sites or to inserting them into the wall. One direction is to cover them with lipid membranes providing an artificial cell. These techniques have been combined with recent developments in molecular biology. The advantage of natural proteins already optimized by nature has been taken for specific tasks, which could be modified by genetic engineering to adopt them for purposes (e.g., such nanospheres can harvest specific substrates or release at a specific site encapsulated materials). A second aspect is that these nanocapsules provide a new class of surfaces which allows study of molecular interactions of surface attached proteins. These studies have permitted new types of measurements and thus provided new insights into protein–protein or protein–ligand interaction. Artificial cells for pharmaceutical and therapeutic applications have been expanded up to the higher range of macrocapsules and down to the nanometer range of nanocapsules and even to the macromolecular range of cross-linked hemoglobin as a blood substitute. Artificial cells have been being prepared by bioencapsulation in the laboratory for medical and biotechnological applications. Advances in molecular biology have resulted in the availability of non-pathogenic genetically engineered microorganisms that can effectively use uremic metabolites for cell growth. The three generations of blood substitutes have been developed based on an original idea of a completely artificial red blood cell.

In Section 6.2, we will focus on the advances in the area of artificial cell and red blood cell substitutes, most of which are based on Chang's concept [675–679]. In Section 6.3, various types of the drug delivery and controlled release are reviewed.

## 6.2. Artificial Cell and Red Blood Cell Substitutes

The artificial cell evolved from Chang's attempts to prepare artificial structures for possible replacement or supplement of deficient cell functions [675–679]. Artificial cells for pharmaceutical and therapeutic applications started as microencapsulation on the micrometer scale. This has expanded up to the higher range of macrocapsules and down to the nanometer range of nanocapsules and even to the macromolecular range of cross-linked hemoglobin as a blood

substitute. Artificial cells are now being prepared by bioencapsulation in the laboratory for medical and biotechnological applications [680–685]. Some exciting developments include research and clinical trials on modified hemoglobin for blood substitutes and the use of artificial cells for enzyme therapy, cell therapy, and gene therapy [686–691]. Like natural cells, biologically active materials inside the artificial cells are retained and prevented from coming into contact with external materials like leucocytes, antibodies, or tryptic enzymes. Molecules smaller than protein can equilibrate rapidly across the ultrathin membrane with a large surface to volume relationship. A number of potential medical applications using artificial cells have been proposed [692, 693]. One of these is hemoperfusion for uremia, intoxication, and hepatic failure [692], which has been developed successfully for routine clinical use [693]. Artificial cells containing enzymes have been used for inborn errors of metabolism and other conditions.

Semipermeable microcapsules containing catalase were implanted into acatalesemic mice, animals with a congenital deficiency in catalase [694], which replaced the deficient enzymes and prevented the animals from the damaging effects of oxidants. The artificial cells also protected the enclosed enzyme from immunological reactions [695]. The artificial cells containing asparaginase implanted into mice with lymphosarcoma delay the onset and growth of lymphosarcoma [11, 696]. The microencapsulated phenylalanine ammonia lyase given orally lowered the elevated phenylalanine levels in phenylketonuria rats [697], because of an extensive recycling of amino acids between the body and the intestine [698], which was developed for clinical trial in phenylketonuria [699].

A drop method was developed for the encapsulation of biological cells [677, 679] by using milder physical cross-linking [700], resulting in alginate–polylysine–alginate (APA) microcapsules containing cells. The preparative procedures and properties of microcapsule artificial kidneys were studied [701, 702]. Microencapsulated xanthine oxidase was used for experimental therapy in Lesch–Nyhan disease [703]. Microencapsulated islets were used as bioartificial endocrine pancreas [700]. The cell encapsulation was developed for cell therapy, including artificial cells containing endocrine tissues, hepatocytes, and other cells for cell therapy [686, 688, 704–707], for potential applications in amyotrophic lateral sclerosis, dwarfism, pain treatment, IgG<sub>1</sub> plasmacytosis, Hemophilia B, Parkinsonism, and axotomized septal cholinergic neurons. The effects on hyperbilirubinemia in Gunn rats were discussed for hepatocytes immobilized by microencapsulation in artificial cells [708]. Daka and Chang reported bilirubin removal by the pseudoperoxidase activity of free and immobilized hemoglobin and hemoglobin coimmobilized with glucose oxidase [709]. Preparation and characterization of xanthine oxidase immobilized by microencapsulation in artificial cells were reported for the removal of hypoxanthine [710]. Even for more immediate clinical applications [711], the ingenious use of capillary fiber to encapsulate cells allows one to implant cells followed by retrieval and reimplantation in clinical trials [711].

Advances in molecular biology have resulted in the availability of nonpathogenic genetically engineered

microorganisms that can effectively use uremic metabolites for cell growth. Prakash and Chang studied the oral use of microencapsulated genetically engineered nonpathogenic *E. coli* DH5 cells containing the Klebsiella aerogenes urease gene in renal failure rats [712–714]. *In vitro* removal of urea, ammonium, electrolytes, and other metabolites was studied [714–717]. Daily oral administration to partially nephrectomized rats including survival studies was investigated [712, 718–720]. Clinical potentials of oral encapsulated *E. coli* DH5 cells were studied [702, 721–723].

Polyhemoglobin has been used as a blood substitute. Native hemoglobin [tetramer] breaks down into half molecules [dimers] after infusion causing renal toxicity and other adverse effects. Chang extended his original approach of artificial cells containing hemoglobin and enzymes [675–677] to form polyhemoglobin—a molecular version of artificial cells which was based on the use of bifunctional agents like diacid [675–677] or glutaraldehyde [724, 725] to cross-link hemoglobin molecules into polyhemoglobin. This glutaraldehyde cross-linked polyhemoglobin approach has been extensively developed more recently [726–734].

Although polyhemoglobin is in the most advanced stages of clinical trial, there are other modified hemoglobins such as recombinant human hemoglobin [728, 735]. Unlike polyhemoglobin these are single tetrameric hemoglobin formed by intramolecular cross-linkage [736, 737] or recombinant human hemoglobin [738]. Clinical trials on these show vasoactivities and other effects of nitrate oxide removal [736–738]. A recombinant human tetrameric hemoglobin with markedly decreased affinity for nitric oxide was developed [739]. Rate of reaction with nitric oxide determines the hypertensive effect of cell-free hemoglobin. When infused into experimental animals, this did not cause vasoactivity.

There are other new generations of modified hemoglobin blood substitutes: Polyhemoglobin stays in the circulation with a half-time of only up to 27 hours. In order to increase this circulation time, Chang's original idea of a complete artificial red blood cell [675–677] is now being developed as a third generation blood substitute. Thus submicrometer lipid membrane microencapsulated hemoglobin [740] has been explored [728, 741, 742]. The surface properties were modified to result in a circulation half-time of about 50 hours [743]. A system was developed based on biodegradable polymer and nanotechnology resulting in polylactide membrane hemoglobin nanocapsules of about 150 nm diameter [744, 745]. This was smaller than the lipid vesicles and contained negligible amounts of lipids. The superoxide dismutase, catalase, and also multienzyme systems were used to prevent the accumulation of methemoglobin [746].

For detailed progress on artificial cell and red blood cell substitutes, refer to the literature [747–805].

### 6.3. Drug Delivery and Controlled Release

The great progress in drug delivery systems has recently been made in the treatment of a variety of diseases. Targeting delivery of drugs to the diseased lesions is one of the most important aspects of the drug delivery system. To convey a sufficient dose of drug to the lesion, suitable carriers of drugs are needed. Nano- and microparticle carriers

have important potential applications for the administration of therapeutic molecules. Nanocapsules, which are ultra-fine oily droplet-coated polymeric substances, are probably one of the most promising candidates for colloidal carriers. Surface engineering by the interfacial deposition method can provide a suitable size distribution and necessary surface characteristics to the nanocapsules. Microparticles and nanoparticles as colloidal drug carriers in the micrometer and submicrometer range have been developed to overcome solubility problems of poorly soluble drugs as well as for long acting injectable depot formulations and specific drug targeting options, and they have also been evaluated for ophthalmic drug delivery purposes. Figure 23 gives a diagrammatic representation of liposomes, nanospheres, and nanocapsules for drug targeting.

Drugs are loaded into the nanoparticles by several methods. One method is by producing the nanocapsules in the presence of the drug. Drugs may also be loaded into empty particles prepared ahead of time. The drug, the polymer, and the means of preparation all influence the type of interaction with the polymer, the attachment of the drug to the nanoparticles or nanocapsules, and the rate of their interaction. Encapsulating drug molecules inside host molecules has obvious benefits: (i) protection of the drug from degradation; (ii) control over the hydrophilic/lipophilic balance of the capsule by modification of the host molecule, and (iii) good potential for targeting of the drug by equipping the capsule with appropriate recognition groups.

Some important practices for which nanocapsules are used include the adsorbing and coating of organs and tissues, peroral administration of drugs, vaccinations, the delivery of anti-inflammatory drugs, and the delivery of drugs for diseases and tumors. Nanocapsules can be targeted to specific organs or tissues by coating their surface with different materials. Nanocapsules are useful in this application due to their stability. Liposomes, on the other hand, often disintegrate due to the surfactants that are present in this method. Nanocapsules are also often used for peroral administration. An example of this can be applied to the digestive system. In order to influence the mode of interaction of the intestinal fluids with the intestine, the properties of these fluids are monitored in different tissues in the gut. Liposomes are often depleted by the salts present in these intestinal fluids, whereas nanoparticles are stable in the presence of these substances. In vaccination methods, nanoparticles have an advantage due to their slow degradation. This slow process allows for a longer interaction of the antigen with the immunocompetent cells of the body. Nanocapsules, as well

**Figure 23.** Diagrammatic representation of liposomes, nanospheres and nanocapsules for drug targeting. From homepage of E. Fattal, <http://efattal.free.fr/>.

as many other colloidal carriers, are enabling new methods for therapy in drug delivery.

The research in this area is being carried out all over the world at a great pace. Research areas cover novel properties that have been developed increased efficiency of drug delivery, improved release profiles and drug targeting. Many kinds of nanocapsules have been synthesized by a combination of different polymers and medicines as the shell and the core of the nanocapsules. The polymers, such as polyalkylcyanoacrylate, polyisobutylcyanoacrylate, poly(*N*- $\alpha$ , *N*- $\epsilon$ -L-lysinediylterephthaloyl), poly(D, L-lactide), poly(ethylcyanoacrylate), isohexylcyanoacrylate, poly- $\epsilon$ -caprolactone, poly(ethylene imine), poly(ethylene oxide-*b*-sebacic acid), polymethylidene, etc., and natural materials, like gelatin, melamine resin, etc., have been used to encapsulate various medicines, like insulin, peptides, indomethacin, cisplatin, calcitonin, doxorubicine, gangliosides, dodecanoate, oligonucleotides, etc. In the Sections 6.3.1–6.3.5, we collect literature with the same or similar topics concerning the materials used for the shell and the core of the nanocapsules. Ocular delivery and *in vitro/in vivo* studies will be represented separately in Sections 6.3.6 and 6.3.7. In the last Section, we will collect the review articles on the topic of drug delivery and controlled release.

### 6.3.1. Polyalkylcyanoacrylate/ Isobutylcyanoacrylate/Insulin/Peptides

Polyalkylcyanoacrylate or isobutylcyanoacrylate nanocapsules were used as a drug carrier also for oral administration [12, 13, 806–809] or enteral absorption [810] of insulin. The mechanism of formation of nanoparticles and nanocapsules of polyisobutyl-2-cyanoacrylate was studied [811]. The absorption of insulin was studied by measuring fasting glycemia in streptozotocin-induced diabetic rats after a single administration of encapsulated insulin (100 units  $\text{kg}^{-1}$ ) at various sites along the gastrointestinal tract [810]. The influence of sulfur dioxide and pH on the preparation and characterization of polyalkylcyanoacrylate nanoparticles was investigated [812]. Oral administration of insulin incorporated into the wall of isobutylcyanoacrylate nanocapsule to diabetic rats induces a long-lasting normalization of their fasting glycemia. The biological action of encapsulated insulin on DNA and glycogen syntheses in Chinese hamster ovary cells transfected with the human insulin receptor gene was examined [813].

Nonobese diabetic mice develop an autoimmune disease with a long prodromal period and constitute a model for investigating the prevention of human type-1 diabetes. Since prophylactic insulin injections reduced the incidence of diabetes in nonobese diabetic mice, a prophylactic strategy was tested to prevent diabetes in nonobese diabetic mice consisting of oral administration of insulin, protected in polyalkylcyanoacrylate nanocapsules from degradation in the gastrointestinal tract [814]. The early feeding with insulin nanocapsules reduced diabetes and insulinitis in the nonobese diabetic mouse model that mimics human type-1 diabetes.

Biological activity of insulin immobilized in a polymer hydrogel modified with a proteolytic enzymes inhibitor was examined in *in vitro* and *in vivo* studies. Immobilization of insulin did not affect its biological activity. Oral administration of the immobilized insulin led to a reliably reduced

concentration of glucose in the blood of test animals. The efficiency of the orally administered preparation amounted to 80% of the efficiency of hypodermally injected native insulin [815].

Physicochemical characterization of insulin-loaded polyisobutylcyanoacrylate nanocapsules obtained by interfacial polymerization was carried out [816]. The mechanism of insulin encapsulation and the type of interactions between the polymer forming the nanocapsule wall and the insulin were studied [817]. These nanocapsules showed unexpected biological activity after intragastric administration [816, 817]. The hypoglycemic effect was characterized by a period of 2 days and a prolonged effect over a period of 20 days. Insulin was found unmodified during the nanoencapsulation process, due to the large amount of ethanol used in the preparation of the nanocapsules that initiated the polymerization of isobutylcyanoacrylate preserving the peptide from a reaction with the monomer. Results of the  $\zeta$  potential measurements showed that insulin was located inside the core of the nanocapsules and not simply adsorbed onto their surface.

Cyclodextrins and their hydrophilic derivatives were used as solubilizers capable of enhancing the loading capacity of liposomes and microparticles. Two possibilities of using cyclodextrins in the design of colloidal carriers were presented [818]. The first possibility consists of increasing the loading capacity of polyisobutylcyanoacrylate nanospheres prepared by anionic polymerization, by employing hydroxypropyl cyclodextrins. The second possibility consists of the spontaneous formation of either nanocapsules or nanospheres by the nanoprecipitation of amphiphilic cyclodextrin diesters.

An improved method for the preparation of alkylcyanoacrylate nanocapsules was proposed that involved the intermediate synthesis of a well defined adduct of a single monomer unit to an ethanol molecule [819]. It led to thinner capsule walls and, generally, to a more reproducible capsule structure. The chemical composition of the intermediate organic phase was studied by nuclear magnetic resonance spectroscopy. The morphology and size of resulting structures was analyzed, applying analytical ultracentrifugation and light microscopic particle tracking. The sizes of capsules depended on the concentrations of the oil and the monomer components.

Alkylcyanoacrylates were polymerized anionically in water medium at different levels of pH. The effect of pH on the molecular weight and softening points of the polymers was studied [820]. Alkylcyanoacrylates were polymerized in suspension by using the combination of methanol-water, and also by using different catalysts such as triethylamine, diazabicyclooctane, and diazabicycloundecane. The polyacrylates were characterized by infrared and nuclear magnetic resonance spectroscopy. The molecular weight, molecular weight distribution, and the softening points of the polymers were determined.

The possibilities of sterilizing polybutylcyanoacrylate nanoparticle suspensions and lyophilized nanoparticle powders by autoclaving or formaldehyde treatment were evaluated [821]. The nanoparticles were fabricated with different stabilizers. In most conditions a significant increase in particle size was determined after autoclaving of the nanoparticle

suspensions and the nanoparticle powders were characterized by impaired resuspension characteristics.

Because poly(butyl  $\alpha$ -cyanoacrylate) was less toxic than poly(isobutyl  $\alpha$ -cyanoacrylate) and its nanocapsules could be orally absorbed via the intestine wall, polymeric nanocapsules as a drug delivery system of peptides were prepared by the interfacial polymerization of butyl  $\alpha$ -cyanoacrylate [822]. The aqueous phase contained a surfactant such as Tween 20 and polymeric stabilizer such as dextrin T-70, dextrin T-40, as well as Poloxamer 188. The organic phase was composed of monomer butyl  $\alpha$ -cyanoacrylate and a cosolvent such as glycerol trioleate or benzyl alcohol in bulky solvent ethanol or acetone.

A method for the determination of the cyclophosphamide content of polyalkylcyanoacrylate nanoparticles was developed [823]. The analyses were carried out by inductively coupled plasma/atomic emission spectrometry (ICP/AES) by measuring the phosphorus content in the drug. The results obtained were compared with those given by high performance liquid chromatography that permits the detection of the cyclophosphamide molecule, and its degradation products.

The ileal uptake of polyalkylcyanoacrylate nanocapsules (less than 300 nm in diameter) was investigated in the rat [824]. Iodized oil (Lipiodol) was used as the tracer for X-ray microprobe analysis in scanning electron microscopy. Polyalkylcyanoacrylate nanocapsules were able to pass through the ileal mucosa of the rat via a paracellular pathway in the nonfollicular epithelium and, most predominantly, via M cells and adjacent enterocytes in Peyer's patches.

The influence of several media (*in vitro* and *ex vivo*) present in the gastrointestinal tract on the stability of polyisobutylcyanoacrylate nanoparticles was investigated [825]. Polyisobutylcyanoacrylate nanoparticles were proven to be stable in a gastric environment and bioerodable in a simulated intestinal medium. Esterase caused a rapid degradation of the nanoparticles that was proportional to the amount of enzyme added to the medium.

The ability of polyisobutylcyanoacrylate nanocapsules was studied to protect insulin from degradation by proteolytic enzymes providing biologically active insulin by the oral route [826]. Insulin was labeled with Texas Red for release studies and microscopy observations. Turbidimetric measurements and electron microscopy observations confirmed that the nanocapsules were degraded in the reconstituted intestinal medium, whereas nanocapsule integrity was preserved in the reconstituted gastric medium.

Doxorubicin-loaded polybutylcyanoacrylate (PBCA) nanoparticles were prepared by an emulsifier-free emulsion polymerization technique [827]. The pH values of the polymerization medium and the weight ratios of doxorubicin to butylcyanoacrylate had a significant effect on the mean particle size. Drug loading and entrapment efficiency increased with increasing pH of the medium. Doxorubicin-loaded polybutylcyanoacrylate nanoparticles carried a positive charge, and the  $\zeta$  potential of drug-loaded nanoparticles increased with the increase of the polymerization pH. Figure 24 shows a TEM photograph of adriamycin-loaded polybutylcyanoacrylate nanoparticles [828].

**Figure 24.** Transmission electron micrograph of adriamycin-loaded polybutylcyanoacrylate nanoparticles. After [828], J. H. Chen et al., *J. Fourth Military Med. Univ.* 21, 89 (2000) [in Chinese]. © 2000, Fourth Military Med. University, China.

The structure of gas-filled poly-*[n*-butyl-2-cyanoacrylate] (BCA) particles was demonstrated by negative staining with uranyl acetate, platinum-carbon shadowing of air-dried material, and thin sectioning of the aqueous suspension of BCA particles, embedded in water-soluble melamine resin [829]. The polymer shell of the hollow particles possessed a globular outer surface and a smoother inner surface.

A copolymeric nanoparticulate drug delivery system (i.e., copolymerized peptide particles) was developed as a carrier for the oral uptake of therapeutic peptides [830], based on the copolymerization of the active peptide derivative with *n*-butylcyanoacrylate (*n*-BCA), the resulting copolymer being formulated as nanoparticles. The peptide luteinizing hormone releasing hormone was used as a model drug to investigate the viability of the approach. The results demonstrated that chemical conjugation of a peptide within a protective particulate matrix was a viable approach for enhancing oral peptide delivery, presumably utilizing the gut-associated lymphoid tissue as a route of delivery [831]. The mechanism of uptake of biodegradable microparticles in Caco-2 cells was found to be microparticle diameter, concentration, and incubation time and temperature dependent [832]. The small diameter microparticles (0.1  $\mu\text{m}$ ) had significantly greater uptake compared to larger diameter microparticles.

The potency of surface coating liposomes with some materials was investigated for oral delivery of peptide drugs [833]. *In vitro* release of insulin, a model peptide, from liposomes in the bile salts solution was markedly reduced by coating the surface with the sugar chain portion of mucin or polyethyleneglycol. Encapsulation of insulin into mucin or polyethyleneglycol completely suppressed the degradation of insulin in the intestinal fluid, whereas uncoated liposomes suppressed it only partially. These results demonstrated that surface coating liposomes with polyethyleneglycol or mucin gained resistance against digestion by bile salts and increased the stability in the gastrointestinal tract.

Nanoparticles composed of new graft copolymers having a hydrophobic backbone and hydrophilic branches were prepared by the dispersion copolymerization of hydrophilic polyvinyl macromonomers with styrene in a polar solvent

[834]. The potential of these nanoparticles as carriers for oral peptide delivery was investigated using salmon calcitonin in rats. The rate of salmon calcitonin incorporated in nanoparticles was high and was affected by the macromonomer structure. Anionic nanoparticles having poly(methacrylic acid) macromonomer chains on their surfaces showed the highest incorporating activity.

Biodegradable polymer membrane nanocapsules containing hemoglobin were prepared with phase separation and polymer precipitation methods using different polymers including polylactic acid and polyisobutylcyanoacrylate [835]. Preliminary *in vivo* tests showed that surface modified nanocapsules containing hemoglobin can survive longer in the circulation.

W/o/w multiple emulsions composed of medium-chain triglycerides containing insulin with aprotinin, a protease inhibitor, and/or sodium taurocholate, an absorption enhancer, were prepared by a two-step emulsification method at 15 °C [836]. Whatever the nature of the substance introduced in the internal aqueous phase, all the emulsions obtained had very similar properties. The main release mechanism was a swelling-breakdown phenomenon after dilution of the emulsions under hypo-osmotic conditions. These emulsions were able to protect insulin against enzymatic degradation *in vitro*.

Poly(alkylcyanoacrylate) nanocapsules were used as biodegradable polymeric drug carriers for subcutaneous and peroral delivery of octreotide, a long-acting somatostatin analog. Their ability to reduce insulin secretion or prolactin secretion in response to oestrogens was studied in adult male rats [837].

In an *ex vivo* study, the absorption of cyclosporine A on bovine cornea after 24 h contact with various drug delivery systems containing 1% cyclosporine A was evaluated in comparison with an olive oil formulation as the reference vehicle for cyclosporine A [838]. The different formulations studied were poly(acrylic acid) polymeric gels in aqueous/nonaqueous solvents, polyisobutylcyanoacrylate nanocapsules, and a combination of both formulations.

### 6.3.2. Indomethacin/Cisplatin/Calcitonin/Doxorubicine

Indomethacin is an anti-inflammatory drug with serious side effects on the gastrointestinal tract. Encapsulation of the drug into nanocapsules allowed the therapeutic activity of the drug to be maintained while eliminating side effects [839]. Freeze-drying the suspension of indomethacin-loaded nanocapsules provided a dosage form that was stable over several years. The physical stability and inhibitory activity of the indomethacin nanocapsules on inflammation and platelet aggregation were evaluated [840]. The encapsulation of approximately 99% indomethacin within orally administered  $\beta\text{CD-C-6}$  nanocapsules with an average size of 194 nm protected against both gastric and intestinal ulceration was compared with an oral administration of an aqueous solution of Indocid (R) [841]. The relative bioavailability was increased by this encapsulation. PLA nanoparticles containing indomethacin were prepared by interfacial deposition of PLA following acetone displacement from a dichloromethane acetone solution toward an aqueous phase [842].

Indomethacin loaded poly(D, L-lactide) nanocapsules were investigated after intravenous and rectal administration to rabbits [843]. A rebound of indomethacin plasma concentrations attributed to enterohepatic circulation of indomethacin was observed with all preparations. Following i.v. infusions, results showed that the poly(D, L-lactide) nanocapsules altered the pharmacokinetics of indomethacin in ways that accelerated the extravascular distribution by enhancing the capture of the colloidal carrier by the liver and, at the same time, modifying the elimination rate of indomethacin. Bioavailability and tolerance of indomethacin as polymeric nanocapsules in humans were investigated [844].

The capacity for increasing the corneal penetration of drugs was investigated for three different colloidal carriers, namely, nanoparticles and nanocapsules made of poly- $\epsilon$ -caprolactone and submicrometer emulsions [845]. The three systems differed in their inner structure and composition, but with a similar size (200–250 nm) and a negative superficial charge (–16 to –42 mV). Release of the encapsulated indomethacin occurred very rapidly upon high dilution in a buffered medium and was independent of the composition of the system.

Influence of benzyl benzoate as oil core on the physicochemical properties of spray-dried powders from polymeric nanocapsules containing indomethacin was studied [846]. Intestinal toxicity exerted by indomethacin was compared to that induced by copper–indomethacinate, free or associated to zwitterionic phospholipids [847]. A single high dose of indomethacin (15 or 20 mg/kg), copper–indomethacinate (15 or 20 mg/kg), or copper–indomethacinate liposomes or nanocapsules (15 mg/kg) was orally administered. Anti-inflammatory activity of the drugs was investigated using the carrageenan-induced paw edema model. Indomethacin induced penetrating ulcerations of the intestine that were maximal at hour 24.

The loading of drugs into ultrafine host vesicles or colloidal capsules in the nanometer size range was an acknowledged technique for the optimization of controlled drug delivery [848, 849]. Two methods for the determination of cisplatin-loaded polyalkylcyanoacrylate nanoparticles were developed [850]. The analyses were carried out by high performance liquid chromatography (HPLC) with UV detection and results were checked with those obtained by inductively coupled plasma-optical emission spectrometry. A nanocapsule formulation with a hydrophilic core was applied to the oral administration of salmon calcitonin in rats [851].

The preparation from w/o microemulsion of polybutylcyanoacrylate nanocapsules incorporating doxorubicin was optimized applying a multivariate experimental design [852, 853]. Overcoming multidrug resistance with the aid of doxorubicin loaded onto the polyisobutylcyanoacrylate nanoparticles was associated with an increased intracellular drug content [854]. Multidrug-resistance bypass in cells exposed to doxorubicin-loaded nanosphere was studied in the absence of endocytosis [855]. The effect of isobutylcyanoacrylate nanoparticles, in the size range of 100–220 nm, on the disposition of doxorubicin was investigated [856].

### 6.3.3. Poly(D, L-Lactide)

A lipophilic derivative of muramyl dipeptide, muramyl tripeptide cholesterol, was incorporated into poly(D, L-lactide) nanocapsules and its immunomodulating properties were assessed *in vitro*. The nanocapsule form was more effective than the free drug in activating rat alveolar macrophages for a cytostatic effect toward syngeneic tumor cells [857, 858]. The lipophilic compound, a peptidomimetic inhibitor, CGP 57813, of human immunodeficiency virus type 1 (HIV-1) protease, was successfully entrapped into poly(D, L-lactic acid) and pH sensitive methacrylic acid copolymers nanoparticles [859]. The intravenous administration to mice of poly(D, L-lactic acid) nanoparticles loaded with CGP 57813 resulted in a two-fold increase of the area under the plasma concentration–time curve, compared to a control solution. The passage of intact poly(D, L-lactic acid) nanoparticles across the gastrointestinal mucosa appears to be very low. Induction of macrophage *no*-synthase by an immunomodulator entrapped within polymeric nanocapsules was studied [860]. Gastrointestinal tolerance following intravenous and oral administration of poly(D, L-Lactide) nanocapsules containing nonsteroidal anti-inflammatory drugs were investigated [861].

The nanocapsules prepared from poly(D, L-lactide) containing a nonsteroidal anti-inflammatory drug, diclofenac, were formulated and their stability during storage at room temperature was studied [862]. The influence of some factors that could affect stability, namely, the type of oily phase used or/and its concentration, the concentrations of drug and of surfactants, was investigated. The pH of the preparation, the particle size, and the quantity of drug remaining (encapsulated and total), and polymer molecular weight were determined at intervals for up to 8 months after nanocapsule preparation.

Atovaquone and rifabutin had potential therapeutic activity against toxoplasmosis but the low water solubility of these drugs reduced their bioavailability [863]. Their formulation as a colloidal suspension of poly(D, L-lactic acid) nanocapsules increased that effectiveness. The atovaquone formulation was more stable than the rifabutin one and was injected at 15 mg/kg per day by the intragastric route to mice infected with *Toxoplasma gondii*.

The mouse macrophage cell line RAW 264.7 was stimulated to produce nitric oxide by muramyltripeptide cholesterol included within biodegradable poly(D, L-lactide) nanocapsules [864]. The aim was to determine whether one or both of the cytokines transforming growth factor- $\beta$  (TGF- $\beta$ ) and interleukin -10 (IL-10) could be responsible for feedback, control seen at high concentrations.

Biodegradable C-14-poly-(D, L-lactic acid) [PLA(50)] nanoparticles coated either with a readily digestible protein albumin or with a nondigestible coating agent, polyvinyl alcohol (PVA), were prepared by the solvent evaporation technique [865]. The nanoparticles were administered perorally to guinea pigs to evaluate the gastrointestinal degradation of their PLA(50) matrix. In the case of PLA(50) nanoparticles coated with digestible albumin, substantial gastrointestinal degradation of the PLA(50) matrix occurred, leading to the passage of a considerable amount (greater than or equal to 45%) of water-soluble products across the gastrointestinal barrier.

The benzathine penicillin G nanoemulsion and nanocapsules were formulated, their physicochemical and stabilizing characteristics were evaluated, and their antimicrobial activity and penicillin *in vitro* release kinetics were determined [866]. Nanoemulsions were produced by the spontaneous emulsification approach and nanocapsules of poly(D, L-lactic acid-co-glycolic acid) (PLGA) polymer were prepared by the method of interfacial deposition of a preformed polymer.

Several formulations of poly( $\epsilon$ -caprolactone) (PCL), PLA, and PLGA nanocapsules containing phenylbutazone were prepared according to the interfacial deposition technique [867]. These formulations differed in the type of polymer used to form the shell of the nanocapsules. Analysis of particle size distribution and encapsulation efficiency of the nanocapsules revealed that the type and molecular weight of polyester used were the main factors influencing these properties. PLA had the highest encapsulation efficiency with the best reproducibility.

The loading capacity of pentamidine-loaded poly(D, L-lactide) nanoparticles, the factors influencing pentamidine release, and the cytotoxicity of nanoparticles prepared by nanoprecipitation method were reported [868]. Various concentrations of pentamidine base and polymer were tested. The influence of the dilution, temperature, and ionic strength was evaluated. A nonlinear increase in drug uptake per unit mass of polymer with the equilibrium pentamidine concentration was found.

The interactions of naked and surface-modified PLA nanocapsules, where PEG was adsorbed or covalently attached, were studied with a macrophage-like cell line [869]. The fluorescent oil marker, DID, was successfully encapsulated in nanocapsules in order to follow their interactions with cells. The cell-associated fluorescence obtained with PEG-PLA nanocapsules was about 3 to 13-fold lower than that obtained with naked-PLA nanocapsules.

The poly(D, L-lactide) nanocapsules containing bovine serum albumin were prepared by means of a modified w/o/w double-emulsion technology [870]. A mixture of glycerin and water was used instead of the traditional stabilizer system in the preparation of polymeric nanocapsules. The results showed that the high viscosity of the mixture and the hydroxyl group of the glycerin were helpful in the formation of the nanocapsules. The prepared nanocapsules had a similar spherical form.

Lectin poly(lactide) microsphere conjugates specifically designed for oral administration were prepared and their activity and specificity in the presence of mucus were characterized [871]. The presence of hydroxyl or amino groups suitable for covalent coupling of lectins by the glutaraldehyde method at the surface of the microspheres was ensured by preparing the particles in the presence of either PVA or bovine serum albumin (BSA).

Although the oral route for insulin delivery is the most convenient, directly administered oral insulin is degraded by proteolytic enzymes in the gastrointestinal (GI) tract. Poly(lactide) was prepared in order to microcapsulate the insulin to avoid the enzymes in the GI [872]. The poor selectivity of photosensitizers for tumor tissue remains a drawback in photodynamic therapy (PDT) and could be improved by adapted formulations. The cellular uptake,

localization, and phototoxicity of meta-tetra(hydroxyphenyl) chlorin (mTHPC) encapsulated in submicronic colloidal carriers were studied in macrophage-like J774 cells and EFT 29 human adenocarcinoma cells [873]. Nanocapsules with an external layer made of poly(D, L-lactic acid), PLA grafted with polyethylene glycol, PLA coated with poloxamer 188 (polox PLA NCs), and oil/water nanoemulsion were examined.

#### 6.3.4. Poly(ethylcyanoacrylate)/ Isohexylcyanoacrylate/ Dipeptide/ Gangliosides

Biocompatible and biodegradable colloidal drug delivery systems were obtained by means of *in-situ* polymerization of alkylcyanoacrylate [874]. In particular, nanocapsules of PECA were prepared by adding the monomer to an organic phase, consisting of Miglyol 812(R) and an organic solvent (ethanol, acetone, or acetonitrile), and subsequently mixing the organic phase with an aqueous phase containing Pluronic F68(R) at different concentrations. The mechanism of formation and the influence of preparation conditions on the quality of nanocapsule formulations were investigated by freeze-fracture electron microscopy and laser light scattering. The mechanism of drug release from PECA nanocapsules was mainly diffusion from the oil core through the intact polymer barrier. Figure 25a gives a diagrammatic representation of a microdelivery particle and Figure 25b shows PECA nanocapsules containing hydroquinone [875].

Macrophages can become cytotoxic toward tumor cells when activated by immunomodulators. Three different muramyl peptides were synthesized: one hydrolyzable lipophilic ester derivative (MTP-Chol) and two nonhydrolyzable lipophilic ether derivatives (MTP-octadecane and MTP-heptadecafluorooctadecane) [876]. Activation of the RAW 264.7 cell line was studied by measuring nitrite production as an indication of NO-synthase activity. The lipophilic ester derivative, incorporated within nanocapsules, was as active as a free muramyl dipeptide, whereas the lipophilic ether derivatives were unable to activate macrophages. The results indicated that lipophilic muramyl peptides needed to be hydrolyzed to yield a hydrosoluble metabolite in order to activate macrophages.

Poly(ethylcyanoacrylate) nanocapsules suitable for use as drug delivery systems were prepared by *in-situ* polymerization, addition of the monomer to an organic phase, and subsequent mixing of the latter to an aqueous phase containing a nonionic surfactant. Different preparation conditions were able to influence the final poly(ethylcyanoacrylate) nanocapsule colloidal suspension [877].

The drug-loaded polymeric nanospheres were prepared composed of the methoxy PEG (MePEG) and PCL that showed a narrow size distribution and average diameter of less than 200 nm [878]. The nanosphere having a relatively high drug-loading efficiency of about 42% was obtained when the feed weight ratio of indomethacin to polymer was 1:1.

The association with poly(alkylcyanoacrylate) nanospheres and nanocapsules of monosialoganglioside GM1 and other chemically modified gangliosides was investigated with the aim of developing a colloidal drug delivery system

**Figure 25.** (a) Diagrammatic representation of a micro-delivery particle and (b) PECA nanoparticles containing hydroquinone. After [875], R. Arshady, in "Microspheres, Microcapsules and Liposomes," MML Series, Vols. 1 and 2. Citus Books, London, 1999. © 1999, Citus Books.

suitable for use by the oral route [879]. Gangliosides were successfully associated with a biodegradable cyanoacrylic carrier either in the form of nanospheres or as nanocapsules, avoiding any degradation of the ganglioside molecule during the polymerization process. The drug loading was found to be more efficient for nanocapsules.

Antihypertensive effects of a nanocapsular form of darodipine, a dihydropyridine calcium entry blocker, were studied [880]. Two problems were addressed, associated with the use of dihydropyridine calcium entry blockers in antihypertensive therapy, namely, potent vasodilation and short half-lives, by incorporating the representative blocker, darodipine, into a nanocapsular vehicle. The effect of various poloxamer coatings on *in vitro* adhesion of isohexylcyanoacrylate nanospheres to rat ileal segments under liquid flow was investigated [881]. Polyisohexylcyanoacrylate nanocapsules containing cyclosporin were prepared by mixing in a 1:2 ratio an oil/ethanol solution of monomer and drug with an aqueous phase [882, 883]. Drug nanoencapsulation rate was controlled by its partition coefficient between the inner (organic) and outer (aqueous) phases. The biodegradable polyisohexylcyanoacrylate nanoparticles were shown to be able to deliver the growth hormone releasing factor as a sustained-release system [884]. Nanocapsules were prepared by interfacial

polymerization of isohexylcyanoacrylate and coated with poloxamers to reduce the recognition and uptake by reticuloendothelial cells of the liver and spleen [885]. Several phthalocyanine derivatives were encapsulated into nanocapsules and their *in vitro* photocytotoxic activity against V-79 cells was compared to that of free drug. Nanoencapsulation did not reduce the activity of amphiphilic drugs while hydrophilic and lipophilic compounds were affected in diverse ways. Body distribution in mice of intravenously injected radiolabeled cyclosporine associated with polyisohexylcyanoacrylate nanocapsules or nanospheres was studied [886].

The nanoparticle uptake by the rat gastrointestinal mucosa, quantitation, and particle-size dependency were studied [887]. Polystyrene microspheres in the size range 50 nm to 3  $\mu\text{m}$  were fed by gavage to female Sprague Dawley rats daily for 10 days at a dose of 1.25 mg/kg. Histological evidence of the uptake of these particles and their absorption across the gastrointestinal tract and passage via the mesentery lymph supply and lymph nodes to the liver and spleen were confirmed by analysis of tissues for the presence of polystyrene by gel permeation chromatography. Measurement of radioactivity of tissues following administration of 100 nm and 1  $\mu\text{m}$  I-125-labelled polystyrene latex particles for 8 days was corroborative although less secure because of the potential lability of the labelled particles.

### 6.3.5. Poly- $\epsilon$ -caprolactone/Poly(ethylene imine)/Poly(ethylene oxide-*b*-sebacic acid) Polymethylidene/Dodecanoate/Oligonucleotides

Two dialkylmethylidenemalonate (DAMM) analogs, diallylmethylidenemalonate (AAMM) and cyclohexylethylmethylidenemalonate (CEMM), were synthesized and evaluated for their capacity to polymerize to stable nanoparticles and to adsorb primaquine diphosphate [888]. The interaction between polystyrene microspheres and the follicle-associated epithelium of rabbit Peyer's patches was examined [889].

In order to evaluate the concentration of a hydrophilic drug, phenobarbitone, in a suspension of poly- $\epsilon$ -caprolactone nanocapsules, a gas chromatographic-mass spectrometric procedure, performed after methylation of the drug, was developed and validated [890]. Treatment with muramyl dipeptide (MDP) or a lipophilic derivative (MTP-Chol) included in nanocapsules renders macrophages cytostatic toward tumor cells. At the same time, nitric oxide synthase (EC 1.14.23) activity was induced, as determined by measurement of the two end products of the reaction (nitrite and L-citrulline) [891].

In order to evaluate the concentration of a hydrophilic drug, phenobarbitone, in a suspension of poly- $\epsilon$ -caprolactone nanocapsules, a gas chromatographic-mass spectrometric procedure, performed after methylation of the drug, was developed and validated [892]. The preparation of primidone-loaded poly- $\epsilon$ -caprolactone nanocapsules according to the interfacial deposition technique was described [893]. The colloidal suspension obtained showed a monomodal size distribution with a mean diameter ranging from 308 to 352 nm. By adjusting the process parameters,

the encapsulation efficiency was about 74% with good reproducibility. Primidone release from the nanocapsules was found to be slower as compared to the oily control solution despite an important burst effect.

Amphiphilic diblock copolymers composed of MePEG and  $\epsilon$ -caprolactone ( $\epsilon$ -CL) were prepared for the formation of micelles [894]. The copolymer was formed by the ring-opening mechanism of  $\epsilon$ -CL in the presence of MePEG containing hydroxyl functional groups at one end of the chain. To estimate their feasibility as vehicles for drugs, MePEG/ $\epsilon$ -CL block copolymeric micelles were prepared by dialysis against water. Indomethacin was incorporated into the hydrophobic inner core of these micelles as a typical model drug for nonsteroidal anti-inflammatory drugs. From the dynamic light scattering measurements, the size of micelle formed was less than 200 nm, and their size increased with the amount of indomethacin encapsulated into the inner core of MePEG/ $\epsilon$ -CL block copolymers.

The influence of factors (pH, enzymes, etc.) chosen partially to mimic *in vivo* conditions on the release of a model drug, indium oxine, from PCL nanocapsules *in vitro* was determined [895]. A nanocapsule suspension, an emulsion (o/w), and a solution in olive oil were prepared in order to compare the release of a radioactive tracer, indium oxine, as a function of time by an *in vitro* dialysis method. Nanocapsules were prepared by interfacial deposition of PCL and characterized by particle size distribution (laser light scattering) and determination of the polymer molecular weight by gel permeation chromatography.

Nanocapsules of poly- $\epsilon$ -caprolactone and Eudragit S90(R) were prepared by using the spray-drying process using colloidal silicon dioxide as a technological carrier [896]. The morphological analysis of the surface at the powders showed that nanocapsules remained intact, and no change in particle size was detected after the spray-drying process.

Various methods were tested for sample preparation, in order to determine progesterone concentration in nanocapsules consisting of benzyl benzoate in a poly- $\epsilon$ -caprolactone shell [897]. The opening of nanocapsules by a dissolution-dilution in acetonitrile was validated.

The efficacy of colloidal particles as drug carriers is closely related to their interaction with proteins and enzymes in different body fluids [898]. A work analyzed the interaction phenomenon between lysozyme, a positively charged enzyme that was highly concentrated in mucosae, and two different drug carriers: nanocapsules made of an oily core coated by the polymer poly- $\epsilon$ -caprolactone (PECL) and nanoparticles made solely of poly- $\epsilon$ -caprolactone [898]. The interaction of lysozyme with these colloidal drug carriers was highly affected by their surface charge.

Polymethylidene malonate nanoparticles were prepared in phosphate buffer through emulsion polymerization of monomeric units; the kinetics of the reaction was monitored by spectrophotometry at 400 nm. Average nanoparticle sizes, molecular weights, and biodegradability of this potential drug carrier were determined under various conditions [899].

One of the major limiting steps for the absorption of peptide drugs from the intestine is proteolytic degradation. To slow this degradation, human calcitonin was trapped in polyacrylamide nanoparticles, and human calcitonin and

insulin were encapsulated with polyisobutylcyanoacrylate [900]. Human calcitonin trapped in polyacrylamide nanoparticles showed no delayed release characteristics and thus would not provide protection from proteases. Proteolytic degradation of human calcitonin and insulin in polyisobutylcyanoacrylate nanocapsules was slower than the free peptides in solution.

A rapid, sensitive, and selective HPLC assay was developed for the simultaneous determination of ethyl clofibrate and its major metabolite, clofibric acid, in plasma of humans and rats [901]. The assay involves extraction of the compounds into chloroform-isoamyl alcohol (99:1, v/v) from plasma acidified with sulfuric acid. The HPLC assay was used to monitor the plasma concentration-time profiles of ethyl clofibrate released from polylactic nanocapsules in both man and rat. Activity of  $\alpha$ -chymotrypsin immobilized in poly(*N,N*-diallyl-*N,N*-didodecylammonium) bromide nanocapsules was studied [902].

The synthesis and the characterization of a poly(2-methyloxazoline)-block-poly(dimethylsiloxane)-block-poly(2-methyloxazoline) triblock copolymer carrying polymerizable groups at both chain ends were described [903]. This copolymer forms vesicular structures in dilute aqueous solution, the size of which can be controlled in the range from 50 up to about 500 nm. The methacrylate end groups of the triblock copolymer can be polymerized in the vesicular aggregates using an UV-induced free radical polymerization.

A diblock copolymer, poly(ethylene oxide-*b*-sebacic acid), was prepared by polycondensation [904]. Its self-assembly in water via a microphase inversion resulted in narrowly distributed stable polymeric nanoparticles with a size around 70 nm. Such formed nanoparticles had a core-shell nanostructure, with the insoluble hydrophobic polysebacic acid blocks as the core and the soluble hydrophilic polyethylene oxide blocks as the protective shell. The core was degradable, and its degradation led to the disintegration of the nanoparticle. The degradation was a first-order reaction, and the degradation rate increased with the dispersion temperature.

ABA block copolymers of polylactide and poly(ethylene glycol) as amphiphilic bioabsorbable polymers were synthesized by the ring-opening polymerization of DL-lactide onto PEG 2000 or PEG 6000 and their structures were characterized on the basis of proton NMR. Biodegradable nanocapsules of an aqueous insulin solution were prepared from the block copolymers and polylactide by an improved interfacial coacervation technique [905]. The diameters of the nanocapsules were mainly dependent on the ratio of the two chains in the block polymers. The size of the nanocapsules decreased with an increase in the amount of surfactant used. More insulin solution resulted in an enlargement of the nanocapsules in diameter.

Poly(ethylene imine) was used for the complexation of dodecanoic acid resulting in a poly(ethylene imine) dodecanoate complex with a lamellar nanostructure and a repeat unit of 2.9 nm [906].

Antisense oligonucleotides are molecules that are able to inhibit gene expression being therefore potentially active for the treatment of viral infections or cancer. Antisense oligonucleotides with base sequences complementary to a

specific RNA can, after binding to intracellular mRNA, selectively modulate the expression of a gene. However, because of their poor stability in biological medium and their weak intracellular penetration, colloidal drugs carriers such as nanoparticles were developed for the delivery of oligonucleotides [907]. Oligonucleotides associated to nanoparticles were shown to be protected against degradation and to penetrate more easily into different types of cells. As a consequence, nanoparticles were shown to improve the efficiency of oligonucleotides for the inhibition of the proliferation of cells expressing the point mutated Ha-ras gene. Nanocapsules were prepared by interfacial polymerization of isobutylcyanoacrylate in a w/o emulsion [908]. A nanotechnology was said to be able to encapsulate oligonucleotides, rather than adsorbing them at the surface of a solid support, which had great potential for oligonucleotide delivery.

EWS Fli-1, a fusion gene resulting from a *t*(11;22) translocation, was found in 90% of both Ewing's sarcoma and primitive neuroectodermal tumor. The polyisobutylcyanoacrylate nanocapsules with an aqueous core were able to encapsulate efficiently high amounts of phosphorothioate oligonucleotides directed against EWS Fli-1 chimeric RNA [909].

### 6.3.6. Ocular

In order to reduce the lacrimal elimination and to increase the intraocular penetration of betaxolol after ocular administration, a drug carrier was prepared, polycaprolactone nanocapsules, containing betaxolol in the base form, which was applied in the medical treatment of glaucoma in rabbits [910–912]. Reduction of cardiovascular side effects associated with ocular administration of metipranolol by inclusion in polymeric nanocapsules was investigated [913]. Antimetastatic activity *in vivo* of MTP-Chol entrapped in polyisobutylcyanoacrylate nanocapsules was studied [914]. With the aim of exploring the potential of poly( $\epsilon$ -caprolactone) nanocapsules as drug carriers for ocular administration, the mechanism of interaction of these nanocapsules with the corneal and conjunctival epithelia was examined [915]. Ocular penetration of 1% cyclosporine A from nanocapsules and conventional formations in rabbit eyes was studied [916]. Topical application of nanocapsules of cyclosporine A on a penetrating keratoplasty rejection model was developed [917].

A research program was initiated to assess the ability of nanospheres to improve the biodelivery of active ingredients to plants [918]. The goal was to obtain stable poly( $\epsilon$ -caprolactone) nanospheres with the smallest size and the largest amount of encapsulated active ingredients, using a nanoprecipitation method.

Chitosan-coated and poly-L-lysine-coated poly( $\epsilon$ -caprolactone) nanocapsules were designed based on a strategy that combines the features of poly( $\epsilon$ -caprolactone) nanocapsules as ocular carriers with the advantages of a cationic mucoadhesive coating and their capacity for increasing the corneal penetration of drugs investigated [919]. The ability of different drug carriers to improve the ocular bioavailability of drugs was investigated in the rabbit eye [920]. The assayed drug carriers were suspensions of nanoparticles, nanocapsules, and microparticles made

of poly( $\epsilon$ -caprolactone) and a submicrometer emulsion. Polyester nanocapsules as new topical ocular delivery systems for cyclosporin A were developed [921–923]. The nanocapsules are an interesting alternative to the olive oil solution or ointments for the delivery of cyclosporin A to the eye [922].

Uptake of cyclosporine A loaded colloidal drug carriers by mouse peritoneal macrophages *in vitro* was studied [924]. The [H-3] cyclosporine A loaded colloidal particles, polylactic acid nanospheres, polylactic acid nanocapsules, and microemulsions, were prepared. The [H-3] cyclosporine A loaded colloidal particles were incubated with MPM for 30 min at 31 °C, then the cells were separated from the colloidal particles and the radioactivity was measured by a liquid scintillation counter.

Efficacy of topical cyclosporine A-loaded nanocapsules on keratoplasty rejection in the rat was evaluated [925]. Cyclosporine A formulated in migliol oil delayed corneal rejection onset, but blood levels were evident in this group. Cyclosporine A-loaded nanocapsules showed no effect on rejection and the drug was not detectable in blood.

Acyclovir-loaded polyethyl-2-cyanoacrylate (PECA) nanospheres were prepared by an emulsion polymerization process in the micellar phase and characterized [926]. The influence of the presence of nonionic surfactant as well as other substances [i.e., 2-hydroxypropyl- $\beta$ -cyclodextrin (HP- $\beta$ -CyD) and PEG] on formulation parameters and loading capacity was investigated. The presence of PEG resulted in an increase of mean size and size distribution. Ocular tolerability of PEG-coated PECA nanospheres was evaluated by the *in vivo* Draize test. The acyclovir-loaded PEG-coated PECA nanospheres showed a significant ( $p < 0.001$ ) increase of drug levels (25-fold) in aqueous humor compared with the free drug or the physical mixture.

The anatomical, physiological, and pharmacological properties of the eye explain the short precorneal residence time and the poor bioavailability of most eyedrop solutions [927]. Many approaches were proposed to increase ocular bioavailability of drugs. Most eyedrops included a viscosity agent in their formulation to significantly prolong residence time although the increased viscosity was limited due to patient discomfort. The developments included biodegradable inserts, eyedrops based on cyclodextrins, liposomes, or nanoparticles.

### 6.3.7. In Vitro/In Vivo Studies

The influence of three different enzymes (amylase, pepsin, and esterase) on the stability of polybutylcyanoacrylate nanoparticles was studied as an *in vitro* investigation using side-by-side diffusion cells [928]. *In vitro* resistance of tumor cells to doxorubicin was fully circumvented by using doxorubicin-loaded nanospheres, consisting of biodegradable polyisohexylcyanoacrylate polymers of 300 nm diameter and containing 2.83 mg of doxorubicin per 31.5 mg of polymer [929]. The *in vitro* release kinetic pattern of indomethacin from poly(D,L-lactide) nanocapsules was studied [930]. *In vivo* evaluation of polyisobutylcyanoacrylate microparticles containing fluorouracil was performed [931]. Effect on cerebral blood-flow, jejunal absorption,

and pharmacological activity and pharmacokinetic evaluation of orally administered indomethacin-loaded polyisobutylcyanoacrylate and poly(D,L-lactide) nanocapsules were investigated [932, 933]. The biliary clearance and enterohepatic circulation of indomethacin in the rabbit was examined [934]. Nanocapsules were used as carriers for oral peptide delivery [935].

Preparation methods of cyanoacrylic nanocapsules or nanoparticles containing phthalocyanines and naphthalocyanines were described [936]. Nanocapsules were obtained by interfacial polymerization in an oil-in-water emulsion. Drug encapsulation efficiency depended on drug concentration, ethanol concentration, and phthalocyanine sulfonation degree and reached 100% in some cases.

Poly(lactic acid) nanocapsules of clofibrate containing soybean oil or medium-chain triglycerides as the oil core were prepared [937]. The *in vitro* drug release kinetic profiles were determined and compared to those of a clofibrate sub-micron emulsion using two different kinetic techniques: the bulk equilibrium reverse dialysis sac technique and the centrifugal ultrafiltration technique.

The physical and chemical properties of tramcinolone acetonide nanocapsules, prepared by interfacial polymerization of isobutyl-2-cyanoacrylate at the oil/water interface, were studied [938]. The joint effect of monomer and oil in organic phase on the size and encapsulation efficiency was analyzed. Polymer coating around the oil droplets caused an important variation in droplet size and encapsulation efficiency. The release of drug from the nanocapsules was investigated *in vitro*.

A pharmaceutical form of atovaquone was developed and its activity against *Toxoplasma gondii* was studied *in vitro* and *in vivo* [939]. Nanocapsules were chosen as the oral dosage form of administration. The *in vitro* activity of atovaquone-loaded nanocapsules against tachyzoites of *T.gondii* (RH stain) was comparable to its suspension form. *In vivo* studies were carried out in murine models of acute and chronic toxoplasmosis. The sensibility of *T.gondii* to atovaquone was different according to the strains and the fact that the activity of atovaquone in the treatment of toxoplasmosis was enhanced when administered in nonparticulate form.

### 6.3.8. Reviews

The nanoparticles are colloidal polymeric drug carriers that hold promise for peroral drug delivery. The peroral administration of nanoparticles was reviewed [940]. Nanoparticles were retained in the gut of rats and mice in small quantities for substantial time periods (up to 6 days). They were taken up in particulate form in the intestine and appeared in the lymph nodes, blood, liver, spleen, and sites of inflammation in the body. Three possibilities in the mechanism of uptake were discussed: (1) intracellular uptake; (2) intercellular/paracellular uptake; and (3) uptake via the M-cells and Peyer's patches in the gut. The uptake was size-dependent; smaller particles were taken up to a higher degree than larger particles. Binding to nanoparticles enhanced the peroral bioavailability of a number of drugs, and a significantly enhanced and prolonged pharmacological activity by binding to nanoparticles was reported for insulin and hydrocortisone.

Nanoparticles and microparticles for the delivery of polypeptides and proteins [941, 942], and for ocular delivery [943] were reviewed. The main objective for these systems was to improve the classical aqueous eyedrop formulations that have major disadvantages like rapid elimination of drugs from the precorneal area. Consequently, colloidal carrier suspensions were designed to combine ophthalmic prolonged action with ease in application of liquid eyedrops. The review summarized the manufacturing methods and the materials used for these delivery systems with respect to ophthalmic purposes. The distribution and penetration pathways of the particulate delivery systems were described. The applications of drug-loaded particles were presented with focus on ophthalmic diseases like glaucoma, inflammations, or infections of the eye. Accordingly, particulate carriers, outlined in the review, included systems loaded with pilocarpine,  $\beta$ -blockers, hydrocortisone, amikacin, and miscellaneous drugs.

The applications of electron microscopic techniques to the characterization and evaluation of drug delivery systems were reviewed [944]. Various EM related techniques such as TEM, SEM, SEM with energy dispersive X-ray microanalysis, and freeze-fracture electron microscopy were extensively used for this purpose. Microcapsules, microspheres, nanocapsules, liposomes, polymeric carriers, and other drug delivery systems were characterized using EM related techniques for their surface topography, size and shape analysis, biodegradation, *in vitro-in vivo* evaluation, and drug excipient interactions and characterization. EM methods are very useful in understanding the mechanism of drug carrier formation, drug release in *in vitro-in vivo* situations, and drug carrier-body fluid interactions, and in studying ultrastructural disposition of drug carriers in body compartments.

A review focused on the gastrointestinal bioadhesion of micro- and nanoparticles [945]. Bioadhesion was obtained by the building of either nonspecific interactions with the mucosal surface, which were driven by the physicochemical properties of the particles and the surfaces, or specific interactions when a ligand attached to the particle was used for the recognition and attachment to a specific site at the mucosal surface. The relative merits of those systems were discussed. Their fate in the gastrointestinal tract, including three different pathways, (i) bioadhesion, (ii) translocation through the mucosa, and (iii) transit and direct fecal elimination, was presented.

The techniques available to prepare biodegradable nanoparticles (nanospheres and nanocapsules) from preformed polymers were reviewed [946]. Four techniques were discussed in terms of their technological advantages and drawbacks: emulsification evaporation, solvent displacement, salting-out, and emulsification diffusion. The proposed mechanism of nanoparticle formation for each technique was described from a physicochemical perspective. The effects of preparative variables on nanoparticle size and drug-entrapment efficiency were discussed.

Microparticulate delivery systems, potential drug/vaccine carriers for poorly bioavailable drugs and vaccines via mucosal (particularly oral) routes, were reviewed [947]. A variety of therapeutic moieties, including peptides and proteins, show enhanced oral uptake when entrapped within various types of microparticulate system constructs, and this

approach was used successfully for the oral, nasal, and rectal delivery of a variety of vaccines. As drug-delivery technology becomes more sophisticated and our understanding of the uptake and immunological mechanisms of mucosal sites becomes more defined, many further microparticulate constructs would emerge and demonstrate their potential.

The contribution of Francis Puisieux and his group to one of the greatest challenges in pharmaceutical science, namely, the development of an oral dosage form for insulin, was reviewed [948]. This review traced their work with liposomes, multiple emulsions, and nanoparticles as insulin vehicles for oral delivery.

Steroid receptors and immunophilin relationships in hormone-dependent cancers, use of long-circulation anti-steroid hormone and/or immunosuppressant carriers as a promising therapeutic approach, were reviewed [949]. General aspects of nanocapsules used in drug delivery systems were reviewed from both a physicochemical and a therapeutic point of view [950]. The preparation methods, ways to characterize this o/w system (size, surface, density, release, stability), and the influence of encapsulation within nanocapsules on the biological activity of numerous drugs were described. Among the indications for the therapeutic use nanocapsules, one can cite solubilization of poorly water-soluble drugs, protection of drugs from inactivation in the gastrointestinal tract, protection of mucosa from the toxicity of drugs, increased permeation of drugs through mucosal surfaces, and prolongation of the blood circulation of injected drugs.

The use of colloidal carriers made of hydrophilic polysaccharides (i.e. chitosan) arose as a promising alternative for improving the transport of such macromolecules across biological surfaces. The approaches aiming to associate macromolecules to chitosan in the form of colloidal structures were reviewed and the evidence of their efficacy in improving the transport of the associated molecule through mucosae and epithelia was analyzed [951]. Chitosan was shown to form colloidal particles and entrap macromolecules through a number of mechanisms, including ionic cross-linking, desolvation, or ionic complexation, though some of these systems were realized only in conjunction with DNA molecules. An alternative involving the chemical modification of chitosan was useful for the association of macromolecules to self-assemblies and vesicles. The *in vivo* efficacy of these chitosan-based colloidal carriers was reported for two different applications: while DNA-chitosan hybrid nanospheres were found to be acceptable transfection carriers, ionically cross-linked chitosan nanoparticles appeared to be efficient vehicles for the transport of peptides across the nasal mucosa.

The progress in the development of biodegradable nanoparticulate systems, including nanospheres, emulsions, and liposomes, was reviewed [952]. The major purpose of lymphatic targeting was to provide an effective anticancer chemotherapy to prevent the metastasis of tumor cells by accumulating the drug in the regional lymph node via subcutaneous administration. The objectives of lymph targeting involved the localization of diagnostic agents to the regional lymph node to visualize the lymphatic vessels before surgery, and the improvement of peroral bioavailability of macromolecular drugs, like polypeptides or proteins. The

*in vivo* study proved that polyisobutylcyanoacrylate nanocapsules showed enhanced accumulation of drug in the lymph node, compared with other carriers such as emulsions and liposomes.

Cyclosporin eyedrops allow local immunoregulation without systemic side effects and are an alternate to local steroids. Specific problems of product setup and clinical studies were reviewed [953]. The main problems in eyedrop preparation are sterility, pH, particles, and lipophilic properties. Numerous excipients were tested including oil solvents, alphacyclodextrin, collagen shields, liposomes, and polyester nanocapsules, but documentation on stability of the molecule was inadequate.

Acrylic nanoparticles for ocular drug delivery were developed [954]. The efficacy of ophthalmic drug delivery systems was governed by their ability to increase the ocular residence time. Several attempts were made to minimize the rapid and extensive precorneal loss of the administered drug. Besides the application of eyedrops with an enhanced viscosity, ocular inserts or soft contact lenses, and colloidal drug carriers, such as nanoparticles or nanocapsules as well as microspheres, were evaluated as ophthalmic delivery systems. In general, acrylic acid derivatives like polyalkyl cyanoacrylates and polyalkyl methacrylates were used for the preparation of drug carrier particles in the size range between 200 and 500 nm. That reviewed summarized the preparation methods of acrylic nanoparticles and their application in several *in vitro* and *in vivo* systems. The pharmacokinetic and pharmacodynamic effects after the application of drug-loaded nanoparticles to rabbit eyes were compared to conventional eyedrop preparations.

The nano/microparticles as drug delivery devices were reviewed [955]. The principal studies where peptide-loaded particles were administered by the oral route were reviewed [956]. The preparation methods and *in vitro* trials were presented and *in vivo* results were discussed with emphasis placed on the peptide blood levels reached or on the biological effects observed.

The advantages and disadvantages of the nanocapsules used in the drug delivery are as follows: There are many similarities between liposomes and nanoparticles. They are similar in size and thus are often used for similar purposes, and both have many advantages and disadvantages. Liposomes have the advantage of primarily consisting of lecithin and cholesterol, which are materials that occur naturally in the human body. Lecithin and cholesterol are also present in the body in large amounts and thus demand good bioacceptability. Nanoparticles or nanocapsules have the advantage of being more stable. Many types of drug targeting depend on good stability. A better penetration of the particles inside the body following administration, as well as longer shelf storage life, has several benefits of the good stability of nanoparticles. Artificial or natural polymers are the primary constituents of nanoparticles. Polymers are usually restricted by their bioacceptability. The bioacceptability is affected by the polymer and the supplementary components, as well as by particle size. A reduction in the particle size of the polymeric particles has many advantages: (1) Intravenous injection can be allowed if there is a decrease in the particle size. (2) Intramuscular and subcutaneous distribution require small particle size. (3) Irritant reactions at

**Figure 26.** Water-soluble polyelectrolyte nanocapsules prepared by use of vesicular polymerisation, which undergo a reversible swelling process on changing pH and/or salt concentration, mimicking certain biological processes. After [1035], M. Sauer and W. Meier, *Chem. Commun.* 1, 55 (2001). © 2001, Royal Society of Chemistry.

the injection site are minimized by using small particle size. (4) Cancerogenic effects depend on particle size. Choosing the appropriate polymer, particle size, and method of production would depend on three major aspects: bioacceptability of the polymer, physicochemical properties of the drug, and the type of therapy the drug should have. Recent advances and many other studies on drug delivery and controlled release are found in the literature [957–1034]. Figure 26 shows water-soluble polyelectrolyte nanocapsules prepared by use of vesicular polymerization, which undergo a reversible swelling process on changing pH and/or salt concentration, mimicking certain biological processes [1035].

## 7. CONCLUDING REMARKS

A comprehensive review has been given of the advances in the area of nanocapsules. The outline of the theoretical background, including the energy levels, the quantum effects, the magic effects, the surfaces/interfaces, and the metastable phases in nanocapsules have been represented. The most applicable nanoencapsulation procedures, including physical, chemical, physicochemical, and mechanical techniques, have been introduced. The physical properties, including optical, electronic, magnetic, and dynamic properties, and the biomedical properties, including artificial cell and red blood cell substitutes, drug delivery, and controlled release, have been reviewed for nanocapsules.

Nanocapsules are the matter in intermediate states between bulk and atomic materials which offer a model system for investigation of the dimensionally confined systems in basic research areas. Nanocapsules have physical properties that differ distinctly from those of bulk materials. As a small limited system, three of the physical dimensions of nanocapsules could approach a length-scale characteristic of a physical phenomenon (with different phenomena being characterized by different length scales), and similarly in the time domain. The quantum size effects could contribute evidently to the properties, which originate mainly from the discreteness of the energy levels, and the breakdown of the

cyclic condition and the translation symmetry in the limited systems. The effects of the quantum interference, the magic number, the surfaces/interfaces, the core/shell structure, the metastable phases, etc. cannot be neglected in nanocapsules. Depending on the size, the shape, the core/shell structure, etc., the properties of nanocapsules could be very different individually, ranging from metals, insulators, and semiconductors, to optical absorption, magnetic hardening, etc.

Sufficiently small materials could aggregate sensitively to various shapes and nanostructures, which could change the properties of the materials. Spontaneous shape selection occurs in the mesoscopic systems, originating from the ability of finite systems to adjust their shape and structure in order to minimize the free energy of the systems. The small size is beautiful also due to the fact that mesoscopic systems could be designed and constructed artificially which would be so different with those formed naturally. It is clear that the properties of the nanocapsules depend sensitively on the procedures for sample preparation.

The different nanocapsules can be prepared by various methods with different mechanisms, which could control the size, the size distribution, the morphology, phases, and structure of the nanocapsules, the thickness of the shell, the size of the grains, etc. Some methods may be suitable for synthesis of only some typical nanocapsules. The most applicable nanoencapsulation procedures include: physical methods such as heat evaporation, arc discharge, laser/electron beam heating, sputtering, etc.; chemical methods such as chemical vapor deposition, solid-state reactions, sol-gel, precipitation, and hydrothermal, solvent, latex, oxidation, polymerization, processes etc.; physicochemical methods such as coacervation-phase separation, etc.; mechanical methods such as air suspension, pan coating, spray-drying and congealing, and multiorifice centrifugation.

Nanocapsules are designed to have a therapeutic action to release drugs in the right place or to have functionality to attack and reduce cancerous cells. Although many applications have not been investigated yet, current developments are becoming increasingly more useful in the field of medicine. Nanocapsules have been intensively studied not only because of the possibilities for controlled release, but also because of increased drug efficacy and reduced toxicity after parenteral administration. The nanocapsules have been formulated into a variety of useful dosage forms including oral liquid suspensions, lotions, creams, ointments, powders, capsules, tablets, and injections. Nanoencapsulation has been applied to solve problems in the development of pharmaceutical dosage forms as well as in cosmetics for several purposes including conversion of liquids to solids, separation of incompatible components in a dosage form, taste-masking, reduction of gastrointestinal irritation, protection of the core materials against atmospheric deterioration, enhancement of stability, and controlled release of active ingredients. Their pharmacological effect has been improved or their secondary effects reduced compared with free drugs after administration by oral, parenteral, or ocular routes. The nanocapsules have been found also to be suitable as biodegradable drug carriers for the administration and controlled release of drugs, like insulin, indomethacin, calcitonin, doxorubicine, gangliosides, oligonucleotides, etc.

Another major activity in the application of the nanocapsules has been focused on the topics of artificial cell and red blood cell substitutes. This is beneficial to the formulation of polymeric artificial nanocapsules, which can be made in a reproducible manner having a specific size and shape and in reasonable quantities. Artificial cells for pharmaceutical and therapeutic applications has been expanded up to the higher range of macrocapsules and down to the nanometer range of nanocapsules and even to the macromolecular range of cross-linked hemoglobin as blood substitutes. Artificial cells have been prepared by bioencapsulation in the laboratory for medical and biotechnological applications. The three generations of blood substitutes have been developed based on an original idea of a complete artificial red blood cell.

Basic research of the structure and properties of the nanocapsules and related issues (like nanotubes [1036–1046]) underlies future technologies, from nanoscale machines, nanotribological systems, cellular injections, and nanocatalysis, to miniaturization of electronic circuitry and novel information storage and retrieval systems. Furthermore, the nanoencapsulation process has been successfully applied to many industries as follows: as controlled-release systems of drugs and bioactive agents in pharmaceuticals; as creams, lotions, and fragrance in cosmetics; microgranules with protective colloids, fertilizers, insecticides, herbicides, microporous capsule walls for controlled release in agriculture; envelope manufacture using microencapsulated glues in adhesives; pigment presscakes, metal phosphate complex microcapsules, encapsulated aluminum flake pigments in pigments; encapsulation of heterogeneous catalysts, spherical alumina-containing particles, dual-walled hard microcapsules, hollow-ceramic-coated spheroid catalyst carriers in catalysts and catalyst carriers; photographic printing, light reflective dye-containing capsules for photographic film; food; paper; plastic; and others, such as microcapsulated liquid lubricants, chemiluminescent warning capsules, encapsulated thermonuclear fuel particles, encapsulated flame retardants, encapsulated liquid explosive compositions, and microcapsulated vulcanizing agents. Due to the length limit of this chapter, we could not have collected all the research work and applications in the fields above. Nevertheless, we are optimistic that nanocapsules as well as nanoencapsulations will be one of the most active fields in nanoscience and nanotechnology. Many novel nanocapsules will be synthesized by many novel procedures which will possess many novel properties that are helpful for a better understanding of the physical phenomena and natural rules in the mesosystems and are applicable in many novel fields and industries.

## GLOSSARY

**Coating** Process of forming the core/shell structures for nanocapsules, which may differ depending on different synthetic methods.

**Core/shell structures** Special structures of a nanocapsule, where the shell can be referred to as a membrane, a wall, a covering, or a coating, while the internal core can be defined as payload, core, encapsulant, fill, active ingredient, IP, or internal ingredient.

**Nanoencapsulations** Processes of encapsulating/coating nanoparticles to form nanocapsules.

**Nanocapsules** Capsules of nanometer size (i.e.,  $10^{-9}$  m), normally composed of a core and a shell that are made of different materials.

**Nanoparticles** Particles of nanometer size (i.e.,  $10^{-9}$  m), normally without a core/shell structure.

References

## 1. INTRODUCTION

In the Middle Ages, Jabir Ibn Haiyan, known by the name of the alchemist Geber, paved the way to modern catalysis, and in the beginning of the 19th century, Berzelius defined for the first time the term catalysis [1]. Fritz Haber introduced the important catalytic formation of ammonia at the end of the 19th century [2]. This process allowed the synthesis of fertilizer and explosives on a large scale, and accelerated industrialization in the western world. Today, the introduction of fertilizers still leaves traces in nature, as manifested in the sudden increase of annual rings in old trees. Most catalytically active materials are obtained by trial and error. Since 1960, however, a molecular understanding of catalytic processes has been emerging. The characterization of the active parts in a catalyst is mainly influenced by the resolution of the analytical instruments in use. Today, nanoprobe are capable of seeing single atoms, and thus, examples are emerging where very small clusters are responsible for the catalytic action. Nellist and Pennycook reported that clusters of two and three Pt atoms exist in industrial, naphtha-reforming catalysts [3]. Thus, catalysts in the nanoscale may have been present since the time of Geber, but could not have been detected with the analytical schemes of those days.

Here, we define nanocatalysis when two important conditions are fulfilled. First, the valence electrons of the active part of a nanocatalyst are highly confined, leading to physical and chemical properties nonscalable from bulk properties.

This condition is true for clusters/particles in the nanometer length scale or smaller. Second, nanocatalysts are designed in a controlled manner. The exploration of material properties in the nonscalable regime has profound consequences. Atomic clusters, for example, exhibit unique size-dependent electronic [4, 5], magnetic [6, 7], and chemical properties [8] that differ from those of bulk materials. In contrast to supported particles of larger size or extended solid surfaces, small clusters adsorbed at specific sites of a support material change their intrinsic properties to a large extent, in particular when charging of the cluster occurs. Nanocatalysts exhibit remarkable quantum size effects and structural fluxionality. This opens new avenues for the atom-by-atom design of nanocatalysts whose chemical activity, specificity, and selectivity can be tuned by controlling the cluster size, through the incorporation of impurity atoms, and via manipulation of the strength of the cluster-support interaction, the degree of charging of the cluster, and by changing their magnetic properties. In a completely different approach, catalytic reactions can be induced by nanodevices, where the energy of the localized electrons inducing the reaction can be tuned by changing the potential of the device. An example is the use of an STM tip in close contact with the reactants. In this review, we present some studies on model systems for nanocatalysts. With such systems, the complexity of working nanocatalysts can be reduced, and in many cases, simple reaction steps can be identified. It has to be pointed out that, in this review, we use the expression "catalysis" when a chemical reaction is catalyzed by a nanoscale system. We are aware, however, that none of the systems/methods presented here was tested to withstand the harsh conditions of real catalysis. We feel, though, that such studies are extremely important for developing guiding principles in nanocatalysis.

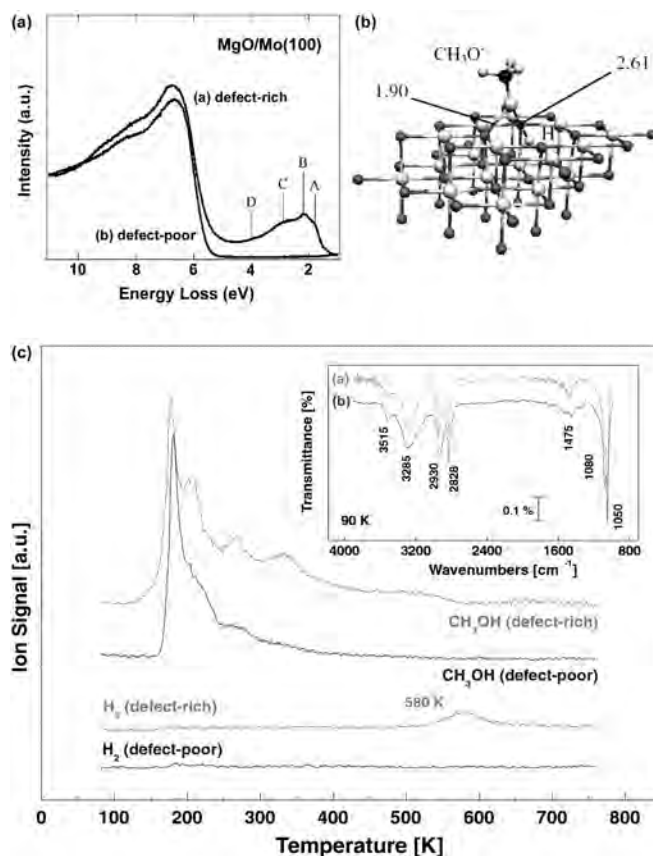

## 2. CHEMICAL REACTIONS ON POINT DEFECTS OF OXIDE SURFACES

In a recent review, Pacchioni presented a detailed classification of point defects on the surfaces of oxide materials [9]. He described at least four major kinds of irregularities: low-coordinated sites, divacancies, impurity atoms, and surface

vacancies. The last category includes cation vacancies, usually called V centers, as well as oxygen vacancies, which are called color centers or F centers (from the German word for “color”—“Farbe”). In a broader sense, an F center is defined as an electron trapped in an anion vacancy, and was first introduced to explain chemical- and radiation-induced coloration of alkali halides. In bivalent oxides, like MgO and CaO, two types of F centers exist. The vacancy containing two electrons is called the F center, and the one containing only one electron is labeled the  $F^+$  center. In both vacancies, the electrons are confined by the Madelung potential of the crystal. Thus, in a first approach, the  $F/F^+$  centers can be described as two/one electrons moving in a quantum box of nanometer length scale, that is,  $F/F^+$  centers are systems with highly confined electrons, and with our definition, they are examples of nanocatalysts.

The unique chemical activity of F centers has been demonstrated recently. In a combined theoretical and experimental study, it was shown that the heterolytic breaking of methanol on MgO thin films is catalyzed by surface oxygen vacancies [10]. In these films, the oxygen vacancies are generated by changing the preparation method [11], for example, the Mg evaporation rate and the oxygen background pressure. In this way, two kinds of films are prepared: defect-poor (Mg evaporation rate: 0.3–0.5 ML/min,  $O_2$  background:  $5 \cdot 10^{-7}$  torr) and defect-rich (Mg evaporation rate: 2–5 ML/min,  $O_2$  background:  $10^{-6}$  torr) films. Both films are annealed to 1200 and 840 K during 10 min, respectively. Auger electron spectroscopy (AES) measurements show a one-to-one stoichiometry for magnesium and oxygen and the absence of any impurity [12]. Typical thicknesses are about ten monolayers, as determined by AES peak intensities [12] and by X-ray photoemission (XPS), using the intensity attenuation of the Mo 3d core level with increasing film coverage [13]. Both films have also been studied by electron energy loss spectroscopy [13]. In contrast to defect-poor films, which are characterized by a loss at about 6 eV in the EEL spectra (Fig. 1a, in good agreement with previous studies on MgO(100) single crystals [14]), the EEL spectra of defect-rich films exhibit characteristic losses between 1 and 4 eV, lying within the MgO bandgap (Fig. 1a). Similar loss structures have been observed before [15], and according to first-principle calculations using large cluster models, they have been attributed to transitions, characteristic of neutral surface F centers in various coordinations on flat terraces, at steps, and at kinks [16]. The density of these oxygen vacancies is estimated to be larger than  $5 \times 10^{13}/\text{cm}^2$ .

The interaction of methanol with the defect-poor and defect-rich films was studied using thermal desorption spectroscopy (TDS) (Fig. 1c). For both films, the desorption of physisorbed methanol at around 180 K is most dominant. On the defect-poor films, small amounts of chemisorbed methanol desorb up to around 350 K. On defect-rich films, the desorption of chemisorbed methanol evolves in three distinct peaks at 200, 260, and 340 K. A small reproducible feature is observed at around 500 K. Most important,  $H_2$  desorbs at 580 K only on defect-rich films. The corresponding infrared spectra taken at 90 K (insets of Fig. 1c) confirm the presence of mainly physisorbed  $CH_3OH$  with the typical vibrational band for the OH group at  $3285\text{ cm}^{-1}$ , bands of the symmetric C–H stretch ( $2930\text{ cm}^{-1}/2828\text{ cm}^{-1}$ ) and

**Figure 1.** (a) EEL spectra of thin defect-poor and defect-rich MgO(100) films grown on Mo(100) at different experimental conditions (see text). A–D are losses, which are attributed theoretically to transitions characteristic of neutral F centers on MgO. (b) Model of an oxygen vacancy at a terrace of a MgO(100) surface with chemisorbed  $CH_3-OH$  ( $CH_3O^-H^+$ ). (c) Thermal desorption spectra of  $CH_3OH$  and  $H_2$  on defect-poor and defect-rich MgO(100) films. Note the desorption of  $H_2$  at 580 K for defect-rich films. The insets show FTIR spectra recorded at 90 K for adsorbed  $CH_3OH$  on both defect-poor and defect-rich films.

the C–H bending ( $1475\text{ cm}^{-1}$ ) modes of the  $CH_3$  group, as well as the C–O vibrational mode at  $1080\text{ cm}^{-1}/1050\text{ cm}^{-1}$ . For defect-poor films, most of the intensity of the vibrational bands disappears between 180 and 200 K, consistent with the desorption observed at 180 K in the TDS. Up to temperatures of about 400 K, small bands are observed for the  $CH_3$ - and C–O bands. Their intensity is decreasing with temperature. These bands are attributed to chemisorbed methanol. As for the defect-rich films, the evolution of the IR spectra with temperature is consistent with the corresponding TDS. Physisorbed methanol desorbs before 200 K (disappearance of the OH band), and the more intense vibrational features of chemisorbed methanol are unambiguously detected up to 360 K. At higher temperatures, a clear peak is observed at  $1070\text{--}1085\text{ cm}^{-1}$  [10]. It is interesting to note that the disappearance of this band correlates with the desorption of  $H_2$  from the surface at around 580 K, and therefore this peak is attributed, in accordance with theoretical studies, to a proton trapped in the cavity of an F center. The calculations show that F centers easily dissociate methanol, giving

a  $\text{CH}_3\text{O}$  group and an  $\text{H}^+$  ion adsorbed into the F center. This adsorbed proton is strongly bound as the dissociation of a neutral H atom,  $\text{F}_s/\text{H}^+ \rightarrow \text{F}_s^+ + \text{H}^\bullet$ , costs 4.1 eV. This represents a crude estimate of the barrier to overcome in order to observe  $\text{H}_2$  desorption from the surface. Once the H atom is detached from the  $\text{F}_s$  center, it will rapidly diffuse on the surface. In fact, the binding of an H atom to an  $\text{O}_{\text{sc}}$  ion on a terrace is about 0.5 eV. Diffusion will eventually lead to recombination with a second H to form  $\text{H}_2$ ;  $\text{H}_2$  is weakly bound to the MgO terrace sites, and at 580 K will immediately desorb. The adsorbed hydrogen gives rise to vibrations of strong intensity at 830–950  $\text{cm}^{-1}$  when isolated, and to an intense band at 1030  $\text{cm}^{-1}$  in the chemisorbed complex shown in Figure 1b. Therefore, the stable species is assigned to H atoms incorporated into oxygen vacancies.

In conclusion, this combined experimental and theoretical study of methanol adsorbed on MgO films with different defect density allows better identification of the surface sites responsible for the MgO reactivity. On the inert terrace sites, only physisorption is observed. Molecular chemisorption, activation, and heterolytic dissociation occur on irregular sites. The low-coordinated Mg–O pairs of ions located at edges and steps can lead to strongly activated, and even dissociated, methanol molecules. Adsorption of  $\text{CH}_3\text{O}$  and  $\text{H}^+$  fragments seems to be preferred over dissociation into  $\text{CH}_3^+$  and  $\text{OH}^-$  units. All of these species are stable on the surface for temperatures up to 350 K, and account for the TDS spectra of the defect-poor films. On defect-rich films (F centers), the O–H bond is selectively dissociated, resulting in the observed desorption of  $\text{H}_2$  at high temperature. Thus, these oxygen vacancy centers, called F centers, act as nanocatalysts.

### 3. CHEMICAL REACTIONS AND CATALYTIC PROCESSES ON FREE AND SUPPORTED CLUSTERS

#### 3.1. Catalytic Processes on Free Metal Clusters

Free clusters are ideal model systems to probe the influence of their intrinsic, size-dependent properties on the catalytic activity due to the lack of any support interactions. Free clusters are prepared by cluster sources [17], and only very low densities are obtained. They are highly unstable at normal conditions and, even under UHV conditions, exothermal catalytic reactions may lead to fragmentation without the presence of a buffer gas. Thus, free clusters may not become relevant for industrial applications. Nevertheless, they are important vehicles to gain a fundamental understanding of nanocatalysis.

The following principle is often used for producing free clusters. The material of interest is evaporated by means of intense laser pulses [18], electrical discharges [19], or highly energetic inert ions [20]. A buffer gas thermalizes the produced ultrahot plasma or supersaturated atomic gas. The mixture expands through a nozzle into the vacuum upon supersonic expansion. By this process, the formed clusters are cooled to cryogenic temperatures, and generate well-defined molecular beams of neutral and charged clusters.

The reactivity of the clusters can then be studied by various experimental techniques, including fast flow reactor kinetics in the postvaporization expansion region of a laser evaporation source [21, 22], ion flow tube reactor kinetics of ionic clusters [23, 24], ion cyclotron resonance [25, 26], guided-ion-beam [27], and ion-trap experiments [28–30]. Which of these techniques is applied depends on the charge state of reactants (neutral, cationic, anionic), on whether the clusters are size-selected before the reaction zone, on single or multiple collisions of the clusters with the reactants, on the pressure of a buffer gas if present, and on the temperature and collision energy of the reactant molecules.

A representative experimental setup may be described in the following way [28]. The cluster anions are produced by a sputter source, and are extracted into a helium-filled quadrupole, where they are cooled down to room temperature and collimated to the axis of the ion optics. A second quadrupole selects a single cluster size. The cluster ions are then transferred with a quadrupole ion guide into an octopole ion trap, which can be continuously cooled from  $T_T = 350$  to 20 K. The potentials on the entrance and exit lenses can be switched in order to fill the trap, store the ions in the trap, and finally extract product ions for mass analysis. Through collisions with a buffer gas (helium or argon) in the trap, the clusters are already thermalized within a few milliseconds. Different reactants can be added to the ion trap under known partial pressures  $p_R$ . Typically, the number of reactant molecules is orders of magnitude higher than the number of clusters, and thus it can be taken as constant. After reaction time  $t_R$ , the charged products are extracted from the trap, and are analyzed by a quadrupole mass spectrometer as a function of  $t_R$ ,  $p_R$ , and  $T_T$ .

With such experimental techniques, the interaction of reactants, for example, CO and  $\text{O}_2$  molecules, or even complete catalytic cycles were observed on small  $\text{Au}_n^-$  anions [30, 31]. By varying the reaction temperatures and measuring the kinetics of the processes, the energetics of complete reaction mechanisms could be obtained and compared with *ab initio* simulations [29, 32]. The reactivity of  $\text{Au}_2^-$  toward  $\text{O}_2$  or CO, as well as the coadsorption of both molecules, revealed an interesting and unexpected selectivity.  $\text{O}_2$  only reacts with even- $n$   $\text{Au}_n^-$  clusters, while odd- $n$  clusters and  $\text{Au}_{16}^-$  are inert. In addition, the reactive clusters adsorb just one  $\text{O}_2$  molecule. The relative reactivities correlate well with measured electron affinities of neutral clusters, suggesting a mechanism involving the adsorption of  $\text{O}_2$  as a one-electron acceptor [33, 34]. The reactivity of gold cluster anions with CO also shows a distinct size selectivity, although less pronounced than the one with  $\text{O}_2$  [35]. In this reaction, the most reactive cluster sizes are  $\text{Au}_{11}$ ,  $\text{Au}_{15}$ , and  $\text{Au}_{19}$ . Most reactive cluster sizes readily adsorb several CO molecules in the saturation limit. Full geometric coverage, for example, one CO per surface gold atom, is, however, never reached. On real catalysts and single crystals, competitive adsorption is usually observed, meaning that, in many examples, CO poisons the active catalysts. This is not true for small  $\text{Au}_n^-$  clusters. On the contrary, for distinct cluster sizes, cooperative adsorption is observed, where the presence of preadsorbates enhances the adsorption probability of subsequent adsorbates. As examples, for  $\text{Au}_3^-$ , preadsorbed CO enables the

adsorption probability of  $O_2$ ;  $Au_2^-$  is inert for the adsorption of CO at around room temperature; the presence of preadsorbed  $O_2$ , however, makes the adsorption possible at this temperature [30]. A similar effect is observed for  $Au_{10}^-$ , where  $O_2$  enhances the adsorption of CO by more than a factor of 5. Finally,  $Au_6^-$  reveals even an enhanced cooperative adsorption with increasing numbers of adsorbate molecules [31].

Let us now turn our attention to  $Au_2^-$ , where a full catalytic cycle could unambiguously be observed by measuring the kinetics of the process at different temperatures [29]. At room temperature, oxygen reacts by a straightforward association reaction mechanism with the dimer anion, as determined from the measured product ion concentration as a function of the reaction time, and the negative dependence of the reaction rate with temperature:

As mentioned above, no adsorption of CO is observed at around room temperature. When both reactants  $O_2$  and CO are introduced into the ion trap, the reaction kinetics of  $Au_2^-$  changes drastically, as seen by the offset in the  $Au_2^-$  signal. This offset increases when the partial pressure of CO is augmented. In addition, at temperatures below 200 K, the intermediate with the stoichiometry  $Au_2(CO)O_2^-$  could be isolated (Fig. 2A and B). The ion stoichiometry clearly shows that CO and  $O_2$  are able to coadsorb onto an  $Au_2^-$  dimer. From the kinetics of all observable ions,  $Au_2^-$ ,  $Au_2O_2^-$ , and  $Au_2(CO)O_2^-$ , measured under a multitude of different reaction conditions, the catalytic conversion of CO to  $CO_2$  could unambiguously be detected. The reaction mechanism that fulfills all of the prerequisites and fits all kinetic data measured under all of the different reaction conditions could be described by the reaction equations below:

By studying these kinetics as a function of concentration and temperature (Fig. 2B), some important findings can be obtained.

1. Undoubtedly,  $O_2$  adsorption precedes CO adsorption in the catalytic reaction. This is further supported by the reaction kinetics of  $Au_2^-$  when solely  $O_2$  or CO are present in the trap: The adsorption of  $O_2$  is by at least a factor of 10 faster than the adsorption of CO molecules [36].
2. These experiments revealed that varying the oxygen partial pressure inside the trap mainly affects the rate constant  $k_1$  in such a way that  $k_1$  rises linearly with increasing  $p(O_2)$ , and to a smaller extent, the rate constant  $k_4$ , which was attributed to the higher abundance of  $Au_2(CO)O_2^-$ .

**Figure 2.** (A) Mass spectra of product ion distributions analyzed after trapping  $Au_2^-$  for 500 ms inside the octopole ion trap filled with 0.02 Pa  $O_2$ , 0.05 Pa CO, and 1.23 Pa He. (a) At a reaction temperature of 300 K, only  $Au_2^-$  and  $Au_2O_2^-$  are detected. No further ion signals are observed at temperatures above 200 K. Cooling further down reveals an additional ion signal appearing at the mass of  $Au_2(CO)O_2^-$ . Mass spectrum (b) shows the ion distribution at 100 K. (B) Product ion concentrations as a function of reaction time for three different reaction temperatures. (a)  $T_r = 190$  K;  $p(O_2) = 0.06$  Pa;  $p(CO) = 0.07$  Pa;  $p(He) = 1.0$  Pa. (b)  $T_r = 150$  K;  $p(O_2) = 0.04$  Pa;  $p(CO) = 0.04$  Pa;  $p(He) = 1.0$  Pa. (c)  $T_r = 100$  K;  $p(O_2) = 0.02$  Pa;  $p(CO) = 0.03$  Pa;  $p(He) = 1.0$  Pa. Open symbols represent the normalized experimental data. The solid lines are obtained by fitting the integrated rate equations of the catalytic reaction cycle (see text) to the experimental data. (C) Five optimized structures (a)–(e) of  $Au_2CO_3^-$ , with bond lengths in angstroms. The relative stability of these structures is shown in Table 1. (a), (b), (c), and (e) are planar, and the two carbonate species (d) and (e) have  $C_{2v}$  symmetry.

3. An increase in the carbon monoxide partial pressure results at room temperature in an increasing back reaction rate  $k_2$  in Eq. (2b), that is, the  $Au_2^-$  offset is increasing. Resolving the kinetics at lower temperatures at 190 K reveals a clearly positive dependence of  $k_4$  [in Eq. 2(c)] on  $p(CO)$ , also correlated to the  $Au_2^-$  offset.
4. Finally, with decreasing temperature, the final equilibrium concentration of  $Au_2(CO)O_2^-$  increases, whereas the  $Au_2O_2^-$  concentration decreases (Fig. 2B). This is consistent with the decreasing rate constants  $k_1$ ,  $k_2$ , and  $k_3$  with increasing temperature, and this negative temperature dependence is indicative of barrierless

reaction steps, explained in the framework of the Lindemann theory [36, 37]. Most importantly, however,  $k_4$  increases with increasing temperature. Hence, an activation barrier is involved in the corresponding reaction [Eq. 2(c)].

Further details of the reaction mechanism were obtained by complementary theoretical simulations [32], revealing that the bonding of  $O_2$  to  $Au_2^-$  is characterized by partial electron transfer ( $0.4e$ ) from the metal cluster to the anti-bonding  $\pi$ -orbital of the oxygen molecule, making the oxygen molecule a superoxo-like species. The binding energy is 1.39 eV. The molecular adsorption is energetically clearly favored over dissociative adsorption. In agreement with the experimental findings, the molecular binding is a nonactivated process, that is, a barrierless reaction channel exists for the approaching oxygen molecule, leading to the described configuration. The binding energy of CO to  $Au_2^-$  is 0.91 eV. The stronger binding of  $O_2$  to  $Au_2^-$  explains the observation that high CO partial pressures are required before CO adsorption can compete with  $O_2$  adsorption as the first reaction step.

Five structures corresponding to the mass of the complex  $Au_2(CO)O_2^-$  theoretically predicted, and the pertinent structural and energetic information are given in Figure 2C and Table 1. Structures (a) and (b) correspond to molecular coadsorption of CO and  $O_2$  to  $Au_2^-$ . From the two molecularly coadsorbed species, CO can readily (without barrier) bind to the end of the Au–Au axis [structure (a)], whereas a barrier of 0.2 eV was found for CO association from the gas phase to the Au–Au bridging site of structure (b). The barrier for forming (b) from (a) via diffusion of CO from the end of the complex to the Au–Au bridge is high, on the order of 0.9 eV. In both structures (a) and (b), the O–O bond is activated to a value typical to a superoxo-species (about 1.35 Å). Structure (c) is close to the stability of structure (a). It contains a reacted O–O–C–O group bound to the  $Au_2$  axis via the carbon atom. The O–O bond is activated to a superoxo state, and this species bears some resemblance to the gold–peroxyformate complex identified in the early experiments of gold atoms in cryogenic CO/ $O_2$  matrices [38]. The formation of this species was investigated via two routes: (1) a Langmuir–Hinshelwood (LH) mechanism that involves diffusion of CO from the bridging position in structure (b), and (2) an Eley–Rideal (ER) mechanism where CO(g) approaches the preformed  $Au_2O_2^-$ . The LH mechanism has a high activation barrier of 1.1 eV, and since the barrier is on the order of the activation energy for CO desorption from structure (b) (1 eV), formation of (c)

from (b) is unlikely. Interestingly, mechanism (2) does not involve an activation barrier.

By far the most stable structures corresponding to the mass of  $Au_2(CO)O_2^-$  are the two carbonate species (d) and (e). Structure (e) requires a preformed  $Au_2O_2^-$  where the molecular axes of  $Au_2$  and  $O_2$  lie parallel to each other. Since this structure of  $Au_2O_2^-$  is 1 eV less stable than the ground state discussed above (the binding energy of oxygen in this configuration is 0.39 eV versus the optimal binding energy of 1.39 eV), it is unlikely to be formed, and consequently, structure (e) does not play a relevant role in the catalytic cycle. On the other hand, formation of the most stable structure (d) by an ER mechanism with CO(g) inserted in the middle of the O–O bond in  $Au_2O_2^-$  requires a barrier of only 0.3 eV, which is easily overcome under the experimental conditions. The absence of the complex  $Au_2C_2O_4^-$  in the experimental mass spectrum, as well as the calculated high barriers for CO diffusion along the Au–Au axis, justify the considerations of only ER mechanisms for the final reaction step [Eq. 2(c)]. It is also worth noting that further intermediates such as  $Au_2O^-$  and  $Au_2CO_2^-$  are not observed experimentally. This leads to only two possible scenarios for the final reaction step 2c: ER reactions of CO(g) with structures (c) or (d), and the reaction proceeds to completion, releasing 2CO<sub>2</sub> molecules. The formation of CO<sub>2</sub> from the reaction between CO(g) and structure (c) (Fig. 2C) involves a low barrier of 0.3 eV, resulting in the formation of a metastable  $Au_2CO_2^-$  complex, where CO<sub>2</sub> is bound to  $Au_2$  via the carbon atom. However, the large heat of reaction (4.75 eV) from the formation of the first CO<sub>2</sub> molecule is much more than that needed to overcome the binding energy (0.52 eV) of the remaining CO<sub>2</sub> to  $Au_2^-$ , readily facilitating its desorption from the metal cluster. The second scenario involves two branches [32]. First, thermal dissociation of CO<sub>2</sub> from the carbonate (d) is endothermic by 1.12 eV, but produces highly reactive  $Au_2O^-$  which reacts without a barrier with CO(g) to produce CO<sub>2</sub>. Second, the ER reaction of CO(g) with (d) to produce CO<sub>2</sub> involves a modest barrier of 0.5 eV, but readily releases two CO<sub>2</sub> molecules since the remaining  $Au_2CO_2^-$  configuration, where CO<sub>2</sub> is bound to  $Au_2$  via one of the oxygen atoms, is unstable. This is the more likely branch to occur in the experiments (100–300 K) described above. Thus, these studies showed that both experimental and theoretical results prove the existence of the full catalytic cycle.

In another example [39, 40], it was demonstrated that gas-phase platinum cluster anions,  $Pt_n^-$  ( $n = 3-7$ ), efficiently catalyze the oxidation of CO to CO<sub>2</sub> in the presence of N<sub>2</sub>O or O<sub>2</sub> near room temperature in a full thermal catalytic reaction cycle. At the end of the process, the intact cluster is regenerated, and each step is exothermic, and occurs rapidly at thermal energies. In these experiments, the produced  $Pt_n^-$  clusters are first thermalized by collisions with a buffer gas. When either O<sub>2</sub> or N<sub>2</sub>O is introduced downstream in the flow tube,  $Pt_nO^-$  and  $Pt_nO_2^-$  ions are formed in rapid exothermic reactions [41]. With the introduction of CO into the gas cell, the  $Pt_n^-$  clusters reappear, as observed with mass spectrometry. From these experiments, it was concluded that neutral CO<sub>2</sub> is stoichiometrically formed on the clusters, and that negligible fragmentation of the metal cluster for  $n \geq 4$  occurs. Further experiments revealed that, at low energies,

**Table 1.** Relative stability, vertical electron detachment energy, binding energy of CO (with  $O_2$  preadsorbed) and binding energy of  $O_2$  (with CO preadsorbed), for the five structures (a)–(e) of  $Au_2CO_3^-$  shown in Figure 2C.

Structure	$\Delta E$ (eV)	VDE (eV)	BE(CO) (eV)	BE( $O_2$ ) (eV)
(a)	2.80	2.82	0.93	1.34
(b)	2.94	3.32	0.78	1.20
(c)	2.82	3.82	0.91	1.32
(d)	0	4.67	3.72	4.14
(e)	1.04	3.38	2.69	3.10

the cross section approaches the calculated collision limit, meaning that the reactions are quite efficient. When  $\text{Pt}_n\text{O}_2^-$  ions are selected initially, sequential loss of oxygen atoms is observed to form two  $\text{CO}_2$  products, as shown by CO pressure dependence studies. This observation implies that  $\text{O}_2$  is dissociatively adsorbed on the metal cluster as oxygen atoms, rather than chemisorbed or physisorbed as molecular  $\text{O}_2$ . Two other observations support this conclusion: (1)  $\text{Pt}_n\text{O}_2^-$  ions produced by reaction of the bare cluster with either  $\text{O}_2$  or  $\text{N}_2\text{O}$  show the same reactivity; and (2) collision-induced dissociation of  $\text{Pt}_n\text{O}_2^-$  shows a loss of oxygen atoms with no  $\text{O}_2$  loss. The regeneration of  $\text{Pt}_n^-$  ions at low energies proves that a full catalytic oxidation cycle can be completed at near room temperature, in either a single-step or a two-step process. Reaction efficiencies for the oxidation of the first CO molecule were measured for  $\text{Pt}_n\text{O}^-$  or  $\text{Pt}_n\text{O}_2^-$  ( $n = 3-6$ ). The reaction efficiencies for a single collision are greater than 40% for  $n \geq 4$ , so only a few collisions would be required for complete conversion. From this, it was concluded that, at near room temperatures, the gas-phase metal cluster anions are better catalysts than the supported catalysts used in current technology for automotive catalytic converters. These need to be heated to high temperatures, on platinum surfaces; temperatures of  $400 \pm 500$  K are typically required for the oxidation of CO [42].

Both examples revealed unique and size-dependent catalytic properties of very small metal clusters. As mentioned in the Introduction, gas-phase clusters will probably never be important in real catalysis; however, such small clusters can be stabilized on support materials, and they may become relevant for future applications.

## 3.2. Chemical Reactions and Catalytic Cycles on Supported Clusters

### 3.2.1. Single Atoms on Oxide Surfaces

F centers can act as nanocatalysts; however, few reactions are catalyzed by oxygen vacancies because only two confined electrons at the same energy level are present. In order to change these two parameters (number of confined electrons and energy levels) without modifying the size of the quantum box, the F center can be decorated with metal atoms to produce a third kind of nanocatalyst: supported atoms on oxide surfaces.

The metal atoms are produced by a recently developed high-frequency laser evaporation source [12]. The positively charged ions are guided by home-built ion optics through differentially pumped vacuum chambers, and are size-selected by a quadrupole mass spectrometer (Extrel Merlin System; mass limits: 1000, 4000, 9000 amu). In these experiments, it is important to deposit only 0.5–0.8% of a monolayer atom ( $1 \text{ ML} = 2 \times 10^{15}$  clusters/ $\text{cm}^2$ ) at 90 K with low kinetic energy in order to land them isolated on the surface and to prevent agglomeration on the defect-rich MgO films. The presence of isolated atoms is confirmed experimentally and theoretically. Experimentally, nickel atoms, dimers, and trimers are used as it is well known that they form stable metalcarbonyls. This carbonyl formation of small deposited  $\text{Ni}_n$  ( $n = 1-3$ ) was studied by exposing the deposited clusters to carbon monoxide. Mass

spectrometry experiments showed that the nuclearity of the formed  $\text{Ni}_n$  carbonyls ( $n = 1-3$ ) is not changed. The absence of, for example,  $\text{Ni}_2(\text{CO})_x$  and  $\text{Ni}_3(\text{CO})_x$  after deposition of Ni atoms directly excludes agglomeration, whereas the absence of  $\text{Ni}(\text{CO})_4$  after depositing  $\text{Ni}_2$  excludes fragmentation of the cluster, relevant for the experiments described in the next section [43]. Second, Monte Carlo simulations revealed that, under such experimental conditions, for example, cluster flux ( $\sim 10^9 \text{ cm}^{-1}$ ), cluster density ( $\sim 10^{13} \text{ cm}^{-1}$ ), and defect density ( $\sim 5 \cdot 10^{13} \text{ cm}^{-1}$ ) on the MgO(100) films, less than 10% of the atoms coalesce when migrating to the trapping centers [44].

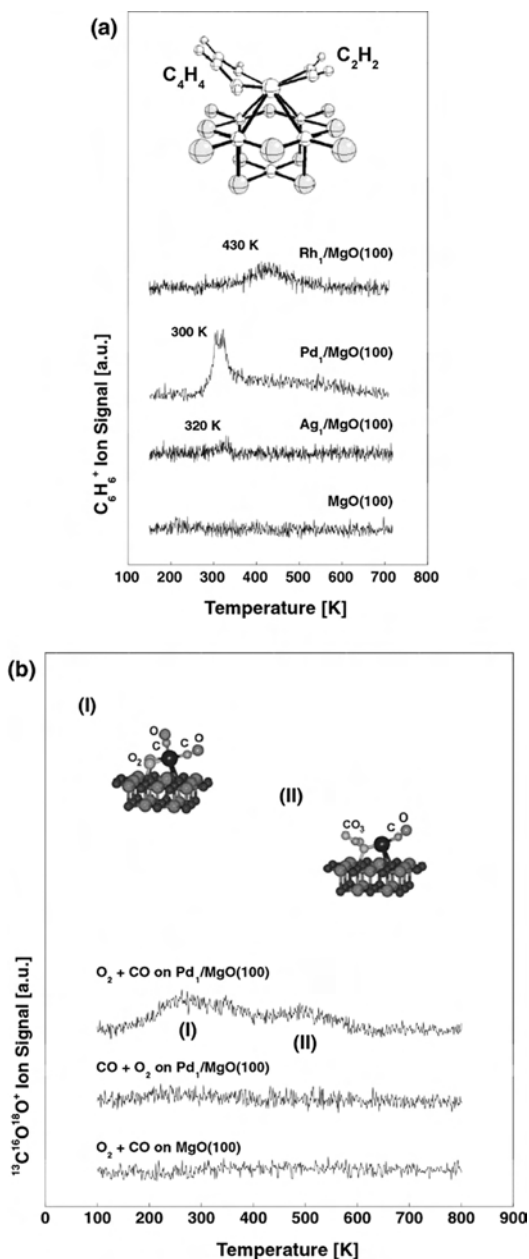

To characterize the model catalysts in detail, it is, however, necessary to identify the adsorption sites of the clusters. One possibility is studying the adsorption of probe molecules on the deposited clusters by means of TDS and Fourier transform infrared (FTIR) spectroscopies. As an example [45], CO desorbs from the adsorbed Pd atoms at a temperature of about 250 K, which corresponds to a binding energy  $E_b$  of about  $0.7 \pm 0.1$  eV. FTIR spectra suggest that, at saturation, two different sites for CO adsorption exist on a single Pd atom. The vibrational frequency of the most stable, singly adsorbed CO molecule is  $2055 \text{ cm}^{-1}$ . Density functional cluster model calculations have been used to model possible defect sites at the MgO surface where the Pd atoms are likely to be adsorbed. CO/Pd complexes located at regular or low-coordinated O anions of the surface exhibit considerably stronger binding energies,  $E_b = 2-2.5$  eV, and larger vibrational shifts than were observed in the experiment. CO/Pd complexes located at oxygen vacancies (F or  $\text{F}^+$  centers) are characterized by much smaller binding energies,  $E_b = 0.5 \pm 0.2$  or  $0.7 \pm 0.2$  eV, which are in agreement with the experimental value. Such comparisons therefore identify adsorption sites of the clusters on the MgO surface; particularly in the examples shown below, these trapping centers are shown to be oxygen vacancies.

After characterizing this type of nanocatalyst consisting of metal atoms trapped on oxygen vacancies, simple reactions like acetylene polymerization or CO oxidation can be studied by means of temperature-programmed reaction studies and infrared spectroscopy.

For cyclotrimerization on Ag, Pd, and Rh atoms and CO oxidation on Pd atoms, the nanocatalysts were exposed at 90 K, using a calibrated molecular beam doser, to about 1 Langmuir (L) of acetylene or 1L of  $^{18}\text{O}_2$  and  $^{13}\text{CO}$ , respectively. In a temperature-programmed reaction (TPR) study, catalytically formed benzene ( $\text{C}_6\text{H}_6$ ), butadiene ( $\text{C}_4\text{H}_6$ ), and butene ( $\text{C}_4\text{H}_8$ ) or  $^{13}\text{C}^{18}\text{O}^{16}\text{O}$  molecules were detected by a mass spectrometer, and were monitored as a function of temperature. It is interesting to note that the reactants ( $^{13}\text{CO}$ ,  $^{18}\text{O}_2$ ,  $\text{C}_2\text{H}_2$ ) are only physisorbed on the MgO, and desorb at temperatures lower than 150 K in all three cases, for example, before the reaction takes place. In addition, the interaction of the product molecules with the model catalysts is weak, as described in [45, 46]. The thermal stabilities of the deposited Pd and Rh atoms were investigated by using Fourier transform infrared spectroscopy and the probe molecule CO. It was found that Pd starts to migrate at around 300 K [45], whereas Rh is stable up to 450 K [47].

Surprisingly, and in contrast to single-crystal studies [48], a single Pd atom already catalyzes the cyclotrimerization

reaction, and the benzene molecule ( $C_6H_6$ ) is desorbing at 300 K (Fig. 3a). No other product molecules of the polymerization reaction (e.g.,  $C_4H_6$ ,  $C_4H_8$ ) are observed. Thus, this model catalyst is highly selective for the polymerization reaction. We note that, on a clean MgO(100) surface,

**Figure 3.** (a) Temperature-programmed reaction (TPR) spectra of  $C_6H_6$  formed on Ag, Pd, and Rh atoms deposited on defect-rich MgO thin films grown on Mo(100) surfaces. As a comparison, the same experiment was performed on a clean defect-rich MgO film. Also shown is the calculated  $(C_4H_4)(C_2H_2)/Pd_1/F_{5c}$  intermediate of the cyclotrimerization reaction on Pd atoms adsorbed on an F center of the MgO(100) surface. (b) TPR spectra of  $CO_2$  from a defect-rich MgO thin film and deposited Pd atoms after exposure to  $O_2$  and CO (lower and upper spectrum), as well as from deposited Pd atoms after exposure to CO and  $O_2$ . Calculated precursors of the two observed mechanisms (I) and (II) are also depicted.

none of the products is formed (Fig. 3a). This surprising result can be rationalized by theoretically studying a palladium atom adsorbed on different MgO sites represented by a cluster of ions embedded in an array of point charges [49]. First, a Pd atom was adsorbed on a five-coordinated oxygen ion on the MgO(001) terrace  $O_{5c}$ ; the binding energy is about 1 eV. It was found that, indeed, the  $Pd(C_4H_4)$  complex, is formed, but the third acetylene molecule is not bound to the complex, and therefore this configuration is catalytically inactive. Other bonding sites for the adsorption of Pd atoms are considered. On four-coordinated step or three-coordinated corner oxygen sites,  $O_{4c}$  and  $O_{3c}$ , respectively, the Pd atom binds slightly stronger, with an energy of 1.2–1.5 eV; in addition, the atom is more reactive. However, on both  $O_{3c}$  and  $O_{4c}$  sites, the third  $C_2H_2$  molecule is only weakly bound or even unbound to the  $Pd(C_4H_4)$  surface complex, with the binding energy smaller than the activation energy of the formation of  $C_6H_6$ . Thus, Pd atoms adsorbed on  $O_{nc}$  sites cannot explain the observed activity. This is consistent with the results of the study on the adsorption properties of CO on Pd<sub>1</sub>/MgO [45], as the experimental results have been rationalized in terms of Pd atoms, which are stabilized on oxygen vacancies (F centers) in neutral or charged states,  $F_s$  or  $F_s^+$ , respectively. The interaction of a Pd atom with the F center is much stronger, 3.4 eV, which makes these centers good candidates for Pd binding. On  $F_s^+$  centers, binding energies of about 2 eV have been computed [45]. The presence of trapped electrons at the defect site results in a more efficient activation of the supported Pd atom. In fact, the complex  $(C_4H_4)(C_2H_2)/Pd_1/F_{5c}$ , Figure 3a, shows a large distortion and a strong interaction of the third  $C_2H_2$  molecule. These results indicate that F and  $F^+$  centers can act as basic sites on the MgO surface, and turn the inactive Pd atom into an active catalyst. Notice that the supported Pd atoms on defect sites not only activate the cyclization reaction, but also favor benzene desorption, as shown by the very small  $(C_6H_6)/Pd_1/F_{5c}$  adsorption energy. The complete reaction path for this specific nanocatalyst has been calculated [49]. The first barrier of the reaction path is the one for the formation of the intermediate  $Pd(C_4H_4)$ , and it is 0.48 eV only. The formation of the  $C_4H_4$  intermediate is thermodynamically favorable by 0.82 eV. On  $(C_4H_4)/Pd_1/F_{5c}$ , the addition of the third acetylene molecule is exothermic by 1.17 eV, leading to a very stable  $(C_4H_4)(C_2H_2)/Pd_1/F_{5c}$  intermediate (Fig. 3a). To transform this intermediate into benzene, one has to overcome a barrier of 0.98 eV. The corresponding energy gain is very large, 3.99 eV, and mainly related to the aromaticity of the benzene ring. Once formed,  $C_6H_6$  is so weakly bound to the supported Pd atom that it immediately desorbs. Thus, the reaction on Pd/ $F_{5c}$  is rate-limited in the last step, the conversion of  $(C_4H_4)(C_2H_2)$  into  $C_6H_6$ . This is different from the Pd(111) surface where the rate-determining step for the reaction is benzene desorption. The calculations are consistent with the experimental data. In fact, on Pd<sub>1</sub>/ $F_{5c}$ , the computed barrier of 0.98 eV corresponds to a desorption temperature of about 300 K, as experimentally observed, Figure 3a. On Pd(111) surfaces, the bonding of benzene is estimated to be  $\approx 1.9$  eV. This binding is consistent with a desorption temperature of 500 K, as observed for a low coverage of  $C_6H_6$  on Pd(111) [50].

The electronic structure of palladium atoms,  $4d^{10}5s^0$ , is unique, and may be responsible for this specific catalytic property for acetylene cyclotrimerization. This raises the question of whether other transition metal atoms are also reactive for this reaction. Results are shown for deposited Rh ( $4d^85s^1$ ) and Ag ( $4d^{10}5s^1$ ) atoms. Ag atoms are almost unreactive (Fig. 3a); on supported Rh atoms, however, benzene is formed, and desorbs at around 430 K (Fig. 3a).

For CO oxidation, it was first verified that the clean MgO(100) thin films are inert; for example, no  $^{13}\text{C}^{16}\text{O}^{18}\text{O}$  was formed in a one-heating-cycle experiment after adsorbing  $^{18}\text{O}_2$  and  $^{13}\text{C}^{16}\text{O}$  (Fig. 3b) or vice versa [51]. When Pd atoms are trapped on the  $F_{5c}$ , preadsorption of oxygen and subsequent saturation of CO leads to the formation of carbon dioxide, with desorption peaks at 260 K and at around 500 K (Fig. 3b). The existence of two desorption peaks in the TPR spectrum (Fig. 3b) suggests the presence of two different reaction mechanisms. Note that preadsorption of  $^{13}\text{CO}$  suppresses the catalytic process as it poisons the nanocatalyst (Fig. 3b). *Ab initio* calculations showed that a single Pd atom strongly binds to the oxygen vacancy (binding energy of 3.31 eV), with a small amount of charge (0.15  $e$ ) transferred to the adsorbed atom. In comparison, the binding energy of Pd atoms to terrace oxygen sites is only 1.16 eV. The enhanced binding to the  $F_{5c}$  is also reflected in the corresponding bonding lengths of 1.65 and 2.17 Å for MgO( $F_{5c}$ )-Pd and MgO-Pd, respectively. Binding of two CO molecules saturates the MgO( $F_{5c}$ )-Pd system; occupying the MgO( $F_{5c}$ )-Pd system with three CO molecules leads to spontaneous (barrierless) desorption of one of the molecules. In the most stable configuration, the two CO molecules are not equivalent; one CO binds on top, and the second adsorbs on the side of the Pd atom (this top-side geometry is similar to that shown in Fig. 3bI, but without the  $\text{O}_2$ ), and the total binding energy of the two CO molecules is 1.62 eV. To study the oxidation mechanisms of CO on MgO( $F_{5c}$ )-Pd, the system was optimized first with coadsorbed  $\text{O}_2$  and two CO molecules. Two stable geometric arrangements were found, with the most stable one shown in Figure 3bI where the CO molecules bind in a top-side configuration, and the  $\text{O}_2$  is adsorbed parallel to the surface on the other side of the Pd atom. The adsorbed  $\text{O}_2$  molecular bond is stretched and activated (1.46 Å compared to the calculated gas-phase value of 1.25 Å). In addition, a stable carbonate complex Pd( $\text{CO}_3$ )(CO) was found (Fig. 3bII), whose binding energy is 4.08 eV larger than the aforementioned Pd( $\text{CO}$ ) $_2$ ( $\text{O}_2$ ) complex. These complexes were identified by comparison of calculated and spectroscopically measured CO vibrational frequencies [52]. Two reaction mechanisms are proposed corresponding to the two  $\text{CO}_2$  peaks observed experimentally (Fig. 3b). At low temperatures, the two relevant precursors are shown in Figure 3bI and 3bII. Corresponding to the  $\text{CO}_2$  desorption peak at 260 K, the following reaction mechanism is proposed. In a competitive process, CO desorbs or is oxidized upon heating. The theoretically estimated activation energies of the two processes are 0.89 eV for desorption and 0.84 for oxidation. The formation of  $\text{CO}_2$  at higher temperatures (corresponding to desorption at around 500 K, Fig. 3b) involves decomposition of the Pd( $\text{CO}_3$ )(CO) carbonate complex (Fig. 3bII).

This mechanism is observed in molecular dynamics simulations where the temperature is controlled to 500 K by Langevin dynamics.

### 3.2.2. Size-Selected Clusters on Oxide Surfaces

By decorating F centers with atoms, it is possible to increase the number of confined electrons, but modifying the size of the quantum box only slightly. By using size-selected clusters instead of atoms, the confinement of the valence electrons is subtler, and the examples presented below reveal the possibility of tuning the efficiency and selectivity of chemical reactions atom by atom by simply changing the cluster size or doping the cluster with impurity atoms. Furthermore, a comparison of the experimental results with first-principles theoretical simulations provides insights into the physical factors and microscopic mechanisms that govern nanocatalysis.

The metal clusters are produced by the same high-frequency laser evaporation source used to produce metal atoms. In this source, a cold He pulse (40 K) thermalizes the laser-produced plasma [12]. Subsequent supersonic expansion of the helium-metal vapor leads to cold clusters with a narrow kinetic energy distribution ( $E_{\text{kin}} \leq 0.2$  eV/atom). The positively charged clusters guided by ion optics through differentially pumped vacuum chambers and size-selected by a quadrupole mass spectrometer (Extrel Merlin System; mass limit: 1000, 4000, 9000 amu) are then deposited with low kinetic energy (<0.2 eV/atom) on MgO(100)/Mo(100) thin films; under these conditions, the clusters softland on the substrate. In fact, when exploring the chemical or catalytic properties of nanoassembled materials consisting of small monodispersed clusters on surfaces, the key challenge is to preserve the identity of the cluster upon deposition. Upon impact, a redistribution of the total energy of the cluster takes place. In the deposition process, this energy consists of the cluster's kinetic and internal energy, the binding energy between the cluster and substrate, and an eventual Coulomb energy between the cluster ion and an induced image charge (metal) or surface-charge density (dielectric) on the support. The amount of this energy is decisive for the degree of melting, disordering, fragmentation, implantation, or rebounding of the cluster. The cluster-surface and Coulomb interactions are intrinsically given by the chosen cluster and support materials, whereas the internal and kinetic energies can be changed, to a large extent, by the experimental conditions. Softlanding is defined as a collision outcome allowing for plastic deformation of the cluster, but not for fragmentation and implantation into the substrate [53]. Molecular dynamic studies [54–56] have shown that cluster implantation occurs at about 1 eV/atom kinetic energy of the cluster, regardless of the cluster-substrate system. Consequently, this value represents the upper kinetic energy limit for softlanding conditions. Softlanding of size-selected  $\text{Si}_{30}$  and  $\text{Si}_{39}$  clusters on Ag(111) was observed in recent low-temperature STM experiments performed at a kinetic energy well below the softlanding limit and without rare buffer layers, that is, under the same experimental conditions as the experiments shown below [57]. Finally, to prepare cluster-assembled nanocatalysts, less than 0.5% of an ML of size-selected clusters ( $1 \text{ ML} = 2 \times 10^{15}$  clusters/cm $^2$ ) are deposited at 90 K,

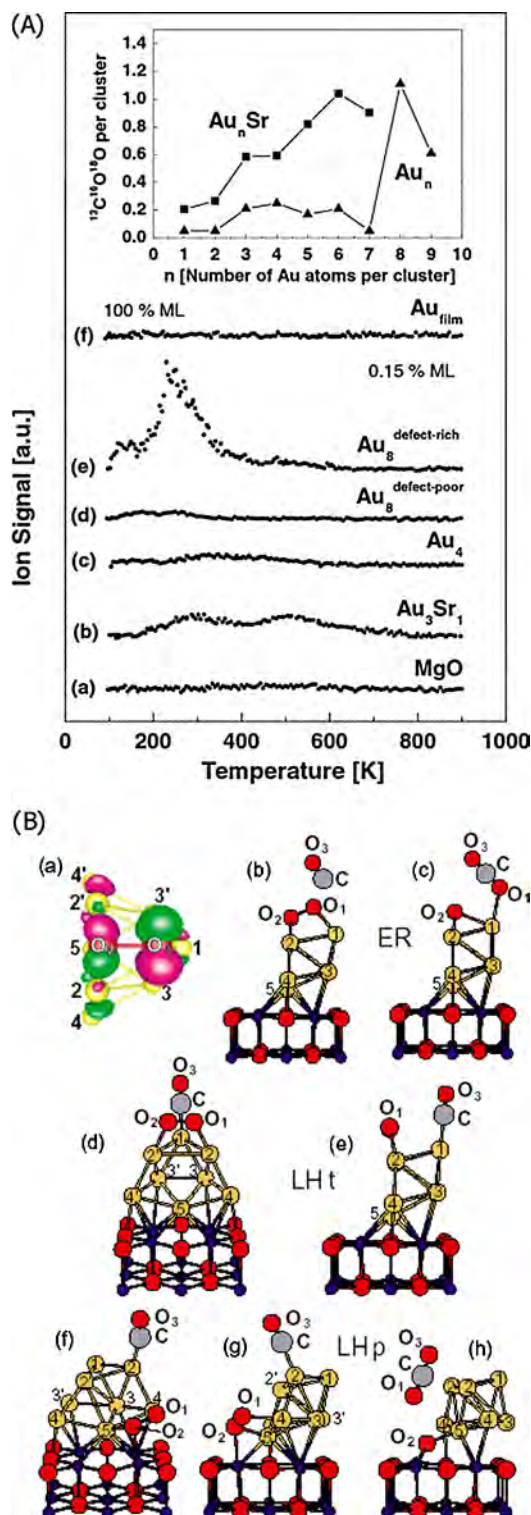

in order to land them isolated on the surface and to prevent agglomeration of the cluster on the surface. Under these experimental conditions, the landing and migration and trapping of the clusters on the surface were investigated with Monte Carlo simulations [44]. These simple calculations show that the preparation of samples with monodispersed clusters is possible only when a small number of clusters is deposited. In order to prepare clusters on identical adsorption sites, it is therefore essential to use support materials with low defect densities for systems with a strong cluster–support interaction or to use surfaces with high defect densities when the cluster–support interaction is weak. The deposition of the clusters on defects is additionally favored by the recently discovered “funnel” effect [7]; *ab initio* calculations revealed that clusters are attracted, for example, by F centers, well before landing on the surface.

### Changing Catalytic Efficiency Atom by Atom: Oxidation of Carbon Monoxide on Pure and Strontium-Doped Gold Nanocatalysts

In the first example, we focus on gold nanocatalysts, which led recently to the most remarkable and rather surprising findings. More specifically, low adsorption energies and high activation barriers for the dissociation of small molecules on extended gold surfaces are responsible for the nobleness of gold as bulk material [58]. Nanosize particles of gold, however, show high and rather unusual catalytic reactivity [59, 60]. While novel heterogeneous catalysis by nanosize gold aggregates supported on oxides is of great significance, the processes underlying the catalytic activity of gold in reduced dimensions and the reaction mechanisms are not yet understood, and still represent an enigma in catalysis. In the following, these issues are addressed theoretically and experimentally through investigations of the low-temperature combustion of CO on size-selected gold clusters,  $Au_n$  ( $n \leq 20$ ), and strontium-doped gold clusters,  $SrAu_n$  ( $n \leq 7$ ), supported on defect-poor and defect-rich MgO(100) films [11, 61].

Subsequent to verification that oxidation of CO does not occur on bare MgO substrate films (with and without defects), the catalyzed combustion of CO by nanosize gold and strontium-doped gold clusters adsorbed on the two different MgO films was studied by temperature-programmed reaction (TPR) experiments. Isotopically labeled  $^{18}O_2$  and  $^{13}CO$  were used to disentangle the  $CO_2$  production on the cluster from an eventual catalytic oxidation of CO involving oxygen atoms from the MgO substrate. Indeed, the  $^{13}CO$  molecule is exclusively oxidized by  $^{18}O_2$  since only the  $^{13}C^{16}O^{18}O$  isotopomer is detected. Furthermore, the experiments revealed that the pure gold clusters up to the heptamer are inert for the oxidation of CO, and that the low-temperature ( $T \sim 250$  K) combustion of CO is most effective for  $Au_8$ . By doping gold clusters with strontium, the number of gold atoms in the smallest catalytic active cluster size is reduced to just three. In addition, these results revealed that, for example,  $Au_8$ , the smallest active cluster size turns inert when depositing it on defect-poor films. This indicates that substrate defects are important when trying to understand the factors which govern the chemical properties of nanoscale, supported clusters (Fig. 4A).

Let us turn our intention first to the reaction mechanism and role of defect sites in the case of  $Au_8$ . When first

**Figure 4.** (A) TPR spectra of  $CO_2$  from a defect-rich MgO thin film (a), various pure and mixed  $Au_n$  and  $Au_nSr$  clusters (b)–(e), as well as from a thin Au-film grown on a defect-rich MgO thin film (f). The reactivity expressed as the number of formed  $CO_2$  molecules per cluster is shown for cluster sizes up to  $Au_9$ . (B) Calculated snapshots of three different reaction mechanisms (ER, LHt, LHp) for the oxidation of CO on  $Au_8$  adsorbed on an F center of an MgO(100) surface.

deposited on MgO(100) films with a vanishing number of F centers, the catalytic activity observed experimentally during one heating cycle reveals a very small combustion of CO at temperatures between 150 and 250 K (Fig. 4a–d). Surprisingly, the CO-combustion on Au<sub>8</sub> at 250 K dramatically increases when depositing the octamer on defect-rich MgO films (Fig. 4a–e). This particular behavior pertains even after several reaction cycles, up to temperatures of 350 K. It indicates that the model catalyst is thermally stable, and the reaction heat of the combustion of CO does not change the cluster's structure, an important issue when using Au<sub>8</sub> as a real catalyst. Evaluating the area of the TPR signal yields the production of about one CO<sub>2</sub> molecule per Au<sub>8</sub> cluster. To explore the energetics and reaction mechanisms underlying the above observations, extensive *ab-initio* simulations were performed [11, 62]. Figure 4B summarizes the energetics and atomic configurations of the initial, transition, and final states proposed for the combustion of CO at 140 and 250 K catalyzed by Au<sub>8</sub> clusters adsorbed on MgO(FC). Both O<sub>2</sub> and CO adsorb on the Au<sub>8</sub> cluster supported on the MgO(100) surface (with or without FC defects). However, the observed single sharply peaked stretch frequency of adsorbed CO with  $\nu_a = 2102 \text{ cm}^{-1}$  compared to  $\nu_a = 2143 \text{ cm}^{-1}$  for the free <sup>12</sup>C<sup>16</sup>O molecule implies a single adsorption site on the cluster, and a rather minor influence of adsorption on the internal structure and bonding of the molecule. Indeed, it is found that, in the optimal adsorption configuration, CO binds on top of an Au atom of the upper triangular facet of the adsorbed Au<sub>8</sub> cluster (see Fig. 4B(d), (f) initial state) with  $d(\text{CO}) = 1.14 \text{ \AA}$  (compared to 1.13 Å in the free molecule) and  $d(\text{AuC}) = 1.92 \text{ \AA}$ . On the other hand, an O<sub>2</sub> molecule may readily adsorb at several sites, both on the upper Au<sub>8</sub> facet (Fig. 4B(d)) and at the interface between the adsorbed gold cluster and the underlying magnesia surface (Fig. 4B(f)). In all cases, the adsorbed molecule is found to be activated to a peroxy O<sub>2</sub><sup>\*</sup> molecular state with a weakened highly stretched intramolecular bond length (1.41–1.46 Å) compared to that in the free molecule (1.24 Å). The activation of the adsorbed oxygen molecule involves occupation of the antibonding  $\pi^*$  molecular orbital (i.e., the molecular oxygen  $\pi_g^*$  orbital oriented parallel to the adsorbing surface), which hybridizes with the orbitals of neighboring gold atoms of the partially negatively charged adsorbed gold cluster.

The two reaction pathways, which may mainly contribute to the observed oxidation of CO, are of the Langmuir–Hinshelwood (LH) type. For the formation of CO<sub>2</sub> at 140 K, the two reactants are initially coadsorbed on the triangular top facet of the Au<sub>8</sub> cluster, with the distance between the carbon atom and one of the peroxy oxygens in this local minimum state equal to 3.11 Å ( $d(\text{CO}_1)$ ) (Fig. 4B(d); initial state); in the following, this LH top-facet reaction mechanism is labeled LHt. Through mapping of the potential energy surface along the C–O<sub>1</sub> reaction coordinate (via total relaxation of the system with the variable C–O<sub>1</sub> distance as a constraint), a rather low energy barrier  $\Delta E_b$  (LHt) = 0.1 eV occurring at  $d_b(\text{CO}_1) \approx 2.0 \text{ \AA}$  is determined for the LHt oxidation channel with the end product of a weakly adsorbed carbon dioxide molecule ( $\sim 0.2 \text{ eV}$ ). The total exothermicity of the reaction  $\text{MgO(FC)/Au}_8 + \text{O}_2(\text{g}) + \text{CO}(\text{g}) \rightarrow \text{MgO(FC)/Au}_8\text{O} + \text{CO}_2(\text{a})$  is  $\sim 4.8 \text{ eV}$ , and it is  $\sim 5 \text{ eV}$  when

the CO<sub>2</sub> product is desorbed; here, (g) and (a) denote gas-phase and adsorbed molecules, respectively. This LHt low-temperature oxidation mechanism was found by these studies (with similar energetics) for reactions on the gold cluster deposited on either a defect-free MgO(100) surface or on one containing an FC, and both are expected to be relatively insensitive to the Au<sub>n</sub> cluster size, correlating with the experimental results. As aforementioned, the higher temperature channel is strongly enhanced for Au<sub>8</sub> supported on a defect-rich MgO(100) support (compare the CO<sub>2</sub> signals at  $\sim 240 \text{ K}$  in Fig. 4A(d), (e)). This trend correlates with the simulations of an LH-periphery (LHp) reaction mechanism, starting with the CO adsorbed on the top facet of the Au<sub>8</sub> cluster and the peroxy O<sub>2</sub><sup>\*</sup> molecule bonded to the periphery of the interfacial layer of the cluster (Fig. 4B-f; initial state), where the distance between the C atom and the oxygen marked O<sub>1</sub> is  $d(\text{CO}_1) = 4.49 \text{ \AA}$ . Indeed, mapping of the potential energy surface along the C–O<sub>1</sub> reaction coordinate revealed for MgO(FC)/Au<sub>8</sub> a rather broad reaction barrier  $\Delta E_b(\text{LHp}) \sim 0.5 \text{ eV}$  at  $d_b(\text{CO}_1) \sim 2.0 \text{ \AA}$ , while for the defect-free substrate, a significantly higher barrier was found,  $\Delta E_b(\text{LHp}) \sim 0.8 \text{ eV}$ ; the reaction product is shown in Figure 4B-h for the MgO(FC)/Au<sub>8</sub> catalyst. Another reaction path was theoretically found, starting from the optimal configuration of O<sub>2</sub><sup>\*</sup> adsorbed on the MgO(FC)/Au<sub>8</sub> catalyst. A gas-phase CO molecule brought to the vicinity of the peroxy molecule reacts spontaneously (without an energy barrier), forming a carbon dioxide molecule weakly bound to the catalyst. This Eley–Rideal (ER)-type reaction mechanism corresponds to the low-temperature generation of (weakly adsorbed) CO<sub>2</sub> through direct reaction of gaseous CO with a preadsorbed peroxy O<sub>2</sub><sup>\*</sup> molecule. This reaction channel can occur even at 90 K, that is, during the initial dosing stage in the experiment.

The catalytic behavior can further be changed by cluster size and impurity doping. To understand the origin of this size-dependent and element-specific behavior, the atomic structure and the electronic spectra of these model catalysts were studied by extensive first-principles simulations, and the optimized structures of Au<sub>8</sub> (with two relevant isomers), Au<sub>4</sub>, and Au<sub>3</sub>Sr adsorbed on MgO(FC) are shown in Figure 5, before (a–d) and after (e–h) O<sub>2</sub> adsorption.

**Figure 5.** Optimized atomic structures of nanocatalysts comprised of Au<sub>8</sub> (a), (b), Au<sub>4</sub> (c), and Au<sub>3</sub>Sr (d) clusters adsorbed at an F center of an MgO(100). For Au<sub>8</sub>, two relevant isomers, separated by an energy difference of 0.29 eV, are shown. The optimal adsorption geometries of the O<sub>2</sub> molecule to these nanocatalysts are shown in panels (e)–(h).

As shown above, these clusters bind to the MgO(FC) surface quite strongly (calculated binding energy of 2.65–4.06 eV), and their binding is significantly enhanced (typically by about 2 eV) due to the F center defects. These high binding energies and the “anchoring” effect by the F centers correlate well with the observed thermal stability of the supported clusters in the TPR experiments. Another important finding pertains to the charge state of the adsorbed clusters—in particular, our calculations predict that the interaction with the surface is accompanied by a charge transfer [11] of  $0.5e$ ,  $0.3e$ , and  $0.3e$  to the adsorbed  $\text{Au}_8$ ,  $\text{Au}_4$ , and  $\text{Au}_3\text{Sr}$  clusters, respectively.

Binding and activation of molecular  $\text{O}_2$  by the model catalyst are necessary elementary steps in the CO oxidation process [63, 64], and thus, understanding the structural, dynamical, electronic, and compositional factors that govern these processes are key to elucidation of the observed size-dependent activity of the  $\text{Au}_n/\text{MgO}(\text{FC})$  model catalysts. Indeed, these first-principles simulations show that the binding energy of  $\text{O}_2$  to the supported  $\text{Au}_n$  clusters and the degree of O–O bond activation are strongly dependent on the cluster size. In contrast, the adsorption energy of CO to the supported clusters is relatively insensitive to the cluster size, and it is higher than that of oxygen (0.7–1.0 eV per CO molecule, depending on coverage). Consequently, in the following, the adsorption and activation of  $\text{O}_2$  by the supported gold nanoclusters is studied in more detail, to illustrate the aforementioned nanocatalytic factors that govern this key reaction step.

**Structural Dynamical Fluxionality** The capability of small clusters to exhibit several structural forms (isomers) of comparable energies, and to interconvert between such isomers at a finite temperature, is one of the hallmarks of cluster science. This unique structural variability may influence the chemical reactivity of nanocatalytic systems in two main ways. First, at a finite temperature, the model catalyst (and, in particular, the cluster component) will form an equilibrium ensemble of coexisting structural configurations, with various isomers exhibiting different chemical reactivities. This is illustrated here via the two structural isomers of the  $\text{Au}_8$  cluster with the two-layered one (Fig. 5b), which is thermodynamically less stable (by 0.29 eV) than the quasipolar isomer (Fig. 5a), showing a higher energy gain upon oxygen adsorption (0.47 eV compared to 0.28 eV for the latter isomer). Second, and most importantly, is the structural dynamic fluxionality of clusters in the course of reactions that expresses itself in the ability of a given structural isomer to dynamically adapt its structure such as to allow the reaction to evolve on the most favorable free-energy path. Such fluxional propensity is illustrated in Figure 5b and f, where the more reactive two-layered  $\text{Au}_8$  cluster is shown to undergo a large structural transformation upon adsorption of molecular oxygen at the “periphery site,” that is, the approximate bi-capped octahedral geometry (Fig. 5b) is transformed to a bi-capped trigonal prism (Fig. 5f). Note that the structural fluxionality is essential for the reaction to occur since it was found that constraining the cluster to maintain its original geometry (Fig. 5b) prevents the adsorption and activation of  $\text{O}_2$ .

**Electronic Size Effects** Understanding the size-dependent electronic structure of the  $\text{Au}_n/\text{MgO}(\text{FC})$  model catalysts, which is fundamental for elucidation of their atom-by-atom controlled reactivity, is facilitated by the analysis of the spectra of the local density of electronic states (LDOS) projected on the oxygen molecule and on the metal cluster; a similar analysis is often employed in the context of the interaction of adsorbates with extended surfaces [65]. The LDOS projected on the  $\text{O}_2$  molecule which is adsorbed at the periphery site (Fig. 5f) of the more reactive isomer of the  $\text{Au}_8/\text{MgO}(\text{FC})$  model catalyst was investigated. All of the prominent peaks of the LDOS spectrum can be unambiguously assigned to orbitals of (free) molecular oxygen origins. In addition, these states overlap with the entire  $d$  band of the  $\text{Au}_8$  cluster in the range of  $-7 \text{ eV} \leq E \leq E_F$ , where  $E_F$  is the Fermi energy. Bonding of the oxygen molecule to the gold octamer mainly involves hybridization of the  $5\sigma$ ,  $1\pi_{\parallel}$ , and  $1\pi_{\perp}$  oxygen states with the gold  $d$  band. Most importantly, the full spin manifold of the antibonding  $2\pi^*$  states of  $\text{O}_2$  is located below  $E_F$ , resulting in strong activation of the  $\text{O}_2$  molecule through occupation of the antibonding orbitals. This leads to weakening of the O–O bond that is reflected in a significant increase of its length (1.43 Å in Fig. 5f) compared to that of the free molecule (1.25 Å). Accompanying the activation process is a change in the spin state of the molecule from a triplet state in the gas phase to a peroxo-like adsorbed state with a zero net spin.

A drastically different scenario is found for the interaction of  $\text{O}_2$  with the smaller gold cluster,  $\text{Au}_4/\text{MgO}(\text{FC})$ , where molecular oxygen adsorbs in an “on-top” configuration, with one of the oxygen atoms binding to a single gold atom (Fig. 5g). This system exhibits rather weak binding of the molecule to the metal cluster (0.18 eV), an almost unperturbed O–O bond length (1.28 Å), and a spin splitting of the oxygen-projected LDOS spectrum. The weak binding is attributed to the narrower  $d$  band of the adsorbed  $\text{Au}_4$  cluster compared to that of  $\text{Au}_8$ , with a consequent lack of overlap between the states at the bottom of the  $d$  band of the gold cluster and the molecular oxygen states with energies  $E < -5 \text{ eV}$ . Moreover, the spin-down antibonding  $2\pi^*_{\perp}$  and  $2\pi^*_{\parallel}$  orbitals of the adsorbed oxygen molecule are now located above  $E_F$  (unlike the case of the larger cluster), which results in no activation of the molecule by the adsorbed  $\text{Au}_4$  cluster.

**Impurity-Doping Effects** Finally, we address the possibility of enhancing the catalytic activity of a nanocluster by designed incorporation (doping) of an impurity, demonstrated here by the catalyzed oxidation of CO on  $\text{Au}_3\text{Sr}/\text{MgO}(\text{FC})$ . The LDOS spectra projected onto the oxygen molecule, the Sr atom, and the  $\text{Au}_3$  part of the metal cluster were obtained. Doping by a single impurity atom significantly changes the bonding and activation of  $\text{O}_2$  compared to the pure gold tetramer,  $\text{Au}_4$ , case; the bonding of  $\text{O}_2$  is mainly to the strontium atom of the  $\text{Au}_3\text{Sr}$  cluster (Fig. 5h), and it is characterized by a substantially higher adsorption energy (1.94 eV compared to 0.18 eV for the configuration shown in Fig. 5g) and a significant activation of the O–O bond that is reflected in an increased bond length of 1.37 Å. This activation is due to occupation of the spin-down  $2\pi^*_{\perp}$  oxygen orbital, resulting in a superoxo-like state of the adsorbate. Bonding of the oxygen molecule

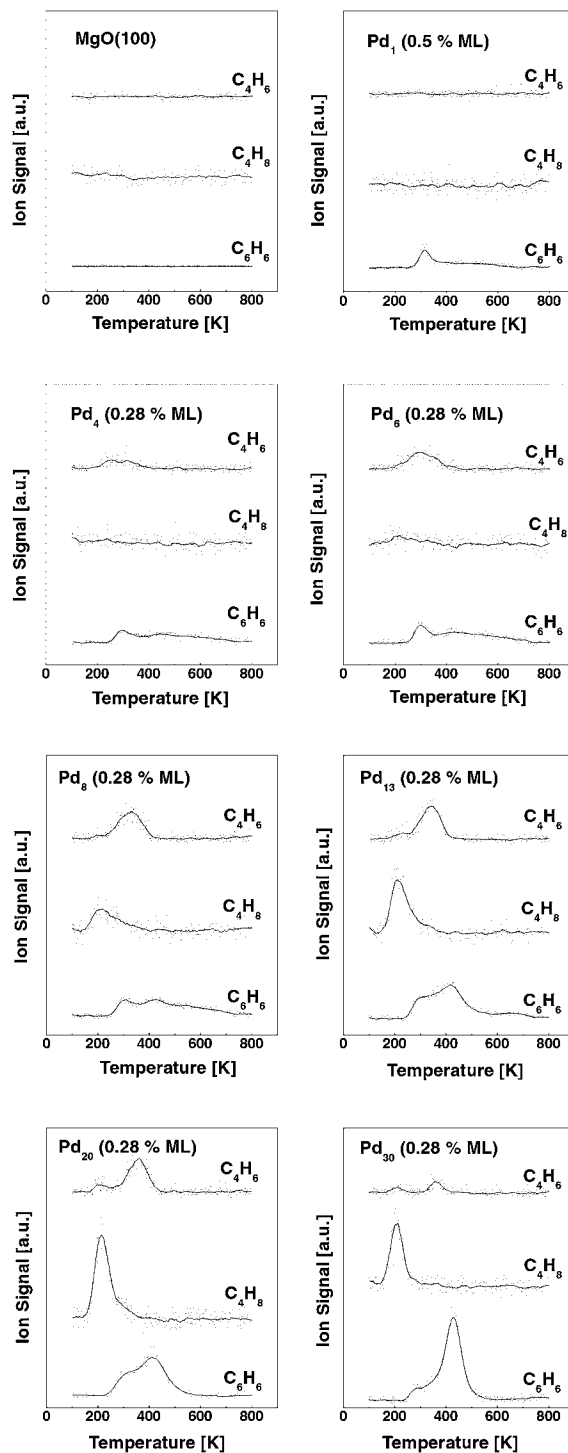

to  $\text{Au}_3\text{Sr}/\text{MgO}(\text{FC})$  occurs via resonances formed between the Sr states in the energy intervals 5–6 eV and 0–1 eV below  $E_F$ , with the spin-up  $1\pi_{\parallel}$  and  $2\pi_{\perp}^*$  states, as well as with the spin-down  $1\pi_{\perp}$  and  $2\pi_{\perp}^*$  orbitals, of the adsorbed activated  $\text{O}_2$ .

### Changing Catalytic Selectivity Atom by Atom: Polymerization of Acetylene on Palladium Nanocatalysts

Another important factor in catalysis is the selectivity of a catalytic reaction. So far, however, information on the atom-by-atom evolution of this astonishing catalytic selectivity is still lacking. In this example, we illustrate such a size-dependent selectivity with the polymerization of acetylene on palladium nanocatalysts [46]. This reaction over supported Pd particles reveals a direct correspondence between reactivities observed on model systems and the behavior of industrial catalysts under working conditions [66]. In ultra-high vacuum (UHV) [67] as well as under high pressure, large palladium particles of typically thousands of atoms show an increased selectivity for the formation of benzene with increasing particle size [66]. In contrast, small palladium particles of typically hundreds of atoms are less selective for the cyclotrimerization, and catalyze butadiene and butene as additional products [66].

The TPR spectra of the different products of the polymerization of acetylene on small, monodispersed palladium clusters supported on defect-rich MgO thin films are shown in Figure 6. Striking atom-by-atom size-dependent reactivities and selectivities are observed. Only the three reaction products  $\text{C}_6\text{H}_6$ ,  $\text{C}_4\text{H}_8$ , and  $\text{C}_4\text{H}_6$  are detected. Remarkably, no  $\text{C}_3\text{H}_n$ ,  $\text{C}_5\text{H}_n$ , and  $\text{C}_8\text{H}_n$  are formed, indicating the absence of C–C bond scission, as already observed on Pd single crystals [68] and Pd particles [66]. Up to  $\text{Pd}_3$ , only benzene is catalyzed, reflecting a high selectivity for the cyclotrimerization of acetylene.  $\text{Pd}_n$  ( $4 \leq n \leq 6$ ) clusters reveal a second reaction channel by catalyzing, in addition, the formation of  $\text{C}_4\text{H}_6$ , which desorbs at around 300 K. The third reaction product,  $\text{C}_4\text{H}_8$ , desorbing at a rather low temperature of 200 K, is clearly observed for  $\text{Pd}_8$ . For this cluster size, the abundance of the three reaction products is similar. For even larger clusters ( $13 \leq n \leq 30$ ), the formation of  $\text{C}_6\text{H}_6$  is increasing with cluster size, whereas the conversion of acetylene into  $\text{C}_4\text{H}_8$  reaches a maximum for  $\text{Pd}_{20}$ . Note that  $\text{Pd}_{30}$  selectively suppresses the formation of  $\text{C}_4\text{H}_6$ . (The peak in the TPR spectrum of  $\text{C}_4\text{H}_6$  at 200 K is part of the fragmentation pattern of  $\text{C}_4\text{H}_8$ .) For  $\text{Pd}_{20}$ , the experiments were repeated in the presence of  $\text{D}_2$  [46];  $\text{D}_2$  was exposed prior to and after  $\text{C}_2\text{H}_2$ . The results clearly indicate that no product containing deuterium is formed. Consequently,  $\text{D}_2$  is not involved in the polymerization reaction. However, the presence of  $\text{D}_2$  opens a new reaction channel, the hydrogenation of acetylene. In addition,  $\text{D}_2$  blocks the active sites on the palladium clusters for the polymerization, as the formation of the products is slightly reduced when exposing  $\text{D}_2$  prior to  $\text{C}_2\text{H}_2$ . On Pd(111), predosing with  $\text{H}_2$  completely suppresses the cyclotrimerization, but enhances the hydrogenation of acetylene to form ethylene [50].

The relative ion intensities of the products in the TPR spectra scale with the product formation by the model catalysts. By integrating the total area of the TPR spectra shown in Figure 6, the number of catalytically produced

**Figure 6.** TPR spectra of the catalytic formation of  $\text{C}_6\text{H}_6$ ,  $\text{C}_4\text{H}_6$ , and  $\text{C}_4\text{H}_8$  for a defect-rich MgO thin film,  $\text{Pd}_1$ ,  $\text{Pd}_4$ ,  $\text{Pd}_6$ ,  $\text{Pd}_8$ ,  $\text{Pd}_{13}$ ,  $\text{Pd}_{20}$ , and  $\text{Pd}_{30}$ . The relative ion intensities are corrected with the relative detection efficiencies of the experiment, and scale with the number of formed product molecules per cluster.

benzene, butadiene, and butene molecules per cluster is obtained and illustrated in Figure 7a. Figure 7b shows the selectivities  $S$  for the formation of the products  $P_1(\text{C}_6\text{H}_6)$ ,  $P_2(\text{C}_4\text{H}_6)$ , and  $P_3(\text{C}_4\text{H}_8)$  for different cluster sizes calculated

**Figure 7.** Reactivity (a) (expressed as the number of product molecules per cluster) and selectivity (b) (expressed as the relative amount in percent) of the polymerization of C<sub>2</sub>H<sub>2</sub> on size-selected Pd<sub>n</sub> (n = 1–30) deposited on defect-rich MgO thin films. Also shown is the relative number of reacted C<sub>2</sub>H<sub>2</sub> as a function of cluster size (c).

from, for example,

$$S(P_1) = \frac{\text{number of } P_1 \text{ per cluster}}{\text{number of } \sum P_n \text{ per cluster}} * 100 [\%]$$

The striking atom-by-atom size-dependent selectivity for the polymerization of acetylene is summarized as follows: C<sub>6</sub>H<sub>6</sub> is catalyzed with a selectivity of 100% on cluster sizes up to Pd<sub>3</sub>. The selectivity for C<sub>4</sub>H<sub>6</sub> reaches a maximum for Pd<sub>6</sub> (~30%), and the production of C<sub>4</sub>H<sub>8</sub> is most efficient (~40%) for Pd<sub>20–25</sub>. If one assumes stoichiometric reactions, as indicated in Figure 7c, and estimates the relative number of C<sub>2</sub>H<sub>2</sub> from Figure 7a, one observes a proportional increase of acetylene with the number of palladium atoms per cluster up to Pd<sub>13</sub>. Surprisingly, at this cluster size, the surface-to-bulk ratio, as well as the coordination number of Pd in the cluster, are changing, as at this size, one Pd atom sits completely in the cluster. In addition, according to the free stoichiometric chemical reactions, each reaction requires a minimum number of Pd atoms, which are three, four, and six. The experimental results are surprisingly consistent, that is, C<sub>4</sub>H<sub>6</sub> is formed for Pd<sub>n</sub> with n ≥ 4 and C<sub>4</sub>H<sub>8</sub> for cluster sizes with n ≥ 6.

Analyzing the products formed on small size-selected Pd<sub>n</sub> (1 ≤ n ≤ 30) clusters deposited on defect-rich MgO(100) thin films indicates that the surface intermediate C<sub>4</sub>H<sub>4</sub> is being produced efficiently on all cluster sizes. Thus, at least two acetylene molecules are adsorbed in a π-bonded configuration at the initial stage of the reaction [69]. The observed size-dependent selectivity may then be understood by regarding the influence of the cluster size to steer the reaction either toward the cyclotrimerization to form C<sub>6</sub>H<sub>6</sub> or toward a direct hydrogen transfer from adsorbed C<sub>2</sub>H<sub>2</sub> to the C<sub>4</sub>H<sub>4</sub> intermediate to catalyze the formation of C<sub>4</sub>H<sub>6</sub> or C<sub>4</sub>H<sub>8</sub>, respectively. Cyclotrimerization is generally observed when a third acetylene molecule is adsorbed in a π-bonded configuration, which results in a change from sp hybridization toward an sp<sup>2</sup> hybridization [70]. This bonding configuration leads to a weak activation of the C–H bond, in analogy to ethylene [71]. The hydrogenation of the Pd<sub>n</sub>(C<sub>4</sub>H<sub>4</sub>) metallocycle, on the other hand, is favored by the adsorption of di-σ/π bonded acetylene to three Pd atoms, effecting a more efficient activation of the C–H bond, in analogy to ethylene [71].

For Pd atoms adsorbed on defect sites, the Pd(C<sub>4</sub>H<sub>4</sub>) intermediate is formed with an energy gain of around 2 eV. A third adsorbed C<sub>2</sub>H<sub>2</sub> molecule is purely π-bonded (Fig. 3a), and the activated acetylene molecule reacts with the intermediate to form benzene with a total exothermicity of about 7 eV. The weakly bound C<sub>6</sub>H<sub>6</sub> (0.3 eV) then desorbs at low temperature from the nanocatalyst [69]. A second reaction channel, the formation of butadiene, C<sub>4</sub>H<sub>6</sub>, opens for Pd<sub>4</sub>. This channel reveals the highest selectivity for Pd<sub>6</sub>; in this case, a third C<sub>2</sub>H<sub>2</sub> molecule can bind in a di-σ/π bond configuration to three Pd atoms. The charge transfer from the substrate to the cluster further enhances the activation of the C–H bonds. For even larger cluster sizes, the adsorption of two di-σ/π-bonded C<sub>2</sub>H<sub>2</sub> molecules becomes possible, and opens up the third reaction path, the formation of C<sub>4</sub>H<sub>8</sub>. In our experiments, this is clearly observed for Pd<sub>8</sub>. Purely geometrical arguments (possible adsorption of two di-σ/π-bonded C<sub>2</sub>H<sub>2</sub> molecules close to the C<sub>4</sub>H<sub>4</sub> intermediate) suggest that this third channel is more pronounced for the larger clusters, and indeed our results show maximal C<sub>4</sub>H<sub>8</sub> formation for cluster sizes of 20–25 Pd atoms. For the largest clusters of the measured range, for example, Pd<sub>30</sub>,

the increased number of metal–metal bonds and the concomitant delocalization of the charge transferred from the substrate to the cluster results in less charge density available for the activation of the C–H bond [72]. Consequently, the cyclotrimerization again becomes more efficient than the hydrogenation of the  $C_4H_4$  intermediate. Going to even larger particles or to Pd(111) single crystals, the cyclotrimerization to benzene is selectively catalyzed.

#### 4. CHEMICAL REACTIONS INDUCED BY CONFINED ELECTRONS

In the examples described above, single chemical bonds of reactants and products are activated, dissociated, and formed by interacting with the electronic states of confined valence electrons of nanoscale systems, such as point defects, free or supported atoms, or clusters. In a completely different approach, single chemical bonds are manipulated by nanoscale devices. Such a device can be an STM (scanning tunneling microscope), where tunneling electrons resonate with single electronic states of molecules to induce chemistry by making and breaking bonds [73]. These two methods for doing chemistry in the nanoscale differ completely. In the first example, confinement is achieved by the system (point defects, atoms, clusters) itself, and in the best case, they may act as real nanocatalysts. The second method uses a nanoscale device, which can be applied to nonlocalized systems for inducing chemistry on the nanoscale.

The use of nanoscale devices for inducing chemical reactions was first introduced by the group of Somorjai in 1994, where a platinum–rhodium tip of an STM operating inside an atmospheric-pressure chemical reactor cell has been used to locally rehydrogenate carbonaceous fragments deposited on the (111) surface of platinum [74]. Recently, the groups of Rieder (FU-Berlin) [75] and Ho (Cornell) [76] used a tip of an STM as a local electron source to induce bond-selected chemistry with a spatial resolution of the atomic scale ( $\sim 1$  Å). With the same device, the induced changes can be imaged with similar spatial resolution. The sharp metal tip of an STM is held in close proximity to a conducting surface. The tip is then positioned above a selected bond of a reactant molecule, and by applying different bias voltages, the energy of the tunneling electrons is tuned to resonate with single bonds. At a tip–surface distance of about 6 Å, this process is dominant, and the overlap of the wavefunctions of the tip and the reactant molecule is negligible. In such a way, a chemically bound CO molecule on Cu(111) could, for example, be transferred to and from the tip in a reversible way [77], or in another example, tunneling-electron-stimulated desorption of H atoms from an Si(100)- $2 \times 1$  surface could be successfully used for nanopatterning [78]. They observed that, for localized and controlled reactions, the energies of the tunneling electrons ought to be below 1 eV (for bias voltages below 1 V). For example, the dissociation of a single  $O_2$  molecule on Pt(111) is confined to the molecule if the bias is less than 0.5 V [79]. However, when the bias is increased to 1.0 V, molecules as far as 100 Å away are also dissociated, even though the electrons are confined to atomic dimensions. The detailed mechanism for this nonlocal effect is not yet understood. In general, they conclude that, for bias voltages larger

than 2.5 V, nonlocal chemistry is dominant, whereas for voltages up to about 1–2 V, local, single-molecule chemistry takes place.

The Cornell group studied the local dissociation of a chemisorbed, single  $O_2$  molecule on Pt(111) in great detail. Obviously, this system is of relevance in catalysis. It is known that oxygen adsorbs molecularly on Pt(111) at temperatures below 100 K [80]. When the temperature is increased to about 150 K, some of the  $O_2$  molecules are desorbing, and the remaining molecules dissociate and recombine and desorb at about 600 K. The bonding configurations of molecular and atomic oxygen on Pt(111) could be detected by low-temperature STM (8–350 K) [79, 81]. The thermodynamically stable atomic O resides in face-centered cubic (fcc) three-fold hollow sites; O atoms on the hexagonal close-packed (hcp) sites are metastable, and can only be created nonthermally by irradiation with electrons or photons [81]. No molecules are observed at (100) steps. They then studied the dissociation of  $O_2$  induced by tunneling electrons on the bridge and three-fold hollow sites of Pt(111) [79]. The adjacent atoms of the underlying Pt atoms on the (111) surface are determined to be 2.77 Å; the observed separation of the two  $O_2$  molecules is 5.54 Å. The STM tip was then positioned about 6 Å above one of the molecules, and a voltage pulse of 0.3 V and 100 ms duration was applied. The sudden change in the tunneling current (12.5 nA) indicates the moment of dissociation. The image taken after the dissociation showed the two O products, one on the hcp site, and the other on the fcc site, as well as the other  $O_2$  molecule, which is not perturbed. The two O products are found to be within two lattice constants of the original molecule, and one–three lattice constants apart. Approximately 1.1 eV/O atom of energy is dissipated upon dissociation through substrate excitations. The rates of energy dissipation and scattering with the corrugated potential of the surface limit the range of motion of the products [82]. Ho and coworkers studied the mechanisms and dynamics of single-bond dissociation by measuring the dissociation rate as a function of bias voltage and tunneling current, and by theoretical modeling of the data [79]. The dissociation rate reveals a power-law dependence on the tunneling current. They proposed a mechanism based on inelastic vibrational excitations of an adsorbed molecule by the tunneling electrons [83–85]. In this process, tunneling electrons inelastically scatter from an adsorbed molecule, and transfer energy to the vibrational modes of the molecule. For the dissociation of  $O_2$ , an energy barrier of 0.35–0.38 eV needs to be overcome via one or multiple vibrational excitations in the ground electronic state. Such a vibrational ladder-climbing process requires one or multiple inelastic scatterings. For a 0.4 V bias used in the reported experiment, the  $O_2$  molecule can be dissociated with a single inelastic scattering event, leading a linear dependence of the dissociation rate with the current. However, at least two scatterings are required for 0.3 V bias, and the discrete nature of the vibrational levels requires three scatterings for 0.2 V bias. As the vibrational relaxation rate is greater than the excitation rate, the most probable path to dissociation is the one with the minimum relaxation probability, which is clearly the path with the fewest transitions. For 0.4 V bias, the bound-to-continuum transition corresponds to a single excitation to overcome

the dissociation barrier of 0.35–0.38 eV. Finally, it is interesting to calculate the electrical energy for this example to dissociate a single  $O_2$  molecule. At a voltage of 0.3 V, a current of 12 nA, and a pulse duration of 30 ms, an energy of  $1.1 \times 10^{-10}$  J is used. For the dissociation of 1 mol  $O_2$ , this corresponds to  $6.5 \times 10^{10}$  kJ/mol!

The dissociation of  $O_2$  is the rate-determining step in the catalytic oxidation of CO on metal surfaces; thus, Hahn and Ho showed in another experiment [86] that the bond-selected chemistry can even be used for inducing this catalytic reaction. After preparing oxygen atoms by dissociating single  $O_2$  molecules with tunneling electrons as described above, they exposed the surface at 13 K to a small amount of CO. The adsorbed reactants and products were then imaged by STM before, during, and after manipulation with the STM tip and reaction of a CO with one of the two O atoms. The CO was moved toward the O atoms by repeatedly applying sample bias pulses over the CO since the CO does not always move toward the O atoms. However, they succeeded in eventually forming the O–CO–O complex. With an additional sample bias pulse over the CO in the complex, they induced the formation of  $CO_2$ , and the product quickly desorbed, leaving the remaining O atom on the surface. From the spatial distribution of STM–IETS (inelastic electron tunneling spectroscopy [87]) intensity, they concluded that the CO in the complex is between the two Ag atoms along the [001] direction, and that the CO may be tilted by the repulsive interaction between the O atom of CO and adsorbed O atoms, as suggested for a transition state in CO oxidation on the Ru(0001) surface [88]. The Ho group illustrated another oxidation pathway by direct transfer of a CO molecule from

the tip to an adsorbed O atom. In this experiment [86], the CO-terminated tip was positioned over one of the O atoms. They applied a +470 mV pulse with the feedback turned off, and a rescanned of the same area showed the remaining O atom on the surface after  $CO_2$  formation.

In another example, the Rieder group induced all of the elementary steps of Ullmann synthesis [89], the formation of biphenyl out of iodobenzene on copper, on individual molecules with an STM in a controlled step-by-step manner, utilizing a variety of manipulation techniques [75]. Two reactant molecules are shown in Figure 8a. The first reaction step is the separation of iodine from iodobenzene by using tunneling electrons (Fig. 8b, c). After dissociation, iodine was moved to terrace sites of the copper surface by lateral manipulation (Fig. 8d). One chemisorbed phenyl reactant was then migrated close to another phenyl by soft lateral manipulation [90] (Fig. 8e). Finally the two phenyls were brought together by molecular excitation by inelastic tunneling (Fig. 8f). Successful chemical association was then verified by pulling the synthesized molecule by its front end with the STM tip.

## 5. SUMMARY

The term nanocatalysis was introduced by Somorjai in 1994, when he used confined electrons of an STM tip to induce an electrochemical process. Earlier experiments on free clusters pointed toward the possibility of using small clusters with intrinsically confined valence electrons as catalysts to tune the properties atom by atom. These two completely different pioneering ideas were further sophisticated during the last few years. It has become possible to use size-selected clusters on surfaces for catalyzing simple chemical reactions, and to tune the catalytic properties with size, as well as to use the tip of an STM to control every step of a chemical reaction on a local scale. With these examples, a deeper understanding of nanocatalytic factors is now emerging, and such studies will have a profound impact on the catalysis of systems at the ultimate size limit.

## GLOSSARY

**Acetylene cyclotrimerization** Formation of benzene from three acetylene molecules.

**Electronic size effects** Varying electronic structure as a function of cluster size.

**F center (FC)** Color center; defect sites (oxygen vacancies) existing on oxide surfaces.

**Impurity-doping effect** Incorporation of impurity atoms into atomic clusters.

**Metal cluster** Assembly of metal atoms exhibiting distinct quantum size effects.

**MgO(100) thin film** Magnesium oxide epitaxially grown on Mo(100) by evaporation of magnesium in an oxygen background.

**Nanodevices** Devices to manufacture materials, and to induce processes on the atomic scale.

**Structural dynamical fluxionality** Interconversion between different structural isomers at finite temperature.

**Figure 8.** Schematic illustration and STM images of the STM tip-induced synthesis steps of biphenyl molecule from iodobenzene. (a) Two iodobenzene molecules adsorbed at a Cu(111) step edge. (b),(c) Iodine is abstracted from both molecules by applying a voltage pulse. (d) Iodine atoms and phenyl molecules are separated by lateral manipulation. (e) An iodine atom is removed onto the lower terrace. (f) The two phenyl molecules are moved together.

**Ullmann synthesis** Formation of biphenyl out of idobenzene.

## ACKNOWLEDGMENTS

This work was supported by the Deutsche Forschungsgemeinschaft (DFG), Alexander von Humboldt-Stiftung, and the Swiss National Science Foundation (SNSF). We are delighted to thank U. Landman, H. Häkkinen, G. Pacchioni, L. Wöste, and Th. Bernhardt for sharing their outstanding expertise with us. We also thank K. Judai, A. S. Wörz, J. Gong, F. Vanolli, A. Sanchez, L. D. Socaciu, J. Hagen, and L. Klinger for an excellent collaboration and stimulating discussions. It is a pleasure to acknowledge fruitful discussions with H.-J. Freund, C. Henry, W.-D. Schneider, R. J. Behm, and E. Schumacher.

## 1. NANOCHEMISTRY: DEFINITIONS AND EXPECTATIONS

The term nanochemistry was originally invented by G. Ozin from Toronto back in 1992 [1]. In this article, Ozin described the state of the field at this point. Nanochemistry is highly related to the larger field of Nanotechnology [2–7], which promises to be a future focus for many sciences (chemistry, physics, engineering, etc.). One might say that nanotechnology contains the disciplines nanochemistry, nanophysics, nanoengineering, and many other disciplines. It might be questionable if such a differentiation makes much sense because as nanotechnology itself is highly interdisciplinary, a topic like nanochemistry cannot be reduced to one field as well. However, a definition as sharp as possible is required.

### 1.1. Definition of Nanochemistry and the Correlation to Nanotechnology

Obviously, the term nanochemistry is composed of the two words “nano” and chemistry. “Nano” is a description of the relevant lengthscales  $l$  or dimensions in this field, namely, the nanometer-sized dimension. Nowadays, this differentiation is not anymore absolutely correct because “nano” can mean everything above molecular dimensions ( $l > 1$  nm) and smaller than macroscopic sizes ( $< 1$   $\mu$ m) [8]. This might

have initiated Ozin to talk about “mesochemistry” rather than nanochemistry some time later [9].

For this chapter, chemistry (the second component of nanochemistry) stands for two sorts of events. Chemistry can mean the construction of larger units from smaller ones (synthetic point-of-view) also represented by the well-known expression “bottom-up approach,” or simple reactions between molecules without forming time-durable chemical bonds (physico-chemical point-of-view). The bottom-up approach stands in contrast to the “top-down approach” taken by nanophysics and nanoengineering. Therefore, nanochemistry is unique.

This new type of matter, created by nanochemistry, smaller than a macroscopic unit but significantly larger than a few pairs of atoms or molecules, should have unique and novel electronical, optical, magnetic, photochemical, electrochemical, catalytical, or mechanical properties (see Section 2.2 about quantum-size effects) and applications. In other words, nanochemistry describes how this special sort of matter can be created and organized by designing new experiments applying well-established chemical methods. Mainly, three strategies for this type of chemical syntheses can be mentioned [8]:

- Sequential formation of covalent bonds. This method allows the generation of structures of limited size but far away from the thermodynamic equilibrium.
- Covalent polymerization. High molecular mass macromolecules are produced. A control about a designed composition in these objects is difficult to achieve.
- Self-organizing synthesis. Smaller units are assembled by weak intermolecular forces (van der Waals, electrostatic) into organized structures. Examples are molecular crystals, liquid crystals, micelles, emulsions, phase-separated polymers, Langmuir–Blodgett films, and self-assembled monolayers. Several orders of magnitude can be addressed this way and the structures are in thermodynamic equilibrium.

On the other hand, the chemistry itself, the way molecules behave, might change when matter is confined to such small length scales as several nanometers. This is an extension of the original meaning of nanochemistry because chemical rules themselves may change.

In clear contrast to this stands nanophysics. Here, a top-down approach tries to scale down objects until they are in the nano-size regime [10]. For instance, one very important technique of nanophysics, is nanolithography [10, 11].

So, how does nanochemistry fit into the concept of nanotechnology and what is nanotechnology? Nanotechnology can be described as an engineering discipline in which the task is to prepare functional devices and structures that have every nanometer-sized subunit (molecules or atoms) in the proper place. Under these conditions, all units with their known properties act together and create new functions. This is just an extremely brief description and the further interested reader is referred to the literature [2–7, 12, 13]. Thus, nanochemistry covers strategies to prepare nanotechnologically relevant devices by a bottom-up approach.

## 1.2. Expectations

The structures that emerge from nanochemical experiments certainly have new and sometimes unexpected properties as will be mentioned later in this article. They are believed to be able to solve many problems (and already did), to overcome established materials, and to initiate completely new fields of applications [14]. Some points of interest are sensors [15–22], molecular recognition [23], controlling the mechanical strength of composites, drug release systems, clean up of environmental pollutants, electrochromic displays or paper, or separation and detection of biomolecules [9].

Two areas of materials derived by nanochemistry are of extraordinary importance. One is the so-called “smart-materials” area. These are materials that are able to dynamically respond to externally applied stimuli (chemical or physical ones) [24–27].

Second, nanostructures are expected to have a significant impact on computer technology via minimization of devices, increase of memory speed, and mesoscopic wires for nanosized electrical circuits [28–31].

Finally, the ultimate goal, which yet sounds like some type of science fiction, is to create nanomachines and finally a special nanomachine called “the assembler.” These types of systems have been defined nicely by G. M. Whitesides [32]:

“I choose to take a machine to be a device performing a task. Going further, a machine has a design; it is constructed following some process; it uses power; it operates according to information built into it when it is fabricated. . . why shouldn't a complex molecular system that performs a function also be considered a machine. . . So the issue is not whether nanoscale machines can exist—they already do—or whether they can be important. . . but rather where we should look for new ideas for design.”

And about the assembler he writes:

“It would be a new type of machine—a universal fabricator. It would make any structure, including itself. . .” The assembler essentially is a nanorobot able to put everything in a nano-device in the proper spot with atom precision.

In the future, it is believed that nearly everything will contain nanotechnology and, therefore, is connected to nanochemistry [6]. In the next section, it will be shown that nature already uses nanotechnology. Interestingly, nature exclusively applies nanochemistry and not nanophysics.

## 2. NANOCHEMICALLY DESIGNED FEATURES IN NATURE

Already Whitesides realized [32] that many prototypes with a nanochemical design can be found in nature driven to perfection by evolution. Some examples should elucidate this.

### 2.1. Examples

#### 2.1.1. Nature's Nanoarchitecture

Nanostructural features and their superior properties were discovered quite early due to the beauty connected to these features. Haeckel, who depicted the skeletal structure of diatoms and radiolariae [33], inspired many scientists and even architects. However, nature is not interested in beauty. Beauty is just an indirect, maybe logical consequence. Structures we find in living organisms, no matter if one considers diatoms, human bones, etc., exhibit maximum performance at minimum metabolic costs [34]. Unlike materials synthesis in the laboratory, living organisms are additionally restricted to prepare their materials at room temperature and neutral pH.

One ideal example for nanoarchitecture in natural systems is the abalone shell nacre. The material is composed of plates of calcium carbonate is used (interestingly, the thermodynamic unfavorable crystal modification aragonite is expressed) and interlayered biopolymer domains. It is assumed that the biopolymers guide the growth of the inorganic crystal phase by selectively binding to selective crystal sides. This model has been supported by Coelfen on the influence of double-hydrophilic polymers mimicking natural systems on the crystal growth of BaSO<sub>4</sub> [35–38]. It was reasonably demonstrated in these articles that the polymer recognizes specific crystal surfaces, adsorbs there, and blocks them for further growth. Crystal planes without polymer grow more and more, and this determines the crystals final shape. Other scientists argue that this model is too simple [39]. This shows that much more understanding about the “bottom-up” mechanisms nature uses is needed in order to be able to mimic such materials. Biomimetics is actually nanochemistry in most parts.

#### 2.1.2. Nature's Nanoparticle Factories

Much of the research attention in nanochemistry was and still is devoted to the production of nanoparticles of various compositions, selective sizes, and shapes, as will be seen later in this review article. Interestingly, there are also different cellular organisms creating and using nanoparticles. One can find Fe<sub>3</sub>O<sub>4</sub>, Fe<sub>3</sub>S<sub>4</sub>, CdS, La(NO<sub>3</sub>)<sub>2</sub>, H<sub>2</sub>UO<sub>2</sub>PO<sub>4</sub>, Ag, Te, Se, Au, and Tc nanoparticles in natural systems [40].

Presumably, the most amazing example is the creation and use of magnetite nanoparticles enabling the use of biomagnetism [41]. The Fe<sub>3</sub>O<sub>4</sub> crystals exhibit a magnetic moment and enable the organism to navigate within the magnetic field of the earth. Many birds possess magnetic senses [42], insects [43], fish [44] do, but interestingly there are also simple bacteria having magnetotactic properties [45]. These bacteria were discovered by Blakemore in 1975 [46]. Magnetotactic bacteria live in anaerobic environments and the magnetic sensor enables them to swim downwards, away

from the oxygen-rich water-air surface [47]. The magnetite particles themselves seem to be formed inside vesicles with a phospholipid/protein membrane, while different vesicles are aligned in chain-like structures. The particles are crystallographically oriented with the [111] crystal axis along the chain direction and the particle sizes range typically from 35–120 nm, which is the single-domain-size range for magnetite.

While magnetite is of real use for the mentioned organisms, it will be evolutionarily favorable especially for bacteria if they would be resistant against dissolved heavy-metal ions. Some microorganisms solve these problems by transforming heavy-metal poisoning into nanoparticle deposits inside the cell. Examples are the deposition of  $\text{Cd}^{2+}$  as CdS nanoparticles [48],  $\text{Ag}^+$  as Silver [49], or  $\text{Au}^{3+}$  as gold [50].

### 2.1.3. Nature's Anti-Freezing Systems

A completely different nanochemical task that nature has to cope with is to avoid crystallization. As temperatures can fall below  $0^\circ\text{C}$  in winter, it would be fatal for many organisms if the cell water starts to freeze and ice crystals grow. Nature's solution is to develop anti-freezing proteins. It seems that the protein possess functional groups in its backbone, which exhibits a geometrical motive fitting to the surface patterns of ice crystals [51]. Similarly to biomineralization, which was previously explained, these biopolymers block the growth of ice nuclei completely.

## 2.2. Quantum-Size Effects

The previous section demonstrated how nature is able to achieve desired mechanical, chemical, optical, magnetic, or electronically properties by making nano objects via nanochemistry ("bottom-up"). For the latter three target properties (electronically, magnetically, and optical) the internal electronic structure of the used nano objects is of particular importance. Indeed, the electronic properties of nanoparticles is somewhat special and, in general, is summarized under the expression quantum-size effects [52–54]. The properties of a semiconductor, for instance, can be related to its electronic structure, a bandgap between an electron-filled band and an electron-empty band (Fig. 1). Similarly, the properties of the atom is given by the energies and occupancies of the atomic orbitals. When the size of the particle is extended by a repetition of atoms in one, two, or three dimensions, a transition from molecular (or atomic) to solid state (or infinite) systems occurs. This transition is characterized by sometimes surprising properties of the nanoparticles and by a high size-dependence of these properties. One typical example is the size-dependence of the color (for instance, the UV/V is a spectrum of gold nanoparticles) [55].

## 2.3. Concluding Remarks

The previous section described just an infinitesimal fraction of nature's solution by nanochemical approaches. Confronted with this perfection, one might suspect that all optimum solutions already exist. Scientists would now just need to find these natural solutions for a particular application or problem and search for ways to translate nature's ideas into technologically realizable approaches. This route

**Figure 1.** Schematic representation of quantum-size effects. The left side of the figure shows matter in decreasing size and the right side indicates the correlating electronic situation. On the atomic scale, one finds atomic orbitals (a s- and p-orbital are shown) separated by a certain energy. When atoms assemble to nanostructures or nanoparticles, respectively,  $x$  atomic orbitals of suitable symmetry lead to  $x$  combinations of orbitals. Every of these orbitals has a distinct energy, symmetry, and spin property. In this respect, the electronic situation of nanostructures is still somewhat similar to atoms. However, there is already delocalization of electrons in a certain volume leading to a decrease in the energy gap between the frontier orbitals. It should also be noticed that surface state (not indicated in the scheme) are of extreme importance for the electronic properties of nanostructures. Finally, when the number of interacting units exceeds a certain threshold, one obtains continuum behavior, the bulk state of matter, respectively. Bands separated by bandgaps have formed.

will be taken and is worth being taken by many groups (biomimetics). But the perfection seen in nature does not automatically mean that there are not better solutions or that there are problems not relevant or existing in nature [56].

One example that could elucidate this is photosynthesis. Photosynthesis transforms light into a different form of energy—chemical energy, respectively. For us, it is much more interesting to transform light into electrical energy, and it can be seen that even conventional solar cells show slightly higher efficiency performances than photosynthetical cells. Many more improvements are possible by nanochemical design as Graetzel et al. showed [57–59]. Nanocrystalline, nanoporous titania films sensitized with viologen dyes [60] are used to adsorb light and create charge carriers. The charges are then separated and collected at the counter electrode. This helps to avoid charge recombination and, therefore, enhances the efficiency, a true nanochemical solution.

Nature's solution can help but they are not the limit. However, it should be noted again that nature is restricted to ambient temperatures and predetermined concentrations of electrolytes. In order to synthesize nanocompounds, organisms cannot raise the cell-internal temperature and just by spending much energy are able to locally increase the

concentration of ions. This is a significant advantage for synthesis in the laboratory but also a challenge—to search for nanochemical routes avoiding extreme conditions.

### 3. NANO-CHEMICAL STRATEGIES: SELF-ASSEMBLY AND THE NANOREACTOR CONCEPT

The bottom-up approaches to prepare nanosized objects as introduced in section 1.1 are mainly covered by two strategies relevant for this review article. These are:

- self-assembly processes
- the nanoreactor concept

Methods, where larger structures are prepared by step-by-step covalent linkage and polymer chemistry, are not taken into consideration here and are not likely to be seen as nanochemical approaches, although the final products may be nanostructures.

Even self-assembly processes are, in principle, a separate topic. However, because self-assembly is of extreme importance for nanochemistry, it will be mentioned exemplarily for the aggregation of amphiphiles in aqueous media (Fig. 2) [61].

#### 3.1. Self-Assembly Processes

Figure 2 shows the principles of self-assembly and the emerging structures for amphiphile molecules in water. Figure 2(a) shows the pure water-air interface. Due to an anisotropic distribution of molecules at this interface, a resulting force pointing inwards to the solvent is present. When amphiphiles are added (Fig. 2(b)), they accumulate at this interface. The hydrophobic tail points towards the gas phase, while the hydrophobic part is located in the aqueous domain. The amphiphile is enriched at the interface until it is fully occupied. All further added molecules need to be dissolved in-phase or can macro-phase separately. However, dispersion of amphiphilic molecules in the continuous phase is possible when micelles are formed due to minimization of interface energy. In a micelle, the hydrophilic units point

**Figure 2.** Schematic presentation of self-assembly processes of amphiphilic molecules. (a) shows the air-water interface and a force diagram; (b–c) shows the enrichment of amphiphiles at the air-water interface and the formation of micelles; (d–e) show higher order structures, dense micellar packings (hexagonal and cubic symmetry), and lyotropic phases (hexagonal, gyroid, and lamellar) obtained for higher amphiphile concentration. Even larger structures (f) are obtained when swelling agents or selective solvents are used—micro-emulsions and vesicles.

towards the solvent while the hydrophobic chains are separated from the water in a hydrophobic core (Fig. 2(c)). By the addition of more and more amphiphile, more and more micelles are formed. They can assemble to dense packings as fcc or bcc (Fig. 2(d)). Furthermore, at some point the micelles fuse and build more continuous structures, so-called lyotropic phases. First, two-dimensional phases as a hexagonal alignment of cylinders are built. Then, at higher concentrations even the cylinders fuse and build sheets of a lamellar lyotropic liquid crystal (Fig. 2(e)). Bicontinuous three-dimensional structures as the gyroid phase can emerge during the transition of hexagonal to lamellar phases. Micelles and lyotropic phases can be swollen by different solvents. The results are emulsions [61], for instance, microemulsions (Fig. 2(f)), or vesicles (Fig. 2(f)). Other self-assembly processes that occur in supramolecular chemistry are described elsewhere [23, 62]. This indicates that self-assembled structures are ideal helpers for nanochemistry due to the structural control over several length scales.

Although these structures themselves are already nanochemical structures, they are much more as will be described later. This builds the basis for the nanoreactor concept which is a most relevant idea for the concept of nanochemistry itself, which will be explained in the next section.

#### 3.2. The Nanoreactor Concept

A common theme of all the presented self-organizing structures is that they divide a macroscopic volume in small compartments. For instance, micelles create spherical compartments (the micellar cores) of just a few nanometer and hydrophobic conditions. Hydrophobic solvents can be introduced that lead to microemulsions (up to 50 nm in size). Inverted systems lead to other core properties (hydrophilic). For vesicles, the size of the compartment can be of the order of micrometers and is hydrophilic in nature.

Amphiphilic self-organized structures represent soft-matter spatial confinements and, therefore, are one prototype for nanoreactors. Chemistry can now be performed in these confinements (Fig. 3).

The requirements that can be identified for a good nanoreactor are quite similar to those present for the macroscopic reactors used in labs (for instance, glassware). The reactor volume should be accessible and the wall material should be able to exhibit variable properties independently from other parameters. The reactor should be controllable in size. This will enable control of the amount of matter (stoichiometry) and energy per nanoreactor.

Concerning these general requirements, hard-matter and soft-matter confinements can be very different as indicated in the following. It is the belief of this author that hard-matter structures, in other words porous materials, are more generally applicable as nanoreactors. However, for certain applications soft-matter nanoreactors can be more suitable. Soft- and hard-matter confinements are compared in Table 1, where + stands for favorable properties. It can be seen that these types of nanoreactors are quite different but often complementary.

As was previously mentioned, the prototype for a hard-matter nanoreactor (a) are porous materials, while the prototype for a soft-matter reactor (b) is an emulsion droplet.

**Figure 3.** The variety of possible nanoreactors is shown and related to size and dimensionality. 0D systems are given for spherical reactors. Here, soft-matter reactors (color-coded red) are dominant (micelles → emulsion droplets → vesicles), although some hard-matter confinements can be found as well (see Section 3). 1D-confinements (cylinders) are mainly found for mesoporous materials (hard matter; blue). 2D-reactor systems (lamellar structures) are relevant for organic-inorganic hybrid materials and some pure inorganic compounds as clays. 3D reactors with a bicontinuous structure can be found in the field of porous materials (hard matter) but also in the case of micro-emulsions (soft-matter).

The nanoreactor volume can be accessed by the precursors equally well. For (a), it is diffusion into the porous system guided by capillary forces and for (b), the reaction educts can be dispersed from the beginning. Addition of chemicals might be more difficult for (a) once the pores are filled, and more easy for (b) because the reactor size is not so much restricted, and the droplets are in contact with a macro-reservoir that is the dispersion solvent. The single nanoreactor volume in a porous medium is neighbored by equal reactors separated by walls and is, therefore, not in direct contact with the macroscopic reservoir outside. The size of soft-matter structures can be easily varied, while it is a bit more difficult for hard-matter confinements to find appropriate templates to create a great diversity of sizes. The reactor volumes of porous materials are quite monodisperse and constant due to the rigid walls. This is often not

**Table 1.** Advantages (+) and disadvantages (–) of different nanochemical confinements.

Reactor requirements	Hard-matter confinement	Soft-matter confinement
Accessibility	+/-	+
Size variation	+/-	+
Monodispersity	+	–
Rigidity of size	+	–
Variation of walls	+	–
Control of stoichiometry	+	–
Control of energy	–	+
Ease of preparation	+	+/-
Processibility	+/-	+

the case for soft-matter structures (b); only in some cases these conditions are fulfilled and polydispersity is a major problem. The walls of soft-matter nanoreactors are always given by the flexible water-surfactant-solvent interface and, therefore, hard to vary systematically. For porous materials (a) on the other hand, modification techniques make nearly every wall composition possible [18, 63–88]. Because in a porous system all reactors are neighbored by equal ones and the reactor volume is constant at a given concentration, the stoichiometry can be easily controlled. For emulsion droplets, exchange processes through the continuous phase can have major effects and the polydispersity of volumes was previously mentioned. To reach energy equilibrium is more difficult for solid materials because one might create gradients from the material’s surface to the interior. It is much easier to reach energy equilibrium for independent particles like nanodroplets. The preparation of soft-matter structures is often very facile and sometimes requires special amphiphiles while the template concept [89] enables a simple way to porous materials. The soft-matter structures mentioned are dispersed in a liquid phase and, therefore, processibility is often advantageous for them in comparison to the solid-state confinements (a).

### 3.3. A General Concept of Nanochemistry

As was described in Section 1, a confinement leading to nanochemistry can have two different effects, namely, effects on molecular processes and effects on processes on a higher scale, which mainly describes the formation of special nanoparticles. Investigations in our group showed that these two areas of nanochemistry can be correlated to the nanoreactor dimensions itself (Fig. 4).

Figure 4 attempts to give a more general concept for nanochemistry. The nanoreactor possesses different structural features on different length scales. The smallest features are directly present at the nanoreactor surface, namely, the chemical surface-bound groups (alcohol, amino groups,

**Figure 4.** Schematic correlation between the nanoreactor features, the emerging nanochemical instruments, and the resulting nanochemical effects. A porous nanoreactor has different features being effective on different scales. On the lowest scale (below nanometer), one finds the functional groups (indicated R) determining the properties of the surface (i). Next, comes the pore sizes (above nm scale) which is also related to the curvature (ii). The next level of complexity is given by the pore shape (iii), and finally the pores are three-dimensionally aligned in space (iv). These different material features are combined at the intersections to three nanochemical instruments leading to three possible nanochemical effects.

etc.). These groups determine the functionality of the surface. Next, the nanoreactor has a certain size. It should also be noted that the radius of the reactor is related to the curvature  $H$  ( $H \propto r^{-2}$ ). On the third level, the nanoreactor has a specific shape. In the fields of nanoporous materials, this shape can range from spherical, cylindrical, worm-type to lamellar. Finally, the single nanoreactors are somehow distributed in three-dimensional space as, for instance, the hexagonal alignment of cylinders. These four structural features can be combined to result in three nanochemical instruments. The functional groups on the reactor surface determine if there is attraction or repulsion between the substrate in the pores and this surface. In case of attraction, molecules are located directly at the reactor's surface and experience the curvature. This combination of surface function and curvate gives the nanochemical instrument (Fig. 4(a)) and it confines molecules to a scale that effects molecular reaction (nanochemical effect). In case there is a slight repulsion, the substrates are located in the reactor volume and, therefore, the complete size of the reactor is relevant. Then the reactor size has to be combined with its shape to give a second nanochemical instrument (Fig. 4(b)). This nanochemical instrument (Fig. 4(b)) can be used to effect and control nanoparticle chemistry. The highest level of complexity is achieved when the shape (and size) is combined with the three-dimensional distribution of the nanoreactors, which results in the third nanochemical instrument (Fig. 4(c)). Now, nanoparticles can be forced into a distinct structural order as well and new materials emerge.

A worked-through example should elucidate this. As will be seen later, possible nanoreactors can be mesoporous silica materials. Silica  $\text{SiO}_2$  is normally derived by the sol-gel process [74, 90–94]. Depending on aging and post-treatment, the surface functionalities of the resulting materials can range from highly polar and protic Si-OH groups to relatively unpolar and unreactive Si-O-Si motives. Bronstein et al. prepared mesoporous silica differing only in pore-surface properties by liquid-liquid extraction and succeeding supercritical drying (silanol-rich material) and by high-temperature calcination (silanol-poor material) [95]. They further investigated the reduction of noble-metal precursors and  $[\text{PdCl}_4]^{2-}$  in such materials. A specific interaction between the  $[\text{PdCl}_4]^{2-}$  precursor and the pore surface, already evident by a change in coloration, is found (Fig. 5b) when the silanol-rich materials are infiltrated with the precursor solution. The palladium precursors are bound to the pore surface. This interaction by a square-planar Pd-complex and an Si-OH group would normally never occur because the Si-OH group is a weak ligand. However, under nanochemical conditions it does, the curvature of the mesopore presumably leads to a release of water from the pore surface when the complex is bound. This water release provides an entropic driving force for the formation of the unusual surface complex (molecular nanochemistry). When the  $[\text{PdCl}_4]^{2-}$  is reduced, this interaction prevents Ostwald-ripening after nucleation of  $\text{Pd}^0$  species to larger crystals. Therefore, no Pd-particles are visible in transmission electron microscopy (TEM) images (see Fig. 5b). It can be concluded that the nanochemical instrument was effective (see Fig. 4(a)). When on the other hand, the silanol-poor

**Figure 5.** It is shown how the pore itself can be used to create new nanostructured matter as metal nanoparticles for instance. When the interaction between the pore walls and the precursors is tuned, it is possible to direct the growth of nanoparticles and obtain control about their size and properties of the hybrid materials (a). When the pore wall binds strongly to the metal precursors, Ostwald-ripening is kinetically suppressed and subnanometer nanoparticles cover the pore walls (b). For repulsive or nonbonding interactions, the size of the nanoparticles, their polydispersity, and their shape is dictated by the pore system.

material is used, this interaction is not present as can also be seen in the “normal color” of the infiltrated material (Fig. 5a). The  $[\text{PdCl}_4]^{2-}$  species that are located in the pore volume are free to move and, therefore, by Ostwald-ripening, larger particles are formed. However, the pore confines the growth of the nanoparticles until they match exactly the size and shape of the nanoreactor pores (see Fig. 5a). Obviously, now the nanochemical instrument (see Fig. 4(b)) is effective. If one would finally increase the loading of this material with more Pd, so that each pore is filled with metal, one would obtain a mutual ordering of the nanoparticles themselves. Via instrument (Fig. 4(c)), a new hybrid material is obtained.

## 4. HARD-MATTER CHEMICAL CONFINEMENTS

Up to this point, this chapter has discussed in a more general fashion, methods and strategies that are involved in nanochemistry. Following will be a highlight of specific achievements using these strategies and concepts.

### 4.1. Porous Materials

Porous materials are characterized by a solid network having voids throughout the material. According to the International Union of Pure and Applied Chemistry (IUPAC), porous materials are characterized by pore size categorized by sorption behavior [96–98]. There are microporous solids with pore sizes smaller than 2 nm, mesoporous materials with pores between 2 nm and 50 nm, and macroporous

materials with pores larger than 50 nm. Naturally, for performing nanochemistry, nanoporous materials are ideal target compounds. To describe nanoporous materials in detail here is beyond the scope of this article, but a comprehensive review can be found in literature of Polarz [2002, #2053].

#### 4.1.1. Zeolites and Catalysis

Zeolites are microporous materials, having very small pores ( $D_p > 2$  nm) that can be represented by the general formula  $M_2/nO \cdot Al_2O_3 \cdot SiO_2 \cdot yH_2O$  [99–101]. If one takes the general concepts about nanochemistry given in Section 3 into account, the substrates in microporous materials will be automatically forced to be at the pore wall. There is no other choice. Therefore, one has to expect effects of these kinds of materials mainly for molecular processes which was introduced as molecular nanochemistry.

This area of nanochemistry is extremely important because it contains zeolitic catalysis. Zeolites are amongst the most important modern catalyst materials [102, 103]. The realm of zeolite catalysis is vast, of course, and the interested reader is referred to the literature of Breck and Corma, respectively [99, 104]. Zeolites are known for their high catalytic activity and high selectivity [105]. In the sense of nanochemistry, zeolites already extend the classical meaning of catalysis, which is to accelerate chemical reactions. Zeolites, for instance in the case of the isomerization of olefins, selectively favor the formation of a particular product [106]. In other words, they alter chemical equilibria in comparison to the unconfined state. The activity of the zeolites is caused by active surface functions (for instance, acid sites) and the high electric fields present in zeolitic channels are summarized as coordination and coulombic effects [107]. Other typical nanochemical factors are the shape and size of zeolite pores favoring the formation of one product due to steric constraints. One product, for instance one isomer, may need slightly more space than the other isomers, so its production is repressed. Other factors are the differences in diffusion behavior and the lack of solvation of reactand molecules [101, 108–113]. It was further discussed by Zicovichwilson et al. that zeolites additionally modify the electronic structures of included guests and thus, increase the reactivity [107].

#### 4.1.2. Mesoporous Materials

As mesoporous materials are characterized by larger and a larger diversity of pore sizes (2–50 nm), these nanoreactor systems can be used to perform both molecular nanochemistry and nanoparticle chemistry.

In this section, we will begin to discuss phenomena where guests confined to the physical space of the ordered mesopore volume show some extraordinary characteristics not present in the bulk state.

One example for the unique feature occurring under confinements in the mesoporous range is the capillary condensation of gases during the sorption process. In comparison to the bulk, the temperature for the capillary critical temperature is far below the bulk critical temperature [114]. This confinement effect is very simple and has been recognized and studied for a long time. It is the basis for the Kelvin

equation (see Eq. 1) and all analytic techniques related to gas sorption.

$$r_p \left( \frac{p}{p_0} \right) = \frac{2\gamma V_L}{RT \ln \left( \frac{p}{p_0} \right)} + t \left( \frac{p}{p_0} \right) \quad (1)$$

$r_p \cong$  pore radius

$\gamma \cong$  surface tension

$t \cong$  thickness of the adsorbate film

$V_L \cong$  molecular volume of the condensate.

However, the development of ordered mesoporous materials allows one to perform much more systematic studies on sorption processes.

Also for water, one of the most common solvents, physical properties are influenced by geometrical confinements. The physical properties of water under confinement conditions are of particular interest due to the similarity to supercooled water in living biological cells. First indications for supercooled water in the pores of MCM-41 were found by Hansen et al. in 1995 [115, 116]. They applied  $^1H$ -NMR techniques to investigate water located in the mesopores and found two transition temperatures—one that was dependent on the pore size ( $T > 222$  K) and one that was independent at  $T = 209$  K. The latter transition point was attributed to water bound to the pore surface as a 5.4 Å thick interface layer. Baker et al. reported that the freezing point of water in MCM-41 is depressed to  $-21$  °C at a pore radius of  $\approx 3.4$  nm [117]. At extremely low temperatures, X-ray diffraction (XRD) data indicated a glassy state of ice (“frustrated nucleation”) while the cubic form of ice was also found [117]. This work was extended and it was seen that a pore system of 4.2 nm pores led to an abrupt crystallization of water to cubic ice at  $T = 232$  K, while the freezing process was very slow in 2.4 nm pores [118]. Quasi elastic neutron scattering revealed that the mobility of water is restricted under confinement [119]. Later, Smirnov et al. also investigates water in the fluid state [120]. With X-ray scattering methods, it was found that water exists in a distorted tetrahedral-like hydrogen-bonded network inside the porous environment.  $H_2O$ – $H_2O$  and  $H_2O$ – $SiO_2$  interactions were present simultaneously.

Other interesting guests are fullerene molecules as  $C_{60}$ . The first systematic study was presented by Rachdi et al. [83].  $C_{60}$  was deposited in MCM-41 with different pore sizes from the gas phase and the electron spin resonance (ESR) spectra were recorded. It could be seen that the confinement through the mesoporous host influenced the electronic band structure of the fullerenes. In contrast to the bulk state, an intense photoluminescence at 642 nm, as well as an emission at 484 nm, was created by inclusion of  $C_{60}$  to MCM-41 [121]. These features were attributed to strong interactions of the fullerene with the silica wall (“passivation of the surface”). Later, Chen et al. published a study with infrared (IR) spectroscopy and claimed that the fullerene reacts with hydroxyl groups on the wall surface (addition to the aromatic ring) during heat treatment [122].

A completely different idea was followed by Alvaro et al. [123]. They adsorbed the methyl viologen cation  $MV^{2+}$  in mobil composition of matter (MCM)-41 and created  $MV^+$  radicals by flash photolysis. The radicals were very time-stable and it was presumed that MCM could act as an

single electron donor. Acidic MCM-41 was loaded with thi-antrene and the corresponding radical cation was formed [124]. It is a very common feature that even very unstable species like radicals have a significant lifetime in ordered mesoporous hosts. The creation rate of radicals of *meso*-tetraphenylporphyrin was higher with increasing pore sizes of MCM-41 and the deactivation was also very slow for other radical cations like *N*-alkylphenothiazines [125–128]. Deactivation processes are also one limitation for photo-induced electron transfer reactions. By investigating the isomerization of *cis*-stilbene, it was shown that the stability and efficiency of the 2,4,6-triphenylpyrylium cation could be enhanced by immobilization in MCM-41 [129]. In particular, it was argued that the strong electrostatic field occurring in porous materials might be responsible for the stabilization of charged species.

Also macromolecules can be guests in porous silicas. They can be introduced via solution impregnation or they are created directly in the porous system as will be shown later.

A very interesting piece of research was presented by Tolbert et al. in 2000 [130, 131]. They could take advantage of some modern developments in the fields of mesoporous materials and polymer chemistry. As a mesoporous host, a MCM-related material that pore channels aligned parallel along one direction, was used. The alignment of the channels was achieved via treatment of the preparation sol under high magnetic fields during the sol–gel transition [130, 131]. This porous glass was then filled with the semiconducting polymer poly[2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylene vinylene]. The pore size of the silica was selected in a way that only one polymer molecule had sufficient room in the pore. This way, the polymer chains were isolated and aligned simultaneously. The composite material was excited and investigated with polarized femtosecond spectroscopy. It was seen that the excited states or the energy, respectively, moves from nonoriented polymer segments outside the silica to the oriented polymer confined to the mesopores. The polymers inside the material finally emit red-shifted light. As a consequence, this nanocomposite mimicks to a certain degree the antenna chromophores in photosynthesis.

In a similar fashion, mesoporous silica have shown their potential for creating new laser materials. Generally, an active laser dye is brought into a porous environment and its laser activity is studied. It was envisioned by Marlow et al. that a whole laser could be produced by using the self-assembly laws [132]. They could prepare a silica-surfactant laser dye (Rhodamine 6G) hybrid material, which had a fibrous morphology. The laser dye is located in the hydrophobic domains of the lyotropic template phase. The fiber was pumped perpendicular to the fiber direction and above a certain threshold, laser activity was detected. Wirnsberger and Stucky and Yang et al., respectively, extended their works [133, 134] and recently they prepared impressive waveguides by a combination of self-assembly and soft-lithography techniques [135]. Mesoporous silica (template removed) was deposited on silicon and as the third layer, they were the waveguides containing the dye-doped-ordered mesoporous silica [134]. The cylindrical channels were aligned throughout the whole waveguide and even the dye seemed to be oriented in the template phase.

As for most of the so-far mentioned examples, guests in the pore system have been quite static; it is an obvious extension to study chemical reactions inside pores.

Several researchers succeeded in the direct preparation of dye molecules in the channels of mesoporous silicas like MCM-41. The photosensitizer cation triphenylpyrylium TPP<sup>+</sup> [129], tris(4-methoxyphenyl)methylum, and malachite green [136] were prepared accordingly. These organic-inorganic hybrid materials can be used as a heterogeneous photosensitizer for the dimerization of cyclohexadienes [85, 137], electron transfer agents [129], and isomerization reaction of *cis*-stilbene [129].

A lot of research has been done in the field of polymerization in ordered mesoporous hosts. The polymer is directly created in the pore system of the silica and this method again organic-inorganic hybrid materials are obtained. It can be envisioned that future generations of these materials display electron and quantum confinement effects for the tailor-made provision of electronic, magnetic, and nonlinear optic effects.

Llewellyn et al. polymerized vinyl acetate, styrene, and methyl methacrylate (MMA) in MCM-41 [138]. It appeared that the termination rate could be decreased in comparison to the bulk polymerization. This leads to a molecular weight that can exceed the bulk situation by an order of magnitude [139]. Similarly, Moller et al. prepared poly(methyl methacrylate) (PMMA) in MCM-41 and MCM-48 [140]. They reported that the polymer dynamics changed dramatically. Cooperative polymer parameters like the glass transition was suppressed in their cases. Goeltner and Weißenberger used a bicontinuous mesoporous silica matrix as the template for the production of porous PMMA polymer monoliths [141]. Other polymer systems were introduced by Johnson et al. [142]. Phenol was adsorbed in MCM-41 and treated with formaldehyde vapor. The resulting phenolic resin was a structural imprint of the pores. After removal of the silica with HF the recovered polymer fibers were used to determine the length of the cylindrical pores in MCM-41 [142]. A two step “nanochemistry” was performed by MacLachlan et al. when he performed the ring-opening polymerization of a silaferrocenophane in MCM-41 and then transformed the polymer into nanoparticles of iron [143]. Polyesters were synthesized from lactones and alcohols in a living polymerization in Al-MCM-41. By using different lactones, block copolymer synthesis was accessible. Interestingly, no polymerization was found for pure SiO<sub>2</sub>-MCM-41 or microporous zeolites [144, 145]. Obviously, the mesopores, as well as the Lewis acidity, is necessary for this reaction. Also, mesoporous materials grafted with organo-metallic complexes have been used for polymerizations. A zirconocene containing silica was used to copolymerize ethylene and propylene [146–148]. It was seen that in the case of a chiral metallocene, selectivity towards isotactic and high molecular-weight polypropylene could be achieved. But a big breakthrough, and presumably the most ideal example of nanochemistry in ordered mesoporous silica materials, was provided by Kageyama et al. in 1999 [149]. They connected a titanocene catalyst covalently to the pore walls of MCM-41. When the polymerization of ethylene is performed the poly(ethylene) chain is hindered to bend backwards, so it has to grow along

the channel axes. This results in the situation where hexagonally aligned polymer fibers leave the MCM-41 “crystals.” Finally, bundles of several polymer fibers with diameters of 30–50 nm are formed. The obtained molecular weight is extremely high ( $M_n = 6.2 \cdot 10^7$ ).

Great attention has been devoted in the preparation of hybrids of a mesoporous silica hosting a conducting polymer [86]. Wu and Bein produced polyaniline in MCM-41 [150]. Aniline vapor was adsorbed by the silica which is then given to a solution of the oxidant to start the polymerization. The aniline filaments were several monomer units long and still had some conductivity [150, 151]. The polymers of Wu and Bein, when investigated, had lower molecular weights than in the corresponding bulk situation indicating diffusional constraints in the mesoporous host. The pore environment, therefore, seems to influence polymerization under confinement in two ways: (i) creating diffusional constraints, and (ii) an increase in the stability of transition states.

Polymer-silica hybrid materials can be further used to prepare carbon-silica hybrids. The preparation of elemental carbon is quite easy to achieve for several precursors. As shown by Wu and Bein, poly(acrylonitrile) confined to the pores of MCM-41 can be pyrolyzed to elemental carbon [152]. The authors argue that the growth of graphene layers is guided by the pores. At a pyrolysis temperature between 1070–1270 K, conductivity determined by microwave conductivity measurements emerged, which exceeded the conductivity of a carbon prepared under nonconfined conditions by one magnitude.

In the meantime carbon-silica nanocomposites with preservation of the mesoporous structure through the carbon have also been achieved by other methods (Fig. 6). One way is chemical vapor deposition of hydrocarbons and succeeding pyrolysis [153]. Other precursors like sucrose [154] are also successful and fascinating, three-dimensional-ordered carbon materials emerge [154–156]. This interesting area of producing ordered, porous carbon materials was reviewed elsewhere [156, 157]. The resulting carbon-silica hybrid materials can be transformed into pure nanostructured carbon materials by removal of the silica matrix via HF etching. The silica-carbon materials and the new carbon materials might become very important. As Mastai et al. showed, the hybrid materials can be applied as so-called selective solar absorbers [158].

**Figure 6.** TEM images of two ordered mesoporous carbon materials CMK-1 and CMK-1 introduced by Ryoo et al. Reprinted with permission from [156], R. Ryoo, *Adv. Mater.* 13, 677 (2001). © 2001, Wiley-VCH.

As was previously described, the other important subfield of nanochemistry in ordered mesoporous materials is the creation of nanoparticles. Here in accordance with Figure 4, the size and shape of the nanoreactor becomes important. Due to the high interface energy once nucleated, nano-sized crystals tend to grow by Ostwald-ripening. This growth can be restricted by performing the crystallization inside the pore system of a mesoporous host. Often caused by quantum-size effects, interesting composite materials are created. Therefore, much of the work has been devoted to prepare semiconductor nanoparticles via this route. Examples are gallium nitride [159], cadmium selenide [160], cadmium sulfide [161], silicon [162, 163], titanium dioxide [164], Germanium [165], Galliumarsenide [166], zinc sulfide [167], and Indium phosphide [168]. Ordered mesoporous silica materials, especially of the MCM-41-type have also been used as matrices for the preparation of metal colloids. In this way, for example, metal nanowires have been produced with Pd [169, 170], Pt [171], or Ag [171, 172].

For all these materials, the relation between pore size and pore shape and the characteristics of the nanoparticles was obvious. A class of materials that is also quite important are derived, when ordered mesoporous silica materials are just supports. Due to the stability of amorphous silica, a huge number of compounds with ordered mesoporous materials as supports have been reported. The most common technique to prepare them is via liquid impregnation or via vapor deposition techniques.

It is known that the acidity of MCM-based materials is relatively low when the acidic centers are incorporated into the network. This is behind the scope of this review article and can be found in the literature of Corma [173]. A different strategy to introduce sufficient acidity for catalytic applications involves deposition of active species inside the pores. Ordered mesoporous  $\text{SiO}_2$  acts as a support or one could again say as a host. Quite often, polyoxometalate species were deposited on ordered mesoporous host systems. In 1994, heteropolyacids of the Keggin-type as, for instance,  $\text{H}_3\text{PW}_{12}\text{O}_{40}$  were taken [174–176]. Interestingly, high loadings up to 50 wt% were achieved without crystallization of the heteropolyacid. The new materials were acidic enough to catalyze even the alkylation of 4-*tert*-butylphenol with isobutene.

MCM-41 is very likely to act as a support for noble metal colloids. Junges et al. produced a MCM-41 with a high Pt loading [177] and catalytic activity for hydrogenation reactions of benzene, naphthalene, phenanthrene, and olefins were demonstrated [73, 178, 179]. For all of these strategies where the goal is to replicate the whole pore system with a different material, two points have to be considered in further detail:

1. if the used precursor solutions wets the pore wall,
2. if the reaction forming the new material is slow enough to avoid pore blocking.

Even more demanding is hydrogenation of aromatics in the presence of sulfur. Due to the shortage of nonregenerable energy sources, future diesel fuels will contain a significant amount of sulfur. To increase the cetane number of the fuel, a certain fraction needs to be hydrogenated by suitable catalysts. Corma et al. found out that Pt on a MCM-41

support was much more stable against sulfur determination than other supporting systems used like  $\text{Al}_2\text{O}_3$  [180].

Only few publications addressed the deposition of metal oxide particles in mesoporous oxides like MCM-41. Abe et al. [181] and, later, Froeba et al. [182] described the synthesis of iron oxide in the pore system of MCM-41. A simple impregnation technique was applied to obtain the final materials. Under similar conditions,  $\text{TiO}_2$  particles for purposes in photocatalysis [164, 183–186] and  $\text{VO}_x$  species in a tetrahedral coordination mode [70, 82, 187] were prepared. A Mo/MCM-41 with molybdenum in the oxidation state +VI are accessible via deposition of molybdocene dichloride as a precursor [188]. Depending on the concentrations of the precursor, discrete molybdate species or smaller polymolybdates were created as Mo K-edge X-ray absorption spectroscopy indicated. The resulting materials were used for the catalytic dehydrogenation of methanol to formaldehyde. A manganese-grafted MCM-41 was prepared via vapor deposition of  $\text{Mn}_2(\text{CO})_{10}$  [189–191]. This resulted in good oxidizing catalysts. Aronson et al. tried to obtain special structures of manganese oxide under confinement of the silica pores since they adapted a method for preparing layered compounds [192]. Unfortunately, this was not the case but the particles have been amorphous. Via deposition and decomposition of  $\text{Co}_2(\text{CO})_8$ , a Co/MCM-41 was created by Kim et al., which was then used to catalyze the Pauson–Khand reaction [193]. Schueth et al. deposited zirconia  $\text{ZrO}_2$ , iron oxide, and two rare metal oxides (europium oxide and yttrium oxide) in MCM-41 and SBA-15 [194]. The  $\text{Fe}_2\text{O}_3/\text{MCM-41}$  was catalytically tested towards the oxidation of  $\text{SO}_2$  to  $\text{SO}_3$ . Already in 1997, a very interesting article was presented by Shephard et al. [195]. They used a relatively complex bimetallic cluster as the precursor for a bimetallic Ru-Ag-O-species confined to MCM-41 pores. The introduction of two different species might be an interesting way to prepare new compounds in the future.

#### 4.1.3. Anodized Alumina: A Route Towards Nanowires

An alternative route towards porous nanoreactors is via the preparation of porous alumina. Porous alumina is prepared via the anodization of aluminum metal in an acidic solution. Further information about this process can be found in the literature by Despic and Parkhutik [196]. Porous alumina membranes have certain typical characteristics:

- They contain cylindrical pores of uniform diameter in a hexagonal array.
- The cylinder axes are strictly perpendicular to the membrane surface plane.

The pores can be produced with a great variety of pore sizes ranging from just 5 nm up to 200 nm [197, 198]. Pore densities on the membrane surface are of the order of  $10^{11}$  pores per  $\text{cm}^2$ . The membrane thickness is typically in the range of 10 to 100 nm.

Within the context of the concepts of nanochemistry described in Section 3.3, it is obvious that porous alumina membranes are ideal to illustrate the impact on particle preparation and materials chemistry. The size and shape of

nanoparticles will be predetermined by the shape and size of the pores. However, the shape and arrangement of new nanostructures is limited to hexagonally aligned cylinders. A nanorod of some material may be used as a nanowire as will be discussed later. Alternatively, hollow tubes, so-called nanofibrils, can be prepared.

Nanotubes and nanofibrils of conducting polymers [199–207], metals [197, 198, 208–216], semiconductors [217, 218], and carbon have been prepared [219].

The materials that one prefers to deposit inside the pores can be produced in several different ways:

- Electrochemical deposition: One face of the membrane is coated by a thin metal film acting as a cathode for the reduction of metals inside the pores. The more metal that is deposited, the longer the metal nanowires get. Also, some conductive polymers as polypyrrole or polyaniline can be deposited electrochemically.
- Chemical reduction.
- Chemical polymerization of organic monomers.
- Sol-gel processes: Sol-gel methods [74, 90–92, 220–222] are mainly used for the preparation of inorganic oxide-type nanostructures as  $\text{TiO}_2$ ,  $\text{ZnO}$ , or  $\text{WO}_3$ .
- Chemical vapor deposition (CVD).

Preparing nanowires by nanochemistry via porous alumina membranes has thus proved to be a very versatile tool. In further experiments, Mallouk et al. attempted to construct electrical circuits capable of performing simple calculations [223–228].

## 4.2. Other Hard Matter Nanoreactor Systems

### 4.2.1. Nanotubes

Recently, a new class of fascinating nanoreactors emerged through and through made from carbon. These are, in the meantime, famous carbon nanotubes and fullerenes [4, 229, 230]. However, fullerenes are not ideal nanoreactors because they are closed-shell objects. Therefore, carbon nanotubes are considered in much more detail here. Carbon nanotubes exhibit three different types of surfaces: the outer and inner surface as well as edges. Carbon nanotubes have been known since the ingenious discovery of Iijima in 1991 [231, 232]. The formation and chemistry of carbon nanotubes is reviewed in much more detail elsewhere [233, 234]. However, some of the nanochemical aspects in the area of carbon nanotubes should be highlighted. First of all, the formation of carbon nanotubes themselves can be seen as a nanochemical event. The thermodynamic stable form of carbon is graphite. When just a finite number of atoms are present to form a carbon allotrope, this situation changes because now the interface energy becomes much more important as the surface-to-volume ratio increases. Additionally, in a graphene layer of just a few nanometers extension, the amount of so-called dangling bonds at the edges of these surfaces becomes significant in determining the total energy of the structure. These dangling bonds become eliminated when the graphene layer folds and bonds to itself. To do so, exactly 12 carbon pentagons are needed—no more and no less. One alternative for stabilization are

the famous fullerenes, which are not described in further detail here [230]. Carbon nanotubes are highly related to fullerenes and can be understood as folded graphene sheets capped by half-fullerene caps. It was recognized very early that there is a tilting angle in the orientation of the graphene sheets leading to helicity [235–237]. This helicity is one of the most important features of carbon nanotubes. Two nanochemical applications of carbon nanotubes have been discussed in depth and often controversially. Much, even worldwide research attention, was focussed on the hydrogen storage properties of carbon nanotubes. The number of publications and groups are countless. Hydrogen uptakes from 0.4–68% hydrogen have been reported but lacked reproducibility [238]. The storage of hydrogen was explained by the small pores in carbon nanotubes and the related capillary pressure expressed by the Kelvin equation [239]. In the meantime, there are also indications that the high hydrogen storage capability is caused by metal impurities instead of the carbon nanotubes themselves [240].

A straightforward application of carbon nanotubes is to use the inner cavity as a nanotemplate for the creation of all kinds of nanowires. The first example for this was shown in 1993 [241] by Iijima himself when he was able to solidify a molten salt inside a carbon nanotube. Due to their good wetting properties, it is also possible to infiltrate the carbon nanotubes with dissolved species in organic solvents [242, 243]. Now the question arises how the solvents are able to penetrate into the internal cavity. Obviously, the carbon nanotubes have to be opened prior to their use as nano-reactors. This can be done by different methods of oxidation [244] and the secret is that the tips with their pentagonal defects are more reactive than the hexagonal sheets. Therefore, carbon nanotubes can be selectively opened at the tips. Interestingly, carbon nanotubes are more stable against oxidation than graphite. This is a result of the closed shell structure of the graphene sheets while graphite possesses exposed edges where oxidation starts.

Carbon nanotubes are representatives of a whole new class of compounds with varying compositions. The most related compounds are the isoelectronic boron-nitride (BN) nanotubes and, later, boron-carbide (BC) nanotubes [245–248].

Recently, some attention was devoted to the preparation of nanotubes with a more classic inorganic composition [240]. Interestingly, for some of these new nanotubes, carbon nanotubes have been used as templates. For instance,  $V_2O_5$  nanotubes have been prepared this way [249], but also strategies using amphiphiles as long-alkyle amines phases as templates are successful [250–252]. The interlayer distance in the latter system is determined by the length of the amines and can range from 1.7 nm to 3.8 nm. Vanadium pentoxide nanotubes are very interesting due to their high catalytic potential, as is  $TiO_2$ . The first examples of titania nanotubes were prepared by using polymer fibers as templates [253, 254]. Tenne et al. reported in 1992 about the preparation of the first chalkogenide nanotubes  $WS_2$  [255].

#### 4.2.2. Polyoxometalates

As was shown previously, complex structures emerge by self-assembly processes of amphiphilic molecules. Examples have been micelles or lyotropic phases.

A completely different system that nevertheless shows incredibly complex structures and a highly interesting nanochemistry are the so-called supramolecular polyoxometalates [256, 257]. It was Mueller et al. who showed in 1994 that solutions of the so-called “molybdenum-blue” contained molecular well-defined species possessing the structure of a giant molecular wheel (Fig. 7) [258]. This discovery is astonishing in two ways. First, molybdenum blue was known since 1783 [259] but its secrets were never unleashed completely until the investigations of Mueller et al. Second, one has to realize the simple way of preparing these compounds: An aqueous solution of a molybdate (for instance,  $Na_2MoO_4$ ) is acidified and a reducing agent is added in a certain amount. Within hours, the complex, highly-ordered giant polyoxometalates form. The first member of this new class of compounds contained 154 Mo atoms and its formula is  $(NH_4)_{28}[Mo_{154}(NO)_{14}O_{448}H_{14}(H_2O)_{70}] \cdot 350H_2O$ . Therefore, its molecular mass is similar to those of small proteins. Under certain conditions, even larger and more complex compounds can be obtained. Further larger giant wheels with the formulae  $[Mo_{176}O_{528}(H_2O)_{63}(CH_3OH)_{17}H_n]^{(32-n)-}$  and  $[H_{16}Mo_{248}O_{720}(H_2O)_{128}]^{16-}$  have been found [260, 261].

Concerning the emergence of these astonishing compounds, Mueller’s analyses [262–265]:

“According to our experiments, the following conditions favor the corresponding emergence of molecular complexity (in several successive reaction steps) at least in the system we are investigating: (1) Abundance of linkable units, that is, building blocks. (2) Possibility of generation of units with high free enthalpy to drive polymerization or growth processes, for example, by formation of  $H_2O$ . (3) Possibility of an easy structural change in the building blocks. (4) Possibility of including hetero elements in the fragments. (5) Possibility to form larger units which can be linked in different ways. (6) Bonding between fragments should neither be too strong nor too weak. (7) Possibility to control the structure-forming processes by templates. (8) Possibility to generate structural defects in reaction intermediates (leading to lacunary structures) by the presence of species which remove building units. (9) Presence of energetically low-lying unoccupied molecular orbitals in the fragments. (10) Possibility to localize and delocalize electrons in different ways in order to gain versatility. (11) Possibility to control and vary the charge (e.g. by protonation, electron transfer reactions, or substitution of building parts).”

Interestingly, under slightly different conditions, a new, closed-shell polyoxometalate with 132 Mo atoms and icosahedral symmetry is built (see Fig. 7b) [266].

**Figure 7.** Two examples of giant polyoxometalate structures, (a) a giant wheel ( $Mo_{174}$ -cluster), and (b) a giant sphere ( $Mo_{132}$  cluster). (b) shows how the internal surface is covered by phosphate groups which have been introduced by the nanochemistry shown in Figure 7a.

Although the formation of these compounds can already be seen as a nanochemical event, the giant polyoxometalates are also promising nanoreactor candidates. These molecules possess well-defined inner cavities and have very high surface areas. From the huge possibilities for nanochemistry [262–265], just two should be selected in the following paragraph.

The spherical  $\text{Mo}_{132}$  cluster shows an astonishing nanochemistry in aqueous solution (Fig. 8a) [267]. A lid of this cluster opens and closes, and the ligands attached to the internal surface can be exchanged. This way, the internal surface of the molecular spheres can be varied from acetate, phosphate, sulfate, to adenosine-mono-phosphate or even phenylphosphonate ligand coverages. This allows the creation of any desired surface and the study of host-guest relations.

The second example (Fig. 8b) shows how the chemisorption of cationic surfactants on the molybdate cluster surface leads to new kinds of amphiphiles assembling to liquid-crystalline polyoxometalate-surfactant hybrid phases [268]. The surfactant selectively binds to the “equator region” of the giant wheel, resulting in a new supramolecular species being hard, hydrophilic, and inorganic in the core, and soft, hydrophobic, and organic in the shell. Therefore,

**Figure 8.** (a) shows the “open-and-shut” nanochemistry present in the  $\text{Mo}_{132}$  cluster system. In solution, the cluster opens and chemical compounds can get access to the internal cavity of the molecular hollow sphere. (b) shows the formation of quadrupolar surfactant-polyoxometalate hybrid amphiphiles and the resulting formation of hexagonally ordered lyotropic phases. A representative TEM micrograph of these liquid crystals is also shown.

these molecules are amphiphiles but with a quadrupolar distribution of different domains. It can be seen that these amphiphiles self-assemble into ordered hexagonal structures (Fig. 8b). Similar phenomena with other polyoxometalate clusters prove the generality of this approach [269–272].

## 5. SOFT-MATTER CHEMICAL CONFINEMENTS

In general, soft-matter chemical confinements are produced by self-assembly processes. The emergence of these structures were briefly explained in Section 2, but it should be pointed out that all nanoreactors themselves are the result of nanochemistry. However, the formations of the nanoreactors, as micelles, for instance, often belong to a completely different field. Therefore, the formation of the soft-matter nanostructures mentioned in this review is seen as a premise. The interested reader is referred to the literature of Antonietti and Goltner [273] concerning the nanochemical origins of the formation of complex soft-matter nanostructures.

### 5.1. Micelles

Simple micelles are formed by even relatively short chain surfactants and correspondingly formed micelles are small (2–4 nm). Additionally, micelles of this type undergo constant reconstruction on a timescale of  $10^{-5}$ – $10^{-9}$  s [274–276]. Therefore, micelles made from low molecular weight surfactant are of limited use as nanoreactors. Additionally, the “filling” of micelles often leads to the formation of emulsions that are discussed in the next section. The high exchange rates between micelles makes it even hard to control the polymerization of polymerizable surfactants although some interesting studies have been published [277–279]. Recently, a review article discussed the use of polymerizable surfactants to produce nanostructures [280].

Much more stable and larger micellar systems can be obtained when heavier amphiphilic block copolymers are used [281, 282]. The size of these micelles is ideal in determining the size of solids formed in the inner core [283–285]. The first step of this nanochemistry involves the loading of micelles with metal salts. Interestingly, this is less difficult than expected. The dispersion efficiency of the block copolymers is so huge that they even incorporate salt crystals into their micelles. The transformation of the precursors follows the loading step. Now kinetic considerations are extremely important. When the nucleation of the resulting material (e.g., the precipitation of sulfide nanoparticles in micelles) is slow, every nanoreactor will only contain one crystal that will grow to its maximum size. On the other hand, when the reaction is performed fast, each micelle will host several nuclei which will remain small [282, 285, 286]. Another ideal example is the production of PbS nanoclusters in block-copolymer micelles [287].

### 5.2. Emulsions, Micro-Emulsions, and Mini-Emulsions

Micelles and lyotropic phases also can be swollen by selective solvents. One possible solvent is a monomer for a succeeding polymerization reaction. The polymerization inside

the droplets leads to a huge variety of spherical nanostructures. This principle leads to the vast field of heterophase polymerization, which is also technologically highly relevant. In an ideal case, monodisperse nanostructures are obtained.

The most obvious choice for emulsion nanoreactors are micro-emulsions due to their thermodynamic stability and the correlating well-predictable properties [61]. The difficulty in using micro-emulsions as polymerization nanoreactors is to find a suitable surfactant system [288]. The approach of using micro-emulsions as nanoreactors enables micro-lattices with varying surface properties (aminated, hydroxylated, bipyridin, etc.) to be prepared [288, 289]. Of particular interest in this respect is also that biochemically relevant groups like enzymes can be incorporated into the surface of the micro-lattices [289–291]. Natural lipids are suitable surfactants for these micro-emulsions because they don't denaturalize the proteins [289–291]. Three-dimensional bicontinuous micro-emulsions can be used to produce interesting porous polymer-network materials [292–294]. One ideal example was presented by Chew et al. [295]. However, micro-emulsions can also be used to control the size of nucleating inorganic species such as  $\text{BaTiO}_3$ , for instance [296].

Another type of interesting nanoreactors are the so-called mini-emulsions [297]. Mini-emulsions are a special type of emulsion containing two immiscible liquids, a surfactant stabilizing the liquid-liquid interface, and an additive soluble in the dispersed phase [298, 299]. Mini-emulsions are kinetically stabilized in contrast to micro-emulsions. It has been shown that the lifetime of mini-emulsion droplets can be of the order of days to months [300], which makes them quite promising nanoreactor systems. One illustrative example for their final application is the preparation of asymmetric zirconyl chloride nanocrystals [301].

### 5.3. Lyotropic Phases

The next level of complexity is given when lyotropic phases (or bicontinuous micro-emulsions) act as hosts for nanochemistry educts as, for instance, the monomers which are then transformed into polymer rods, sponges, or sheets [302, 303]. It is evident in these experiments that due to their flexibility lyotropic phases are not able to effectively shape the formed polymers. The thermodynamic contribution of the forming polymer becomes more and more significant for the composite system in time [292]. The confinement of the polymer chains to the dimensions of the lyotropic phase is equivalent to a significant decrease in entropy. The polymer breaks free and destroys the order on a nanoscale. Although the produced materials are quite interesting [293, 304], lyotropic phases are of limited use to act as nanoreactors for polymerization reactions. For instance, Akagi et al. polymerized acetylene inside a thermotropic (nematic) chiral liquid crystal leading to helical fibers [305]. Although the final product is very interesting, it could not be predicted. The interested reader can find a more detailed review about polymerization in lyotropic phases in [306, 307].

### 5.4. Vesicles

Vesicles are practically a solvent droplet enclosed by a bi- or multi-layer made from surfactants. The size of vesicles is quite polydispersive and can exceed the nano-dimension

significantly. Therefore, vesicles are no favorable nanoreactors. However, there have been some reports in the literature that assign vesicles as nanoreactors. For example, Nardin et al. incorporated channel proteins into the walls of a vesicle containing polymerizable block copolymers amphiphiles [308], or Hubert et al. used vesicles to produce hollow silica spheres [309].

## 6. SUMMARY

We have seen that a nearly infinite number of single nanostructures (nanospheres, nanowires, etc.) with various compositions can be created by nanochemistry, where the key concept seems to be in step where the nanoreactor determines the accessible space for the chemical process. Definitely, this field will grow further and scientists will start to investigate the key properties of these new nanostructures.

However, if one comes back once again to the comparison to natural systems, it becomes obvious that working natural systems do not contain single nanostructures, although nature uses similar nanochemical methods. To obtain functional systems, the single nanostructures need to be implemented into a complex system [310] of nanostructures. These complex systems will eventually have two features: Every single nanostructures has to be exactly in the right place. The result of the interactions between the nanostructures might not be a linear one, but the superior functionality might result from synergistic effects and is, therefore, hard to predict or plan. These two problems need to be solved in the future in order to create functional nanodevices. It will not be enough to count on self-assembly processes. Additionally, still (and unlike to natural systems) the creation of particular nanostructures require unique nanochemical conditions. It follows that a necessary variety of nanostructures (let's imagine a device made from nanowires and semiconductor quantum dots) can only be currently produced step-by-step (first the nanowires and then the quantum dots). The next question that arises is how these independent nanostructures can be put in the right place (connected to each other). Currently, the only way to realize this is to use nanoengineering techniques that are yet limited.

Furthermore, current nanostructures and their already realized assemblies are static. Once they are formed, their phenotype and properties are fixed. This paradigm might be broken if one succeeds in connecting the mostly inorganic nanostructures to functional polymeric units with so-called smart properties [24–27]. Nanochemistry is the only possibility in obtaining these functional organic-inorganic nanocomposites.

As already indicated in the concept for nanochemistry described in more detail in Section 3.2, the current success in nanochemistry has been made in the field of nanoparticle chemistry. Single nanostructures have been obtained. The step to higher lengthscales seems to be quite easy to realize (creation of new materials by nanochemistry) as some examples have already demonstrated. The effect of spatial confinements on molecular chemical processes is much less explored.

## GLOSSARY

**Biom mineralization** A process used by nature to structure inorganic matter on the nanoscale using structure directing organic auxiliaries.

**Bottom-up** Describes one approach, mostly taken in chemistry, to derive nanostructured matter. Starting from atoms materials growth is initiated and stopped in the nano-regime when the objects reach a desired size.

**Hard-matter** Self-organized structures containing inorganic units.

**Lyotropic phases** Liquid crystals of an amphiphilic system in water.

**MCM-41** The first ordered mesoporous silica material. It possesses a hexagonal system of cylindrical 3 nm wide pores.

**Nanoreactor** A reaction vessel of a size of just few nanometers.

**Soft-matter** Self-organized structures containing organic units.

**Top-down** Describes one approach, mostly taken in physics, to derive nanostructured matter. Starting from bulk-materials matter is made smaller and smaller as much as possible.

## 1. INTRODUCTION

An aggregate of atoms or molecules is commonly referred to as a cluster. The number of particles per cluster can be as small as two (dimer) up to several thousands. From the point of view of fundamental research, the physics of these agglomerates is of enormous interest. The possible realization of size-controlled clusters gives the promising opportunity of exploring the evolution of material properties step by step from the single atom to the bulk, following the modifications due to the addition of one or a few particles at a time. In addition, from a technological point of view, cluster and nanoscale physics are opening innovative frontiers in applied research and material science. In fact, quantum effects due to reduced dimensionality dramatically modify the geometrical, electronic, optical, and magnetic properties of materials, offering the unique opportunity of realizing innovative artificial materials that can be tailored toward a specific aim. This field is therefore very important, since the characteristics of any agglomerate can strongly depend not only on its size but also on its shape, as in on the specific spatial confinement. Since the pioneering work of Esaki and Tsu [1], the fabrication of layers with thickness of the order of nanometers is largely adopted for band gap “tailoring,” mainly in the fields of semiconductors and technological devices. A great impulse was certainly given by the advent of

sophisticated growth techniques such as molecular beam epitaxy or chemical vapor deposition, capable of controlling at the atomic level the interface between alternate films. Common nomenclature is by now widely accepted for nanosized structures: two-dimensional confined films are referred to as superlattices or quantum wells and one dimensional structures are named quantum wires, whereas zero-dimensional agglomerates are called quantum dots. For identifying an ensemble of atoms or molecules, we will adopt the term cluster since it does not contain any specific implication about the shape, which therefore can be of spherical or island-like configuration. The description of any cluster-related problem can also become dramatically complicated whenever the initial state properties, due to the cluster itself, are entangled with the so-called final state interactions, due to the presence of a substrate where the cluster usually is deposited, or a matrix containing embedded clusters. Of course, it would be greatly preferable to analyze an in-flight cluster if the intrinsic cluster characteristics should be investigated, avoiding therefore any influence of spurious contributions or interactions as those caused by a support. However, in several cases the presence of a matrix is absolutely necessary for the utilization of the clusters, for example, as catalysts or as luminescent centers; we mention, for example, the enormous interest found in microelectronics due to possible construction of predefined optical transitions by using size selected Si clusters and other semiconductor nanostructures [2–6]. Another interesting field is represented by the magnetic properties of low-dimension systems. Consider that in transition metals the average orbital magnetic moment is strongly dependent on the local coordination number; in fact, it is larger for open surfaces [7], with great implications on magneto-anisotropy of thin depositions. Superparamagnetic-ferromagnetic transitions, giant or colossal magneto-resistance etc., are other important examples in applications for magnetic recording, information transmission, sensors, and devices. Although the applied technological aspects have stimulated many studies, we also would like to point out the importance of clusters in

fundamental research. The investigation of phase transitions for rare gas clusters or films [8], “reentrant layering” [9], solid–liquid interface [8, 10, 11] are some important focuses of theoretical and experimental papers.

This paper presents an overview of investigation of small clusters by extended X-ray absorption fine structure (EXAFS) spectroscopy, which is a powerful tool for studying the structures of clusters. This article is organized as follows: first, we describe the spectroscopic technique in a plain style, avoiding complicated mathematical expressions, but referring the expert reader to a wide range of literature for details. In the sections following we give examples of metal, semiconductor, and rare gas clusters. Finally, molecular clusters will be briefly discussed.

## 2. EXAFS: GENERAL CONSIDERATIONS

The analysis of a cluster is not an easy task, considering the very small size of these structures. Cluster confinement is very often obtained with a size dispersion around an average value; this usually implies experimental information averaged over the size distribution. For the structural characterization of these aggregates, the X-ray diffraction is not a suitable technique since it requires a long range order to get the interference pattern typical of an ordered crystal. However, X-ray absorption offers a powerful tool for exploring the short range environment around a specific element as in the present case. In fact, if we look at the transmission spectrum of a thin metal foil (see Fig. 1), we observe a typical curve showing an absorption edge, corresponding to a core electron excitation from an internal shell, followed by a structured curve presenting some oscillations that can persist up to about 1000 eV after the threshold. These oscillations, absent in a gas, are caused by an interference effect of the photoelectron wave emitted by the absorbing

**Figure 1.** Transmission spectrum at the Co  $K$ -edge as a function of the photon energy;  $d$  is the thickness of the metal foil;  $\mu(E)$  is the absorption coefficient.

atom, with the surrounding atoms in the condensed state. This effect is called extended X-ray absorption fine structure (EXAFS), and, as explained in the following sections, gives very important information about the coordination shells around the absorbing atoms. For each coordination shell around the absorbers, we can obtain the radial distance, the coordination number, and the relative squared vibrational amplitude, due to the thermal disorder. For complicated situations, only the parameters of a single coordination shell can be extracted, but in simpler configurations even five or more shells can be disentangled, obtaining the corresponding parameters.

There is general agreement that the first experimental observation of the structured post-edge absorption curve should be attributed to Fricke [12] and Hertz [13] in 1920. In the same year Kossel [14] developed the first theory for explaining the near-edge structure. At that time, quantum mechanics was at its very beginning with contributions by Louis De Broglie, E. Schrödinger, P. Debye, A. Einstein, etc., and several efforts were made for explaining the observed effect [15, 16]. Also the modifications of the spectra as a function of the temperature [17] contributed toward the understanding of the experimental observations, as can be found in excellent historical reviews on EXAFS development [18, 19]. The initial theoretical attempts for a coherent interpretation of this effect, however, were based on a long range order theory, which we now know is incorrect to account for the effect. Therefore the technique was neither fully understood nor widely used until the development of a short range theory, reported for the first time by Sayers, Stern, and Lytle [20] on how to analyze the spectra using a Fourier transform algorithm. Since that time, a great proliferation of important contributions (see, e.g., recent reviews [21–23] and references therein) demonstrated the enormous relevance of this technique for investigating the short range environment around a specific absorber. Long range order is not necessary: Systems such as diluted solutions, biological molecules, disordered alloys, catalysts, atomic or molecular intercalated compounds, layered structures, and clusters can be investigated. In addition, for mixed compounds where two or more atomic species can be distinctly excited, independent EXAFS spectra can be collected around the corresponding edges, permitting a cross check of the information acquired at the single site, with high reliability of the specific structural details.

The great progress obtained in the analysis of smaller and smaller agglomerates should be attributed not only to the advent of the actual short range theory provided in 1971 [20], but also to the use of more brilliant X-ray sources such as modern synchrotrons. In fact, the EXAFS effect is a probabilistic interference effect implying a cross section, such as an overall interaction probability, which can be very small. If we consider, for example, that the case displayed in Figure 1 is referred to the cobalt  $K$  edge, we can give the following data: the  $K$  threshold is at 7709 eV corresponding to the excitation of a  $1s$  electron up to the Fermi level, with a total X-ray cross section of  $3360.6 \text{ cm}^{-1}$  immediately above threshold and smoothly decaying for higher energy. Similarly, as a further example, for indium the  $K$  threshold is at 27,940 eV with a total X-ray cross section of  $334 \text{ cm}^{-1}$  immediately above threshold; as shown in Figure 2, the  $L_I$  edge

**Figure 2.** Energy scheme for a metal, showing the  $K$  and  $L$  absorption edges related to the excitation of an electron from the corresponding core level up to the Fermi level.

due to  $2s$  electron excitations is at 4238 eV,  $L_{II}$  edge, due to  $2p_{1/2}$  electrons at 3938 eV and  $L_{III}$  edge due to  $2p_{3/2}$  electrons at 3730 eV. The respective total cross sections are 9889, 12,024, and 13,889  $\text{cm}^{-1}$ .

The usual absorption law for a radiation beam of intensity  $I_0$ , partially transmitted through a layer of material is:  $I = I_0 \exp(-\mu d)$ , where  $\mu$  is the absorption coefficient and  $d$  the thickness of the material crossed by the X-ray beam; a suitable reduction of intensity of  $1/e$  can be obtained for a thickness of 3  $\mu\text{m}$  for the Co  $K$  edge, 33  $\mu\text{m}$ , for the In  $K$ -edge, 1  $\mu\text{m}$  for the In  $L_I$  edge and so on. Note that the photoelectric cross section with respect to the total at this energy is smaller than a few percent [24], or, the most important effect is the photoelectric one, but it varies as a function of the photon energy. As our effect is extracted from the structures of the  $\mu$  coefficient, energy dependent, it is obvious that an excellent statistical measurement should be performed of both  $I$  and  $I_0$ . The first, however, depends on the equivalent thickness of absorbers under the beam and therefore very diluted samples or small clusters embedded into a light matrix can be investigated when a high photon flux is available. Therefore, today synchrotrons are the most used sources; in fact, they provide a tunable energy through the use of monochromators, so that a long range of about 1000 eV can be explored past the threshold. Consider, for example, the European Synchrotron Radiation Facility (ESRF) where electrons in the storage ring reach an energy of 6 GeV, with a current higher than 200 mA in multibunch mode (see details at the Website [www.esrf.fr](http://www.esrf.fr)) and a lifetime longer than 30 hours. The brilliance of the photon beam obtained at 100 keV from an

undulator insertion device in multibunch mode can be as high as  $10^{19}$  phot/s/0.1 bw/mm<sup>2</sup>/mrad<sup>2</sup>. Even in the bending magnet beamlines, the flux at sample is larger than  $10^{11}$ – $10^{12}$  phot/s with a resolution  $\Delta E/E = 10^{-5}$ . Therefore, good EXAFS spectra can be collected in a reasonable time by scanning the energy of the photons in steps of 1–2 eV. Different detection methods can be used according to the experimental conditions of the sample to be investigated; we only mention the transmission, the fluorescence, and the total electron yield methods [25–27].

### 3. EXAFS: BASIC PRINCIPLES

As mentioned previously, since 1920 [12] the observations of X-ray absorption spectra realized that, at energies higher than typical thresholds, the absorption curve of condensed matter is not monotonic but contains some oscillations extending sometimes up to several hundreds of electronvolts beyond the threshold. This effect, called X-ray absorption fine structure (XAFS) [28] or extended XAFS (EXAFS) spectroscopy [18], is by now well understood, and a qualitative explanation will be given in the present section, whereas a more detailed treatment can be found in several excellent review articles [21–23, 25–27].

Let us consider, for the sake of clarity, a thin few- $\mu\text{m}$ -thick crystalline film made of a single element (e.g., Co as in Fig. 1). If the material is illuminated by an X-ray beam with energy  $E_p = h\nu$ , core electrons (let us suppose  $1s$  electrons, as in Fig. 1) can absorb the photon energy by photoelectric effect; if this energy is higher than the electron binding energy with respect to the vacuum, ejection of the electron occurs. This happens with a well known probability. The escaping electron, according to the Einstein theory, acquires a kinetic energy equal to the residual energy  $E = h\nu - E_0$  where  $\nu$  is the frequency of the X-ray and  $E_0$  the binding energy of the electron of the atomic element in consideration. In the wave description, the photoelectron has a wavelength  $\lambda = 2\pi/k = h/p = h/(2mE)^{1/2} = 1.23(E)^{-1/2}$  nm ( $E$  in eV units) where  $k$  is the electron wavelength,  $h$  the Planck's constant,  $p$  and  $m$  are the electron momentum and mass, respectively. Note that, in the following, for atomic distances the unit angstrom ( $\text{\AA}$ ) is often adopted because of its wide use in this field: 1 nm =  $10^{-9}$  m = 10  $\text{\AA}$ .

Therefore the electron possesses a wavelength  $\lambda$  and a velocity  $v$  depending on its residual energy (see Fig. 3). If this energy is, for example 100 eV, then  $\lambda = 0.12$  nm and  $v = 5.9 \times 10^{15}$  nm/s. If we consider that, as in modern synchrotrons, the X-ray beam energy can be tuned in a wide range, we can collect transmission spectra as a function of the X-ray energy, going, for example, from 200 eV before the threshold up to about 1000 eV beyond the threshold. From the simple formula  $I = I_0 \exp(-\mu(E)d)$  we can extract the absorption coefficient  $\mu(E) = \ln(I_0/I)/d$ , where  $d$  is the thickness of the metal film,  $I_0$  and  $I$  the intensity of the X-ray beam incident and transmitted from the metal layer, respectively. The coefficient  $\mu(E)$  is experimentally observed energy dependent, since the photoelectric cross section, involving electron transitions, does depend on the photon energy. However, it is without any structure in a gas-like sample, as in when the atoms of the material are very

**Figure 3.** Photoelectron wavelength due to the extra-energy retained by the electron as kinetic energy after the absorption of the photon energy  $h\nu$ ;  $E_0$  is the electron binding energy.

far apart from each other; otherwise a structured oscillatory behavior (see Fig. 1) is observed. After the threshold, the EXAFS spectrum is conventionally indicated by:  $\chi(E) = \mu(E) - \mu_0(E) / \mu_{edge}$ , where  $\mu_0$  is the background absorption, or, the average continuous and structureless absorption that can be obtained just averaging over the oscillatory behavior;  $\mu_{edge}$  is a normalization factor that can be approximately obtained by the jump of the curve at the absorption edge.

A qualitative argument can show how to discriminate the two energy regions of the spectrum: the first between the threshold and about 30 eV above the edge, and the second at higher energy. In the first, the so-called XANES (X-ray absorption near edge structure), the electron wavelength is longer than the inter-atomic distance and the photoelectron “sees” many scatterers at a time; the interaction thus requires a many-body description. In the higher energy region of the spectrum, on the contrary, the photoelectron can be described by a short wavelength spherical wave; here, simple two-body interaction can be used and a simplified plane wave description of the photoelectron is quite adequate. In such a case, the EXAFS oscillations can be described as an interference effect between the outgoing photoelectron wave and the part of the same wave backscattered by the neighboring atoms; a simple schematic representation of the scattering process is shown in Figure 4; if the mutual interatomic distance is  $r_j$ , the phase difference between the two waves is of the order of  $2kr_j$ ,  $2r_j$  being the extra space traveled by the scattered wave with respect to the other in a time of the order of  $10^{-16}$  s. If the electron excitation is from a  $s$  state, averaging over the orientation of the sample, the oscillatory behavior of  $\chi$  as a function of the wave vector  $k$  is as follows [22, 29, 30]:

$$\begin{aligned} \chi(k) = & \sum_j \frac{S_0^2 N_j}{k r_j^2} F_j(k, \pi) \exp(-2\sigma_j^2 k^2) \\ & \times \exp(-2r_j/l_j) \exp[C_{4j}(k)] \\ & \times \sin[2kr_j + \theta_j(k) + 2\delta_{aj}(k) + C_{3j}(k)] \quad (1) \end{aligned}$$

**Figure 4.** Schematic representation of the interference process. (A) represents the absorbing atom; (B) and (C) are two backscatterer atoms belonging to different coordination shells. The spherical photoelectron wave, emitted by the absorber (A), is represented by the circles (full line) and propagates toward the surrounding atoms; these backscatter the wave (dashed lines) towards the central atom. The EXAFS spectrum is originated by the interference between the outgoing wave from (A) and the backscattered wave from (B) and (C).

The  $\chi(k)$  curve extracted from the spectrum shown in Fig. 1 is reported in Figure 5.

Equation (1) describes the relative variation of the absorption coefficient  $\mu$  because of the modifications of the photoelectron wave function at the origin (i.e., at the center of the absorbing atom) caused by the scattering of the photoelectron wave.

This scattering can be provoked by an atom in the  $j$ -th coordination shell around the absorber; this shell has  $N_j$  atoms at  $r_j$  distance, with a backscattering amplitude  $F_j(k, \pi)$ .

Equation (1) takes into account the following effects:

1. The phase shift  $2kr_j$ ; this is due to the travel of the photoelectron toward the scatterer  $j$  and back to the absorber ( $2r_j$ ).

**Figure 5.** EXAFS curve  $\chi(k)$  as a function of the photoelectron wave vector  $k$ . Note that  $1 \text{ \AA} = 0.1 \text{ nm}$ ,  $1 \text{ \AA}^{-1} = 10 \text{ nm}^{-1}$ .

2. The phase shift  $\theta_j$  due to the scatterer.
3. The phase shift due to the absorber,  $2\delta_{aj}$ , counted two times because the photoelectron interacts with the absorber when it goes out and when comes back after being scattered. This shift takes also into account the core hole remaining in the center atom because of the electron ejection; actually this hole gives a unit positive extra charge seen by the escaping electron.
4. The relative thermal vibrational attenuation  $\exp(-2 \times \sigma_j^2 k^2)$ , called Debye–Waller (DW) factor, taking into account the static and dynamic disorder.
5. The cumulants  $C_{3j}(k)$  and  $C_{4j}(k)$ ; these are higher order corrections: the first enters the sine term, the second is another term entering the amplitude.
6. A damping factor  $\exp(-2r_j/l_j)$  taking into account how the wave is attenuated during the path  $2r_j$  because of the photoelectron mean free path  $l_j$ .
7. The  $S_0^2$  factor, an amplitude factor caused by shake-up or shake-off processes.

We now explain in more detail the various factors entering into Eq. (1), observing, first, that this equation can be considered as a sum of products of two factors, an amplitude factor  $A_j(k)$ , and a phase factor  $\sin[\Phi_j(k)]$ , over the  $j$  coordination shells:  $\chi(k) = \sum_j \chi_j(k) = \sum_j A_j(k) \sin[\Phi_j(k)]$ .

### 3.1. Amplitude Factor

The amplitude term  $A_j$  of the  $j$ -th coordination shell is determined by several weighting factors:

$$A_j(k) = \frac{S_0^2 N_j}{k r_j^2} F_j(k, \pi) \exp(-2\sigma_j^2 k^2) \times \exp(-2r_j/l_j) \exp[C_{4j}(k)] \quad (2)$$

First of all, it depends on  $F_j(k, \pi)$  the backscattering amplitude factor of the specific atom acting as a backscatterer of the photoelectron wave; here, the dependence of  $F$  on the wavevector  $k$  is explicitly indicated, together with the angle  $\pi$  due to the backscattering at  $180^\circ$ .

Each atom in the  $j$ -th coordination shell (formed by  $N_j$  identical atoms put at  $r_j$  distance from the central one) contributes by the factor  $F$  and, therefore, in the formula the factor  $N_j$  appears, whereas at the denominator  $k r_j^2$  is due to spherical wave factors [26]. The  $F$  factor can be calculated with high accuracy [31] using a plane wave approximation [32], valid as long as the dimensions of the atoms are small with respect to the curvature of the real spherical wave. Improved approximations were provided by successive contributions [33,34]; meanwhile curved wave treatments including multiple scattering effects, inelastic losses, and more accurate potentials were developed with better calculated amplitude and phase factors [35–38].

A damping factor in the amplitude is due to the thermal motion of the atoms, supposed of harmonic type  $\exp(-2\sigma_j^2 k^2)$ . This term appears in order to take into account the relative movement of the pair absorber-scatterer as a function of the temperature; it also includes the zero point energy, as in the static disorder of the absorber and of the scatterer, assuming that both are distributed according to a Gaussian function at a relative distance  $r_j$ :  $\sigma^2(T) = \sigma_0^2 + \sigma_{dyn}^2(T)$ .

Note that the static contribution  $\sigma_0^2$  can be deduced by measuring the DW factor as a function of the temperature, extrapolating the value for  $T = 0$  K.

A second damping factor  $\exp(-2r_j/l_j)$  is related to the finite mean free path of the electron, due to inelastic losses along the electron trajectory;  $l_j$  takes into account the mutual interaction with the medium, and it is a rather short length as in photoemission or Auger processes [39]. At the electron energy involved in EXAFS spectroscopy (30–1000 eV),  $l_j$  ranges between 0.5–1.5 nm for monoatomic crystals, somewhat higher for composite materials. The physical meaning of  $l_j$  can be regarded as the length over which coherence of the photoelectron wave for generating interference effect is still maintained; this length is therefore affected not only by inelastic losses but also by finite hole lifetime, by relaxation effects, etc. Details can be found in the literature [26]. In some cases [40], better approximations were obtained by subtracting an additional parameter from the path length  $r_j$  of the photoelectron, modifying the exponent of the damping factor as  $[-2(r_j - \beta)/l_j]$ . For the first shell of dichlorides and tetrahedral semiconductors [40], a value of the  $\beta$  parameter equal to the nearest neighbor distance was found. Determination of the electron mean free path  $l_j$ , as a function of the energy, with this algorithm can be found in Ref. [40] for some semiconductors such as Ge, GaAs, ZnSe, and CuBr.

$S_0^2$  factor is an amplitude reduction factor due to electron excitations from atomic low binding energy states. Some excess energy of the photoelectron escaping from the core level of the absorber can be transferred to valence electrons to produce transitions toward higher internal empty bands (shake-up processes) and/or toward the external continuum states (shake-off processes). This reduction factor was calculated by Carlson et al. [41] and was observed [27,42] with a  $k$  dependence up to  $80 \text{ nm}^{-1}$  roughly decreasing from 1.0 to 0.8. Often, however,  $S_0^2$  is considered as a constant ( $k$ -independent) factor and fitted in an ad hoc parameter. Values of  $S_0^2$  factor are reported in several papers in the range 0.7–0.8, but in some cases different values were obtained: for Au at the  $L_{III}$  edge, observed at 28 K, a value of  $S_0^2 = 1.1$  was adopted (see Ref. [43]); similarly,  $S_0^2$  was fixed at 1.09 for Ge, 1.11 for  $\text{GeCl}_4$ , and 1.08 for  $\text{Br}_2$  [37]; all these last measurements were done at the  $K$ -edge and at  $T = 300$  K.

### 3.2. Phase Factor

The sine term

$$\sin[2kr_j + \theta_j(k) + 2\delta_{aj}(k) + C_{3j}(k)] \quad (3)$$

is very important, as it gives the oscillating behavior as a function of  $k$  with a frequency  $2r_j$  somewhat modified by the phase shifts. The superposition of sinusoidal terms, weighted by different amplitudes, can in principle be disentangled by a Fourier transform (FT), which should provide a peak for each coordination shell containing structural information about that shell. Figure 6, for example, displays the FT of the EXAFS curve  $\chi(k)$ , shown in Figure 5 for a Co metal foil, weighted by  $k^3$ . This curve shows the peaks corresponding to the first, second, third, and fourth

**Figure 6.** Fourier transform of the EXAFS curve  $\chi(k)$  weighted by  $k^3$ . The peaks correspond to the first, second, third, and fourth coordination shell for an hcp Co metal. In the first shell 12 Co atoms are located at 2.507 Å (the two subshells of the hcp lattice are not distinguishable since their distance differs by 0.01 Å), in the second 6 atoms at 3.54 Å, etc.

coordination shell of an hcp Co lattice, and can be used as a model compound, considering that the parameters of a Co crystal are well known. In fact, a direct comparison of the experimentally observed data for the unknown sample with reference spectra (provided that these are analyzed in the same conditions) provides the desired parameters.

An alternative equally feasible procedure can be a multi-parameter fitting of the  $\chi(k)$ , summing individual contributions with the proper structural parameters. Fortunately, this is not a prohibitive task because of the finite electron mean free path, appearing in the  $\chi(k)$  amplitude as the damping factor  $\exp[-2r_j/l_j(k)]$ . Only a few coordination shells actually remain in the sum, usually giving well separated peaks in the FT, with a reasonable number of parameters. Each peak of the Fourier transform is located at the interatomic distance  $r_j$  somewhat shifted by two phase shifts  $\delta_{aj}$  and  $\theta_j$ ; these enter the sine argument since the photoelectron is not a free particle but is influenced by the local potentials. The first  $\delta_a(k)$  is due [44] to the absorber, and it appears twice, as already mentioned, because the photoelectron is affected two times by the emitting atom, once at the emission and again on its way back;  $\delta_a(k)$  depends on the angular momentum quantum number and takes into account the potential of the central atom. The second  $\theta(k)$  is introduced by the scatterer and depends on the effective potential seen by the photoelectron during the scattering, which in turn depends on the photoelectron kinetic energy.

It is worth pointing out that the electron emission, leaving a hole in the core state, produces an atomic excited state, which tends to relax by some mechanism. The electron afterward can be restored in the hole. In any case, the perturbation introduced by the core hole involves all the atomic levels since they feel an internal charge augmented by  $+e$ . Therefore, several problems arise, concerning the core hole

width, the screening, the relaxation of the system, etc. On the other hand, the hole filling will be accomplished with a finite lifetime depending on the filling mechanism: For light elements the most probable is an Auger decay, for heavy elements a radiative (fluorescence) emission [45]. If we assume a core hole width  $W$  of about 2 eV [46], the Heisenberg principle gives a lifetime  $\Delta t = \hbar/W = 3.3 \times 10^{-16}$  s longer than the travel time of the photoelectron, calculated above. Therefore, it is assumed that the photoelectron and the outer electrons of the central atom see a  $Z + 1$  positive charge ( $Z$  is the atomic number), as in an electron charge missing from the negative cloud; actually, the relaxation time  $\tau_r$  of any atomic level is roughly proportional to the inverse of its binding energy  $E_b$ , and this implies  $\tau_r = \hbar/E_b$ . For binding energies higher than 20 eV, the corresponding relaxation time is shorter than  $3.3 \times 10^{-17}$  s. When comparing these values with the transit time of the photoelectron, which is of the order of  $10^{-16}$  s, care should be taken when assuming a time-dependent potential seen by the photoelectron. In practice, it is assumed that small perturbations can be accounted for by varying the phase shifts and by choosing ad hoc the threshold energy  $E_0$ , which is usually treated as a parameter adjustable within  $\pm 10$  eV around the edge.

### 3.3. Cumulants

As already mentioned, the short range pair distribution is probed by this technique through the Debye–Waller factor, accounting for the relative thermal vibrations. However, this conclusion is valid only for harmonic interactions and further corrections should be introduced when the nearest-neighbors distance distribution cannot be approximated by a Gaussian curve. In fact, EXAFS spectroscopy can also be quite valuable to detect anharmonic interactions through two (or more) refinement terms, which should be introduced into the  $\chi(k)$  formula. The first correction is the third cumulant  $C_3 = -(4/3)\sigma_j^{(3)}k^3$  (and eventually other higher-order odd terms) entering the phase of the sine term; the second is the fourth cumulant  $C_4 = (2/3)\sigma_j^{(4)}k^4$  (and eventually other higher-order even terms), which modifies the amplitude. A detailed analysis including the cumulants [29] was performed for a CuBr sample, investigated at different temperatures for the first shell contribution identified by Fourier filtering on both the Cu  $K$  edge and the Br  $K$  edge. The  $C_3$  and  $C_4$  cumulants were found not at all negligible even at about  $T = 210$  K; average values of  $\sigma^{(3)} = 0.23 \pm 0.04 \times 10^{-3} \text{ \AA}^3$  and  $\sigma^{(4)} = 0.32 \pm 0.12 \times 10^{-4} \text{ \AA}^4$  were obtained. Therefore, anharmonic behavior of single-particle Cu ions was deduced, although correlated motion was ignored. Small quantum effects [30] were also recently observed on the third cumulant at least for Ge, since a deviation from the classical  $T^2$  dependence was observed as a function of the temperature. Such effects were considered negligible for AgI and CdSe crystals.

## 4. EXAFS DATA ANALYSIS

As already mentioned, several methods have been developed for detecting an EXAFS spectrum; each one of these methods aims at optimizing the final spectrum characteristics (signal-to-noise ratio, resolution, etc.) for the specific

sample investigated. We mention only some of them here. The most frequently used is the transmission method, monitoring  $I$  and  $I_0$  (Fig. 1) and obtaining the absorption coefficient  $\mu$  as outlined in Section 2.

This method requires a uniform layer of material, illuminated by all the photons of the beam, a part of which (about 10%) should be absorbed. This method is therefore not adequate for a very low signal, due to a very low concentration or dilution in solid solutions, implanted materials, surface layers, impurities or clusters embedded into a matrix, etc. In these cases, different methods such as fluorescence or total electron yield should be used. These methods give a low signal proportional to the total absorption. For a detailed discussion of the best experimental conditions suggested by a panel of experts in this field, we recommend the report of an international workshop held in 1988 [47], where advantages and disadvantages of each experimental procedure can be found together with the evaluation of the experimental uncertainties. Of course, each detection scheme has its own peculiarity (e.g., electrons can escape only from a thin layer of the order of a few nm) and, therefore, should be used with great care, paying attention to all the probabilities or cross sections involved. Also of great importance are the correct choice of the proper concentration when using fluorescence detection [48] and the optimal thickness for absorption detection [49]. The procedure for the EXAFS data analysis can be found in many papers [25, 26]. Here, we give only a brief summary. In order to extract from a  $K$ -edge absorption spectrum a normalized  $\chi(k)$ , the first steps consist in:

1. Choice of the  $E_0$  threshold, often obtained by the maximum of the first derivative.
2. Fitting of the pre-edge region for background correction.
3. Fitting of the post edge curve by a continuous spline averaging the oscillations; this fit is subtracted for extracting the oscillation spectrum.
4. Evaluation of the jump at the threshold and consequent normalization.
5. Conversion from an energy scale to a wave vector scale so to obtain the  $\chi(k)$ .

The following step is represented by the FT of  $k^n\chi(k)$  where the weight  $k^n$  ( $n = 1, 2, 3$ ) can be inserted for the amplification of the oscillations of the  $\chi(k)$  curve, compensating for the attenuation of the experimental signal at high  $k$  values. In principle, the introduced weighting factor should not at all influence the information contained in the data; therefore, *a fortiori*, the FT of the weighted  $k^n\chi(k)$  should preserve the physical information since only the relative intensity of the various features can be modified. Of course, any comparison with a reference compound implies identical treatment of the compared data. A good check consists of verifying the previous point for different weighting factors. Each peak of the FT contains the physical information related to the distance, coordination number, and DW factor plus eventually the cumulants  $C_3$  and  $C_4$  for that shell. These parameters should be extracted. Two methods will be briefly presented in the next paragraph: the ratio method and the fitting method. Both imply phase and amplitude transferability.

## 5. PHASE AND AMPLITUDE TRANSFERABILITY

As mentioned in the previous sections, each term of Eq. (1) is a function of several parameters that should be determined. From the experimental data, after some manipulation sketched above, the total  $\chi(k)$  can be obtained, but this requires the conversion from an energy scale to a  $k$ -wavevector scale. This is possible if the "threshold"  $E_0$  is known, since  $k = \sqrt{2m(h\nu - E_0)/\hbar^2}$ . Unfortunately,  $E_0$  is not a well-defined energy in the absorption spectrum and several options can be adopted [26]. Note in fact that, as photoemission experiments have revealed [46, 50–52], chemical shifts can be caused by a different chemical environment. In order to overcome this difficulty, as outlined above, it is usual to treat the energy  $E_0$  as a free parameter in a range of about  $\pm 10$  eV around the jump of the absorption curve. This procedure assumes as negligible some effects due to valence or conduction bands, multiple scattering, core relaxation, etc., and applies the so-called phase transferability. This term resumes the concept that the phase function (at energy higher than 30 eV from the threshold) can be transferred from a known system to an unknown one, having however as absorber-scatterer the same pair of atoms. This is absolutely correct, such as when observing small modifications due only to the variation of temperature on the same crystalline sample, using, as a reference, the spectrum at a given temperature and looking only at the relative modifications. The use of an experimental reference is always preferable [53] and sometimes necessary whenever calculated phase shifts are not usable. In fact, if a careful Fourier transform is performed on the experimental  $\chi(k)$ , a new curve is obtained in the real space with several peaks related to the positions  $r_1, r_2, \dots, r_j$  of some coordination shells. Of course, the absolute distance  $r_j$  can be determined only if the proper phase shifts can be summed. Fortunately, very good theoretical calculations have provided accurate tables [31, 54] of such shifts. Today, more refined data can be obtained by computer programs (FEFF [33, 38, 55], GNXAS [56–58], etc.) which can also evaluate such shifts.

Similarly to the phase transferability, when the chemical environment between two different systems is reasonably quite similar and one of them is absolutely known, it is possible to assume amplitude transferability. Both phase and amplitude transferability imply independence of the chemical environment. Great care should be taken when assuming this concept of transferability, as in several cases where discrepancies were pointed out with respect to confirmed results [59].

We should point out that the transferability of the electron mean free path from a reference bulk sample to a small particle was questioned by Zhao and Montano [60]. These authors in fact emphasized that different contributions due to inelastic scattering should be ascribed to the surface of the cluster; they calculated the electron mean free path  $l$  as a function of the size for an Al particle. For a 1.0 nm Al cluster,  $l$  is about 60% of the value of the bulk. The use of a wrong  $l$  can cause an incorrect evaluation of the coordination number which can be therefore underestimated.

In general, careful use of the transferability concept is in any case very important since the comparison with a

reference compound is always necessary for the determination of the EXAFS parameters of unknown systems. To this purpose, for a long period the so-called ratio method was largely applied, whereas a fitting method is currently preferred.

### 5.1. Ratio Method

We recall that in the FT of the  $\chi(k)$ , a single peak in the real space can be worked out [25, 61] by means of a Fourier back-transform allowing one to extract a single oscillating contribution  $\chi_j(k)$  by separating amplitude and phase function. We can extract for each coordination shell its amplitude and phase by a two step algorithm: First, by Fourier transforming the entire  $\chi$  (multiplied by a window function [25, 26]) the various shells in real space are separately obtained; second, by a back FT of a single peak we can separate amplitude and phase of that peak from everything else.

If a reference compound can be experimentally processed in the same manner as the unknown sample under investigation, we can directly and separately compare the two phases and the two amplitudes.

For the phase concerned, if the phase of a single shell  $j$  is extracted as

$$\Phi = 2kr + \alpha \quad (4)$$

where  $\alpha$  is the total phase shift for that shell, we remark that a direct comparison can be performed with the phase of the reference obtained with the same procedure; in fact, dropping the index  $j$ , we can write the difference for the selected shell as

$$\Delta\Phi = \Phi - \Phi_{ref} = 2kr - 2k'r_{ref} + \alpha - \alpha_{ref} \quad (5)$$

If a plot of the phase shift (5) is performed as a function of  $k$ , we can obtain a linear plot passing through the origin:  $\Delta\Phi = 2k(r - r_{ref})$ , when the  $E_0$  value for the sample investigated can approximately make  $\alpha = \alpha_{ref}$  and  $k = k'$ ; from the slope of this straight line we can obtain the wanted value  $r$ .

In a similar procedure, writing the amplitude as

$$A(k) = \frac{N}{kr^2} F \exp[-2k^2\sigma^2] \exp(-2r/l) \quad (6)$$

where the cumulant contribution was neglected, we can compare with a known reference system, denoted by the index  $ref$ , and analyzed in the same way as the unknown:

$$\ln \frac{A(k)}{A_{ref}} = \ln \frac{Nr_{ref}^2}{r^2 N_{ref}} + 2k^2[\sigma_{ref}^2 - \sigma^2] + \left[ \frac{r_{ref}}{l_{ref}} - \frac{r}{l} \right] \quad (7)$$

Assuming the last term as negligible ( $l_{ref} \approx l$ , and the electron mean free path long enough with respect to the interatomic distance) [26], and knowing the reference parameters, we can plot as a function of  $k^2$  the curve  $\ln \frac{A(k)}{A_{ref}}$  evaluated experimentally. This curve should be a straight line having a slope equal to  $2[\sigma_{ref}^2 - \sigma^2]$  and an intercept for  $k = 0$  at the value  $\ln Nr_{ref}^2/r^2 N_{ref}$ . This procedure permits the determination of  $r$ ,  $N$ , and  $\sigma$  with good approximation.

The ratio method is instructive and was reported only for didactic purposes but presents several limitations [25–27]. In

fact the results obtained by the ratio method can be altered because of several approximations related to the choice of  $E_0$ , the data analysis, systematic errors, mean free path, etc.

### 5.2. Fitting Method

To date, a more sophisticated method is largely adopted combining theoretical calculations and multiparameter fitting. In fact, accurate theories were developed that take into account a curved wave description of the photoelectron, multiple scattering, relative vibrational behavior, electron mean free path, cumulants contributions for each shell, etc. All of these points are introduced into computer programs continuously updated such as FEFF [33, 38, 55] or GNXAS [56–58], which allow several tests on the experimental data: Typically the first check is done on the reference spectra collected in the same experimental conditions as the currently investigated sample. As the reference is well known by definition, its parameters, assumed correct, can be used for a double check, as in for a cross verification about the method and about the simulation. In fact, the first check is performed on the method itself, using the reference spectra, and verifying that the potentials adopted, the phase shifts calculated, the backscattering amplitude, etc. provide the correct environment and are consistent with the hypothesized structure. This permits the reproduction of the reference  $\chi(k)$  and its FT with self-consistent parameters.

Secondly, the simulation can be pursued searching, shell by shell, for the convenient parameters reproducing each shell of the FT, and afterward fitting the entire FT curve and the total  $\chi(k)$ . This implies not only that each oscillating contribution  $\chi_j(k)$  be correct, but also the multiscattering contributions (with three or more compatible paths) for that lattice and base be conveniently approximated.

Since the desired parameters are determined by accurately fitting one by one each shell in the FT (or all the shells together if the entire original  $\chi(k)$  is fitted), the fitting procedure should be accurately guided. Otherwise the mathematics can give any kind of results, especially when many shells are involved. Examples of fitting results can be found in the next section.

It is worth mentioning that a strong correlation exists between  $N$  and  $\sigma$ ; an analysis of this correlation [53] has shown a linear dependence of the relative uncertainties on the number of electrons  $Z$  of the backscattering atom. On the contrary,  $E_0$  and  $r$  for a given shell are not strongly correlated, as in the modification of  $E_0$  practically does not alter the correspondent shell distance since the change in  $E_0$  modifies mainly the low  $k$ -values of the  $\chi(k)$  whereas  $r$  is determined by the frequency of the oscillation. In fact, the fitting accuracy of the EXAFS technique in the evaluation of the interatomic distances can be better than 0.001 nm.

## 6. CHARACTERIZATION OF NANOCCLUSERS

We now describe the application of the EXAFS technique to a selected ensemble of clusters, showing how this tool has uniquely permitted a gain in structural characterization of nanodimensional systems. For a cluster population, the

knowledge of the interatomic distances and of the coordination numbers of a few shells around the absorbers allows us to determine the geometrical configuration averaged over the size distribution. Whenever the clusters are embedded in a different environment, this spectroscopy, sensitive to the specific atomic species in the couple absorber-backscatterer, can distinguish between internal and surface configuration. Also the thermodynamic parameters (Debye–Waller factor and/or Debye temperature), deduced by the vibrational behavior of  $\sigma^2$  as a function of the temperature, contribute toward this goal, by distinguishing the amplitude of the relative vibrations and therefore, their modifications, with respect to the bulk, can give valuable information related to the mutual binding forces.

### 6.1. Metal Clusters (Cu, Ag, Au)

Noble metal clusters were studied particularly for fundamental research, since they can address the morphology changes from the isolated atom to small clusters to bulk metal, mainly in relation to the study of the electronic and structural properties, catalysis, etc. As early as 1979 [62], copper clusters were studied by the EXAFS technique with particular emphasis to the determination of lattice contraction or expansion as a function of the cluster size. This is in fact an important question related to the reduced dimensionality and to the broken symmetry of the crystal.

Clusters of course should not interact with the substrate, or at least minimal interaction should be guaranteed. To this purpose, in this investigation, clusters were evaporated on a 500 nm polymer film, covered by a carbon overlayer 5–10 nm thick to avoid contamination; multiple layers were superimposed in order to obtain a reasonably good signal-to-noise ratio. Few coverages were explored: for Cu, from  $8 \times 10^{14}$  at/cm<sup>2</sup> up to  $8 \times 10^{16}$  at/cm<sup>2</sup>; samples were checked by transmission electron microscopy aimed at obtaining the size of the deposited clusters; at  $8 \times 10^{16}$  at/cm<sup>2</sup> the deposition corresponded to a continuous film, whereas the diameter of clusters obtained at  $8 \times 10^{15}$  was measured as 4–4.5 nm, about 1.3 nm at  $2.6 \times 10^{15}$  at/cm<sup>2</sup>, and 0.5 nm at  $8 \times 10^{14}$  at/cm<sup>2</sup>. The authors, analyzing the Fourier transforms of the EXAFS spectra, reported a Cu–Cu first distance of 0.256 nm for the thick film and a contraction of 9% for the smallest size ( $d = 0.5$  nm), about 3% for  $d = 1.7$  nm, and only 1% for  $d = 4$ –4.5 nm. Probably these values are somewhat overestimated. In fact, no detailed analysis was reported for the other parameters entering the EXAFS expression, such as the coordination numbers or the disorder as a function of the size. As a matter of fact, some doubts were raised by a Danish group [63] about the real contraction observed in small particles. In this paper, it is claimed that the average interatomic bond length should be independent of the particle size at least for diameters larger than 0.8 nm. In addition, it is shown that the anharmonic motion of atoms at the surface is strongly related to the anharmonicity of the radial distribution function  $g(r)$ . However, in EXAFS experiments, the FT of the data is usually performed by cutting the low  $k$  values of the  $\chi(k)$  curve dominated by multiple scattering, and assuming a  $g(r)$  of Gaussian form. This assumption can strongly modify the average values obtained by this spectroscopy, as the size

of the observed clusters (having a larger surface-to-volume ratio) becomes smaller.

With the contraction, for the lowest coverage a concomitant energy shift of the threshold was also observed toward higher binding energy of 0.7 eV. This is a well known effect in photoemission experiments [46, 50, 51] performed as a function of the size. A more refined investigation was reported in 1986 [64] by preparation of copper clusters ( $d = 0.7$ –1.5 nm) in an inert solid Ar matrix held at liquid helium temperature (4.2 K). This artifice prevents any interaction with the substrate. The EXAFS experiments were performed at Stanford Synchrotron Laboratory both in transmission and in fluorescence.

In Figure 7, some results from [64] are reproduced: The FT of  $k^3\chi(k)$  for a Cu foil and for Cu clusters 1 nm average diameter are shown. For this size, an average coordination number equal to 6, 3, and 5, respectively, for the first, second, and third shell was determined. For comparison, in the same figure the FT for Cu clusters was simulated with the following parameters: first, second, and third shell distance as for the bulk, coordination numbers 6, 3, and 5, respectively; Debye–Waller factors  $25, 29, \text{ and } 56 \times 10^{-4} \text{ \AA}^2$  respectively.

**Figure 7.** This figure shows the experimental data obtained by means of the FT of the  $\chi(k)$  weighted by  $k^3$ , for a Cu cluster of 10 Å (average diameter). For comparison the corresponding spectra for a Cu metal foil (experimental), and for a Cu cluster of the same size (calculated). Adapted from [64], P. Montano et al., *Phys. Rev. Lett.* 56, 2076 (1986). © 1986, American Physical Society.

Several interesting results were observed:

1. The first concerns, as above, a chemical shift of the edge of 1.4 eV towards higher binding energy.
2. The Xanes region for the clusters shows modifications related to the absence of fourth and higher shell atoms in the cluster, as visible in Figure 7.
3. Cu dimers were found with Cu-Cu distance of 0.223 nm; in fact, in Figure 3 of [64] the FT of the spectrum contains two peaks due to Cu-dimers (shorter distance) and to more distant Cu-Cu pairs in larger clusters ( $d = 0.6\text{--}0.7$  nm).
4. Contraction of the nearest-neighbors (nn) distance was found to be quite smaller than in earlier papers, and of the order of 1–1.5% for Cu clusters with  $d = 0.7\text{--}1.5$  nm.
5. As higher coordination shells are visible in the FT, a qualitative speculation can be done to calculate the number of surface atoms in specified clusters.

Whenever the clusters are deposited in or embedded into a noninert matrix (such as an oxide), as expected, the interaction of the surface of the cluster with the matrix atoms can modify the intrinsic properties of the clusters, their growth morphology, and the interface bonds [65]. However, it was demonstrated that the boundaries of nanocrystals should not be considered anomalous [66], as claimed by some authors [67] who hypothesized a completely disordered surface layer without any short range order.

Silver clusters also were investigated [68] for an average size of  $d = 2.5\text{--}13$  nm; the EXAFS data analyzed by the ratio method allowed only the determination of a nn contraction, which reached 0.004 nm, whereas the coordination numbers could not be accurately determined. Furthermore, in this case the near edge region around the  $K$  threshold did not show any significant modification with respect to the bulk. In contrast, the photoemission measurements on the core level Ag  $3d_{3/2}$  and  $3d_{5/2}$  have displayed a metal–nonmetal transition at about 100 atoms/cluster, with a shift of about 1.8 eV [51].

On gold clusters, a large debate was developed when conflicting results were reported [43, 69–73] about the structural and dynamical parameters for small size agglomerates. Actually, gold is an ideal element for studying size effects because of its great stability without any tendency to bind foreign impurities. Therefore, gold clusters prepared by different techniques were studied by EXAFS spectroscopy for a structural investigation; of course other complementary experiments were conducted, such as transmission electron microscopy (TEM) [43], core level and valence band photoemission spectroscopy [50], etc.

In EXAFS experiments performed on gold clusters since 1985, for more than a decade [43, 69–73], the data analysis was progressively more and more sophisticated with attention not only to the interatomic distance but also to the coordination number and to the DW factor. As gold is a heavy atom, EXAFS was collected on  $L_{III}$  edge, as it is legitimate [26], and also much more convenient as the cross section is higher at this energy by a factor 33 than at the  $K$  edge.

The disorder was also studied as a function of the temperature, also identifying the static contribution of the DW factor at a few degrees Kelvin. Recalling the Beni and Platzman

theory [74], we point out the several terms entering the DW factor of the EXAFS spectra and the difference with respect to the conventional X-ray diffraction. In X-ray diffraction, in fact, the Debye–Waller factor takes into account the total atomic mean square thermal displacement, whereas in EXAFS technique a pair of atoms is always involved and therefore the DW factor is a direct measurement of the mean square relative displacement of the pair absorber-backscatterer. For a monoatomic cubic crystal, using the Debye approximation for the density of states, Beni and Platzman gave the following expressions for the EXAFS DW factor of a pair at a distance  $r$  [71, 74]

$$\sigma^2 = \sigma_{diff}^2 - \sigma_{corr}^2$$

$$\sigma_{diff}^2(T) = \frac{3\hbar^2}{Mk_B\Theta_D} \left[ 0.25 + \frac{T^2}{\Theta_D^2} \right] G(T)$$

$$\sigma_{corr}^2(T) = \frac{3\hbar^2}{Mk_B\Theta_D} \left[ \frac{1 - \cos(rQ_D)}{\cos(rQ_D)} + \frac{T^2}{\Theta_D^2} H(T) \right]$$

$$G(T) = \int_0^{x_D} \frac{x dx}{\exp(x) - 1}$$

$$H(T) = \int_0^{x_D} \frac{\sin(\omega x) dx}{\omega[\exp(x) - 1]}$$

where  $\sigma_{diff}^2$  and  $\sigma_{corr}^2$  are the diffraction and correlated atomic root mean square displacement, respectively,  $\Theta_D$  and  $Q_D$  are the Debye temperature and the Debye wave vector,  $x_D = \frac{\Theta_D}{T}$  and  $\omega = \frac{rQ_D}{x_D}$ ,  $M$  is the atomic mass,  $k_B$  and  $\hbar$  are respectively the Boltzmann constant and the Planck constant divided by  $2\pi$ .

An extension of the previous formulae was developed for gold clusters [71], showing a decrease of the Debye temperature with respect to the bulk of the order of 10% for a diameter of the clusters of 3 nm. This decrease was explained by the contribution of the surface atoms having a higher mobility in the cluster, and applying the free-bounded sphere density of states in a Debye approximation.

In Figure 8, EXAFS spectra taken at different temperatures are displayed for bulk gold; these curves allow a precise determination of the dependence on the temperature of the DW factor for the bulk metal [71]. In Figure 9, in fact, the experimental  $\sigma^2$  for bulk gold gives a good agreement with the theory if a Debye temperature of 165 K is used. These authors, analyzing the cluster data with respect to the bulk, found a lower Debye temperature for clusters, accounting for surface mode contributions. The Debye temperature for a cluster of 1.5 nm diameter was reduced to 140 K, whereas for a 9.3 nm diameter was 150 K. Furthermore, small contraction was obtained for the nearest-neighbors first shell distance up to 0.005 nm.

In contrast with these data, another experiment was reported in 1990 for a  $\text{Au}_{55}$  single size cluster [72]. In principle an experimental investigation of clusters with a well defined size constitutes an excellent opportunity for obtaining very clear results, which should not be averaged over a size distribution. However, these  $\text{Au}_{55}$  clusters were chemically produced using a  $\text{ClAuP}(\text{C}_6\text{H}_5)_3$  compound in benzene reduced by diborane. This implied the presence of ligands, which were taken into account by monitoring the Au-Cl

**Figure 8.** This figure shows the  $\chi(k)$  spectrum weighted by  $k$ , for a Au foil at three different temperatures. signal from sodium chloroaurate. Here, Au–Au distance is found to be 0.231 nm with a total coordination number of 7.8, so that clusters were assumed of cubooctahedron shape with 12 triphenylphosphine and 6 Cl ligands. The analysis of the mean squared relative displacement lead to the conclusion that the clusters vibrate about 40% less than the bulk gold. Can the ligands be responsible for these different conclusions?

In this context, a more recent paper was published in 1995 [43]. In this paper, gold was evaporated at a very low rate on a thin mylar substrate, and afterward a few monolayers of mylar were deposited on the gold clusters so as to prevent any size modification. This process repeated many times produced a number of mylar layers containing gold clusters inside. Transmission electron micrographs confirmed a distribution of spherical clusters whose peak was at about 1.6 nm with a half width at half height of about 0.8 nm. EXAFS spectra were taken at the  $L_{III}$  edge at  $T = 28$  K.

As visible in the Fourier transform of figure 3 of Ref. [43], whereas the reference bulk gold shows first and higher shells peaks, the cluster ensemble presents only the nearest neighbors (nn) peak without higher features. These are missing not only because of the low signal-to-noise ratio but very likely also because of possible incoherent contributions due to a spread of distances; this last effect can cause, for higher shells, an attenuation of the amplitude further reduced when the surface layer is taken into account. A detailed fitting procedure is here performed with or without additional parameters (cumulants); as mentioned above, great care should be paid since i) the correlated parameters  $N$  and/or  $\sigma$  can be easily overestimated; ii) the use of cumulants can improve the fit, but somewhat modifies the peak position. These points stress that a speculative intelligent physics should always prevail over a crude mathematics. In fact, as reported in Table 1, an increase of  $N$  implies also the increase of  $\sigma$  for a best fit of the data; however, a detailed comparison with theoretical structures using the calculated parameters gives several possible scenarios. The most reliable was found for a mixture of three preferential sizes (38, 201, and 309 atoms/cluster) having truncated cubo-octahedral structures, composing the clusters with percentages respectively of 85%, 10%, and 5%. These results indicate a quite low nn contraction, an average coordination number of 8.7, and a DW factor  $\sigma^2 = 5.8 \times 10^{-3} \text{ \AA}^2$ ; furthermore, no evidence of  $C_3$

**Table 1.** Size  $d$ , nearest-neighbor distance  $r$ , coordination number  $N$ , and Debye–Waller factor  $\sigma^2$  for some gold cluster structures compared with the experimental fitting data for a cluster and for a bulk Au crystal.

Structure	$d$ (Å)	$r$ (Å)	$N$	$\sigma^2$ ( $\times 10^{-4} \text{ \AA}^2$ )
38 truncated octahedral	11.6	2.78	7.6	60.0
55 cubo-octahedral	13.8	2.78	7.9	46.0
55 icosahedral	13.6	2.81	8.5	80.0
201 truncated octahedral	20.5	2.83	9.4	45.0
309 cubo-octahedral	25.2	2.83	9.6	42.0
309 icosahedral	25.4	2.85	10.0	76.0
561 cubo-octahedral	30.8	2.84	10.0	38.0
561 icosahedral	30.1	2.85	10.0	70.0

and  $C_4$  cumulants was detected, showing that the harmonic approximation gives an adequate description of the vibrational behavior of these nanocrystals. The significantly lower value of the mean squared relative displacement detected for these cluster samples with respect to the value obtained for  $Au_{55}$  clusters [73] was ascribed to the higher temperature and to the presence of ligands in these monosized agglomerates.

Bimetallic clusters also were studied by this technique. We mention Ag-Cu and Au-Cu clusters [75] supported by a silica matrix. Owing to the slight miscibility, a higher segregation of copper in the interior of the cluster was found for Ag-Cu agglomerates, whereas gold rich region was preferentially detected on the surface.

Furthermore, it is worth mentioning the studies on metal catalysts [76] and the novel method for supporting Pt nanoparticles [77] using porous carbon nanotubes.

## 6.2. Clusters of Magnetic Elements (Fe, Co, Ni)

Magnetic materials exhibit very interesting properties for several fundamental and applied aspects. The confinement in small clusters, nanostructures, or superlattices has opened a great and growing number of exciting research studies [78–89]. We refer the reader to the wide literature, mentioning only a few topics particularly studied at present: the magnetic anisotropies of ultrafine Co agglomerates, the saturation ferromagnetism of  $Ni_{13}$  and  $Co_{13}$ , the important effects due to the matrix hosting the clusters [82–84], etc. In addition Fe, Co, and Ni are of particular interest because of possible structural transitions, size and temperature dependent. In Fe, for example, a transition from ferromagnetic bcc  $\alpha$  phase to fcc  $\gamma$  antiferromagnetic phase is observed at about 1183 K. Instead, cobalt metal structure is hexagonal close packed up to 725 K, whereas at higher temperatures a phase transition to fcc occurs. Co clusters seem to exhibit fcc structure, but other possible forms such as truncated octahedra [87], icosahedra [88], or chainlike agglomerates [89] can be obtained. On the other hand, Co films were grown in a bcc metastable phase [90] using epitaxial deposition on GaAs(110), with a lattice constant of 2.827 Å. In a silver matrix, a low concentration of Co shows an initial stage of Co in substitutional and dimer form with subsequent segregation and precipitation [85].

This topic then teems with challenging perspectives in particular related to the geometrical configuration of the clusters [88] and to the dynamical behavior under thermal treatment.

EXAFS and XANES spectroscopy therefore appear quite valuable for this investigation, involving the cluster confinement into a defined matrix, such as Co in Ag [78, 79], permitting one to distinguish whether Co faces another cobalt or an interface silver atom. In such a case, in order to obtain a very low cluster size, several methods were employed including ion implantation and molecular beam epitaxy, so as to have a homogeneous Co depth profile over about 800 nm, ranging from 0.1 at. % up to 6.0 at. %.

Experiments were performed at the GILDA beamline of the ESRF, Grenoble, France, around the Co K edge (7709 eV), in the range 7500–8700 eV, and in fluorescence

mode using 6 ultrapure Ge detectors cooled at 77 K. In these investigations, the samples were investigated at different temperatures, from 77 K up to 225 K.

The FT plots of the  $k\chi(k)$  spectra for some Co/Ag samples and their best fits (see Figs. 10 and 11) showed very interesting features [78, 79]:

First, the first, second, and third shell peaks are now split into two components corresponding to Co and Ag atoms around the Co absorber. This was attributed by the authors to evident clustering, since on the average a Co atom “sees” around itself partially atoms of the same species and partially atoms of the matrix; the relative weights depend on the size of the cluster and thus on the surface to volume ratio.

Second, in the most diluted (0.1%) sample, Co dimers were obtained, whereas clusters of different sizes (8 and 20 atoms/cluster) grew in the as prepared materials at 6% (co-evaporated sample) and 1.9% (implanted sample). After

**Figure 10.** This figure shows the  $\chi(k)$  spectrum weighted by  $k$ , for some dilutions of cobalt in a silver matrix; for comparison, also the corresponding curve of a Co foil is displayed. Note the modifications of the curves with respect to one other. Adapted from [79], G. Faraci et al., “Physics of Low Dimensional Systems” (J. L. Moran-Lopez, Ed.), 2001. © 2001, Kluwer Academic-Plenum.

**Figure 11.** This figure shows the FT of two EXAFS  $\chi(k)$  curves weighted by  $k$ ; in the upper curves, the data for a diluted Co sample (dotted) are shown together with the fitting curve obtained using the FEFFIT code [33, 37, 38, 55]; for comparison, in the lower part of this figure, the corresponding curve for a Co metal foil is reported. Note that in the diluted sample, the Co-Co features are mixed up with the Co-Ag peaks. Adapted from [78], G. Faraci et al., *Phys. Rev. Lett.* 86, 3566 (2001a). © 2001, American Physical Society.

annealing at 350 °C, the cluster size increased up to 80 and 136 atoms/cluster, respectively, with a strong dependence on the preparation details; in fact, implantation at lower concentration caused larger clustering than molecular beam epitaxial evaporation. As already pointed out, for each sample the FT of the EXAFS spectra showed remarkable peaks corresponding to first, second, third, and even fourth coordination shells. Also, these features were analyzed and found to be split into two components, and the respective parameters corroborated the indications of the first shell.

The conclusion of a preferential arrangement of small Co clusters (dimers or chain of dimers) was advanced for 0.1 at. % Co in Ag supported by Mössbauer investigation of the primary stages of Co precipitation in Ag [91].

For discriminating between a dimer and other possible small clusters, some models were developed to compare the average first, second, and third coordination numbers; a multiple dimer configuration is displayed in Figure 12 with the dimers disposed along the fcc square faces of the Ag lattice in orthogonal direction to each other. This corresponded to a first, second, and third average coordination respectively calculated equal to 1, 0.83, 1.67, very close to the experimental ones.

Some complementary information was reported from the XANES spectra, shown in Figure 13; for the dimer

**Figure 12.** The top part of the figure displays the silver lattice (fcc) with 4 Co dimers put in quasi-substitutional position, at orthogonal angle to each other, and along opposite square faces of the lattice; the lower part, a Co cluster of 19 atoms is shown, with a first (12 atoms) and a second (6 atoms) shell around the central atom, in fcc configuration.

**Figure 13.** This figure shows the near edge structure of Co/Ag samples, where Co dimers, 8-atom clusters, and 136-atom clusters in a silver matrix are present. For reference the corresponding curve of a Co foil is reported in order to show the evolution of the curves: it is evident a hcp-fcc phase transition. Adapted from [79], G. Faraci et al., "Physics of Low Dimensional Systems" (J. L. Moran-Lopez, Ed.), 2001. © 2001, Kluwer Academic-Plenum.

ensemble, a chemical environment similar to that of an Ag matrix seems progressively modified towards that of the bulk cobalt as the size of the Co clusters increases.

The reported DW factors permitted evaluation of the corresponding Debye temperature  $\Theta_D$  for the different situations presently described. Values of  $\Theta_D = 418$  K at  $T = 77$  K (with a calculated  $\sigma^2 = 27 \times 10^{-4} \text{ \AA}^2$ ) obtained for bulk Co compares with  $\Theta_D = 285$  K for Co-Co at the dilution 1.9 at. % and  $\Theta_D = 260$  K at 6 at. % with a marked reduction with respect to the Co bulk value. This was attributed to a less rigid environment due to the soft Ag host lattice, through the large fraction of Co-Ag interface bonds; these bonds vibrate with a  $\Theta_D = 200$  K close to that of bulk silver.

Another study deals with a Co/Pt multilayer, prepared by electron beam deposition alternating Pt 1.8 nm films and Co 0.2 nm single layer. Polarized EXAFS spectra [92] at the Co *K*-edge were performed by orientation of the polarized electric field of the synchrotron radiation almost perpendicular or parallel to the film surface. The direct comparison of the corresponding EXAFS spectra and of their FT showed a strong anisotropy: In fact, data with in-plane polarization indicated intermixing at the Co/Pt interface whereas those measured with out-of-plane polarization showed an abrupt interface structure between Co and Pt clusters.

### 6.3. Clusters of Rare Gases: Ar, Kr, Xe

Rare gases are a class of very important elements for fundamental physics, since their electronic configurations with completely filled  $s^2$  (He) or  $s^2p^6$  shells (Ne, Ar, Kr, Xe, Ra) can give crystals with a very low binding energy of van der Waals type. Crystals of inert gases are transparent insulators, with low cohesive energy and low melting point (24 K for Ne, 84 K for Ar, 117 K for Kr, 161 K for Xe). Therefore, when introduced into a solid matrix, these inert gases tend to form clusters or bubbles. Ion implantation represents the most common and simple method for obtaining a uniform ensemble of rare gas agglomerates into a host layer a few hundred nm thick, using the proper ion beam, ion fluence, and implantation energy.

However, a semiconductor substrate can be amorphized by this method because of the large energy exchanged during the implantation process. As a consequence, it is necessary to anneal the sample for obtaining a crystalline substrate reconstruction; an alternative method can be the implantation at high temperature. Although noble gas inclusions in a solid matrix were obtained in the past as gaseous bubbles, in 1984 it was noted that small clusters of a rare gas could be confined in solid phase at room temperature, using the large pressure exerted by the host lattice against the foreign atoms, pushed into nanocavities within the matrix. These existed already in the as-prepared samples or as a consequence of an annealing process. Due to the very different nature of the substrate, thermal treatment, preparation process (fluence, implantation energy, ion penetration depth and profile, induced damage, etc.), and implanted rare gas, a large amount of data was collected by several experimental techniques. In 1984, overpressurized bubbles containing liquid Ne and solid clusters of Ar and Xe were observed [93] in Al at room temperature by transmission electron microscopy (TEM) and electron energy loss spectroscopy. Similar results

were obtained [94] for Ar, Kr, and Xe in Al with an epitaxial alignment of the solid noble gas with the matrix.

On this subject an excellent review can be found in the *Proceedings of the NATO Advanced Research Workshop* held in 1990 [95], and in a more recent article [96], both treating this matter with many details. We limit ourselves to mention the most relevant results and some controversial points. Of course the possibility of obtaining solid noble gases at room temperature, without resorting to more complicated apparatus such as the diamond anvil cells for getting high pressure, stimulated many studies for fundamental and applied reasons.

In implanted metals, Ar, Kr, and Xe form 1–2 nm radius solid clusters already at concentration 3–5 at. % with fcc lattice as observed by TEM [97], XRD [98], and EXAFS [99]. The nanocrystal inclusions at RT should be pressurized by the host matrix with a large pressure of the order of 1 GPa as confirmed by the pressure-volume curves [100–103].

In implanted Si, a more complicated scenario is determined by the amorphization of the matrix implanted at RT. In fact, while Ar was clearly detected in as-implanted samples [99] as crystalline agglomerates, Kr and Xe were not observed in the early agglomeration stage after simple implantation at high fluence; in the annealed samples, on the contrary, the rare gas was detected in compressed solid or fluid phase [104, 105].

Typical spectra for Xe/Si are shown in Figure 14, for several temperatures. We point out here that for fluid bubbles, the atoms of the clusters are in quite disordered configuration similar to liquid or amorphous systems. For such cases [23], the use of standard EXAFS expressions including the third and fourth cumulants are not adequate, since the absorber-backscatterer pair can be at a relative distance with asymmetric non-Gaussian distribution and/or anharmonic vibrational behavior.

**Figure 14.** Fluorescence spectra of Xe implanted in a Si layer. Solid Xe clusters are evident at low temperature for the presence of high EXAFS oscillations damped at room temperature.

A correct average of the EXAFS formula over the effective pair distribution function  $g(r)$  can present many difficulties both because of the low- $k$  cut-off used in EXAFS analysis and the dramatic reduction of the signal-to-noise ratio. This can give an apparent bond length contraction and an incorrect evaluation of the coordination number. For these reasons, whenever fluid clusters are involved, a more accurate analysis ascertaining the consistency of the parameters should be performed. We suggest a cross check between EXAFS and XRD techniques.

In the literature, EXAFS characterization of fcc Ar clusters in Al and Si [99] at 300 K gave, in as implanted samples, a nearest-neighbors contraction of  $0.31 \pm 0.05$  Å for Ar/Al, whereas a higher value of  $0.42 \pm 0.05$  Å was deduced for Ar/Si. The overpressure obtained by this contraction was evaluated in 2.5 and 4.4 GPa, respectively. From the corresponding Debye–Waller factors, the authors calculated the increase of the Debye temperature  $\Theta_D$  due to the overpressure: Crystalline bulk Ar at low temperature has a  $\Theta_D = 93$  K, whereas the compressed nanocrystals reach a harder value of 212 K in Al and 300 K in Si, in agreement with values obtained by the thermodynamical equations [102] using the Grüneisen parameter  $\gamma_G$  and the isothermal compressibility  $\beta$ :  $-\gamma_G = \partial \ln \Theta_D / \partial \ln V$ ,  $-\beta = \partial \ln V / \partial P$ .

According to the authors, the very low value of the coordination numbers should be attributed to the quite small percentage of Ar in crystalline configuration with a large amount in disordered fluid or gas-like phase, contributing to the background. Similar results were reported for Xe in annealed Si [104], where a fraction of Xe atoms is found condensed in solid fcc clusters contracted by  $0.41 \pm 0.06$  Å at room temperature and by  $0.12 \pm 0.06$  Å at 70 K well below the Xe melting point (161 K). The value of the Debye temperature was obtained from the nearest-neighbor contraction and, independently, from the Debye–Waller factor with a nice agreement. These determinations, however, did not take into account any cumulant correction, so that some overestimation of the parameters could occur at temperature higher than the melting point where some clusters could be in a size range for which fluid or disordered configurations can be mixed up with reduced size clusters in crystal phase.

Actually, a recent XRD contribution for as-implanted Xe in Si [105] found, at room temperature, compressed fluid bubbles with 1 nm radius and a first coordination number of only 6 Xe, with a mutual distance of 4.22 Å reduced with respect to the value 4.37 Å of liquid Xe.

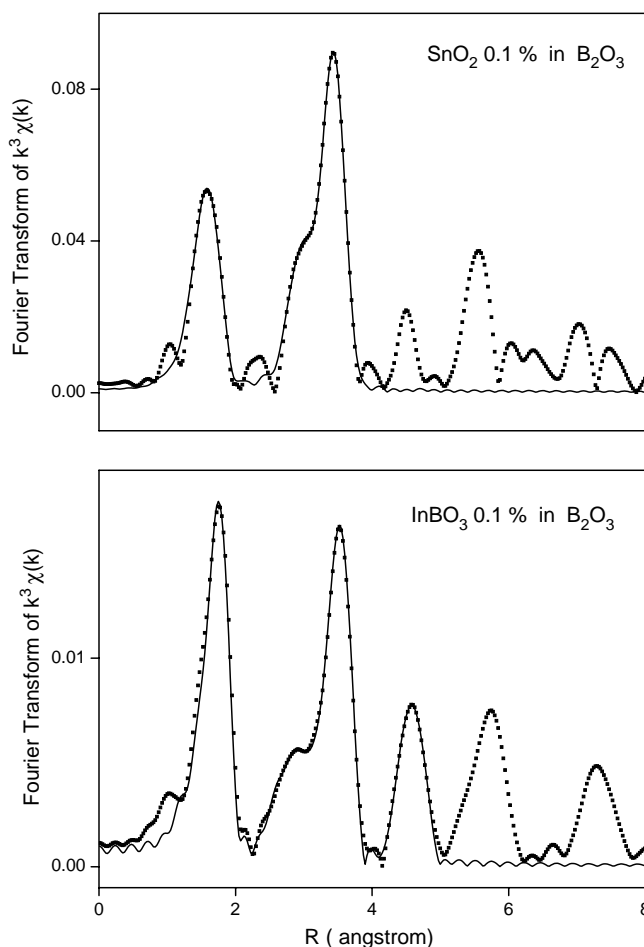

The reduction of the coordination, as far as the temperature increases beyond the transition temperature between the solid and the liquid phase, could be explained by a possible configuration of rare gas clusters with a solid small nucleus surrounded by a wide shell in liquid or amorphous phase. This last scenario has not been explored yet.

#### 6.4. Clusters of Binary and Ternary Compounds

It is worth mentioning some other experiments performed on molecular clusters [106], nanocrystals of semiconducting oxides [107], quantum dots [108], intercalated compounds [109–112], alloy clusters [113, 114], etc. Among the above

topics, recent accurate measurements concern the characterization of quantum dots (QD) of reduced size confined in a glass matrix ( $B_2O_3$ ) by a simple melting process. The objects of these studies were luminescent  $InBO_3$  [107] or semiconducting oxide  $SnO_2$  [108], since their confinement in the nanometer range can modify the absorption and the emission radiative transitions. For these clusters the EXAFS technique also can give accurate information about the average size of the QD, through the determination of the coordination numbers of several coordination shells; these can be compared with calculations performed for each shell, for example, in ternary compounds [107]; here, as shown in Figure 15, first In-O, second In-B, third In-O, and fourth In-In shell have been separately fitted and the corresponding parameters evaluated. The fitting procedure followed the FEFF code [33, 38, 55], shell by shell, using the corresponding parameters as best fit variables.

In Figure 16, we report the calculations related to the  $InBO_3$  and  $SnO_2$  structure, respectively, rhombohedral and distorted octahedral, as a function of the size; the simulation is very simple; it is enough to determine the geometric position of each atom in the corresponding structure; supposing a spherical atomic distribution of fixed size, it is now possible

**Figure 15.** The figure displays the FT curves for 0.1% diluted solution of indium borate and tin dioxide in a glass matrix, at 77 K. Also shown is the corresponding fit. Note the different relative heights of the features present in the spectra, due to the coordination number of the peak.

**Figure 16.** Typical average coordination numbers as a function of the total atoms in the cluster. In the upper data, the first shell average coordination is shown for a Xe solid cluster with fcc lattice; the bulk crystal value is 12. In the lower data, it is reported the fourth shell average coordination for an indium borate cluster with rhombohedral lattice; the bulk value is 6. The lines are a guide to the eye. Adapted from [107], © 2002, American Physical Society.

to count the number of atoms around each absorber inside the sphere and afterward to average the obtained data.

From the previous analysis, we can deduce the very important result related to the comparison between the experimental coordination number of each shell with the corresponding value calculated as a function of the radius  $r$  for a spherical nanocrystal of the material under study. For a spherical distribution of atoms with definite lattice configuration, or fcc, it is easy to evaluate the coordination number around each atom, calculating the average between all the atoms in the cluster. Surface atoms of course contribute much less than the internal ones, so that the average depends on the relative contribution of the surface-to-volume, as in on the ratio  $4\pi r^2 \rho_s / (4/3)\pi r^3 \rho_v = 3\rho_s / r\rho_v$ , where  $\rho_s$  and  $\rho_v$  are the surface and volume atom densities, respectively.

In these experiments, a glass matrix of boron oxide was used, and a simple melting procedure was adopted for synthesized quantum dots. For  $\text{InBO}_3$  clusters, a large range of dilution between 0.3% and 2.0% gave the same QD size of about 3 nm radius. For  $\text{SnO}_2$  it was instead possible to modify the QD size just by changing the concentration of the solute in the matrix: in fact, the QD radius obtained in this last case was 0.5, 1.0, and 1.4 nm for 0.1, 0.2, and 0.3% dilution of the semiconductor in the glass, respectively.

Another interesting study [115] concerns the growth of clusters with the “inverted hut” structure found for SiGe alloy in Si/Ge superlattices. These nanocrystals, observed by EXAFS, were determined as confined in the Si/Ge superlattice beneath the Ge wetting layer and grown into the Si deposition. Ge hut clusters, investigated by scanning tunneling microscopy and X-ray diffraction, were detected almost

fully strained with a minor misfit at the Ge/Si interface [116]; their density dramatically increases by capping the Ge layer with 6 Å of silicon [117], although the silicon-germanium intermixing in Ge/Si(100) islands varies as a function of the deposition temperature [118, 119]. Note, however, that the shape of Ge clusters on a Si(100) surface can be dependent on the hydrogen termination of the Si surface; in fact, when the Si surface is exposed to atomic hydrogen, large dome-shaped Ge clusters were observed; otherwise hut-shaped clusters grow with smaller size [120].

## GLOSSARY

**Cumulant** Correction factor in Exafs equation; the third cumulant enters the sine term, the fourth cumulant affects the amplitude. Generally they are  $k$  dependent.

**Fermi level** For a metal, it indicates the highest occupied electron state, at  $T = 0$  K, in the conduction energy band; for a semiconductor, it indicates usually the chemical potential, an energy level (commonly not an occupied state) in the prohibited energy gap between the valence and the conduction band, controlling the number of electron and hole occupied states in the mentioned bands.

**Phase shift** Shift of the photoelectron wave phase, that can be caused in the photoelectron emission from the absorber, or in the photoelectron scattering process.

**Shake-off** Electron transition from the valence band toward the external continuum states.

**Shake-up** Electron transition from the valence band toward a higher state of an internal empty band.

## ACKNOWLEDGMENTS

The author is grateful to Prof. Moog Gan Chow for a critical reading of the manuscript and to Prof. Agata R. Pennisi for helpful suggestions.

## 1. INTRODUCTION

There is a tremendous worldwide interest in the area of nanotechnology, which encompasses the synthesis, organization, and application of materials on a nanoscale. The field of nanotechnology is highly interdisciplinary, and involves concepts from chemistry, physics, biology, and engineering with applications in electronic and photonic devices, computing and information technologies, health care, biotechnology, and clean-energy production. Further, the nanoscale materials are of great fundamental interest due to their exceptional optical, electrical, and magnetic properties, which are markedly different from those of the bulk. These properties are strongly dependent on the size and shape of the particle owing to their very small dimension and fundamental change in the coordination, symmetry, and confinement [1, 2]. Thus, the unique size-dependent electronic, optical, and chemical properties of nanoparticles have triggered considerable research activities, and have attracted significant attention in developing new-generation engineered materials, biological and photosensors, as well as advanced devices such as information storage processes, lasers, switches, transistors, light-emitting diodes, nonlinear

optics, photocatalysts, solar cells, and so on [3–8]. Moreover, the nanocrystals also exhibit remarkable physical phenomena such as enhanced local field effects for metals, quantum confinement for semiconductors, and superparamagnetism for magnetic materials. Hence, research and developmental activities on nanoscale magnetic metallic clusters/particles/crystals such as Fe, Co, and Ni have been intensively studied because of their fundamental characteristics, as well as several diverse applications in high-density magnetic recording media, magnetic (ferro) fluids, color imaging, magnetic refrigeration, and so on [7, 8]. In fact, the intrinsic magnetic properties are strongly influenced by the particle size; nanoscale magnetic particles usually display specific features such as superparamagnetism and quantum tunneling of magnetization [9–11]. Another well-known cluster-related concept is the so-called quantum size effect, which arises as a result of the (blue) shift in the optical absorption edge of nanoparticles [12]. On the other hand, nanowires/nanofilaments/nanofibers/nanorods have also attracted great interest because of the outstanding physicochemical properties and novel physics that they exhibit, as well as their potential applications as interconnects or functional components in future mesoscopic and optoelectronic devices [13, 14].

## 2. NANOMATERIALS IN CONFINED ENVIRONMENT

Traditionally, colloidal solutions [15], porous glasses [16], and certain polymers [17] have been used as hosts for the preparation of nanosized materials. In addition, several other approaches have also been considered for the synthesis of nanoparticles in aqueous as well as nonaqueous media by adopting chemical, sonolytic, radiolytic, and photolytic reactions [6]. Nanosized metal, metalloid, and semiconductor nanofilaments have been prepared using various methods such as templating [18, 19], photochemistry [20], seeding [21, 22], and electrochemistry [23, 24]. However, all of these methods are neither efficient in generating clusters of uniform size nor chemically inert toward

the guest molecules. Therefore, the self-assembly of nanoparticles into ordered morphologies is one of the promising alternatives, and hence forms the topic of current interest. Further, they are also expected to create nanostructured materials with unique physicochemical properties. Therefore, it has been realized that the preparation of nano-sized materials in periodic zeolitic pores is a viable option, and hence they have been considered as ideal systems for the growth of nanostructures [12, 25–28]. Indeed, the well-defined, regular nanoporous structure of zeolite (microporous) molecular sieves offers several advantages, including a unique microenvironment for the controlled assembling of nanostructured materials [27–42], and that the encapsulated metal/metal-oxide nanoclusters formed in these ordered porous materials can potentially be used in a variety of applications, including optics, electronics, sensors, and catalysis [33, 35]. Further, they also provide a simple way of coupling the reactivity of the metal complexes with the robustness and stereochemistry of the host matrix. Nevertheless, from the viewpoint of nanoclusters in a confined environment, only little effort has been directed. At this juncture, it is important to mention here that, according to the IUPAC nomenclature, the porous materials are classified into three types according to their pore diameters [43]: microporous (<2 nm), mesoporous (2–50 nm), and macroporous (>50 nm). The exceptionally large pore structure, for example, of mesoporous materials allows controlling the particle size, as well as the organization of nanoparticles in an orderly manner.

Thus, the confinement of nanoclusters/nanofilaments in the cavities/voids/pores of nanoporous inorganic matrices is attracting much more attention as a way to stabilize highly dispersed metals, metalloids, semiconductors, and so on, in the form of atoms, clusters, filaments, or colloids, and to prevent their coalescence into larger, ill-defined aggregates [44–56]. These new materials, however, are significantly different from the recently extensively reported glass–metal colloidal composites and organic–inorganic hybrid nanocomposites [57, 58]. Thus, the encapsulation or loading of mono- and bimetallic species, metalloids, mono- and mixed-metal oxides, polymers, and so on, in the form of clusters or filaments in so-called periodic porous molecular sieve materials possessing well-ordered and controllable nanopores with a narrow pore size distribution, has stimulated great interest owing to their novel properties and exotic applications [44, 45, 48, 59–66]. For example, Ag-loaded porous silica displays an optical switching effect and surface oxidation behavior [46], while the encapsulation or entrapment of metal complexes provides a convenient route for the heterogenization of homogeneous catalytic processes as these hybrid catalysts offer the advantage of site isolation, shape selectivity, and enhanced activity in several organic transformations with easy product separation and catalyst recovery [29].

### 3. MOLECULAR SIEVE HOST

The development of open-framework inorganic materials, for example, silica and carbon, of well-defined geometry with a precise and easily controllable pore shape and size, is of great importance in many areas of modern science and

technology. They attract much attention as catalysts, catalytic supports, and selective adsorbents, as well as templates for making new materials.

## 4. MICROPOROUS MOLECULAR SIEVES

Periodic microporous materials, for example, zeolites and zeolite-type materials, can exclusively be used for a variety of applications, including sorbents, ion exchangers, shape-selective catalysts, and molecular hosts [37–42]. The well-defined and uniform pore systems act as a suitable reaction chamber/support for the controlled assembling of nanocrystals, as well as for the encapsulation of organic/inorganic molecules within the voids of a zeolite host [28].

### 4.1. Nanoclusters/Nanoparticles in Microporous Materials

One of the fascinating examples of encapsulated species in zeolitic pores is the so-called “ship-in-bottle” metal complexes such as metallophthalocyanines and metal carbonyls in zeolites, which have been proposed as enzyme mimics [29, 67–80]. For steric reasons, these complexes have to be assembled *in-situ* by allowing the building blocks to diffuse through the windows of the zeolite cages and condense around a metal ion previously introduced into the voids by ion exchange. As shown in Figure 1, for example, several metal ions, including Co, Ru, Rh, Ir, Pd, and Pt, have been impregnated in the zeolite-Y matrix, followed by carbonylation, leading to the selective formation of triangular prismatic metal carbonyl clusters of the type  $[M_3(CO)_6]_n^{2-}$  ( $M = Co, Ru, Rh, \text{ and } Pt; n = 2-6$ ). Decarbonylation of the resulting metal carbonyl clusters in the void space yields metal

**Figure 1.** (a) Ship-in-bottle synthesis of Pt carbonyl clusters  $[Pt_3 \cdot (CO)_6]_n^{2-}$  ( $n = 3$  or  $4$ ) in zeolite-Y. Adapted with permission from [79], A. Fukuoka et al., *Catal. Today* 66, 21 (2001). © 2001, Elsevier Science. (b) Structure of Pt carbonyl anion clusters  $[Pt_3(CO)_6]_n^{2-}$  ( $n = 1, 2, \text{ and } 6$ ). Adapted with permission from [76], M. Sasaki et al., *J. Mol. Catal. A* 141, 223 (1999). © 1999, Elsevier Science.

nanoclusters. However, it is to be noted here that these complexes are forced to adopt a distorted geometry owing to the encapsulation of such larger complexes into the constrained environment. For example, the incorporation of a planar Co (II) phthalocyanine molecule in the super cage of zeolite-Y is considerably distorted [80] since the end-to-end diagonal distance (15 Å) of the neat complex is larger than the pore size of zeolite-Y (12.7 Å). This is clearly reflected in the magnetic measurements, where an increase in the magnetic moment of the entrapped complex is noticed (Fig. 2). However, when this moiety is encapsulated in much larger voids of the mesovoids of the so-called MCM-41 phase (for a detailed account, see Section 5), where it retains the square planar geometry, the magnetic moment values are similar to the free or neat complex.

On the other hand, luminescent Si nanoclusters have been encapsulated in the supercages of zeolite-Y [49] by adsorbing and anchoring disilane, followed by gentle thermolysis (Fig. 3). Further, the steric restriction imposed by the host ensures that disilane molecules are exclusively entrapped in the  $\alpha$  cages, and that the resulting Si clusters show atypical bandgap energy (2.2 eV). Likewise, unusual structure and stability have also been observed in the case of the  $\text{FeO}_x$  nanoclusters in ZSM-5 [81]. Also, CdS and PbS nanoparticles have been prepared from the respective metal ion-exchanged zeolites by reaction with  $\text{H}_2\text{S}$  [25]. In the same way, the loading of CdS and GaP nanoclusters in zeolite-Y and ultrastable zeolite-Y has also been reported [28]. More recently, the inclusion of solvatochromic dye Nile red in the pores of zeolites such as zeolite-Y, ZSM-5, and LTA (Fig. 4) has been reported, and the highly siliceous form of these zeolites can act as optical sensors [82]. Although the microporous (zeolite and zeolite-type) materials provide excellent hosts as a result of their crystalline network, well-defined pore size, and pore size distribution, their applications are, however, limited by the relatively small internal pore sizes and pore openings. On the other hand, the invention of ordered mesoporous materials [83, 84] in the early 1990s

**Figure 2.** Temperature variation of magnetic susceptibilities of Co(II) phthalocyanine (free) complex ( $\Delta$ ), Co(II) phthalocyanine encapsulated in zeolite-Y ( $\square$ ), and Co(II) phthalocyanine encapsulated in MCM-41 ( $\circ$ ). has opened a wide range of opportunities in porous solids, and has created new opportunities, not only in catalysis, but also has opened up new avenues in the areas of advanced materials, ion exchange, and environmental pollution control strategies [44, 45, 48, 59–66].

## 5. MESOPOROUS MOLECULAR SIEVES

The discovery of the so-called M41S family of periodic mesoporous materials [83, 84] has broadened the scope of applications in several areas [59–66], as well as opening new opportunities in the development of nanomaterials [44, 45, 48]. As illustrated in Figure 5, the mesostructures have been grouped into four main categories. Two of them have been identified as the thermally stable structures, viz. MCM-41 having a hexagonal structure with unidirectional

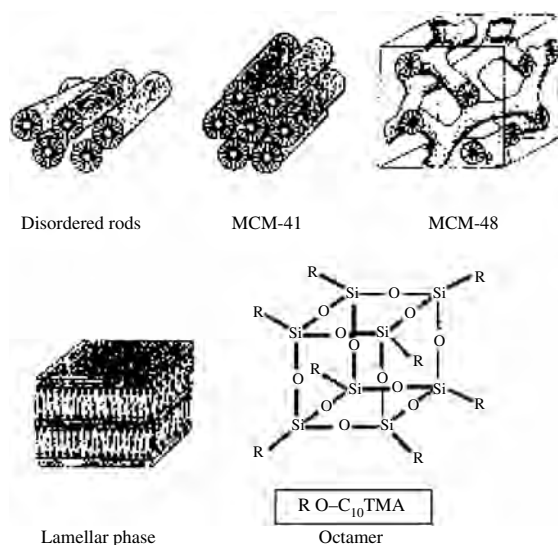

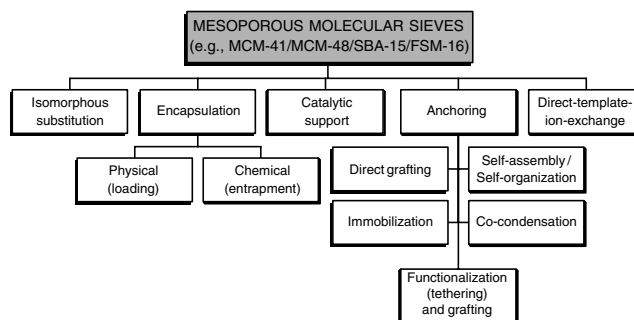

**Figure 4.** Schematic representation of the encapsulation of Nile Red in faujasite. Adapted with permission from [82], J. L. Meinershagen and T. Bein, *J. Am. Chem. Soc.* 121, 448 (1999). © 1999, American Chemical Society.

(both ordered and disordered) pore structure, and MCM-48 displaying a cubic structure with a three-dimensional pore system. Two other phases, viz. lamellar MCM-50 and molecular organic octamer, a surfactant-silica composite species ( $\text{surf}, \text{SiO}_{2.5}$ )<sub>8</sub>, are unstable. Thus, two of the stable members, that is, MCM-41 and MCM-48, can comfortably trap the guest molecules in the mesopores, and hence form perfect candidates for the loading and encapsulation of metal/semiconductor nanoclusters and nanofilaments with controlled size and shape. Owing to some of these unique and excellent characteristics such as the flexibility in terms of synthetic conditions, pore size tuning (2–20 nm), high surface area (1000–1600  $\text{m}^2 \cdot \text{g}^{-1}$ ), large internal hydroxyl groups (40–60%), framework substitution, and so on (for recent reviews, see [64] and [65]), in recent years, the scientific community has witnessed a great deal of work and rapid expansion of the activities in mesoporous materials (Fig. 6).

The well-defined regular pore size and shape, very large pore volume, huge surface area, tunable pore opening, narrow pore size distribution, and structural diversity of these materials are widely exploited for the selective adsorption of a variety of gases, liquids, and solids, and they also provide

**Figure 5.** Formation of various mesophases. Adapted with permission from [64], P. Selvam et al., *Ind. Eng. Chem. Res.* 40, 3237 (2001). © 2001, American Chemical Society.

**Figure 6.** Schematic representation of the various possible modifications of the mesoporous materials.

a suitable matrix for the control growth of nanostructured materials [44, 45, 48, 59–66]. The mesoporous materials have been synthesized via the polymerization of inorganic species such as silica, alumina, and so on, around a periodic bulky organic template, for example, surfactant micelles or polyethylene oxide or copolymers (Table 1) [64]. After the thermal treatment (calcination) of the synthesized materials, for example, MCM-41 (see Fig. 5), a hollow cylindrical porous matrix is obtained whose cavities are the perfect replicas of the organic species (Fig. 7). Numerous silica-based mesostructured materials such as MCM-41 [83, 84], MCM-48 [83, 84], FSM-16 [85, 86], HMS [87, 88], and SBA-15 [89, 90] with different pore sizes, shapes, and periodicities have been prepared by varying the synthesis conditions and the surfactant molecules (Table 2) [64]. In addition, the literature provides many nonsilica mesostructured materials of mono- and mixed-metal oxides, for example, aluminophosphates [91], transition metal oxides [92–95], and so on. These materials, including a new (organic-inorganic) hybrid HMM-1 [96], are frequently used as templates to synthesize various metal nanoclusters and nanowires by photo- and hydrogen reduction and different composite/ceramic nanoparticles by impregnation and calcination.

## 6. NANOCCLUSERS/NANOFILAMENTS IN MESOPOROUS BULK MATERIALS

As described in the previous section, the mesoporous materials have many favorable properties in conjunction with high thermal, hydrothermal, chemical, and mechanical stability. Therefore, they are highly conducive for a number of important applications, thus providing real opportunities in the area of separation technology, heterogeneous catalysis, and sensors, and in the synthesis of novel nanostructured materials such as metals, metalloids, oxides, chalcogenides, and so on [44, 45, 48, 56, 59–66, 97–108]. Other guest molecules encapsulated within the mesopore channels include several organic and inorganic polymers, complex ions, photocatalysts, chemically active colloids, semiconducting particles, luminescent silicon clusters, conducting polymer and carbon filaments, fullerenes, long-chain alkythiolates, enzymes, and a wide variety of organic, inorganic, and organometallic compounds [44, 45, 48, 109–118].

**Table 1.** Physical properties of various mesoporous silica materials.

Mesophase terminology	Dimensionality and crystal system and space group	Unit cell dimension (nm)	Mean pore size (nm)
MCM-41	2D, hexagonal, P6mm	$a = 4.04$	3.25

## 6.1. Nanomono- and Nanobimetallic Clusters and Nanofilaments

Recently, the ship-in-bottle synthesis methodology (Fig. 8) has been adopted for the encapsulation of larger complexes into mesopore channels [55, 73, 76, 79, 11, 119–121], and they can be transformed into nanometal clusters (1.5 nm size) by the controlled removal of CO (partial decarbonylation). In a similar manner, Pt nanoparticles and Pt nanowires of 2–4 nm diameter and 50–500 nm length have been prepared in the channels of FSM-16 by the reduction of H<sub>2</sub>PtCl<sub>6</sub> followed by the exposure to <sup>60</sup>Co  $\gamma$ -ray or UV light ( $\lambda_{\max} = 254$  nm) in the presence of 2-propanol and water at 300 K. In contrast, H<sub>2</sub> reduction of H<sub>2</sub>PtCl<sub>6</sub>/FSM-16 at 673 K resulted in the formation of Pt nanoparticles (Fig. 9). It is also interesting to note that the Pt wires consist of a single-crystal phase of Pt (110) having a lattice

**Figure 7.** Catalytically active sites (e.g., Ti or Mo) on the interior surfaces of MCM-41. The inset shows the disordered walls of the mesopores structure. Adapted with permission from [66], J. M. Thomas et al., *Chem. Commun.* 2921 (2002). © 2002, Royal Society of Chemistry.

fringe of 2.27 Å. However, the Pt nanofilaments are scattered and rather uniformly formed in alignment with the ordered channels of FSM-16 (Fig. 10).

At this juncture, it is also interesting to note that the Pt nanowires and Pt nanoparticles in FSM-16 display a unique IR spectrum for CO adsorption (Fig. 11), and that the latter yields a linear CO band at 2060 cm<sup>-1</sup> with an intensity over an order of magnitude higher than the former. In fact, the chemisorption measurements of CO and H<sub>2</sub> on Pt nanowire in FSM-16 showed that the adsorbed amounts are much smaller (about an order of magnitude) than those on Pt nanoparticles in FSM-16 [76]. In a similar way, Rh nanoparticles have also been prepared in FSM-16 by calcination of RhCl<sub>3</sub>/FSM-16 at 673 K and subsequent reduction with H<sub>2</sub>. Pt–Rh nanowires of 2.5 nm diameter and 10–50 nm length have been prepared in FSM-16 by the photoreduction of FSM-16 coimpregnated with H<sub>2</sub>PtCl<sub>6</sub> and RhCl<sub>3</sub> [120]. Mono- (Pt and Rh) and bimetallic (Pt–Rh and Pt–Pd) nanowires in hybrid (organic–inorganic) mesoporous materials (HMM-1) have also been synthesized by photoreduction of H<sub>2</sub>PtCl<sub>6</sub>·6H<sub>2</sub>O and/or RhCl<sub>3</sub>·3H<sub>2</sub>O and/or H<sub>2</sub>PdCl<sub>4</sub> [55]. Accordingly, the HMM-1 host was impregnated with an aqueous solution of the respective salts, and the sample was irradiated, in the presence of water and methanol, with a high-pressure mercury lamp (100 W, 250–600 nm) at room temperature (Fig. 12). Interestingly, the Pt–Pd/HMM-1 system shows a huge increase in the magnetic susceptibility below 90 K (Fig. 13), which is two–three orders of magnitude higher than the sum of the values of bulk Pt and Pd. The unusual enhancement of the magnetization may be attributed to the low dimensionality of the bimetallic wires.

On the other hand, Au nanoparticles have been prepared in the mesopore channels of monolithic porous silica [122] and FSM-16 [119] by soaking chloroauric acid (HAuCl<sub>4</sub>), followed by thermal reduction in hydrogen atmosphere. Uniform Ag nanowires have also been synthesized inside the channels of SBA-15 by wet impregnation of AgNO<sub>3</sub>, followed by thermal decomposition [52]. Likewise, impregnation of MCM-41 with an organic solution of a well-defined low-oxidation-state heterometallic organometallic cluster of

**Table 2.** Various mesoporous silicas based on 2D hexagonal (P6mm) MCM-41 structure.

Mesophase terminology	Silica sources	Surfactant/templates	Reaction conditions
MCM-41	Sodium silicate	Alkyltrimethyl-ammonium halides	Hydrothermal synthesis at 373 K for 144 h
FSM-16	Sodium kanemite	Cetyltrimethyl-ammonium chloride	Silica/surfactant/water mixture heated at 343 K under stirring. After 3 h, pH adjusted to 8.5, and again heated at 343 K for 3 h
FSM-16	Sodium kanemite	Cetyltrimethyl-ammonium chloride	Silica: surfactant ratio = 1:20 (w/w); final pH = 11.3 (without adjustment); stirred at 353 K for 3 h
SBA-3	Tetraalkyl orthosilicate	Cetyltrimethyl-ammonium bromide + HBr	Silica/surfactant/acid/water mixture stirred at room temperature (RT) for $\geq 30$ min
SBA-15	Tetraalkyl orthosilicate	Poly(ethylene oxide) oligomers— $C_{16}EO_{10}^c$ Triblock copolymer $EO_{20}PO_{70}EO_{20}^c$	Silica/surfactant/water mixture heated at 373 K for 24 h
MLMS <sup>a</sup>	Tetraalkyl orthosilicate	Triblock copolymers— $EO_{106}PO_{70}EO_{106}$	Silica/surfactant/water mixture heated at 313 K for 24 h
HMP <sup>b</sup>	Tetramethyl orthosilicate	$C_{12}EO_8$ (octaethylene glycol monododecyl ether)	Silica/surfactant/water mixture was aged for 18 h at room temperature; the ratio of surfactant to water was 50 wt%
	Cab-O-Sil	Glycosilicate surfactant <sup>f</sup>	Nonaqueous synthesis: the mixture is aged at 353 K for 3 days
MSM <sup>c</sup>	$(NH_4)_2SiF_6$	Cetyltrimethyl-ammonium bromide	Silica/surfactant/water mixture (pH = 8) stirred at RT for 1 h
MMS <sup>d</sup>	$H_2SiF_6$	Cetyltrimethylammonium bromide	Silica/surfactant/water mixture (pH = 7–8) aged at 343 K for 5 h

the type  $[NEt_4]-[Co_3Ru(CO)_{12}]$  into pores followed by thermal treatment (523–773 K) under inert atmosphere leads to highly dispersed magnetic nanoparticles at temperatures as low as 523 K [53]. The magnetic measurements at room temperature show no open (hysteresis) loop for the doped MCM-41 treated below 623 K, which is consistent with the particle sizes. On the other hand, the xerogels display a ferromagnetic behavior when treated at or above 523 K (Fig. 14). Nanostructured Pt wires have been synthesized in MCM-41, MCM-48, or SBA-15 by the impregnation method using an aqueous solution of  $Pt(NH_3)_4(NO_3)_2$ , followed by reduction in hydrogen at 573 K [54, 123, 124]. Nanoparticles of Ag, Pd, and Pt have also been prepared in AlMCM-41 by loading of the metal ions, followed by reduction in hydrogen [125]. The conduction electron paramagnetic resonance line width studies of these nanoclusters incorporated in the aluminosilicate matrix indicate that the line widths are independent of metal ion loading, which suggests that the metal particles are located inside the mesopore channels, and the size of the particle is constrained by the channel diameter. In the same way, nano-sized Ni metal particles (1–2 nm) also have been prepared in an AlMCM-41 host by ion exchange in an aqueous solution, followed by reduction with sodium borohydride [126]. The resulting nanoparticles showed superparamagnetic behavior with a blocking temperature of 5 K.

Recently, template syntheses of Au nanowires and nanoparticles onto FSM-16 have been reported by the chemical vapor deposition (CVD) or wet impregnation methods with subsequent reduction [121]; see Figure 15. In the case

of the former method, initially, an organogold (III) complex ( $AuMe_2(HFA)$ ; HFA = hexafluoroacetylacetoato) was adsorbed on the mesoporous matrix, followed by irradiation using UV light, leading to the formation of Au nanowires (diameter, 2.5 nm; mean length, 17.1 nm). On the other hand, in the case of the latter, the sample was impregnated using  $HAuCl_4$  at pH 5, followed by reduction in  $H_2$  at 673 K, giving a mixture of Au nanowires and nanoparticles. In contrast,  $H_2$  reduction of the impregnated sample prepared at pH 10 produces a homogeneously dispersed Au nanoparticle in FSM-16 with a mean diameter 1.7 nm. A novel supercritical fluid solution phase technique has also been utilized to fill the channels of a hexagonal mesoporous silica matrix with quantum-confined Si nanowires [127] as well as Pt nanoclusters [128]. The Si nanowires were formed within the mesopores by degrading diphenylsilane in a high-pressure reaction cell at 773 K and 375 bar [127]. The high diffusivity of the supercritical fluid phase, on the order of  $10^{-3}$ – $10^{-4}$   $cm^2 \cdot s^{-1}$ , enables rapid diffusion of the reactant precursor into the pores of the silica matrix, where swift nucleation and growth of the particles occur, resulting in a reaction rate much faster (several orders of magnitude) that is obtainable using traditional vapor-phase or liquid-phase deposition methods [48, 106, 129]. In the same way, size-controlled Pt nanoparticles were prepared using supercritical solvents. Accordingly,  $Pt(acac)_2$  ( $acac$  = acetylacetonate) dissolved in supercritical  $CO_2$  with acetone was loaded into FSM-16, followed by reduction in flowing  $H_2$  [128]. On the other hand, Ge was deposited using vapor-phase epitaxy, where the mesophase walls acted as anchor points to

seed the nucleation of semiconductor clusters in the channels [106].

## 6.2. Metal-Oxide Nanoclusters

The dispersion of nanosized metal-oxide particles has been carried out within the pores of mesoporous silica by soaking (loading) the corresponding metal salts in the host matrix, followed by thermal decomposition (Fig. 16). In other words, the nanocrystals are prepared via the adsorption/impregnation of the metallic precursor, or by the chemical modification of the mesopores, followed by thermal treatment [44, 45, 48, 56, 118]. Figure 17 illustrates a representative example of a direct imaging of the filling of the mesopores of MCM-41 by metal/semiconductor clusters. Several metal-oxide particles, including  $\text{TiO}_2$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{ZnO}$ , and  $\text{PbO}$ , have been dispersed within the pores of mesoporous MCM-41 and MCM-48 by soaking the corresponding metal salts via adsorption or wet impregnation of the metallic precursors or by chemical modification of the mesophases, followed by thermal decomposition [56, 97, 99, 101, 104, 105, 130–133]. Transmission electron microscopy studies demonstrated that the particle size of the incorporated  $\text{Fe}_2\text{O}_3$  in the mesopores of MCM-48 and  $\text{ZnO}$  nanoclusters in MCM-41 is smaller than the pore diameter [99, 134]. Further, it is interesting to note that the entrapped

**Figure 13.** Temperature dependence of magnetic susceptibility for Pt-Pd/HMM-1, Pt-Rh/HMM-1, and Pt/HMM-1. Adapted with permission from [55], A. Fukuoka et al., *J. Am. Chem. Soc.* 123, 3373 (2001). © 2001, American Chemical Society.

**Figure 14.** Isothermal magnetic measurements at room temperature of MCM-41 (a) and silica xerogels (b) impregnated with a saturated THF solution of  $[\text{NET}_4][\text{Co}_3\text{Ru}(\text{CO})_{12}]$ , after 1 h treatment under Ar at 773 K. Commun.* 1271 (2000). © 2000, Royal Society of Chemistry.

$\text{Fe}_2\text{O}_3$  shows an unusual bandgap energy of  $>4.0$  eV as compared to 2.14 eV for the bulk oxide [104]. Similarly, highly dispersed monometal oxides such as  $\text{Fe}_2\text{O}_3$ ,  $\text{Fe}_3\text{O}_4$ ,  $\text{Co}_2\text{O}_3$ , and  $\text{Co}_3\text{O}_4$ , as well as bimetallic (or mixed-metal) oxides, for example,  $\text{CoFe}_2\text{O}_4$ , have also been synthesized within the mesopore channels of MCM-48 by multiple impregnation/drying/calcination cycles [24, 99]. In a similar way, uniform nanosized crystallites of  $\text{U}_3\text{O}_8$  have been dispersed in mesopores of MCM-41 and MCM-48 by direct exchange of the template cations with the uranyl ( $\text{UO}_2^{2+}$ ) ions, followed by calcination in air at 823 K [118]; see Figure 18. This method makes use of the unique interfacial properties of selectively functionalized mesoporous materials to deliver uranyl ions inside the channels via an ion-exchange reaction, thereby minimizing the uncontrolled precipitation reaction of uranyl ions outside the mesopores. The dispersed nanoparticles of  $\text{U}_3\text{O}_8$  are found to exhibit higher catalytic activity for the decomposition of methanol as compared to bulk  $\text{U}_3\text{O}_8$  or MCM-48 [107, 108]. Alternatively, the preparation of size-controllable  $\text{Fe}_3\text{O}_4$  nanoparticles has been reported by the alkaline oxidation of a ferrous ion adsorbed in sulfonated mesoporous styrene-divinylbenzene copolymer [135]. On the other hand, rhodium oxide ( $\text{RhO}_x$ ) nanoparticles, with different coordination spheres of Rh ions, in an MCM-41 host have been prepared by the hydrothermal

synthesis of Rh–MCM-41, followed by calcination in air at 823 K [136].

### 6.2.1. Iron-Oxide Nanoparticles in MCM-41/MCM-48

Although many studies report the encapsulation of metal-oxide nanoparticles in mesoporous materials, the interpretation of experimental data, however, requires careful

**Figure 17.** (a) TEM micrograph of block copolymer micelles containing an inorganic precursor. (b) TEM micrograph of block copolymer micelles containing inorganic nanoparticles.

**Figure 18.** Schematic representation of direct ion-exchange process in MCM-41 and MCM-48.

analysis owing to the complication involved in the loading of these clusters into the host matrix. The host materials possess various kinds of sites, for the accommodation of guest atoms, molecules, and ions, viz. framework and extra framework, in addition to the pores (nonframework site). In fact, the guests can also react with both the framework and extra-framework sites, even at ambient condition, rather than simply occupying/residing the pores. For example, under the standard loading/impregnation conditions, metal ions such as  $\text{Al}^{3+}$  and  $\text{Fe}^{3+}$  substitute isomorphously in the silicate framework of MCM-41 and MCM-48, resulting in the formation of AIMCM-41 [137], AIMCM-48 [138], FeMCM-41 [101, 105, 139], and FeHMS [140]. Thus, the loading of  $\text{Fe}^{3+}$ , for example, in MCM-41 and MCM-48, not only results in the formation of  $\text{Fe}_2\text{O}_3$  (or  $\text{FeO}_x$ ) nanoclusters in the mesovoids, but also substitutes (isomorphously) in the silicate matrix [105, 141]. The resulting nonframework ( $\text{Fe}_2\text{O}_3$  nanoclusters) and framework trivalent iron (FeMCM-41/FeMCM-48) exhibit superparamagnetic and paramagnetic properties, respectively. In this regard, if the loaded nanoparticles reside exclusively inside the mesopores of MCM-41 and MCM-48, then no significant change is expected in the X-ray diffraction data. On the other hand, it is interesting to note that the  $d_{100}$ -spacing values of the  $\text{Fe}_2\text{O}_3$ -loaded MCM-41 ( $d_{100} = 38.71 \text{ \AA}$ ) are significantly higher as compared to the unloaded MCM-41 ( $d_{100} = 36.18 \text{ \AA}$ ); see also Figure 19. A similar observation

**Figure 19.** XRD patterns of: (a) calcined MCM-41, (b) FeO(OH)/MCM-41, (c)  $\text{Fe}_2\text{O}_3$ /MCM-41. Adapted with permission from [56], S. E. Dapurkar et al., *Catal. Today* 68, 63 (2001). © 2001, Elsevier Science.

was also noted for  $\text{Fe}_2\text{O}_3/\text{MCM-48}$  ( $d_{211} = 37.80 \text{ \AA}$ ) and  $\text{MCM-48}$  ( $d_{211} = 36.40 \text{ \AA}$ ) [140]. Such an expansion in the interplanar distances is in line with the isomorphous substitution of  $\text{Fe}^{3+}$  for the  $\text{Si}^{4+}$  in the silicate framework of MCM-41 [142, 143]. A comparable expansion in lattice parameter has also been observed for  $\text{Fe}^{2+}$ -exchanged MCM-41 [144]. In contrast, a decrease in  $d_{100}$  spacing was also reported for the  $\text{Fe}_2\text{O}_3$ -encapsulated MCM-41 [104].

Figure 20 depicts the DRUV-Vis spectra of various iron-containing MCM-41 and MCM-48, including bulk  $\text{Fe}_2\text{O}_3$  [105, 140]. As expected, the bulk  $\text{Fe}_2\text{O}_3$  [Fig. 20(f)] shows a broad band with a strong maximum at 560 nm arising from all possible  $d-d$  transitions. On the other hand, the loaded samples show absorption bands at 250 nm [Fig. 20(b)–(4e)]. The significant shift in the absorption bands is attributed to the encapsulation of  $\text{Fe}_2\text{O}_3$  nanoparticles inside the mesopores [97, 104, 145]. In fact, such a large (blue) shift in the absorption maxima of bulk or colloidal  $\text{Fe}_2\text{O}_3$  is associated with the transition in the particle size from bulk to the molecular order, viz. the quantum size effect [97, 104, 145–149]. At this juncture, it is interesting to note that no bulk  $\text{Fe}_2\text{O}_3$  particles exist on the outer surface (no absorption in the region 350–550 nm) of MCM-41 and MCM-48 unless the metal ion concentration exceeds 0.01M [Fig. 20(c) and (d)]. It is, however, interesting to note that the absorption band [Fig. 20(e)] for the isomorphously substituted metal ions in the mesoporous framework, for example,  $\text{FeMCM-41}$  [142, 143] and  $\text{FeMCM-48}$  [140], also appears nearly in the same region as that of the incorporated nanoparticles, viz.  $\text{Fe}_2\text{O}_3/\text{MCM-41}$ , and  $\text{Fe}_2\text{O}_3/\text{MCM-48}$ , thus complicating the spectral analysis. Figure 21 presents the EPR spectra of  $\text{Fe}_2\text{O}_3$ -loaded MCM-41 and MCM-48, as well as  $\text{FeMCM-48}$

**Figure 20.** DRUV-Vis spectra of: (a)  $\text{Fe}_2\text{O}_3/\text{MCM-41}$ , (b)  $\text{Fe}_2\text{O}_3/\text{MCM-48}$ , (c)  $\text{Fe}_2\text{O}_3/\text{MCM-41}$  (0.01 M), (d)  $\text{Fe}_2\text{O}_3/\text{MCM-41}$  (0.1 M), (e)  $\text{FeMCM-48}$ , (f) bulk  $\text{Fe}_2\text{O}_3$ . [105, 140]. As can be seen from this figure, four different signals appeared at various  $g_{\text{eff}}$  values: 7.4, 4.3, 2.2, and 1.99. On the basis of signal assignment, the transitions at 7.4, 4.3, and 1.99 are attributed to (paramagnetic)  $\text{Fe}^{3+}$  in distorted and symmetrical tetrahedral framework sites, while the weak signal at 2.2, which is prominent at 77 K, is assigned to nano-sized (superparamagnetic) clusters within the mesopores, which is in agreement with the literature [150].

Figure 22 shows the Mössbauer spectra of  $\text{Fe}_2\text{O}_3/\text{MCM-41}$  recorded at different temperatures [105]. The room-temperature (295 K) spectrum is composed of quadrupole doublets corresponding to (framework) paramagnetic and (nonframework) superparamagnetic species, which is indicative of high-spin (paramagnetic)  $\text{Fe}^{3+}$  in the tetrahedral framework. A similar observation has also been reported in certain microporous ferrisilicate [36, 151, 152] and  $\text{FeMCM-41}$  [101]; see Figure 23. However, upon cooling to 23 K ( $\text{Fe}_2\text{O}_3/\text{MCM-41}$ ) or 15 K ( $\text{FeMCM-41}$ ), a strong quadrupole doublet (due to high-spin  $\text{Fe}^{3+}$ ) along with a weak six-line pattern are also noticed. The latter is typical characteristic of superparamagnetic particles at low temperatures, which disappears as the temperature increases, ca. 77 K [153, 154]. Further, this observation is well supported by the temperature dependence of the susceptibility measurements for  $\text{FeMCM-41}$  [101]. Figure 24 shows the temperature dependence of the normal ( $\chi'$ ) and reciprocal ( $-1/\chi'$ ) susceptibilities of  $\text{FeMCM-41}$ . The low temperature (<150 K) part of the Curie-Weiss fit, a straight line passing through the origin, shows the paramagnetic

**Figure 22.** Mössbauer spectra of: (a)  $\text{Fe}_2\text{O}_3/\text{MCM-41}$ . Adapted with permission from [105], P. Selvam et al., *Catal. Today* 68, 69 (2001). © 2001, Elsevier Science.

behavior due to the isolated  $\text{Fe}^{3+}$  in the framework structure of MCM-41. On the other hand, the upward bending of the curve at higher temperatures ( $>150$  K) is attributed to the dependence of spontaneous magnetization on temperature. That is, the magnetic characteristics depart from the paramagnetic behavior due to the interaction between the constituent ions of the small clusters [155] that may be present in the system, viz. the superparamagnetic particles. Thus, the above findings clearly support the hypothesis of the coexistence of both paramagnetic and superparamagnetic species in the loaded samples which, however, cannot be distinguished by DRUV-Vis studies.

### 6.3. Metal Chalcogenide Nanoclusters and Nanofilaments

Metal sulfide nanoparticles, for example, CdS, have been synthesized within the mesopores of MCM-41 by the functionalization with 3-mercaptopropyltrimethoxysilane [156]. It was also noticed that the particle size decreases with an increasing number of thiol groups, while the increase of temperature resulted in an increase in the particle size. Alternatively, controlled synthesis of CdS nanoparticles inside MCM-41 has been described using an ion-exchange reaction, in a similar way as that described for the preparation of  $\text{U}_3\text{O}_8$  nanoparticles (see Fig. 18), followed by sulphidation with  $\text{H}_2\text{S}$  [157]. In order to have complete control of the nanoparticles inside the pore channels, the external surface is selectively functionalized with inert hydrophobic

**Figure 23.** Mössbauer spectra of FeMCM-41(50): (a) 300 K and (b) 15 K, (c) FeMCM-41(100), (d) FeMCM-41(200). Adapted with permission from [101], P. Selvam et al., in "Recent Trends in Catalysis" (V. Murugesan, B. Arabindoo, and M. Palanichamy, Eds.), p. 556. 1999. © 1999, Narosa Publishing House, New Delhi.

**Figure 24.** Temperature dependence of susceptibility of FeMCM-41. Adapted with permission from [101], P. Selvam et al., in "Recent Trends in Catalysis" (V. Murugesan, B. Arabindoo, and M. Palanichamy, Eds.), 1999. © 1999, Narosa Publishing House, New Delhi.

phenyl groups (Fig. 25), which eliminates the possibility of adsorption of hydrophilic metal ions on the external surfaces during the ion-exchange reaction, thereby directing charged hydrophilic species selectively into the mesopore channels. Crystalline CdS nanoarrays have also been prepared through a single precursor decomposition route at a low temperature, employing mesoporous SBA-15 as a template [158]. In this case, SBA-15 is first impregnated with an aqueous solution of cadmium thioglycolate, followed by drying and thermal treatment at 433 K, resulting in a CdS–SBA-15 composite. The template-free CdS, having a surface area as high as  $101 \text{ m}^2 \cdot \text{g}^{-1}$ , was then obtained by the dissolution of the silica matrix with NaOH. On the other hand, the nanoparticles/nanofilaments may also be isolated from the porous matrix by treating them with HF [28, 54]. On the contrary, the CdS nanoparticles formed in reverse micelles have also been incorporated into thiol-modified mesoporous materials [50, 112], where a particle-sieving effect was observed, that is, the amount of incorporated nanoparticles decreases with an increase of the particle size or a decrease of the pore size.

High-quality nanocrystalline CoP clusters have been obtained by grafting diphosphine-substituted molecular Co clusters ( $\text{Co}_4(\text{CO})_{10}(\mu\text{-dppa})$ ;  $\mu\text{-dppa} = (\text{Ph}_2\text{P})_2\text{NH}$ ) onto an alkoxy-silyl-substituted short-bite diphosphine,  $(\text{Ph}_2\text{P})_2 \cdot \text{N}(\text{CH}_2)_3\text{Si}(\text{OMe})_3$ , functionalized SBA-15, followed by thermal treatment under inert atmosphere [159]. At this juncture, it is quite fascinating to note that inorganic nanowires of certain metal sulfides can be produced inside a liquid-crystal template; see Figure 26 [160]. Accordingly, at first, an inverted Hexagonal liquid crystal from oligo (ethylene oxide) oleyl ether amphiphiles was produced, followed by the impregnation of  $\text{Zn}(\text{NO}_3)_2$  using  $\text{CS}_2$  or thiourea. The doped crystals were then irradiated with  $\gamma$  rays to produce ZnS *in-situ* through a radical process. The ZnS thus precipitated takes the shape of the tube-like pores in the liquid-crystal templates, resulting in  $\sim 5 \text{ nm}$  diameter nanofibers. More importantly, several close-packed nanowires tend to aggregate into bundles of 10–30 nm diameter, duplicating the hexagonal structure of the inverted micelles formed by amphiphiles.

#### 6.4. Nanometal-Supported Nanometal-Oxide Clusters

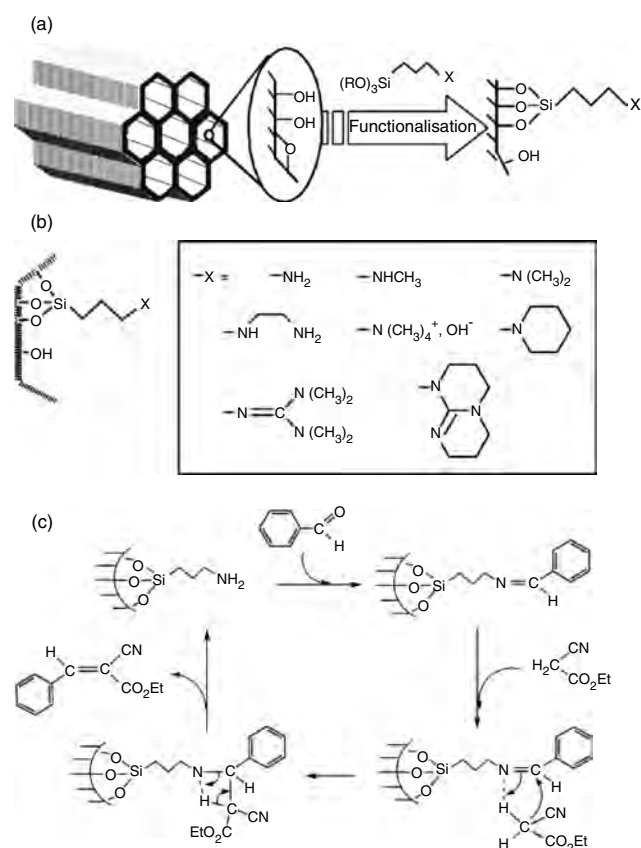

The ship-in-bottle synthesis strategy described earlier (see Fig. 8) has also been adopted successfully for the preparation of novel Pt-supported titania ( $\text{TiO}_2$ ) or zirconia ( $\text{ZrO}_2$ ) in the mesoporous channels of FSM-16 molecular sieves by the modification of the pores with  $\text{TiO}_2$  or  $\text{ZrO}_2$  by impregnation and hydrolysis of the respective alkoxides followed by thermal decomposition [119, 161]. Accordingly, Pt carbonyl clusters of the type  $[\text{Pt}_3(\text{CO})_6]_n^{2-}$  ( $n = 4\text{--}6$ ) were deposited on the preadsorbed  $\text{TiO}_2$  or  $\text{ZrO}_2$  in the mesoporous matrix by the reaction of  $\text{H}_2\text{PtCl}_6$  with CO and  $\text{H}_2\text{O}$  at 323 K (Fig. 27). In a similar way, the preparation of Pt-supported  $\text{Fe}_2\text{O}_3$  nanoclusters has also been demonstrated by the photodeposition technique [104]. In other words, the presence of iron-oxide nanoparticles in the pores of MCM-41 has also been confirmed by platinum loading on iron-oxide particles [97, 104].

#### 6.5. Metal Complexes, Metalloenzymes, and Molecular Materials

The modification of the mesoporous silica surface with covalently bonded organic species, especially functional organosilanes [159, 162, 163], has attracted much attention in order to design hybrid materials for advanced applications, for example, in catalysis, selective adsorption of organics and metals, and so on. Functionalization of MCM-41 has been achieved by silanation (Fig. 28) of the surface using 3-amino and 3-halogeno-propyl alkoxy-silane. The grafted halogeno organic moieties [Fig. 28(a)] have been further modified by halogen substitution of other functions such as primary, secondary, and tertiary amines, diamines ammonium hydroxide, and guanidines [Fig. 28(b)]. It was found that the mesoporous silica-bound primary and tertiary amine functions [Fig. 28(c)] have been effective catalysts for Knoevenagel condensation and selective monoglyceride synthesis.

**Figure 27.** Schematic representation of the preparation and transformation of the Pt/TiO<sub>2</sub> cluster in FSM-16. Adapted with permission from [104], M. Iwamoto et al., *J. Mol. Catal. A* 155, 143 (2000). © 2000, Elsevier Science.

**Figure 28.** (a) Functionalization of MCM-41 surface. (b) Organic bases anchored on the functionalized surface. (c) Catalytic cycle during Knoevenagel condensation using MCM-41-grafted primary amine form. Adapted with permission from [163], D. Brunel et al., *Catal. Today* 73, 139 (2002). © 2002, Elsevier Science.

On the other hand, ship-in-bottle synthesis methodology has also been adopted for the grafting of larger complexes into mesopore channels of FSM-16 and MCM-41, for example, hybrid composites of metalloporphyrins and fullerenes [164], fullerenes (C<sub>60</sub> and C<sub>70</sub>; Fig. 29) [165, 166], trinuclear oxomolybdenum complex [Mo<sub>3</sub>O(CCH<sub>3</sub>)(OAc)<sub>6</sub>(MeOH)<sub>3</sub>] [167], polynuclear molybdenum complexes [168], ruthenium complexes having bipyridine and chloride ligands [169], Cu (II) phthalocyanine [170], and so on. For example, the Cu (II) phthalocyanine was formed within the mesopores of previously ion-exchanged Cu-MCM-41 by CVD of 1,2-dicyanobenzene; see Figure 30. Unlike the Cu phthalocyanine complex entrapped in zeolite-Y, the complex encapsulated in the MCM-41 showed (Fig. 2) nearly the same magnetic moment value [80], which is similar to the free or neat complex, suggesting that the planar geometry of the complex is retained in the mesopores. On the other hand, Pt cluster anions such as [Pt<sub>3</sub>(CO)<sub>6</sub>]<sub>5</sub><sup>2-</sup> and [Pt<sub>3</sub>(CO)<sub>6</sub>]<sub>6</sub><sup>2-</sup> have been respectively prepared in the mesoporous channels of FSM-16 via [Pt(CO)Cl<sub>3</sub>]<sup>-</sup> and *cis*-Pt(CO)<sub>2</sub>Cl<sub>2</sub> by the reductive carbonylation of H<sub>2</sub>PtCl<sub>6</sub>·6H<sub>2</sub>O at 323 K [76, 171]. They exhibit markedly higher catalytic activities for <sup>13</sup>CO exchange and water-gas shift reactions at ambient temperatures as compared with [Pt<sub>3</sub>(CO)<sub>6</sub>]<sub>5</sub><sup>2-</sup> and [Pt<sub>3</sub>(CO)<sub>6</sub>]<sub>4</sub><sup>2-</sup> clusters encapsulated in zeolite-Y.

Since the immobilization of enzymes in a confined environment improves the stability, enzymes such as horseradish peroxidase (HRP) and subtilisin have been immobilized in FSM-16 and MCM-41 (Fig. 31), prepared with a cationic surfactant, whose pore sizes were just over the molecular diameters (~43 Å) of the enzymes [172, 173]. It is also interesting to note here that the immobilized HRP on FSM-16 and MCM-41 with a pore diameter of 50 Å showed the highest enzymatic activity [Fig. 31(b)]. The immobilized enzymes on the other mesoporous materials including large [90 Å; Fig. 31(c)] or small [30 Å; Fig. 31(a)] pore-sized FSM-16 showed lower enzymatic activity and thermal stability. Thus, both surface character and size matching between pore sizes and the molecular diameters of HRP

**Figure 29.** Preparation of fullerene-grafted mesoporous FSM-16. Adapted with permission from [165], A. Fukuoka et al., *Catal. Lett.* 68, 241 (2000). © 2000, Plenum Publishing Corporation.

**Figure 30.** Ship-in-bottle synthesis of Cu (II) phthalocyanine complex in MCM-41.

were important in achieving high enzymatic activity and high thermal stability. However, no appreciable adsorption of the enzymes was noted for SBA-15 prepared with a nonionic surfactant [172, 173].

### 6.6. Conducting Polymeric Filaments

In the recent past, nanometer electronic materials have been created by the chemical/electrochemical polymerization of monomers inside the porous structures. The molecular wires thus produced inside the pore system are several hundred molecules long, and show significant conductivity while encapsulated. They possess a blend of interesting electronic, optical, and mechanical properties [174], which makes it possible to use them in situations where inorganic materials are unsuitable. Furthermore, the conducting polymer films have attracted wide attention due to their unique properties, such as easy synthesis by chemical methods, reversible and adjustable conductivity, and so on. In addition, enhanced electronic conductivities are obtained if polymers with enhanced molecular and supramolecular order, that is, a polymer containing fewer conjugation-interrupting defect sites, can be prepared. In this regard, template synthesis of such materials provides a route for enhancing the order, and therefore the conductivity [175].

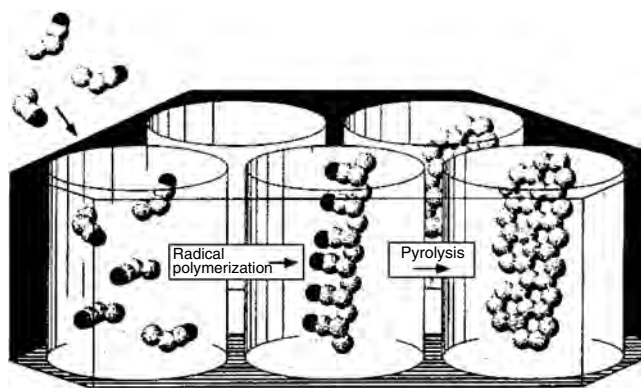

**Figure 31.** Schematic models of immobilized HRP in FSM-16 with various pore sizes: (a) 30 Å, (b) 50 Å, and (c) 90 Å. Adapted with permission from [173], H. Takahashi et al., *Micropor. Mesopor. Mater.* 44–45, 755 (2001). © 2001, Elsevier Science.

Conducting polymeric materials can also be grown electrochemically within the host material [176, 177] or chemically with oxidizing agents [178]. Previous studies [45, 175, 179] have shown the formation of intrazeolite polyaniline by chemical oxidation. However, these filaments do not show any significant conductivity [45, 178]. This may be due to the small pore dimension of the zeolites used for the preparation, which may possibly restrict the oxidant/counter ion to enter inside the pore, and may result in an incomplete polymerization/oxidation. On the other hand, conducting polyaniline filaments (Fig. 32) have been produced inside the mesopore channels of AlMCM-41 by chemical oxidation [44]. Accordingly, the adsorption of aniline into the dehydrated host, followed by reaction with peroxydisulfate ( $(\text{NH}_4)_2\text{S}_2\text{O}_8$ ), leads to encapsulated polyaniline filaments, which show significant conductivity. Likewise, the entrapment of graphite-type carbon wires in mesoporous MCM-41 (Fig. 33) has also been demonstrated [45]. First, acrylonitrile monomers are introduced through vapor or solution transfer in the channels, and are subsequently polymerized with radical initiators such as  $\text{K}_2\text{S}_2\text{O}_8$  or  $\text{NaHSO}_3$ . Pyrolysis of the resulting polyacrylonitrile produces filaments whose microwave conductivity is higher by an order of magnitude than that of bulk carbonized polyacrylonitrile. Likewise, 3-methacryloxypropyl species grafted onto the surface of mesoporous materials act as seeds for the polymerization of these monomers, leading to the formation of polymethacrylate fibres [180]. On the other hand, radical polymerization of methyl methacrylate in the presence of initiators such as 2,2'-azobisisobutyronitrile or benzoyl peroxide has been carried out within the channels of a MCM-41 [181]. Linear nanofibers of polyethylene with ultrahigh molecular weight (6,200,000) and a diameter of 30–50 nm have been produced through an “extrusion polymerization” mechanism, as illustrated in Figure 34 [182], in which a new class of mesoporous silica fibers is used as a support for ethylene polymerization with titanocene in conjunction with methylalumoxane (MAO) as a cocatalyst. Similarly, polymerization of cyclohexyl vinyl ether within MCM-41 channels yields hybrid materials [183].

**Figure 32.** Schematic representation of the growth of polyaniline filaments in the channels of mesoporous AlMCM-41. Adapted with permission from [44], C.-G. Wu and T. Bein, *Science* 264, 1757 (1994). © 1994, American Association for the Advancement of Science.

**Figure 33.** Schematic representation of the growth of carbon wires in the channels of mesoporous MCM-41. Adapted with permission from [45], C.-G. Wu and T. Bein, *Science* 266, 1013 (1994). © 1994, American Association for the Advancement of Science.

On the other hand, electrochemical polymerization of aniline to polyaniline was carried out inside the mesoporous channels of an MCM-41 molecular sieve host [102]. The distinct color (peacock blue) change at higher potentials, not seen in the case of conventional electrochemically polymerized films, could be an indication of intrazeolite polymerization. *In-situ* UV-Vis and resistance/conductance studies confirm the formation of intrazeolite polyaniline chains. The electrochemical behavior of polyaniline films was examined by cyclic voltammetry in aqueous 0.5 M  $\text{H}_2\text{SO}_4$ . Interesting changes in the redox behavior of polyaniline have been observed on using different forms of siliceous MCM-41 (condition A: time taken for bridging = 45 min;  $R_{\text{max}}/R_{\text{min}} = 126$ ) and AlMCM-41 (condition B: time taken for bridging = 45 min;  $R_{\text{max}}/R_{\text{min}} = 1585$ ). The cyclic voltammograms (Figs. 35 and 36) give three rapid and reversible redox systems, which are typical of polyaniline. They are referred to as (1,1'), (2,2'), and (3,3') systems. The second one (2,2') becomes more prominent after the oxidation of aniline at higher potential. It has generally been attributed to a quinone-hydroquinone type of redox process. The peaks (1,1') are associated with a

Selvam et al., in “Recent Trends in Catalysis” (V. Murugesan, B. Arabindoo, and M. Palanichamy, Eds.), p. 550. 1999. © 1999, Narosa Publishing House, New Delhi.

deprotonation-protonation reaction, and are strongly pH dependent, with  $\partial E_p/\partial \text{pH} \cong 59 \text{ mV}$ .

Figure 37 depicts the measured resistance of polyaniline films. In all of the cases, the polymer is highly resistive at  $-0.2 \text{ V}$ , and the anodic polarization results in a decrease of the resistance. The minimum in the resistance is observed between 0.1 and 0.7 V, with a sharp increase in resistance on further anodic polarization. The results of *in-situ* UV-Vis studies are presented in Figure 38. The absorbance at 320 and 420 nm is shown as a function of potential for polyaniline grown on an ATO glass [184], ITO + MCM-41, and ITO + AlMCM-41 [102]. Again, one can see that the

behavior of the polymer films is distinctly different. There is a small change in the shape of these two bands for each sample. These two bands have generally been found to be complementary. The change in shape and the differences in potential dependence must be attributed to the different environments in which the polymer is grown and studied. This supports our visual observation of the intrazeolite polymerized samples as compared to samples polymerized on an open surface. These are the first definitive results relating the conductivity to the electrochemical potential

**Figure 38.** Absorbance versus potential for polyaniline grown on different substrates. Adapted with permission from [102], P. Selvam et al., in "Recent Trends in Catalysis" (V. Murugesan, B. Arabindoo, and M. Palanichamy, Eds.), p. 550. 1999. © 1999, Narosa Publishing House, New Delhi.

for intrazeolite polymerized polyaniline. It was found that the UV-Vis data also show a shift from interfacial polymerization data. The conductivity of template-synthesized polyaniline changes with the change in the extent of acidic sites in the host. Therefore, the fabrication of these types of stabilized conducting systems will be important for the understanding of charge transport at the nanometer scale, and for the development of nanosized electronic devices. Similar experiments have been performed with acetonitrile, *p*-nitroniline, and pyrrole; however, it is difficult to control the properties of the composite material.

## 7. NANOPARTICLES/NANOWIRES IN MESOPOROUS FILMS

Up to now enormous amount of studies have concerned the growth of nanoparticles inside the pores of bulk (powder) materials. However, for several optical applications, it would be better to dispose of coatings filled with nanoparticle arrays instead of powders. The direct growth of semiconductor nanostructures, for example, has the distinct advantage of no process-induced damage or defects, as frequently observed in the nanofabricated wires and dots. Several groups have reported the synthesis of nanoparticle-loaded mesoporous films using different methodologies [128, 185–189]. A new route [185] describes the preparation of high-density nanometer-scale SiGe quantum dots on ordered mesoporous silica-coated Si substrate. On the other hand, Si nanoclusters were grown on mesoporous film by CVD [128] during the formation of Ag nanoparticles within a mesoporous template-structured silica film, which includes ion exchange with  $\text{Ag}(\text{NH}_3)_2^+$  followed by reduction [186]. Likewise, the synthesis of CdS quantum dots inside 3D hexagonal mesoporous silica films has been reported by a chemical route employing wet impregnation of Cd ions, followed by precipitation using  $\text{H}_2\text{S}$ . These two steps were also repeated until the film saturation was obtained [187]. Uniform nanoparticles of Au and Pt with ordered structures were deposited on mesoporous silica films, and the unsupported Au nanoparticle, isolated by the dissolution of silica film in dilute HF and 1-dodecanethiol solution [188]. Recently, novel mesostructured titania in the form of monolith and film samples have shown to function as nanovessels for trapping metal complexes of the type  $\text{Ag}^+$ ,  $\text{AuCl}_4^-$ , and  $\text{PtCl}_6^{2-}$  which, upon thermal treatment, transformed to the respective metal clusters [189].

# Nanocomposites of Polymers and Inorganic Particles

Walter Caseri

ETH Zentrum, Zürich, Switzerland

## CONTENTS

1. Introduction
  2. Early Investigations
  3. Preparation of Nanocomposites
  4. Properties of Nanocomposites
- Glossary  
References

## 1. INTRODUCTION

This chapter deals with composites comprised of polymers and inorganic nanoparticles of rather uniform shape. Such composites are attributed to the class of nanocomposites because of the small size of the embedded particles, while the polymer phase is continuous. The attribution of particles to the class of nanoparticles is somewhat arbitrary; often particles of dimensions up to 50–100 nm are assigned to this notion, and expressions such as nanosized particles, colloids, or, occasionally, ultrafine particles are also used to designate particles as nanoparticles. The small size of the incorporated particles can induce materials properties which differ from those of related composites containing larger particles, for example, as a result of an extremely large interface area, which can readily amount to  $10^7$ – $10^9$  m<sup>2</sup> in a cube meter of nanocomposite, or a markedly reduced scattering of visible light. The latter is important if transparent or translucent materials are required for optical applications. This intensity loss of transmitted light by scattering can be estimated with the equation [1]

$$\frac{I}{I_0} = e^{-\left[\frac{3\phi_p x r^3}{4\lambda^4} \left(\frac{n_p}{n_m} - 1\right)\right]}$$

which is valid for spheric particles with radius  $r$  and refractive index  $n_p$  dispersed in a matrix with refractive index  $n_m$ , with  $I$  the intensity of the transmitted and  $I_0$  of the incident light,  $\phi_p$  the volume fraction of the particles,  $\lambda$  the wavelength of the incident light, and  $x$  the optical path length. From the above equation, it is evident that composites with

thicknesses in the millimeter range can be virtually transparent if the particle diameter is below ca. 50 nm even for high volume contents of inorganic particles or large refractive index differences between polymer and particles, provided the particles are randomly dispersed in the polymer matrix. If, however, the particles are present as agglomerates, light scattering is significantly enhanced even if the size of the primary particles is far below the wavelength of the incident light. Note that composites of polymers and inorganic particles typically contain particles or particle aggregates with dimensions in the  $\mu\text{m}$  range [2, 3]; that is, they are opaque unless the refractive indices of the components are equal [4].

Many physical properties of metals and semiconductors are determined by correlated interactions of many atoms [5, 6]. The energy levels of the basic units split upon formation of clusters and particles into more and more components with increasing number of atoms until they attain the quasi-continuous band structure of the bulk solid [6]. As a consequence, optical and electronic characteristics of nanoparticles can differ from those of the bulk materials and in addition depend on the particle size [7–19]. The particle diameter at which optical changes become significant depends on the substance and amounts to ca. 2 nm for CdSe, 2.8 nm for GaAs, 20 nm for PbS, and 46 nm for PbSe [20]. The bandgap energy and the absorption threshold of CdS begins to differ significantly from the bulk values at particle diameters around 10 nm [21]. Ultraviolet/visible (UV/vis) absorption spectra of nanoparticles can depend on the size of the nanoparticles and differ markedly from those of larger particles or the bulk solids. The UV/vis absorption spectrum of CdS particles of ca. 4 nm diameter with a narrow size distribution showed a well pronounced maximum at 368 nm and no essential absorption above 420 nm [22] while the spectrum of bulk CdS was characterized by a continuous decrease in absorbance in the wavelength range of 300–550 nm [23]. CdSe particles of 3.9 nm diameter exhibited an absorption edge of 558 nm and a bandgap of 2.22 eV compared to more than 700 nm and 1.74 eV, respectively, for bulk CdSe [24]. As a consequence of the variations of the spectra in the visible range on the particle size, the color of related nanocomposites can depend on the particle size.

For example, poly(vinyl alcohol) containing gold particles [25–27] of average size 9.5, 43, and 79 nm displayed in transmission the red, purple, and blue color of the corresponding nanoparticles [28, 29].

Finally, it should be noted that the sizes of the inorganic particles in nanocomposites always vary to some extent although “monodisperse” particles are occasionally mentioned in the literature. However, these particles usually show some polydispersity when the size distribution is carefully analyzed, and accordingly the expression “particles with narrow size distribution” better represents the status. The particle sizes in the literature as well as in this chapter typically refer to number average particle diameters  $d_n$

$$d_n = \frac{\sum_i n_i d_i}{\sum_i n_i}$$

with  $n_i$  the number of particles of diameter  $d_i$ . Since physical properties (e.g., the refractive index of nanocomposites) are related rather with the volume fraction of the particles, the volume-weighted average diameter  $d_v$  may also be of interest, where

$$d_v = \sqrt[3]{\frac{\sum_i n_i d_i^3}{\sum_i n_i}}$$

The number-weighted and the volume-weighted average diameters of the particles differ often by 20–30%, which is, fortunately, usually of little importance for the conclusions from the respective experiments.

## 2. EARLY INVESTIGATIONS

### 2.1. Colloids

Gold belongs to the substances which have been the focus of numerous studies from the beginning of chemistry. In the course of the experiments with this metal in ancient times, gold nanoparticles have obviously been prepared centuries ago. For example, such particles were synthesized *in-situ* in water by Paracelsus around 1570 [30, 31]. He used the resulting gold-containing liquid, called *aurum potabile* (potable gold), for medical purposes. The *aurum potabile* could also be gained as a viscous substance [31], probably due to the presence of organic compounds which adsorbed at the surface of the gold particles. Other matter described centuries ago most likely also contained nanoparticles of gold [32] or silver (*luna potabile*) [33]. In particular, glass was colored with metal nanoparticles for at least the middle of the 16th century (so-called gold ruby glasses) [34]. In a recipe from Neri published in 1662, a transparent ruby glass was prepared starting from bulk gold which was treated several times with *aqua regia* [35]. The resulting gold salts were calcined for many days until a red powder arose which was mixed slowly with glass. Purple, violet, brown, or almost black colloidal gold powders were manufactured in 1765 as paints for enamel [36]. These materials were fabricated by dissolution of gold in *aqua regia*, and the nanoparticles were subsequently precipitated as powders by reduction of the *in-situ* prepared gold(III) ions with tin.

Since the color of gold nanoparticles differs from that of bulk gold, as indicated in the Introduction, there was some confusion about the nature of the nanoparticles for a long time, although, for instance, Macquer believed already in 1774 that the *aurum potabile* indeed contained extremely small gold particles [37]. Nobel prize winner Ostwald, a pioneer in colloid chemistry, attributed the first experimental evidence for the elemental nature of gold colloids to Richter [38]. Richter described among many other experiments that fine gold powders with a golden appearance could be transformed into violet powders and vice versa by mechanical treatments [39]. Further, the chemical behavior of violet gold powders agreed with typical characteristics of bulk gold: the powders did not dissolve in hydrochloric acid but in *aqua regia*, and the powders formed an amalgam with mercury. In addition, bulk gold could be converted by certain chemical treatments into violet powder without a significant difference in mass. Richter also perceived that the color of some gold powders depended on the observation angle, and he suggested that the color of very small gold particles was determined by refraction of light. Further evidence for the elemental nature of gold nanoparticles was found around 1860 by Fischer [40] and Faraday [41, 42]. Faraday suggested that the color of colloidal gold in its elemental state depends on the particle size. Based on the observation that it was possible to prepare blue from red gold dispersions but not reverse and that blue particles precipitated much faster than red ones, Faraday assumed that the blue particles were larger in size than the red ones [41, 42]. The purification of colloids from reaction side products by dialysis was described by Graham in 1862 [43]. For instance, silver [44] or red aqueous gold dispersions [45] did not penetrate dialysis membranes, even under application of an electric field, which clearly indicated that colloids indeed consisted of particles. Besides gold and silver, colloids of other substances were also synthesized 100–150 years ago. For example, reduction of  $\text{PtCl}_4$  with hydrazine in aqueous solution yielded colloidal platinum [44], colloidal  $\text{SiO}_2$  was obtained by hydrolysis of tetramethoxysilane [46], colloidal aluminum oxides by hydrolysis of aluminum chloride [43], colloidal iron oxides by hydrolysis of iron chloride [43], and colloidal  $\text{TiO}_2$  by treatment of a gellike titanate with a small amount of hydrochloric acid followed by dialysis [47].

Already before electron microscopes were available, the dimensions of nanoparticles were determined with ultramicroscopes [48, 49] which had been invented by Siedentopf and Zsigmondy in 1903 [48]. These instruments allowed the visualization of colloids by light scattering which enabled the detection of particles in dilute systems below the resolution limit of optical microscopes. The particle size was finally estimated as the edge length of a cube with volume  $V = A/(\rho \cdot n)$ , where  $A$  denotes the total mass of the particles in a volume unit,  $\rho$  denotes the density of the particles, and  $n$  denotes the number of particles in a volume unit, whereby the number of particles was counted with the help of the ultramicroscope [49]. In the first report on an ultramicroscope [48], various glass-gold nanocomposites were investigated, and average gold particle diameters were found down to the resolution limit which amounts to ca. 6 nm for gold [50] and which depends not only on the particle size but also

on the optical constants of particles and matrix [49]. Generally, the resolution limit of metal particles is particularly low [49], while typical values for metal oxides and organic colloids lie in the range of 30–40 nm [50]. Diameters of gold particles obtained with ultramicroscopy were confirmed by Scherrer in 1918 from analysis of the linewidth in X-ray diffraction patterns [51]. Scherrer also showed then for the first time that the gold lattice in colloidal and bulk gold is identical [51].

In 1904, Kirchner and Zsigmondy suggested that the color of metal particles can depend not only on the size of the primary particles but also on the distance between the particles [52, 53]. Their conclusion is based on the observation that nanocomposites of colloidal silver or gold and gelatin reversibly changed color from blue to red upon swelling with water or acetic acid, and in addition they found a bathochromic shift of the absorption maximum in the UV/vis spectra upon drying of the materials. The influence of the particle size and the distance between particles on the colors of gold was described theoretically by Maxwell Garnett around 1905 [54, 55]. A little later, Mie and his Ph.D. student Steubing measured quantitatively the scattered and the absorbed light intensity of illuminated dispersions of gold nanoparticles [8–11]. They found that the intensity loss of the transmitted light in dispersions of gold particles with diameter below 50 nm originated preferentially from absorption [8–11], but scattering became more pronounced for larger particles [56] (in fact, it has since been reported that light scattering in colloidal gold solutions manifests visually only for particle diameters above 50 nm) [57], and they fortified their observations with a theoretical fundament.

## 2.2. Polymer–Inorganic Nanocomposites

Nanocomposites of polymers and inorganic colloids were prepared in 1833 [58]. The first step in nanocomposite manufacture was the dissolution of gold in *aqua regia*. A part of the volatile contents of the resulting solution was evaporated at elevated temperature until a solid skin formed at the surface of the solution. Thereafter, the solution was allowed to cool to room temperature whereupon the solution transformed completely to a solid, hygroscopic matter containing gold salts. The solids were rapidly dissolved in water. This solution was mixed with a solution containing dissolved  $\text{SnCl}_2$  and gum arabic, whereupon red gold colloids arose by reduction of the gold salts with tin(II) ions. Upon addition of ethanol, a gold–gum arabic nanocomposite was obtained by coprecipitation. A few decades later, nanocomposites of gum and silver were also described [59]. Similarly to the gold–gum arabic nanocomposites, those with silver were gained by coprecipitation upon addition of ethanol to an aqueous phase containing gum and *in-situ* prepared silver colloids.

Very remarkably, polymer nanocomposites with uniaxially oriented assemblies of inorganic particles were prepared around 1900 [60, 61]. An uniaxial orientation of particle assemblies was indicated by the dichroic behavior of the respective samples (i.e., their colors changed under observation in linear polarized light upon rotation of the polarizer). As an example, plant and animal fibrils, such as linen, cotton, spruce, or chitin, were first treated with solutions of

silver nitrate, silver acetate, or gold chloride [60]. The metal ions, which were incorporated in the fibrils, were reduced to elemental metal particles by exposure to light. The color of such samples was different for parallel and perpendicular orientation of the polarization direction of the light with respect to the fiber axis, for example red and blue green for gold in spruce wood fibers. Further, dichroic nanocomposite films were produced with gelatin as the matrix polymer [61]. The gelatin was impregnated with gold chloride solution, subsequently drawn, dried, and finally irradiated with light, whereupon elemental gold formed. Dichroic samples were also obtained when gelatin was mixed with colloidal gold or silver before drying and drawing [61]. Up to 1930, dichroic fibers were prepared with a number of metals other than gold or silver, such as rhodium, osmium, palladium, platinum, or copper, but also with nonmetals (e.g., phosphorous, sulfur, or iodine) [62–66]. Based on Scherrer's equation, the particle diameters of silver and gold crystallites in dichroic samples were determined in fibers of ramie, hemp, bamboo, silk, wool, viscose, and cellulose acetate, and values between 5 and 14 nm were found [67]. The ringlike interference patterns of the metal crystallites in oriented ramie fibers revealed that the individual primary crystallites themselves were not oriented [66, 68], indicating that the dichroism was indeed the result of a cooperative effect involving many particles.

## 3. PREPARATION OF NANOCOMPOSITES

### 3.1. Inorganic Colloids

Typical specific surface free energies of inorganic solids amount to 500–2000  $\text{mJ/m}^2$  [69, 70] compared to 20–50  $\text{mJ/m}^2$  for polymers [71]. As a result of the high values of the inorganic compounds, nanocomposites can be far from equilibrium [72] if the interfacial energy in the system is not compensated by interactions between the polymer and the inorganic particles. As a consequence, agglomeration of inorganic colloids can in fact be a problem in the synthesis of nanocomposites [73, 74]. Once the nanocomposites are formed, however, the activation energy needed for reaching the equilibrium state is too high to allow one to establish the equilibrium in a perceptible period. For example, in nanocomposites comprising an ethylene–methacrylic acid copolymer and ca. 3% v/v PbS, the agglomeration of PbS was estimated to require periods of  $10^5$  years at 25 °C [17], and nanocomposites of gold colloids in amine-terminated poly(ethyleneoxide) were found to be essentially unchanged for more than a year [75]. In powders consisting of bare, isolated nanoparticles, however, the high specific surface energies of inorganic materials cause the primary particles typically to agglomerate to secondary particles. In this case, the common methods of technical composite fabrication, which are based on the mixing of polymer and isolated powders, are usually not successful for the preparation of nanocomposites with randomly dispersed primary particles because the aggregates commonly do not break into their primary particles during the procedures applied for the nanocomposite manufacture. Therefore, agglomeration makes the use of grinded particles difficult for the preparation of nanocomposites with randomly dispersed particles.

In addition, the energy transferred to the particles by the grinding process can induce changes in the constitution of the surface region [76–81]. Therefore, grinded nanoparticles have quite rarely been used for nanocomposite fabrication but examples still exist. Silicon particles of 20–40 nm diameter were prepared with high energy milling of powders which were subsequently subjected in ethanolic suspension to ultrasound [82, 83]. After sedimentation of the coarse fractions, dispersions of silicon nanoparticles were obtained which were suited for the incorporation in polymers.

Agglomeration of nanoparticles is frequently avoided by *in-situ* synthesis (i.e., the particles are not isolated but used in the as-prepared dispersions for the incorporation in polymers). This method was used for, for example, the preparation of nanocomposites with PbS which can easily be synthesized in aqueous solution by combination of water-soluble lead(II) salts [e.g., lead(II) acetate or lead(II) nitrate] and H<sub>2</sub>S, alkaline metal sulfides, or organic sulfides such as thioacetamide [84–86]. Hydrolysis is often a suited reaction for *in-situ* nanoparticle fabrication, which was used, for example, for the synthesis of silica particles from tetraethoxysilane [87–89]. While many inorganic salts which are suited as starting materials for the synthesis of nanoparticles are better soluble in water than in organic solvents, there also exist numerous inorganic compounds which are soluble in organic solvents, thus allowing the *in-situ* preparation of nanoparticles also in such media. For instance, CdS or Cu<sub>2</sub>S colloids were prepared in *N*-methylpyrrolidone by addition of Li<sub>2</sub>S to a solution of Cd(CF<sub>3</sub>SO<sub>3</sub>)<sub>2</sub> or [Cu(CH<sub>3</sub>CN)<sub>4</sub>](CF<sub>3</sub>SO<sub>3</sub>)<sub>3</sub>, respectively [90], or colloids of elemental platinum in styrene were produced from tris(styrene)platinum(0) dissolved in styrene [91]. The tris(styrene)platinum(0) decomposed under formation of nanoparticles simply upon evaporation of a part of the styrene at reduced pressure and ambient temperature.

As an alternative to the *in-situ* preparation of the inorganic particles, colloids with a strongly bound surface layer of organic molecules may be used if they can be isolated and if the primary particles can be redispersed. Here, agglomeration is suppressed by the surface layer which markedly diminishes the specific surface free energy and, therefore, tends to decrease the attraction between the particles. Surface-modified colloids may be present as viscous substances or solids. In the last decade, a number of well defined surface-modified colloids have been isolated, for example, gold or silver nanoparticles with phosphines or thiols attached to their surfaces [92–102], CdS covered with aromatic or aliphatic thiols [23, 103–107], CdSe coated with tri-*n*-octylphosphine oxide [108] or pyridine [109], thioglycerol-capped CdTe nanoparticles [110], or stearic acid-modified CaCO<sub>3</sub> [111]. Dispersible colloidal silver covered with a citrate layer could have been prepared already more than 100 years ago [112, 113].

### 3.2. Incorporation of Nanoparticles in Polymers

Nanoparticles are frequently incorporated in polymers using dispersions of *in-situ* synthesized nanoparticles or surface-modified colloids in presence of a polymer which is dissolved in the dispersions. If the polymer destabilizes the colloidal

dispersion, the particles can precipitate together with the polymer (coprecipitation), which was described for example for the fabrication of poly(ethylene oxide)–PbS nanocomposites [84]. On the other hand, polymers stabilize colloidal dispersions in many systems. In such cases, coprecipitation can often be induced by addition of a nonsolvent for the polymer. Upon precipitation of the polymer, the nanoparticles then precipitate as well. This principle was applied for instance for the preparation of nanocomposites comprising poly(aniline) and CdS or Cu<sub>2</sub>S which coprecipitated after addition of ethanol to a mixture of the nanoparticles and the polymer in *N*-methylpyrrolidone [90]. The coprecipitation methods typically yield powders while for many applications or physical investigations films are required. Films can readily be obtained by evaporation of the solvent in a system containing both dispersed particles and dissolved polymer, which was applied, for example, in the case of dispersed dodecanethiol-modified gold particles and dissolved poly(ethylene) in *p*-xylene [102]. Another method for the preparation of nanocomposite films is the spin coating process which was applied, for example, at a dispersion of dodecanethiol-coated gold particles dispersed in a poly(phenylmethylsilane) solution in toluene [100]. If the particles have been prepared *in-situ*, attention has to be paid to the reaction by-products stemming from the particle synthesis since those by-products could be incorporated in nanocomposites in particular when they are prepared by solvent evaporation or spin coating. In this respect, the formation of volatile by-products is advantageous, as for example in nanocomposites produced by solvent evaporation or spin coating from aqueous gelatin–PbS systems where acetic acid resulted as the by-product of the reaction of lead(II) acetate and hydrogen sulfide [85]. Ultrathin nanocomposite films were prepared with the Langmuir–Blodgett (LB) technique [114, 115]. For example, *in-situ* synthesized Fe<sub>3</sub>O<sub>4</sub> colloids were codeposited with a poly(maleic acid ester) as LB films on glass substrates [114]. Nanoparticles were also produced *in-situ* in LB layers. When Langmuir–Blodgett films of poly(aniline) or poly(3-octylthiophene) were deposited together with cadmium arachidate on quartz or ZnSe substrates, CdS nanoparticles formed upon exposure to gaseous H<sub>2</sub>S [115].

When surface-modified colloids are available, nanocomposites may be obtained by addition of the nanoparticles to a polymer melt as in the example of dodecanethiol-coated silver colloids which were mixed in an extruder at 180 °C for 10 min with poly(ethylene) and further homogenized by compression molding at 180 °C [101]. Polymer melts were also employed for the synthesis of metal colloids prepared *in-situ* from a dissolved precursor [116]. Upon dropping solutions with the precursors to polymer melts at 200–260 °C, elemental metals formed under concomitant evaporation of the solvent and mixing of the solid components. For example, Cu(HCOO)<sub>2</sub>, Ti(C<sub>6</sub>H<sub>5</sub>CH<sub>2</sub>)<sub>4</sub>, or Fe(CO)<sub>5</sub> decomposed into the respective metal colloids under release of volatile reaction by-products [116]. This method was found to be suited also for the preparation of large amounts of nanocomposites (i.e., in the kilogram range) [116].

While polymers have been frequently employed in their final states for nanocomposite preparation, they have

also been synthesized *in-situ* in presence of dispersed nanoparticles which become trapped in the matrix after polymerization. This method can be particularly suited for polymers which are, in the final state, widely insoluble in common solvents. As an example for nanocomposite fabrication starting with monomers, surface-modified CdS particles were dispersed in a diisocyanate and a diol or dithiol, respectively, and poly(urethanes) or poly(thiourethanes), respectively, were subsequently obtained by polyaddition [104, 105]. Polymerization can also proceed in microemulsions (e.g., in systems consisting of an aqueous phase with *in-situ* prepared PbS colloids and an organic phase containing vinyl monomers) [86]. The latter were polymerized *in-situ* with the help of the UV initiator 2,2-dimethoxy-2-phenylacetophenone. Nanocomposite films have also been fabricated by coevaporation of an inorganic species and a monomer. While the monomer undergoes *in-situ* polymerization upon deposition on a substrate, the inorganic vapors grow to nanoparticles in the matrix. As an example, paracyclophane was evaporated and heated in the evaporation zone to 650–700 °C which caused a conversion to *p*-xylylene [117]. These vapors were codeposited with palladium, tin, or copper vapors on quartz slides which were cooled to –196 °C. Upon warming to room temperature, the *p*-xylylene polymerized to poly(*p*-xylylene) which is otherwise difficult to process.

The final step in nanocomposite preparation can also proceed in the solid polymer matrix, in particular by reaction of a precursor which has been previously incorporated in the matrix. Also in this case, the by-products from the reaction only leave the matrix if they are sufficiently volatile. In the simplest case, the particles are synthesized by thermal decomposition of the precursor. For example, copper formate embedded in poly(2-vinylpyridine) was reduced to elemental copper nanoparticles under formation of H<sub>2</sub> and CO<sub>2</sub> after heating to temperatures above 125 °C [118], and decomposition of silver heptafluorobutyrate or sodium tetrachloroaurate(III) in poly(vinyl butyral) to elemental metal colloids proceeded at 150 °C [119]. Another possibility is conversion of an incorporated precursor with a gaseous reagent, such as the synthesis of PbS colloids in an ethylene–methacrylic acid copolymer by reaction of Pb(CH<sub>3</sub>COO)<sub>2</sub> with gaseous H<sub>2</sub>S [14, 15, 17, 120], or with a dissolved reagent, such as the synthesis of PbS nanoparticles in poly(aniline) (PANI) by contact of Pb(NO<sub>3</sub>)<sub>2</sub>–PANI films with a Na<sub>2</sub>S solution [121]. Rarely, nanocomposites were produced by diffusion of dispersed nanoparticles into a polymer matrix. In the ideal case, the polymer swells but does not dissolve in the dispersing agent thus creating space for the diffusing particles. As an example, CdTe–poly(aniline) nanocomposites were prepared by exposure of a PANI film to an aqueous dispersion of thioglycerol-capped CdTe particles [121].

## 4. PROPERTIES OF NANOCOMPOSITES

### 4.1. Absorption of Visible Light

Nanocomposites containing colored colloids can act as color filters. Such materials were obtained, for instance, with poly(vinyl alcohol) and gold [28]. The sizes of the gold parti-

cles were varied by reduction of tetrachloroaurate(III) with various amounts of citrate [26, 27]. Aqueous suspensions with *in-situ* generated gold particles were mixed with aqueous poly(vinyl alcohol) solutions and nanocomposites were produced by casting followed by evaporation of the water [28]. According to the color of the gold colloids [26, 57], the nanocomposites appeared in transmission pink at 16 nm, purple at 43 nm, and blue at 79 nm diameter of the gold particles [28]. The color of the materials with the particles of 16 and 43 nm diameter did not vary with the observation angle but the samples with 79 nm particle diameter changed their color under oblique observation where they looked brown due to the Tyndall effect [26]. Similar observations were reported for gold dispersed in liquids [26, 57].

Color filters comprising poly(*N*-vinylpyrrolidone) and silver particles were prepared starting from a solution of Ag(NO<sub>3</sub>)<sub>2</sub> and the polymer in ethylene glycol which also acted as the reducing agent for the silver salt [122, 123]. Nanocomposites containing 2–8% w/w silver were coprecipitated with acetone and reprecipitated from ethanol with acetone [122, 123]. Depending on the reaction conditions, translucent yellow or red color filters were obtained [122, 123] with particle diameters between 6 and 12 nm [123]. The smallest particles resulted when the reaction solutions were mixed fast under sonication or strong stirring [123]. It was proposed that the use of polymers other than poly(*N*-vinylpyrrolidone), for example, poly(vinyl alcohol) or poly(methylvinylether), could change the color of the particles and, correspondingly, of the nanocomposites since the Fermi level depends not only on the particle size but also on the interaction of the particles with the surrounding molecules, according to the formula [123]

$$\Delta\varepsilon_F = \frac{2}{3}\varepsilon_F \frac{n_s}{N} x \delta_e$$

with  $\Delta\varepsilon_F$  the difference in the Fermi level  $\varepsilon_F$ ,  $n_s$  the number of atoms at the surface of a particle,  $N$  the total number of atoms in a particle,  $x$  the fraction of the surface atoms chemically interacting with functional groups of the surroundings, and  $\delta_e$  the fractional charge associated with each chemically interacting moiety.

Irradiation of colorless photochromic nanocomposites can also lead to color filters. Transparent aqueous solutions of a commercially available polynuclear phosphotungstic acid and poly(acrylamide) were used for the preparation of films of 2.1 μm thickness by evaporation of the water [124]. The resulting nanocomposites contained 9% or 38% w/w phosphotungstic acid particles with diameters of 45–55 and 55–65 nm, respectively, for the two phosphotungstic acid contents. Before UV irradiation, optical absorption spectra of the films did not show bands between 400 and 1000 nm. However, phosphotungstic acid readily undergoes redox processes under irradiation which results in colored species. Accordingly, upon irradiation of the nanocomposites with a mercury lamp, the samples with 9% w/w phosphotungstic acid became blue exhibiting in UV/vis spectra a shoulder at 490 nm and a very broad absorption maximum at

620 nm while the samples with 38% w/w phosphotungstic acid turned to brown with a very broad absorption maximum at 540 nm in UV/vis spectra.

## 4.2. Absorption of UV Radiation

Polymers often undergo unwanted reactions under the action of ultraviolet light. As a consequence, mechanical or optical properties can be affected by UV irradiation. The organic stabilizers which are commonly added to avoid such undesired effects are, however, consumed over long periods of time, in particular upon exposure to intense light. Further, attention has to be paid to migration of organic UV stabilizers. Inorganic particles which absorb UV light close to the visible wavelength range in which they are transparent are interesting alternatives for the UV protection of polymers. Numerous inorganic particles are UV-stable and, in addition, do not migrate in polymers.

In order to prepare a visually transparent material which absorbs UV light, nanocomposites of ZnO and a statistical copolymer of ethylene and vinyl acetate (EVA) were produced starting from immersion of EVA in a diethyl zinc solution [125]. The zinc compound diffused rapidly into the polymer. When the films were removed from the solution, the diethyl zinc trapped in the polymer hydrolyzed after contact with the ambient humidity, leading to the formation of ZnO colloids with diameters around 10 nm. After immersion of an EVA sheet of 194  $\mu\text{m}$  thickness at  $-15^\circ\text{C}$  for 40 min in the diethyl zinc solution, the resulting ZnO particles were concentrated in a region of 1–2  $\mu\text{m}$  thickness to the surface because of the limited diffusion rate of the diethyl zinc. Hence, the bulk mechanical properties of the polymer were not affected by the presence of the ZnO. The nanocomposites absorbed UV light up to 370–380 nm while light loss by scattering was virtually absent in the visible wavelength range.

Visually transparent nanocomposites of ZnO and poly(propylene) (PP) or poly(ethylene) (PE) were also described [126]. Unfortunately, the ZnO source is not evident and there is some uncertainty in the diameter of the ZnO particles which seems to be 20 nm in a figure caption but was denoted with 180 nm in the experimental section; the latter diameter appears to be too large to be suited for visually transparent nanocomposites. Nonetheless, the UV-protective effect of the ZnO colloids was clearly demonstrated. Upon exposure to UV radiation, discoloration of PP or carbonyl formation in PE was substantially reduced by the presence of 1–2% w/w ZnO. It also appeared that ZnO colloids reduced the thermally induced cross-linking of poly(propylene) [127].

Nanoparticles of rutile, a crystal modification of  $\text{TiO}_2$ , of ca. 2 nm diameter and a surface coating of dodecylbenzenesulfonic acid (DBSA) were isolated and dispersed in solutions of polymers in dichloromethane [128]. Nanocomposites were produced from those dispersions by casting followed by solvent evaporation at ambient conditions. Thus, films of ca. 100  $\mu\text{m}$  thickness and 4% w/w DBSA-coated rutile were prepared with poly(styrene) or a poly(carbonate) based on bisphenol A. The nanocomposites appeared transparent to the eye but absorbed UV light to a high extent up to ca. 300 nm.

## 4.3. Iridescence

Nanocomposites with particles forming a regular lattice in a polymer matrix have been prepared with silica particles synthesized *in-situ* by hydrolysis of tetraethoxysilane in a mixture of water, ethanol, and ammonia [87, 88]. The particles were of a diameter around 150 nm, if not otherwise indicated, and very uniform in size [87, 88]. The surfaces of the particles were modified by conversion of the surface hydroxyl groups with 3-(trimethoxysilyl)propyl methacrylate [87, 88]. The solvents in the silica dispersions were exchanged first with methanol and then with methyl methacrylate (MMA) [88] or methyl acrylate (MA) [87] by dialysis. Thus, dispersions of 35–40% w/w (19.5–22.7% v/v) silica in MMA or 35–45% w/w in MA were produced in liquid cells of 1 mm thickness in the case of MMA and 264  $\mu\text{m}$  thickness in the case of MA. After periods ranging from minutes to days, depending on the system, the cloudy dispersions became iridescent, indicating the formation of a lattice [88] which induced diffraction of light according to Bragg's equation [87],

$$\lambda = 2nd \sin \theta$$

with  $\lambda$  the wavelength of diffracted light,  $d$  the interplanar spacing,  $n$  the refractive index of the dispersion, and  $\theta$  the Bragg angle. The iridescence also manifested in UV/vis spectra of silica samples in MMA which were investigated with the incident beam perpendicular to the face of the liquid cell. After 7 d storage of the dispersions, a sharp band appeared at 554 nm at a silica volume fraction  $\phi$  of 0.195 [88]. This band must originate in diffraction of light at the lattice formed by the particles because neither silica itself nor methyl acrylate absorbs in the visible wavelength range. Application of Bragg's equation results in an interplanar spacing  $d$  of 176 nm ( $n = 1.4210$ ) in those specimens.

For the production of nanocomposites, MMA was polymerized in the dispersions by irradiation at ambient temperature with a mercury lamp in presence of a photoinitiator, 2,2-dimethoxy-2-phenylacetophenone [88]. It has been suggested, but not proven, that methacrylate groups bound to the silica surfaces reacted with the growing poly(methyl methacrylate) chains. Due to the shrinking of the volume of the organic phase upon polymerization,  $\phi$  increased from 0.195 to 0.235 and accordingly the absorption maximum in UV/vis spectra of the nanocomposites shifted from 554 nm in the MMA dispersion to 490 nm in the polymer. The absorption band corresponded to an interplanar spacing of 190 nm according to Bragg's equation ( $n = 1.4819$ ) and was still relatively sharp [full width at half maximum (FWHM) 13.6 nm] although somewhat broader than before polymerization (FWHM 4.0 nm). Scanning electron microscopy images revealed a hexagonal pattern of the spheric silica particles with a distance between two adjacent centers of 234 nm and to a large spacing between two adjacent surfaces of 82 nm. Therefore, the order in the dispersions seems to be rather due to long-range interactions than to close packing of the spheres.

Dispersions with MA were investigated with silica particles of diameter 142, 153, and 330 nm [87]. The weight fraction  $f$  of silica in these dispersions amounted typically

to 0.40 but in the case of the particles with 153 nm diameter dispersions with  $f$  of 0.35 and 0.45 were also prepared. In all samples, distinct absorption maxima arose in UV/vis spectra, with a FWHM of 4–6 nm at the samples with particle diameters 142 and 153 nm. At the samples with particle diameter 330 nm, the lines were considerably broader (FWHM of 35–50 nm) which may indicate a less pronounced order of the particles in those dispersions. At  $f$  of 0.40, the maximum absorption wavelength  $\lambda_{\max}$  decreased from 600 nm for a particle diameter  $l = 330$  nm to  $\lambda_{\max}$  of 490 nm for  $l = 142$  nm, corresponding to a decrease in the distance between the lattice planes from 211 to 173 nm (calculated with Bragg's equation). Further,  $\lambda_{\max}$  decreased in dispersions with particles of  $l = 153$  nm with increasing silica content from 582 nm at  $f = 0.35$  to 528 nm at  $f = 0.45$ .

Nanocomposites were also prepared by photopolymerization of MA analogous to the samples with MMA described above [87]. SEM images of thin sections of those materials showed hexagonally ordered arrays of silica particles. A blueshift of  $\lambda_{\max}$  around 30 nm and an increase in the full width at half maximum from ca. 5 to 15 nm was observed upon polymerization. The absorption maximum in UV/vis spectra and the distances of the lattice planes decreased with increasing silica content (particle diameter 153 nm). For  $f = 0.35$  and 0.45, respectively,  $\lambda_{\max}$  decreased from 502 to 466 nm and the lattice plane distance from 171 to 159 nm. The absorption bands were still quite narrow after polymerization (FWHM around 15 nm). When a film containing 40% w/w silica of particle diameter 153 nm was stretched up to 35%,  $\lambda_{\max}$  decreased linearly with increasing stretching ratio from 486 to 440 nm. After the stress was released, the films adopted their original lengths within 2–4 h and reached the initial  $\lambda_{\max}$  within 2–4 nm. Upon tilting the films away from perpendicular incidence of the incoming light to an incidence angle of 68°,  $\lambda_{\max}$  shifted from 490 to 472 nm, in agreement with Bragg's law.

#### 4.4. Dichroism

As mentioned in the historical outline above, dichroic nanocomposites on the basis of natural polymers were described already 100 years ago. It was supposed that the dichroism resulted from the formation of uniaxially oriented particle assemblies [63, 67, 129]. More recently, dichroic nanocomposites have been prepared with synthetic polymers, in particular poly(vinyl alcohol) (PVAL) and PE [28, 29, 101, 102, 130–132]. Dichroism was induced by drawing of the respective isotropic nanocomposites. In the PVAL systems, colloids of elemental gold were synthesized *in-situ* by reduction of  $[\text{AuCl}_4]^-$  with citrate in aqueous solution. After mixing the as-prepared gold dispersions with aqueous PVAL solutions, nanocomposites were obtained after solvent evaporation [28, 29]. These materials, which contained 5% w/w gold and reaction by-products stemming from the reduction of tetrachloroaurate(III) with sodium citrate, were drawn at 120 °C up to maximum draw ratios of 5. Transmission electron microscopy revealed linear particle assemblies which were oriented in the drawing direction and which caused a dichroic behavior. In polarized light, the color of the

drawn nanocomposites depended on the angle  $\varphi$  between the polarization direction of the incident light and the drawing direction of the films. Nanocomposites with gold particles of a diameter of 16 nm appeared blue at  $\varphi = 0^\circ$  and red at  $\varphi = 90^\circ$ , and accordingly the absorption maximum shifted from 772 nm ( $\varphi = 0^\circ$ ) to 528 nm ( $\varphi = 90^\circ$ ).

For the preparation of nanocomposites with PE as the matrix polymer, gold and silver nanoparticles coated with a self-assembled monolayer of dodecanethiol were used [28, 29, 101, 102, 130–132]. The colloid diameters were around 2–3 nm in the case of gold and around 4–5 nm of silver. In PE–silver samples, the particle size increased from approximately 4 to 10 nm upon annealing at 180 °C for 15 h which caused a shift of the absorption maximum of the particles from 435 to 463 nm. In order to obtain nanocomposites, the surface-modified particles were either dispersed in *p*-xylene–PE solutions at 130 °C followed by solvent evaporation, or the particles were mixed with PE in the molten state. The resulting isotropic materials, which contained usually 2 or 4% w/w colloid, were oriented by drawing on a hot stage at 120 °C to typical draw ratios around 15. In order to obtain highly dichroic nanocomposites with dodecanethiol-modified gold, the colloids were kept in a PE–*p*-xylene solution at 130 °C for 300 min [102, 132]. During this period, the color of the dispersion and the resulting nanocomposites changed from brown to blue. It seems that the heating caused a partial desorption of the dodecanethiol layer which favored an agglomeration of the particles; agglomerates in TEM images were indeed found in samples which had been preannealed for 300 min. In the case of silver, aggregates were obviously present already in the xylene dispersion prior to film manufacturing, as evident from TEM images [101, 130]. Upon drawing of the nanocomposites, arrays of nanoparticles formed along the drawing direction (as evident from TEM images) [101, 102, 130, 132], probably as a consequence of the tensile deformation in the drawing process [101].

In polarized light, the UV-vis spectra of the drawn gold–PE or silver–PE nanocomposites strongly depended on  $\varphi$ . At  $\varphi = 0^\circ$  the absorption maximum,  $\lambda_{\max}(0)$ , appeared at higher wavelengths than at  $\varphi = 90^\circ$ ,  $\lambda_{\max}(90)$ , and the spectra were further characterized by isosbestic points [101, 102, 130, 131]. For example, a PE–silver nanocomposite showed a  $\lambda_{\max}(0)$  at 489 nm,  $\lambda_{\max}(90)$  at 398 nm, and an isosbestic point at 425 nm, and a PE–gold nanocomposite a  $\lambda_{\max}(0)$  at 669 nm, a  $\lambda_{\max}(90)$  at 545 nm, and isosbestic points at 483 and 541 nm. The difference between  $\lambda_{\max}(0)$  and  $\lambda_{\max}(90)$  was essentially independent of the fabrication method (solution casting or melt processing) of the silver–PE nanocomposites [101]. When the gold content in PE was varied between 0.9 and 7.4% w/w, most pronounced differences in the absorption maxima at  $\varphi = 0^\circ$  and  $\varphi = 90^\circ$  were observed at particle contents of 2–4% w/w [102]. The optical behavior of the dichroic nanocomposites resembled that of systems with wire-type metal nanoparticles [133–138] or oriented metal strips [139] which also showed isosbestic points and a variation of the absorption maxima on  $\varphi$ . According to the dependence of  $\lambda_{\max}$  on  $\varphi$ , the color of the drawn nanocomposites changed with variation of  $\varphi$ . PE–silver films appeared red and yellow at  $\varphi$  of 0° and 90°, respectively,

annealed PE–silver films appeared purple and amber, and PE–gold films appeared blue and red. Such materials are potentially useful in liquid crystal display applications. When the top polarizer in a twisted-nematic electro-optical cell was replaced by dichroic nanocomposites, the display appeared bicolored [102, 109].

## 4.5. Nonlinear Optical Properties

Materials with nonlinear optical (NLO) properties are of interest for optical switching and wavelength manipulation [20]. Nanocomposites which exhibit NLO effects have been described thoroughly in two recent reviews [20, 21]. For example, in nanocomposites comprised of surface-modified CdSe particles and poly(methyl methacrylate), third-order nonlinear susceptibilities ( $\chi^3$ ) ranging from  $6.5 \times 10^{-8}$  to  $2.9 \times 10^{-7}$  esu were found [20]. Silver or gold nanoparticles prepared by reduction of respective metal salts at 150 °C in poly(vinyl butyral) films yielded materials with  $\chi^3$  of  $2 \times 10^{-9}$  and  $1 \times 10^{-8}$  esu and  $\chi^3/\alpha$  (where  $\alpha$  denotes the absorption coefficient) of  $1 \times 10^{-12}$  and  $2 \times 10^{-12}$  esu/cm, respectively (i.e.,  $\chi^3/\alpha$  was on the same order for both metals while  $\chi^3$  of the gold nanocomposites strongly exceeded the value of the films containing silver) [119]. This observation was attributed to the different local field enhancements inside the metal particles. The local field factor  $f_1$  is 2.2 for gold and 7.1 for silver, and  $\chi^3$  is proportional to the fourth power of this factor. Nanocomposites with nonlinear optical properties were also prepared with gold particles coated with a dodecanethiol monolayer [100]. The materials were obtained by dispersion of the particles in methylmethacrylate which was subsequently polymerized with a radical initiator or by spin coating of gold dispersed in a poly(phenylmethylsilane) solution. The highest  $\chi^3$  values observed with the two polymer matrices were around  $10^{-12}$  esu.

More recently, a nonlinear refractive index of  $-6.8 \times 10^{-12}$  cm<sup>2</sup>/W was found for nanocomposites comprising cubic PbS nanocrystals of ca. 5 nm edge length and a polymer prepared *in-situ* from a mixture of monomers and oligomers [86]. This nonlinear refractive index of the nanocomposite was clearly above that of bulk PbS measured under the same conditions ( $1.71 \times 10^{-14}$  cm<sup>2</sup>/W). This was explained as follows: As the particle size decreases, the ratio between surface and volume increases and consequently recombination of induced charge carriers at the surface becomes more important [86]. In semiconductor nanocrystals, a large percentage of defects are located at the surface which can act as traps for electron and hole annihilation unless these defects are passivated [108]. Hence, the trapping of charge carriers at the surface is influenced by the interaction of the surface atoms with the matrix [86]. It was assumed that coordination of carboxylic acid groups from the polymer to lead atoms reduced the trapping probability of electrons at the surface while the holes were rather localized at the surface and that, as a consequence, the surface-induced separation of charge between delocalized electrons and localized holes was the origin of the large nonlinear optical response in the PbS nanoparticles [86].

## 4.6. Extreme Refractive Index

### 4.6.1. General Remarks

The refractive index is a key feature in optical applications. The refractive indices of most organic polymers are located in the relatively narrow range of 1.3 and 1.7 [140]. Isotropic refractive indices around 2.1, found, for example, for poly(thiophene) or aromatic poly(imides) [141–143], are extraordinarily high for polymers. The theoretical lower limit of the refractive index of organic polymers has been estimated to be close to 1.29 [144]. It appears that an isotropic refractive index above 2.5 or below 1.25 has not been reported so far for a pure organic polymer. Inorganic materials cover a more extended range of refractive indices. For example, the refractive indices of silicon, germanium, and GaAs are above 3.5 at wavelengths of 413, 620, and 827 nm, whereas the refractive index of silver is below 0.2 at those wavelengths [145]. As a consequence, the incorporation of inorganic nanoparticles with extreme refractive indices in organic polymers can result in composite materials with refractive indices outside of the typical range of organic polymers.

### 4.6.2. High Refractive Index

The high refractive index of PbS over a broad wavelength range (4.0–4.6 between ca. 420 nm and 11  $\mu$ m [145]) and the straightforward synthesis of colloidal PbS renders PbS attractive for model experiments on the refractive index modification of polymer nanocomposites. Nanocomposites with PbS contents above 20% v/v were prepared with different methods [84, 85]. As the polymer matrix, poly(vinyl alcohol), poly(acrylamide), poly(acrylic acid), poly(ethylene oxide), and gelatin were employed. In particular, ultrahigh refractive index materials were described with poly(ethylene oxide) (PEO) [84]. These materials were readily obtained by addition of a H<sub>2</sub>S solution to a PEO-Pb(CH<sub>3</sub>COO)<sub>2</sub> solution, whereupon nanocomposites with a PbS content of 88% w/w (ca. 50% v/v) and particle size of 19 nm precipitated immediately. In numerous PEO–PbS samples, refractive indices between 2.9 and 3.4 were measured at wavelengths of 632.8 and 1295 nm.

Dissolution of gelatin in a solution of Pb(CH<sub>3</sub>COO)<sub>2</sub> at 50–60 °C followed by cooling to room temperature and addition of an aqueous H<sub>2</sub>S solution resulted in a stable gelatin–PbS dispersion with acetic acid as reaction by-product [85]. This dispersion was suited for the preparation of films with thicknesses in the range of 40 nm–1  $\mu$ m by spin coating. The films, which contained crystalline particles of diameters below 15–20 nm, stayed homogeneous up to PbS contents of 86.4% w/w. Refractive indices of samples with 30–86% w/w (17–53% v/v) PbS were determined at 632.8 nm [85]. The highest refractive indices, 2.4–2.5, were measured at PbS contents between 82 and 86% w/w (45–53% v/v). Within the experimental precision, the refractive indices increased linearly with increasing volume content of PbS by 0.0193 per % v/v of PbS. The regression analysis resulted in an extrapolated refractive index of  $1.49 \pm 0.05$  at 0% v/v PbS and  $3.4 \pm 0.1$  at 100% v/v PbS. While the former value agreed with the refractive index of pristine gelatin ( $1.537 \pm 0.008$ ), the latter was clearly below the refractive index of bulk PbS (ca. 4.3 at

633 nm [145]). This difference between the refractive index of the colloidal and the bulk PbS is supposed to be predominantly due to a refractive index dependence on the particle size, as shown in the next paragraph. Linear dependencies of refractive indices of nanocomposites on the volume fraction of the particles have also been found for other systems [83, 146–148]. Theoretical considerations are in agreement with a linear or a nonlinear relation between the refractive index of composites and the volume content of the incorporated particles, depending on the model [83, 140, 149, 150]. In the systems described experimentally, some deviation from the linear relationship might be consistent with the experiments especially at high particle loadings because of the precision of the experiments.

The size of PbS particles in nanocomposites with PEO varied by the presence of various amounts of acetic acid or sodium dodecylsulfate (SDS), respectively, during the *in-situ* synthesis of PbS from  $\text{Pb}(\text{CH}_3\text{COO})_2$  and  $\text{H}_2\text{S}$  [151]. Acetic acid caused an increase and SDS caused a decrease in the size of the PbS colloids, and after coprecipitation, nanocomposites containing particles with average sizes between 4 and 80 nm were obtained. The materials containing particles above ca. 20–25 nm diameter showed refractive indices of 3.5–3.8 at 632.8 nm and 3.3–3.7 at 1295 nm whereas the refractive indices of the samples with particles below ca. 20 nm decreased continuously at both wavelengths down to 1.7–1.8 for 4 nm diameter. The refractive indices of the PbS particles were estimated by linear extrapolation of the PbS volume content to 100% as mentioned above for the example of PbS–gelatin nanocomposites. At 632.8 and 1300 nm, refractive indices of ca. 4.0–4.3 were thus calculated for PbS particles with sizes above ca. 20 nm. These values are in the range of those reported for bulk PbS (4.3 at 619.9 and 1300 nm [145]). However, the extrapolated refractive indices of PbS decreased at 632.8 and 1300 nm at average diameters below 15–20 nm, as supported by theoretical analyses [16, 152]. For diameters of 4 nm, the extrapolated refractive indices for the PbS colloids were as low as 2.3 at 632.8 nm and 2.0 at 1300 nm.

Silicon is also an attractive inorganic component for nanocomposites with high refractive index. The refractive index of silicon amounts to 5.57 at 400 nm and 3.91 at 620 nm [83]. Compared to PbS, the absorption coefficient of silicon (0.34 at 400 nm, 0.022 at 620 nm) [83] is by far lower (2.02 at 400 nm and 1.77 at 620 nm for PbS [145]). Hence, nanocomposites with silicon should exhibit lower absorbance at the visible wavelengths than materials with PbS at the same volume fraction of inorganic particles [83]. Silicon nanoparticles, which are difficult to synthesize by chemical procedures in solution, were prepared by high-energy milling of coarser particles. After dispersion of the grinded silicon powders in ethanol and centrifugation, the supernatant liquid contained particles with average diameters of 20–40 nm. Finally the ethanol dispersion was added to a gelatin solution, and films were produced by spin coating. The films contained 50% w/w (ca. 64% v/v) silicon. X-ray diffraction proved that the silicon particles contained at least a crystalline core, which might be surrounded by a layer of amorphous silica since it was obvious from infrared spectra that the surface of the particles was covered by an oxide layer. The refractive index of the nanocomposites was measured

between 400 and 1000 nm. It gradually decreased from 3.3 at 400 nm to 2.5 at 1000 nm, in agreement with the assumption that the refractive index of the nanocomposites was proportional to the volume fractions and the refractive indices of the components, as mentioned above for the PbS–gelatin system.

High refractive index nanocomposites of poly(ethylene oxide) and various iron sulfides were prepared by *in-situ* synthesis starting from iron(II) and iron(III) salts, such as  $\text{FeCl}_2$ ,  $\text{FeSO}_4$ ,  $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$  (Mohr's salt), or  $\text{FeCl}_3$  [153]. These compounds were converted in an aqueous poly(ethylene oxide) solution with  $\text{H}_2\text{S}$ , NaHS,  $\text{Na}_2\text{S}$ , or a sodium oligosulfide at different pH values, temperatures, and reaction times. Nanocomposites coprecipitated upon formation of the iron sulfides. The highest refractive indices were found to be 2.6–2.8 at 632.8 and 1295 nm. In those samples, greigite ( $\text{Fe}_3\text{S}_4$ ) and mackinawite ( $\text{FeS}_{1-x}$ ) were identified as the iron sulfides by X-ray analysis. The iron sulfide particles were very small and could essentially not be visualized clearly in TEM images.

#### 4.6.3. Low Refractive Index

The refractive index of gold is below 0.5 between wavelengths of 540 and 1450 nm [145]. The incorporation of gold in polymers should therefore result in nanocomposites with very low refractive indices. The synthesis of gold nanoparticles is well established as evident from the above historic outline. For the production of low refractive index nanocomposites, gelatin and  $\text{H}[\text{AuCl}_4]$  were dissolved in a water–acetone mixture [146]. Upon addition of hydrazine hydrate, colloidal gold formed rapidly. Nanocomposite films were obtained from the gelatin–gold dispersions by spin coating. Scanning electron microscopy disclosed that reaction by-products crystallized at the surface of these films. Fortunately, those by-products could easily be removed by a brief dipping of the films in cold water. The nanocomposites contained 9.5–92.9% w/w (0.7–48% v/v) gold and showed the typical colors of colloidal gold [57, 154] (i.e., the nanocomposites appeared blue at high and purple–reddish at low gold contents). The particle diameters increased from 6.7 nm in a nanocomposite containing 9.5% w/w gold to ca. 50 nm at the highest gold contents. The lowest refractive indices, 0.96 at 632.8 nm and 1.04 at 1295 nm, were observed for a film containing 92.9% w/w gold (note that the refractive index of bulk gold is ca. 0.2 lower at 632.8 nm than at 1295 nm [145]). Since the nanocomposite surfaces were not ideally flat and the refractive indices were determined by ellipsometry, the incident laser light was scattered more pronouncedly at 632.8 nm than at 1295 nm. As a result, a number of samples were better suited for refractive index determinations at the higher wavelength at which a linear dependency of the refractive index on the volume content of gold was observed. Due to the low refractive index of gold, the refractive index of the nanocomposites decreased by 0.00994 per % v/v of gold. Extrapolation of the refractive index to 0% v/v gold resulted in a value of  $1.53 \pm 0.04$ , that is, close to the value of pristine gelatin ( $1.491 \pm 0.011$  at 1295 nm), and extrapolation to 100% v/v gold yielded a refractive index of  $0.51 \pm 0.07$  which is in the range of that of bulk gold (0.403 at 1291 nm [145]).

#### 4.7. Photoconductivity

Upon irradiation of light, semiconductors can induce charges in polymers. A semiconducting polymer matrix is able to transport the charge carriers (electrons or holes) which have been generated in the nanoparticles upon irradiation of light and which subsequently move to the surface [155]. Thus, photoconducting composites can be created, for example, by combination of a *p*-type semiconducting polymer matrix such as PANI and *n*-type semiconducting particles such as CdS or PbS. In nanocomposites, the large internal interface area enables an efficient separation of photoinduced charges and the number of carrier traps caused by the so-called grain boundaries between particles and matrix is reduced [155, 156]. The amount of nanoparticles required for photoconductivity is typically a few weight percent [155]. Hence, the respective particle fractions are well below the percolation threshold of ca. 15% v/v [155] (note that the density of inorganic materials is usually above that of polymers).

Photoconducting nanocomposites were prepared with PANI as matrix polymer. In a dispersion of TiO<sub>2</sub> particles (30% rutile and 70% anatase) in aqueous aniline, the latter was polymerized *in-situ* with peroxydisulfate [157]. After coprecipitation of the PANI and the TiO<sub>2</sub> with methanol, nanocomposites with 11–61% w/w TiO<sub>2</sub> of a diameter of 21 nm were obtained. Under the applied experimental conditions, poly(aniline) itself showed only little photoconductivity, if at all, but in presence of TiO<sub>2</sub> a photocurrent was observed with the highest values at irradiation at the absorption maximum of the TiO<sub>2</sub> particles of 337 nm. This indicates an improved efficiency in exciton dissociation in the presence of TiO<sub>2</sub>. Upon irradiation, electrons appear to be transferred from PANI to TiO<sub>2</sub> and the charges move subsequently to the respective electrodes. At a TiO<sub>2</sub> content of 33% w/w and irradiation with monochromatic light of a wavelength of 344 nm at an intensity of 19.5 μW/cm<sup>2</sup>, a short-circuit current density of 3 μA/cm<sup>2</sup> and an open-circuit voltage of 790 mV were measured. As another example, nanocomposites comprising PANI and PbS of a diameter of 2.6 nm, prepared by exposure of a PANI film containing lead(II) nitrate to an aqueous solution of sodium sulfide, showed photoconductivity in the entire visible spectrum with quantum yields on the order of 10<sup>-4</sup> [121].

Nanocomposites of poly(*N*-vinylcarbazole) (PVK), a hole-transporting polymer, and CdS also showed photoconductivity [106, 107, 158]. Materials containing CdS particles of 1–2 nm diameter were produced by spin coating from thioglycerol-capped CdS dispersed in a PVK solution in pyridine [107]. Films of 3–5 μm thickness were obtained. The photoconductivity  $\sigma$  at an applied field of 54 V/μm and an irradiation wavelength of 514.5 nm increased linearly with increasing intensity *I* of the incident light. At *I* = 3 W/cm<sup>2</sup>, a  $\sigma$  around  $8 \times 10^{-11}$  S/cm was measured. This indicates an absence of a bimolecular recombination mechanism which would lead to a dependency of  $\sigma$  on *I*<sup>2</sup>. Because the CdS content (ca. 1% w/w) lay clearly below the percolation threshold, it was assumed that the photoconductivity mechanism was initiated by absorption of a photon by a CdS particle whereas PVK acted as the charge transporting medium. It is not evident how the charges were transported through the bound surface layer to the polymer matrix.

Probably, a part of the organic layer bound to the surface was removed during nanocomposite fabrication. Other PVK–CdS nanocomposites were prepared by exposure of a spin-coated PVK–[Cd<sub>10</sub>S<sub>4</sub>(C<sub>6</sub>H<sub>5</sub>S)<sub>12</sub>] film to gaseous H<sub>2</sub>S [106]. The resulting materials contained ca. 1% v/v CdS of average diameter 1.6 nm. These nanocomposites showed a low dark conductivity but irradiation at 340 nm induced photoconductivity with a charge generation efficiency of 0.16.

Photoconductivity was also observed for nanocomposites of PVK and HgS colloids of ca. 10 nm diameter or PbS particles of ca. 50 nm diameter [159]. The mercury-containing materials were produced from polymer films which contained Hg(CH<sub>3</sub>COO)<sub>2</sub> and, in addition, a plasticizer and a chromophore. The films were exposed to H<sub>2</sub>S whereupon HgS formed. The volatile by-product acetic acid was removed under vacuum. For the manufacture of the composites with PbS, particles modified with *p*-thiocresol at their surfaces were dispersed in an organic solvent and casted together with PVK. The photocharge generation quantum efficiency increased with increasing electric field (*E*<sub>0</sub>) to ca. 0.12 at *E*<sub>0</sub> = 20 V/μm in the PVK–PbS and to ca. 0.002 at *E*<sub>0</sub> = 80 V/μm in the PVK–HgS nanocomposites.

#### 4.8. Catalytic Activity

The high specific surface area of the colloids in nanocomposites can render such materials suited for heterogeneous catalysis because of the large contact area between the particles and the reacting agents. As an example, catalytic active nanocomposites composed of silica and 10–13% w/w Nafion<sup>®</sup>, a perfluorinated resin with sulfonic acid groups, were prepared via two different routes [160]. In one method, colloidal silica (specific surface area 500 m<sup>2</sup>/g) was suspended in a 2-propanol–water mixture in the presence of Nafion<sup>®</sup>. After stirring for 2 h, the volatile components were removed by evaporation. In the other method, which probably yielded nanocomposites with less agglomerated particles, the silica was synthesized *in-situ* by hydrolysis of Si(OC<sub>2</sub>H<sub>5</sub>)<sub>4</sub>. The nanocomposites catalyzed the reaction of toluene with 1-bromoadamantane at 111 °C, the conversion of allyl phenyl ether to *o*-allyl phenol in benzene at 80 °C, and the transformation of phenyl acetate to phenol in nitrobenzene at 220 °C. In all those catalytic processes, the composites with the *in-situ* synthesized silica were clearly more effective than the materials prepared with the preformed colloids, the differences in the initial rate amounting to a factor of ca. 5–20,000, depending on the reaction. The catalysts with the preformed particles, however, often showed better selectivity in the catalytic reactions. For example, the transformation of phenyl acetate to phenol proceeded with an initial rate of 95 mmol/(min g<sub>catalyst</sub>) with the *in-situ* prepared and 0.0055 mmol/(min g<sub>catalyst</sub>) with the preformed silica but the latter produced phenol as the only detectable product while the fraction of phenol in the former was around 45% since other products such as 4-hydroxyacetophenone also arose. Remarkably, when phenol was added, 4-hydroxyacetophenone emerged exclusively with the nanocomposite containing the *in-situ* prepared silica.

Photocatalytic processes may be particularly favored by nanoparticles since the diffusion of electrons and holes

in nanoparticles is probably more efficient than in large particles [104]. Photoconductive nanocomposites were produced by dispersion of surface-modified CdS nanoparticles in toluene containing hexamethylene diisocyanate and an aromatic dithiol [104]. The diisocyanate and the dithiol were polymerized *in-situ* yielding a poly(thiourethane) with a Cd content of 1–2 mol/kg. While related composites containing bulk CdS did not exhibit a significant photocatalytic activity for the production of hydrogen from a 2-propanol/water mixture, the nanocomposites caused evolution of hydrogen. After a delay period of a few hours, hydrogen evolved linearly at a rate of ca. 0.04  $\mu\text{mol}/(\mu\text{mol Cd/h})$  for benzylthiol-modified (CdS-BT) and ca. 0.025  $\mu\text{mol}/(\mu\text{mol Cd/h})$  for phenylthiol-modified particles (CdS-PT) [104]. This difference could arise as a consequence of a higher agglomeration tendency of CdS-PT compared to CdS-BT (i.e., a reduced contact area of the CdS particles and the reacting agents in the case of CdS-PT) or as a consequence of a hampered transfer of the photogenerated electrons in CdS-PT to the reactive species [104]. Similarly, poly(urethanes) containing 0.07–0.14 mol CdS/kg composite were prepared with surface-modified CdS particles [105]. The polymer was prepared *in-situ* in a dispersion of CdS in dimethylsulfoxide containing dissolved ethylene glycol and toluenediyl-2,4-diisocyanate. Upon irradiation of the resulting materials with a xenon lamp, 2-propanol decomposed catalytically under release of hydrogen. The reaction was characterized by a delay period of ca. 1.5 h, thereafter hydrogen evolved proportionally to the irradiation time. After 18 h, 0.4–0.6  $\mu\text{mol H}_2/\mu\text{mol Cd}$  were produced.

Other photocatalytically active nanocomposites were produced by *in-situ* synthesis of CdS or ZnS in a reverse micellar system in water and isooctane [161]. Upon addition of hexamethyl diisocyanate, a polyurea formed under the effect of the water present in the system. The resulting materials contained 1.71 mmol/kg CdS of 4.7 nm diameter or 1.56 mmol/kg ZnS of 4.4 nm diameter, respectively. In aqueous suspensions containing 10% v/v 2-propanol, irradiation with a xenon lamp induced the generation of  $\text{H}_2$ . After 18 h, 2.6 mmol  $\text{H}_2$  per kg CdS–polyurea and 8.6 mmol  $\text{H}_2$  per kg ZnS–polyurea composite evolved.

## GLOSSARY

**Aurum potable** Dispersion of gold nanoparticles prepared in medieval times, mainly for medical purposes.

**Coprecipitation** Simultaneous precipitation of different species, for example, of nanoparticles and polymer.

**Dichroism** Difference in colors when an oriented material is viewed in linearly polarized light with the orientation axis parallel and perpendicular, respectively, to the polarization plane.

**Gold ruby glass** Ruby nanocomposite comprising gold colloids in a glass matrix, fabricated in medieval times where it was used in particular as colored church windows.

**Photochromism** Color change under the action of visible or ultraviolet light.

**Spin coating** Technique for the preparation of thin films, based on the placement of a dissolved substance on a rotating substrate whereupon the liquid is distributed uniformly

over the substrate and the solvent evaporates leaving a thin film of the substance on the substrate.

**Ultramicroscope** Apparatus for the determination of particle diameters below the wavelength of visual light, based on the visualization of the particles by light scattering.

## 1. INTRODUCTION

In this chapter, we survey a variety of aspects of theoretical models of computation, with an emphasis on those modeling issues that are particularly important for the engineering of efficient nanoscale computers.

Most traditional models of computing (such as those treated in Savage's textbook [1]) ignore a number of important fundamental physical effects that can dramatically impact computational performance at the nanoscale, such as the basic thermodynamic limits on information processing [2], and the possibility of utilizing quantum physical superpositions (essentially, weighted combinations) of logic states [3]. New, alternative models of computing that allow *reversible computing* [4], while respecting the laws of thermodynamics may (gradually, over the next ~50 years) achieve a level of performance and cost efficiency on all types of computational tasks that is literally *thousands* of times greater than the best that is physically possible using conventional *irreversible* models [5]. Also, those models that are not only reversible but also allow coherent *quantum computing*, based on self-interference of entangled superpositions of states, furthermore permit expressing algorithms (for at least some special-purpose problems) that require *exponentially* fewer steps in these models than the best known algorithms in the older models that do not [3].

Because of such discrepancies, the scope and precision of our models of computation *must* be revised and extended in

order to take these new considerations into account, if we wish our models to continue to be an accurate and powerful guide to the engineering design of computer architectures and to the performance of algorithms, even as technology approaches the nanoscale. We describe some ways in which this has already been done, by the author and others, show some example results of this modeling effort (such as the quantitative performance advantages of reversible and quantum computing quoted previously), describe a variety of proposed nanocomputing technologies, and identify which technologies have the potential to implement these most powerful models. We conclude with a discussion of future work that is needed to further develop and flesh out these models to the point where future nanocomputer engineers and programmers will find them maximally useful.

### 1.1. Definition of “Nanocomputer”

For purposes of this chapter, a *nanocomputer* is simply any computer whose *characteristic length scale*—the average spacing between the centers of neighboring primitive functional components, such as transistors or other switching elements—falls within the three-orders-of-magnitude-wide range that is centered on 1 nanometer (that is, ~0.032 to ~32 nanometers). (Anything in the next larger range might be better called a *microcomputer* and anything in the next smaller range, if that were possible, a *picocomputer*.)

Under this definition, note that even traditional semiconductor-based computers are expected to qualify as nanocomputers in only about 13 more years—to wit, the semiconductor industry's goals [6] specify that the *pitch* between neighboring wires should fall only slightly above this range, specifically at a level of 44 nanometers, by 2016. Furthermore, the semiconductor industry's stated milestones such as this have historically proven conservative, and indeed, Intel [7], IBM [8], and AMD [9] have already demonstrated ~10-nm gate-length field-effect transistors in the lab which, if aggressively packed together, might allow a pitch below the 30-nm *nanoscale* mark within 10 years, which historically is the approximate lag time between laboratory demonstrations of transistors and their availability in commercial processors. (Of course, if some alternative,

non-transistor-based nanotechnology development proceeds especially rapidly, this scale might be reached even sooner.)

Note that by focusing on the *pitch* rather than *diameter* of the primitive elements, we insist that computers based on narrow-diameter components, such as the carbon nanotube [10] or semiconductor nanowire [11] logic gates that have already been demonstrated, would not count as viable nanocomputers *unless* the average *spacing*, as well as the size, of these devices across a large and economically manufacturable array is made sufficiently small, which has not yet been accomplished, but which may be in the future.

## 1.2. Theoretical Models of Computing—Key Model Components

Now, what do we mean by a theoretical model of computing? In general, a theoretical model of any size computer (whether “nano” or not) can involve a number of different aspects that are relevant to computer engineering, any of which may be more or less abstract (or even left completely unspecified) in any particular model. These modeling areas include:

1. A *device model* specifies the physical and/or information-processing characteristics of the individual, lowest level information-processing functional elements (*devices*, which we will sometimes call *bit devices* when they are based on binary information encodings, to distinguish them from larger machines) within the computer.
2. A *technology scaling model* specifies how device characteristics change as the physical dimensions of the devices are scaled to smaller sizes, when this is possible.
3. An *interconnection model* specifies how information is communicated between devices. When wires are considered to be one of these types of devices, the interconnect model can be considered part of the device model. But wires and other types of permanent physical structures are not the only possible way for devices to communicate; various types of interconnects involving physical entities moving through free space are also conceivable. The precise nature of the interconnection model has greater implications than one might at first expect.
4. A *timing model* specifies how the activities of different devices are to be synchronized with each other. The timing model also has more of an impact than might at first be realized.
5. A *processing architecture model*, or just *architecture*, specifies how devices are *functionally* connected to form a larger unit called a *processor*, which is complex enough to be programmed to carry out any desired type of computation, or at least, to carry out a specific type of computation on different input information.
6. A (*capacity*) *scaling model* is a more general sort of architecture (sometimes called an *architecture family* [12]) that allows the capacity of the processor (in bits of storage, and/or ops-per-cycle of performance) to be scaled up, via some specified regular transformation, to ever-larger sizes. This stands in contrast to nonscalable architectures where the processor is specified to have a fixed, constant number of bits of state, and ops-per-cycle of performance. The most common type of scaling model is a *multiprocessor* scaling model, which defines larger processors as simply being assemblages of smaller processors that are interconnected together, using some processor-level interconnect model, which might be different from the interconnect model that is used at the device level.
7. An *energy transfer model* specifies how “clean” power is to be supplied, and “dirty” power (waste heat) removed, from all parts of a scaled processor. The energy system can also be viewed from an informational perspective as supplying known information in a standard state (in the stable power signal) and removing unknown information (entropy, in the waste heat). As such, it is subject to the fundamental limits on information processing to be discussed.
8. A *programming model* specifies how the computer can be configured to carry out different types of computations (as opposed to just performing the same computation on different input information). A programming model that happens to be based on traditional types of computer machine-language instructions is called an *instruction set architecture*, but other, radically different types of programming models also exist, such as those that are used today to program field-programmable gate arrays (which are general-purpose reconfigurable logic circuits) and dataflow-style machines, as well as earlier, more abstract models such as Turing machines and cellular automata. A high-level programming language is a very abstract sort of programming model that is relatively far removed from the architecture of any specific machine and that is usually translated into a more architecture-specific programming model such as machine language, before execution by the hardware.
9. An *error handling model* sets forth a scheme for dealing with hardware errors, whether they be *defects* (persistent errors due to malformation or degradation of device structures during manufacturing or operation) or *faults* (dynamically arising temporary errors, due to, example, thermal noise, cosmic rays, energy leakage, or quantum tunneling). Techniques such as error correction codes, J. Baylis, *Error-Correcting Codes*, Chapman-Hall, London, 1998, and defect-tolerant architectures, J. Heath, P. Kuekes, G. Snider, S. Williams, “A defect-Tolerant Computer Architecture: Opportunities for Nanotechnology,” *Science* 280, 1716 (1998), can dynamically detect such errors and correct them (in the case of faults) or work around them (in the case of defects). Note that each new error occurrence generates some entropy which must eventually be removed from the machine by the energy transfer system, if it is not to accumulate to the point of total degradation of the machine’s structure.
10. A *performance model* can be used to determine quantitatively (to some degree of accuracy) how quickly any specific algorithm implemented in the programming model will execute on the specific architecture.

Performance can be considered a special case of *cost efficiency*, in which cost is considered to be directly proportional to time (which is appropriate in many circumstances).

11. A *cost model* quantifies the *cost*, according to one or more measures, of manufacturing a computer of given capacity, and/or of executing a specified computation on it. Note that a performance model can actually be considered to be a special case of a cost model in which there is a single cost measure, namely *execution time*; performance (or “quickness”) is just the reciprocal of this. As we will discuss, it is also useful to consider other physically reasonable cost measures such as energy costs, spacetime-proportional costs, and total dollar cost of both energy and spacetime. Whatever the cost measure, *cost efficiency* (or just *efficiency*) in general is the ratio between the minimum possible cost to perform a computation and the actual cost. Even if the minimum possible cost of a computation is unknown, we know that to maximize the cost efficiency of a given task, we must minimize its actual cost.

### 1.3. Desiderata for Models of Computing

What do we want our models of computing to be like? Well, here are some properties that we might desire a computer model to have:

- *Ease of programming*: The programming model (when specified) should be intuitive and easy for programmers to understand and work with.
- *Ease of implementation*: It should be possible and straightforward to design and build actual physical implementations of the given architecture.
- *Physical realism*: The predictions of the cost/performance model should be, at least approximately, physically realizable in feasible implementations. This feature, though it is very important for real-world engineering purposes, is unfortunately neglected by many of the theoretical models that have been studied in some of the more pure-mathematics-oriented branches of computer science (more on this issue later).
- *Efficiency*: The cost efficiency achievable by programs running on top of direct physical implementations of the model should be as high as possible, ideally close to 100% (best possible), but in practice at least lower bounded by some constant minimum level of efficiency that holds independently of parameters of the application (more on this later).
- *Technology independence*: If possible, the model should be applicable to a wide range of different possible technologies for its physical implementation, rather than being tied to a very specific technology. Later we will give an example of a technology-independent model. However, technology-specific models do also play an important role, for example, for accurately assessing the efficiency characteristics of that particular technology.

### 1.4. Physical Realism

A theoretical model of computation (at whatever level of abstraction) that includes at least a programming model, an architecture, and a performance or cost model will be called *physically realistic* (abbreviated *PR*) if it does not significantly overstate the performance or (understate the cost) for executing any algorithm on top of physically possible implementations of that architecture. Physical realism is also (somewhat cryptically) termed *congruence* in some of the parallel computing literature (cf. [83]).

As we will survey, not all of the theoretical models of computation that have traditionally been studied by computer scientists are actually physically realistic, according to our best-available present-day understanding of physical law; some even overstate performance (or more generally, cost efficiency) by multiplicative factors that become unboundedly large as one increases the capacity of the machine. These factors can be anywhere from polynomially large in the machine capacity [*e.g.*, for irreversible three-dimensional (3D) mesh models, which ignore the laws of thermodynamics] to exponentially large or even larger (*e.g.*, seemingly so for nondeterministic models, and also for unrealistically profligate interconnect models that ignore the speed-of-light limit). This lack of realism may be acceptable from the perspective of studying the pure mathematical structure of various models in the abstract, but, as engineers, we prefer for our models to correspond well to reality. So we must be careful in our modeling not to overstate what physics can do, or we may mislead ourselves into wasting time designing, building, and programming machines that cannot possibly live up to the unrealistic performance expectations that we may have for them if we are fooled and believe some of the traditional models.

### 1.5. Scalability of Efficiency

Similarly, computer modeling will also not well serve us if it significantly *understates* what physics can do, that is, if the architecture and programming model do not allow one to express algorithms that are as cost efficient as is physically possible. Of course, no specific mechanism (other than raw physics itself) can be expected to be exactly maximally cost efficient for *all* computations, but we will argue that it is possible to devise physically realistic models that understate the best physically possible cost efficiency of computations by only, at most, a reasonably small (that is, not astronomically large) constant factor, and one that furthermore does not increase as the machine is scaled to larger capacities. We call such models *universally maximally scalable* (*UMS*). Models possessing this UMS property (in addition to physical realism) would be the ideal architectural templates for the detailed design and engineering of future general-purpose nanocomputers, since they would pose no barrier to an application algorithm designer’s choosing and programming the most cost-efficient, physically possible algorithm for any given computational task.

As we will survey, out of the various physically realistic traditional models of computation that have been proposed to date, absolutely *none* so far have qualified as UMS models. We describe some new candidates for UMS models that

we have recently proposed, and we mention the possible remaining flaws in these models that may still prevent them from being *completely* accurate across all regimes of physically possible computations in the very long term.

## 2. FUNDAMENTAL PHYSICS OF COMPUTING

Let us begin by briefly reviewing how the capabilities and limitations of computers are impacted by very general considerations within the well-established consensus model of fundamental physics, known as the Standard Model of particle physics.

The Standard Model is not yet complete, in that it does not yet incorporate all aspects of Einstein’s General Theory of Relativity (another well-established model), and so various new models that attempt to merge the two theories are currently in development, such as String Theory [13], M-Theory [13], and Loop Quantum Gravity [14]. Whichever extension of the Standard Model (if any) turns out to be correct will doubtless have some implications for the ultimate limits of computing; however, any modifications that these extensions might make to the current models are only expected to become relevant at an energy density scale that is so high that we do not expect these modifications to be technologically relevant any time soon (in this century, say). It seems that the Standard Model suffices for characterizing the ultimate limits of all more near-term technologies.

Tables 1 and 2 summarize the major limiting factors imposed by the laws of physics as we know them, as well the opportunities for increased computational power afforded by those laws. More detailed accounts of these limits can be found in [4, 15, 16].

### 2.1. Concepts of Physical Information Processing

In this section, we give a brief overview of a number of basic concepts that are needed for a correct physical understanding of information processing. This can also be viewed as an explanation of basic physical concepts *themselves* in terms of information processing. Reference [24] develops some of these ideas in more detail. Some of the following identities and definitions may be considered approximate and even a bit speculative, given that we do not yet have a complete computational model of physics, but they can all be argued to be roughly correct, at least to first order.

#### 2.1.1. States

A *state* or *configuration* of a system can be understood as a complete description of that system that is valid, in principle, at some point in time. Quantum mechanics, or specifically, Heisenberg’s *uncertainty principle*, teaches us that not all of the mathematically different states that a physical system may be in are actually *operationally distinguishable* from each other by *any* physically possible attempt to discriminate them

**Table 1.** Summary of all known ways in which fundamental physical principles limit information processing.

Physical considerations	Limits on computational capabilities
1. Principle of locality; speed-of-light limit on velocity of propagation of information through space.	1a. Lower bound on communications latency across systems of given diameter [12, 17].
2. Wave aspect of quantum mechanics; uncertainty principle.	2a. Upper bound on information capacity for systems of given diameter and energy [15, 16].
3. Considerations 1 and 2, taken together.	3a. Upper bound on rate of bits communicated per unit area, with given power [4, 15].
4. Fundamental quantum relationship between frequency and energy.	3b. Lower bound for average random access time for a memory of given size and energy density.
5. Reversibility of quantum mechanics; thermodynamic relationships between information and energy.	4a. Upper bound on rate of useful bit operations per second in systems containing a given amount of free energy [16, 18].
6. Considerations 3 and 5, taken together.	5a. Lower bound on energy wasted per irreversible bit operation, given external temperature [19].
7. Second law of thermodynamics; rate of entropy increase is $>0$ in all nonequilibrium systems.	5b. Upper bound on rate of irreversible bit operations performed per watt of power consumption, given external temperature [4].
8. Adiabatic theorem of quantum mechanics.	6a. Upper bound on sustainable rate of irreversible bit operations within an enclosure of given area and external temperature [20].
9. Considerations 6 and 8 taken together.	7a. $>0$ rate of energy waste per bit stored.
10. Gravity, as per Einstein’s theory of general relativity.	7b. Upper bound on number of bits stably stored, given rate of heat removal and rate of entropy generation per bit [21].
	8a. Energy waste proportional to speed in reversible bit-operations [22].
	9a. Upper bound on rate of reversible operations given system diameter, device quality, heat flux or power limits, and external temperature [21].
	10a. Upper bounds on internal energy of computers of given diameter, in turn limiting their speed and capacity [4].

*Note:* Many older models of computation fail to respect all of these limits and therefore are physically unrealistic, except in restricted regimes in which these constraints are far away. Constraint 1 already affects communication delays and computer performance today. Constraints 2–9 are still far from being reached today, but they are all expected to become important limiting factors over the course of the next 50 years. Larger scale analogs to these fundamental considerations are also important today. In contrast, constraint 10 requires extremely high energy densities (near black hole density) in order to become relevant and therefore is not expected to be a concern any time in the near future (the next 100 years, for example).

**Table 2.** Summary of ways in which physics offers opportunities for more cost-efficient computing than would have been thought possible using earlier, physically realistic (but overly conservative) models of computation that ignored those opportunities.

Physical observations	Opportunities for computing
1. Events can occur in different places at the same time.	Parallel computation; a machine can perform different operations in different devices simultaneously [23].
2. Our universe has three (and only three) usable spatial dimensions.	The number of bit locations accessible within a given time delay can scale up as quickly as (at most) the third power of the delay; this fact can help performance of some parallel algorithms, compared to the 2D or 1D cases [17, 23].
3. Some types of physical transformations can occur in a way that generates an amount of entropy approaching zero.	Such nearly <i>reversible</i> transformations can perform computations with less loss of free energy, and as a result less total cost in many situations, compared to irreversible methods. This is called <i>reversible computing</i> [4].
4. Quantum mechanics allows a system to be in a superposition (weighted sum) of many distinct states simultaneously.	Carefully controlled systems that use superposition states can take shortcuts to arrive at solutions to some problems in many fewer steps than is known to be possible using other methods. This is called <i>quantum computing</i> [3].

*Note:* Parallelism is already heavily used at many levels, from logic circuits to wide-area distributed computing, as are architectural configurations that take some advantage of all three dimensions of space, though to a limited extent (constraint 6 in Table 1 is an important limit on three-dimensional computing today). Reversible computing and quantum computing, in contrast, are still very much in the research stage today, but they are both expected to become increasingly important for competitive computing as device sizes approach the nanoscale. Reversible computing is important because it directly alleviates constraints 5 and 6 from Table 1 (which are already relevant, in a scaled-up way, today), and quantum computing offers a totally new class of algorithms that will be important in and of themselves for certain problems, regardless of whether quantum computing turns out to be useful for general-purpose algorithms, or whether general-purpose nanocomputing itself even becomes feasible.

[25]. Fundamentally, this is because not all pairs of quantum states are totally mutually exclusive with each other. Rather, states can *overlap*, in a certain mathematically well-defined way, which results in the phenomenon that a system that is prepared in a certain state has a necessarily diffuse sort of *presence*, so to speak, a presence that extends to partly include other, sufficiently nearby states as well.

### 2.1.2. State Space

The *state space* of a system is the set of all of its possible states. In quantum theory, a state space has the mathematical structure of a Hilbert space (a complex vector space having an inner product operation).

### 2.1.3. Dimensionality

The *dimensionality* of a system's state space is simply the number of states in a maximum-sized set of states that are all mutually exclusive (mutually orthogonal vectors). For example, the spin orientation of a single spin one-half subatomic particle has two distinguishable states and thus has a state space of dimensionality 2. Two such particles together have four distinct states, and a four-dimensional state space.

### 2.1.4. Amount of Information

The total *amount of information* contained in a system is just the logarithm of the dimensionality of its state space, that is, the logarithm of its maximum number of mutually distinguishable states [26]. The base of the logarithm is arbitrary and yields a corresponding unit of information. Taking the log base 2 measures the information in units of bits (binary digits). Using the natural logarithm (base  $e \approx 2.717, \dots$ ), the corresponding information unit is called the *nat*. The physical quantities that are traditionally known as Boltzmann's constant  $k_B$  and the ideal gas constant  $R$  are simply different names for 1 nat of information, but they are usually

expressed in different (though still compatible) units, such as Joules per Kelvin, or kilocalories per mole per Kelvin, and are usually also reserved specifically for discussing information that happens to be entropy.

Note that the total amount of information contained in any system is constant over time, so long as its maximum number of states is also. This is the case for any system with constant total energy and volume.

### 2.1.5. Information

The *specific* information that is in a system (as opposed to the *amount* of information) is the particular *choice* of state, itself. We can say that the actual state of a system *is* the information in the system.

### 2.1.6. Entropy

Entropy  $S$  was originally just an unnamed, abstract quantity (the ratio between heat and temperature) of unknown physical significance when its usefulness in thermodynamic calculations was first recognized by Rudolph Clausius in 1850. But entropy is now understood to simply represent that portion of the information in a system that is not redundant (correlated) with the information in other parts; that is, it cannot be derived from the other information. As such, the distinction between which pieces of physical information are effectively entropy, and which are not, depends, to some extent, on the information-processing capabilities of the entity that might be doing the deriving. A specific body of information may appear at first to be haphazard and random, but with sufficient processing, we may eventually notice an underlying order to it.

Right now, the amount of information that is under explicit control within our computers is just a tiny fraction of the total physical information in the world around us,

and so we do not notice the effect that information processing capabilities can have on entropy. But, as computation approaches the nanoscale, an increasingly large fraction of the information inherent in the physical material making up our computer circuits will be explicitly manipulated for computational purposes, and as a result, the ultimate computational nature of entropy will start to become more and more apparent. As we will see, it turns out that the amount of entropy that a nanocomputer produces actually depends heavily on whether its design recognizes that all of the information that it deterministically computes is actually *not* entropy, since it was derived from other information in the machine and therefore is redundant with it. Current machine designs ignore this fact and simply discard intermediate results after they are no longer needed, irreversibly committing them to the great entropy dump in the sky. (Literally: the discarded information flows out of the machine and eventually out into space.)

So, to sum up, entropy is defined as simply any and all information whose identity (as opposed to amount) happens to be unknown by a given entity of interest, an entity whose interactions with the system we are concerned with describing. (This entity in question can itself be any kind of system, from a human to a logic gate.) The state of *knowing* can itself be defined in terms of the presence of accessible correlations between the state of the knower and the state of the system in question, but we will not get into that here.

### 2.1.7. Subsystems

Consider a maximal set of distinguishable states of a system. If this set is partitioned into  $N$  equal-sized subsets, then the selection of one subset from the partition can be considered a *part* of the state of the whole system. It corresponds to a *subsystem* of the original system. The amount of information in the subsystem is  $\log N$ . This much of the whole system's information can be considered to be located *in* the subsystem. Two subsystems are *independent* if they partition the state space along independent (orthogonal) directions, so to speak. (This concept can be made more precise but we will not do so here.) A set of mutually independent subsystems is *complete* if specifying the state of each subsystem is enough to specify the state of the whole system exactly. A minimal-sized subsystem (one that cannot be further broken down into independent subsystems) is sometimes also called a *degree of freedom*.

### 2.1.8. Bit Systems

A *bit system* or just *bit* is any degree of freedom that contains only 1 bit of information, that is, a bit is a partition of the state set into two equal sized parts. Note the dual usage of the word *bit* to refer to both a unit for an amount of information and to a system containing an amount of information that is equal to that unit. These uses should not be confused. Systems of sizes other than 1 bit can also be defined, for example bytes, words, *etc.*

### 2.1.9. Transformations

A *transformation* is an operation on the state space, mapping each state to the corresponding state resulting from the transformation. It is a fundamental fact of quantum

mechanics (and all Hamiltonian mechanical theories, more generally) that the transformations corresponding to the passage of time are reversible (that is, one-to-one, invertible, bijective). The *size* of a given transformation can be described in terms of the average distance between old states and new states, by some appropriate metric.

### 2.1.10. Operations

A *primitive orthogonalizing operation* (or just *operation* for short) is a transformation that maps *at least one* state to some new state that is distinguishable from the original state, and that cannot be composed of smaller operations. An operation is *on* a particular subsystem if it does not change the state of any independent subsystem. An operation on a bit system is called a *bit operation* (and similarly for other sizes of systems). Two operations *commute* if performing them in either order has the same net effect. Operations on independent systems always commute.

### 2.1.11. Transformation Trajectory

A transformation trajectory is a transformation expressed as a sequence of (primitive orthogonalizing) operations, or pieces of such operations, operating on individual degrees of freedom (*e.g.*, a quantum logic network Nielsen and Chuang [3]).

### 2.1.12. Number of Operations

The total *number of operations* that take place along a given transformation trajectory can be defined. *Planck's constant*  $h$  (or  $\hbar \stackrel{\text{def}}{=} h/2$ ) can be viewed as a unit for expressing a number of operations. The unreduced Planck's constant  $h$  represents two primitive operations (for example, a complete rotation of a particle spin through an angle of  $360^\circ$ ), while the reduced constant  $\hbar$  represents a fraction  $1/\pi$  of a primitive operation, for example, a rotation of a spin through an angle of only 1 radian.

### 2.1.13. Steps

A *complete parallel update step* or just *step* is a transformation of a system that can be described by composing operations on each subsystem in some maximal, complete set of subsystems, such that the total number of operations in bits is equal to the amount of information in bits. In other words, it is a complete overhaul of *all* of the state information in the system, whereas an *operation* on the system only potentially changes some *part* of the state.

### 2.1.14. Dynamics

The *dynamics* of a system specifies a transformation trajectory that is followed as the system evolves in time.

### 2.1.15. Amount of Time

Given the dynamics, the amount of time itself can be defined in terms of the number of steps taken by some fixed reference subsystem, during a given trajectory taken by the

system. Note that if the system and the reference subsystem are both taken to be just the whole universe, then time just represents the total “amount of change” in the universe, in terms of number of parallel update steps performed. (Such concepts harken back to the relativist philosophies of Leibniz and Mach which helped inspire Einstein’s general relativity [27].)

### 2.1.16. Energy

Now, the *energy* in a subsystem is the rate at which primitive operations are taking place in that subsystem, according to its dynamics. In other words, energy is *activity*; it is *computing* itself. This can be proven from basic quantum theory [16, 18, 28].

As a simple way to see this, consider any quantum system with any subsystem whose physical Hamiltonian induces any two energy eigenstates of distinct energies; call these states  $|0\rangle$  and  $|2E\rangle$  arbitrarily. Now, if the subsystem happens to be in the state  $|0\rangle + |2E\rangle$ , which has (expected) energy  $E$ , then the quantum time evolution given by the system’s Hamiltonian takes it to the orthogonal state  $|0\rangle - |2E\rangle$  in time  $(\hbar/4)/E$ . Margolus and Levitin [18] show that a system with energy  $E$  can never change to an orthogonal state any faster than this, no matter what its initial state. Therefore, we can say that any  $E$ -sized chunk of energy is, every  $\hbar/4E$  time, “performing” the operation “If I am in this subsystem and its state is  $|0\rangle + |2E\rangle$ , make its state  $|0\rangle - |2E\rangle$ , otherwise . . . .” This transformation counts as an operation, by our definition, because it does orthogonalize *some* states. However, this particular operation is somewhat limited in its power, because the subsystem in question subsequently immediately cycles right back to its original state. We call this special case an *inverting op* (*iop*); its magnitude in terms of Planck’s constant is  $(\hbar/4)$ . Margolus and Levitin show that an op that instead takes a system to the next state in a repeating cycle of  $N$  states requires more iops worth of time, in fact,  $2(N-1)/N$  times more ops, or  $[(N-1)/2N]\hbar$ .

In the limit as the cycle length  $N$  approaches infinity (as it does in any complex system), the time per orthogonal transition approaches 2 iops worth, or  $(\hbar/2)$ , so we define this as the magnitude of a generic “op” as previously.

Incidentally, when applying the Margolus–Levitin relation to the example of a simple freely rotating system,  $N$  can be argued to be equal to the system’s total angular momentum quantum number  $l$  plus 1, and with a few more steps, it turns out that the relation can be used to independently confirm the usual angular momentum quantization formula  $(L/\hbar)^2 = l(l+1)$ , much more easily than by the usual derivation found in quantum physics textbooks.

### 2.1.17. Heat

Heat is just the energy in those subsystems whose state information is entirely unknown (entropy).

### 2.1.18. Temperature

The *temperature* of a subsystem is the average rate at which complete update steps are taking place in that subsystem (*i.e.*, the average rate of operations per bit) [28]. Note that energy divided by temperature gives the amount of information in the subsystem. This is, historically, how physical

information (in the form of entropy) was first noticed as an important thermodynamic quantity (by Rudolph Clausius, in 1850), even before the fact that it was really just information was understood.

Note that the *reciprocal* of temperature is just the time required for a complete step that, on average, updates all parts of the state information, once each.

This definition of temperature, in contrast to traditional ones, is general enough that it applies not just to systems in a maximum-entropy equilibrium state (all of whose information is entropy), but more generally to any system, even systems in a completely known state with no entropy, which according to traditional definitions of temperature would always be at absolute zero. However, for any system we can also identify a *thermal temperature* which is the average temperature of any of its subsystems whose state information is entropy, and then consistently define that the thermal temperature of a system having *no* entropy is zero. Thermal temperature is, then, just the traditional thermodynamic concept of temperature. But our more general temperature concept is somewhat more flexible.

Note also that energy spontaneously flows from “hot” subsystems to “cold” ones, rather than vice versa, simply because the fast-changing pieces of energy in the hot system more frequently traverse the trajectories through state space that cross over the boundary between the two systems.

These are enough definitions to support our later discussions in this chapter. A more complete discussion of the relationships between physics and information processing can be found in [24] (in progress).

Discussions of *quantum information* and how it extends the classical concepts of information can be found in [3].

## 3. TRADITIONAL MODELS OF COMPUTATION

In this section, we systematically survey a wide variety of early models of computing and identify exactly which of the limits or opportunities listed in the previous section each one fails to account for, which result in the model’s lacking one or the other of the properties of PR or UMS. Furthermore, we consider what types of costs are respected in the model.

In the next section, we will present the newer models which may actually come close to being both PR and UMS for all practical purposes in the foreseeable future.

Here are some contributions to real-world costs that an economically thorough cost model ought to take into account:

1. Manufacturing cost to build a machine that can perform a given computation. We may expect this to be roughly proportional to its total information capacity. However, if the machine can be reused for more than one computation, then the cost model should account for this properly (cf. item 3a below).
2. Costs that may be considered to scale roughly proportionally to the execution time of programs, but not to the machine’s manufacturing cost, such as, for example, the inconvenience cost to the user of waiting to receive a desired result.

3. Costs that can be expected to scale proportionally to both execution time *and* manufacturing cost, such as:
  - a. Hardware *rental* cost, or essentially manufacturing cost amortized per unit time, given some fixed expected lifetime for the machine.
  - b. Maintenance and operation costs for the machine per unit time, including cost of energy used by components that are operating at constant power levels.
  - c. Opportunity cost foregone by not applying the machine’s capacity toward some alternative useful purpose.
4. Total cost of energy spent for the computation. We list this separately from item 3b because later we will see that there are significant components of energy that are *not* necessarily proportional to spacetime usage.

Traditional computational complexity theory (cf. [29]) considers purely time-proportional costs like item 2, simplified to just the total number of discrete time-steps (clock ticks) performed (*i.e.*, assuming a fixed rate of steps per unit time), and dubbed *time complexity*. It also considers a rough measure of manufacturing cost, in the form of the total number of bits of storage required to perform the computation and calls this *space complexity*. However, most work in complexity theory does not combine the two in the natural way suggested by items 2b–2e, which is that real costs are usually proportional to *both* space and time, or in other words to the *spacetime* utilized, that is to say, the cost to *rent* the required amount of hardware for the amount of time needed to perform the computation, and to other costs that can be assumed to scale proportionally to this quantity, such as maintenance cost, opportunity cost, and energy used (typically).

Some cost models in complexity theory count the number of fixed-size computational *operations* that are performed, rather than the number of parallel steps. This comes closer

to spacetime cost but still does not quite hit the mark, since there are real costs even associated with those bits that are just sitting statically and not being operated on at all (hardware rental cost, maintenance cost, opportunity cost).

Newer models such as VLSI theory (very large scale integrated circuits cf. [30]) address these problems somewhat by considering the *hardware efficiency* of algorithms, which is essentially the reciprocal of their spacetime usage. However, these models still do not usually integrate the cost of energy into the analysis in a way that treats it as somewhat independent from spacetime cost, which it is, as we will see.

Table 3 summarizes how a variety of existing theoretical models of computation fare with respect to the fundamental limits and opportunities discussed in Section 2, and the costs discussed previously. A discussion follows.

### 3.1. Turing Machines

The *Turing machine* [31] was the first universal, physically evocative (as opposed to totally abstract and formal) model of computation. It has a single fixed-size processor (the *head*) and a memory laid out in one dimension that is accessed in serial fashion (the *tape*). The Turing machine model does not violate any of the fundamental physical limits on information processing, and therefore it is physically realistic.

However, since a Turing machine has only a single, fixed-size “processor” (the tape head), it does not leverage the possibility of parallelism. Multitape and multihead Turing machines provide limited parallelism, but true parallelism in the model requires that the number of processors must be scaled up in proportion to the information capacity of the machine. Turing machine models usually do not try to do this, but later we will see other models that do.

It is possible to analyze space and time costs in a Turing machine model, but the joint spacetime cost is not usually a concern, since the model has such understated efficiency in any case. Due to its drastic suboptimality, the Turing

**Table 3.** We can compare various models of computation as to which fundamental physical limits they violate (see Table 1), which opportunities for more efficient computing they leverage (Table 2), and which aspects of cost they take into account.

Model	Fundamental limits violated										Opportunities leveraged				Costs considered			
	1	2	3	4	5	6	7	8	9	10	1	2	3	4	1	2	3	4
Turing machine [31]												1			✓	✓	1/2	
RAM machine [32]			× (b)									∞			✓	✓	1/2	
PRAMs, <i>etc.</i>			× (b)								✓	∞			✓	✓	1/2	
1D cellular automata [33]											✓	1			✓	✓	✓	
2D cellular automata [33]											✓	2			✓	✓	✓	
3D cellular automata [33]						×				×	✓	3			✓	✓	✓	
Reversible logic networks [34]			× (b)				×	×			✓	∞	✓		✓	✓	✓	✓
Quantum logic networks [35]			× (b)								✓	∞	✓	✓	✓	✓	✓	✓
Reversible 3D mesh [4]										×	✓	2–3	✓		✓	✓	✓	✓
Quantum R3M [4]										×	✓	2–3	✓	✓	✓	✓	✓	✓

*Note:* Opportunity #2 gives the number of dimensions explicitly or implicitly assumed by the model; three or more is unrealistic, two or less is underambitious. Cost measure #3 (spacetime) is denoted “half-way considered” if spacetime cost *could* be easily measured in the model but is typically ignored instead. Note that the quantum reversible 3D mesh model described in Section 6 (first introduced in [4]) strictly dominates all earlier models in realism and comprehensiveness, so long as gravity (limit #10) is not a concern, which we can expect to remain true for very long time. (This limit would only become relevant if/when we come to build computer systems of near black-hole density, *e.g.*, by building them out of several suns’ worth of matter, or alternatively by somehow achieving an average device-pitch scale nearly as small as the Planck length scale of fundamental particles. Both of these possibilities seem *extremely* distant at present, to say the least.)

machine and related models are primarily only suitable for the following purposes:

- Determining whether a desired class of computations is possible to do at all, even given unlimited resources (its *computability*).
- Proving that other models of computation are universal, by showing that they are capable of simulating a Turing machine.
- Determining the time required to perform a computation to a very rough degree of accuracy, that is, to within a polynomial factor (a factor growing as  $\sim n^k$  where  $n$  is the size of the input data set and  $k$  is any constant). The *strong Church's thesis* [36] is the hypothesis that Turing machines are satisfactory for this purpose. However, results in quantum computing suggest strongly that ordinary nonquantum Turing machines may actually *overstate* the physically required minimum time to solve some problems by *exponentially large* factors (that is, factors growing roughly like  $e^n$ ) [3], in which case the strong Church's thesis would be false.
- Determining the space (measured as number of bits) required to perform a computation within a constant factor.

These concerns are generic ones in computing and are not tied to nanocomputing specifically but can be used in that context as well. However, if one wishes a more precise model of costs to perform a desired computation than can be provided by Turing machines, one must turn to other models.

### 3.2. RAM Machine

One limitation of the Turing machine was that since the memory tape was laid out serially in only one dimension, merely traversing it to arrive at a desired item consumed a large portion of the machine's time. For early electronic memories, in contrast, the time required for a signal to traverse the distance through the machine was negligible in comparison to the time taken to perform logic operations. Therefore, it was useful to model memory access as requiring only a single step, regardless of the physical distance to the desired memory location. This fast memory access model is the defining characteristic of the RAM or random-access machine model of computation [32]. The RAM model is occasionally called the von Neumann machine model, after the inventor of architectures having a central processing unit (CPU) with a separate random-access memory for storing programs and data. The RAM model is also sometimes extended to a parallel model called the PRAM.

Today, however, individual transistors have become so fast that the speed-of-light travel time across an ordinary-sized machine is becoming a significant limiting factor on the time required to access memory, especially for computations requiring large-scale supercomputers having large numbers of processors. For example, at the 3 GHz processor clock speeds that are now routinely available in commercial off-the-shelf microprocessors, light can only travel 10 cm in one clock cycle, so the memory accessible within a round-trip latency of one cycle is limited to, at most, the amount that will fit within a 5-cm radius sphere centered on the processor. (In practice, at present, the situation is even

worse than this, because the time to access today's commercial memory technologies is much greater than the speed-of-light travel time.) And, when considering a wide-area distributed computation, communication halfway around the Earth (*i.e.*,  $\sim 20,000$  km) requires at least 200 million clock cycles! Delays like these can be worked around somewhat by using architectural *latency hiding* techniques in processor architectures and parallel algorithms, but only to a very limited extent [12, 37]. Furthermore, these problems are only going to get worse as clock speeds continue to increase. Communication time is no longer insignificant, except for the restricted class of parallel computations that require only very infrequent communication between processors, or for serial computations that require only small amounts of memory. For more general purposes, the RAM-type model is no longer tenable.

Slightly more realistic than the RAM are models that explicitly take communication time into account, to some extent, by describing a network of processing nodes or logic gates that pass information to each other along explicit communication links. However, depending on the topology of the interconnection network, these models may not be physically realistic either. *Binary trees*, *fat trees*, *hypercubes*, and *butterfly* or *omega* networks are all examples of interconnection patterns in which the number of locations accessible within  $n$  hops grows much faster than  $n^3$ , and therefore, these networks are impossible to implement with unit-time hops above a certain scale within ordinary 3D space. The *only* scalable networks in 3D space are the locally connected or *mesh*-type networks, and subgraphs of these [12, 17].

### 3.3. Cellular Automata

Cellular automaton (CA) models, also originally due to von Neumann [33], improve upon the RAM-type or abstract-network model in that they explicitly recognize the constraints imposed by communication delays through ordinary Euclidean space. CAs are essentially equivalent to mesh-interconnected networks of fixed-capacity processors. The one-dimensional and two-dimensional CA variations are entirely physically realistic, and the 2D CA can be used as a starting point for developing a more detailed theoretical or engineering model of today's planar circuits, such as, for example, the VLSI theory of Leiserson [30].

However, ordinary CAs break down physically when one tries to extend them to three dimensions, because the entropy that is inevitably produced by irreversible operations within a 3D volume cannot escape quickly enough through the 2D surface. To circumvent this constraint while still making some use of the third dimension requires avoiding entropy production using *reversible* models, such as we will discuss in Section 4.1. These models can be shown to have better cost-efficiency scaling than *any* physically possible nonreversible models, even when taking the overheads associated with reversibility into account [4].

Finally, all of these models, in their *traditional* form, miss the opportunity afforded by quantum mechanics of allowing machine states that are *superpositions* (weighted combinations) of many possible states, within a single piece of hardware, which apparently opens up drastic shortcuts to the solution of at least certain specialized types of problems. We will discuss quantum models further in Section 4.2.

## 4. NEW MODELS OF NANOCOMPUTERS

Computer technology already is forced to contend with the limits to communication delays imposed by the speed-of-light limit. Over the next 20–50 years, we can expect the limits that thermodynamics and quantum mechanics place on bit energies, sizes, and bit-device speeds to become plainly manifest as well. Other fundamental constraints, such as the one that gravity imposes on machine size (namely, that any sufficiently large 3D computer with a fixed energy density will collapse under its own gravity to form a black hole) are still very far away (probably many centuries) from being relevant.

So what we want is to have a model of computation that is physically realistic, at least with respect to the relatively near-term constraints, and that also provides a cost efficiency that scales as well as possible with increasing computation size, for all classes of computations. We can argue that there is an existence proof that such a model must be possible, for the laws of physics *themselves* comprise such a model, when looked at from a computational perspective. However, raw physics does not provide a very convenient programming model, so our task is to develop a higher level programming model that scales as well as possible, while also providing a relatively easy-to-understand, comprehensible framework for programming.

In Sections 4.1 and 4.2 we survey a couple of new classes of models which attempt to make progress toward this goal, namely the reversible and quantum models.

### 4.1. Reversible Computing

The fundamental insight of reversible computing is that there is absolutely nothing about fundamental physics that in any way requires that the free energy that goes into bit manipulations must be discarded after each operation, in the form of waste heat. This is because bits that have been computed are not (yet) entropy, because they are derived from, and thus correlated with, other bits that are present in the machine. Present-day computers constantly discard temporary results that are no longer needed, in order to free up storage space for newer information. This act of wanton erasure causes the old information and energy associated with those bits to be relegated to the degraded status of effectively becoming entropy and heat, respectively. Once this is done, it cannot be undone, since the second law of thermodynamics tells us that entropy can never be destroyed. Information erasure is irreversible [19].

However, we can *avoid* this act of “trashification” of bits by instead *recycling* bits that are no longer needed, by taking advantage of their redundancy with other bits present in the machine to restore the unneeded bits to a standard state (say “0” for an empty memory cell), while leaving the bit’s associated energy (or most of it, anyway) in the machine, in the form of free energy which can go on to perform another useful computational operation [38].

#### 4.1.1. Adiabatic Principle

Of course, no machine is perfect, so even in a reversible machine, some of the kinetic energy associated with the performance of each operation goes astray. Such events are

called *adiabatic losses*. The detailed accounting of adiabatic losses can be proven from basic quantum theory as in the *adiabatic* theorem [39], which tells us that as a system proceeds along a given trajectory under the influence of slowly changing externally applied forces, the total energy dissipation is proportional to the speed with which the external forces change; however, rather than getting into the technical mathematical details of this theorem here, we discuss some more intuitive ways to understand it.

First, the amount of adiabatic loss is roughly proportional to the number of elementary quantum operations performed, and thus to the energy involved in carrying out transition times the time over which it is performed, divided by a technology-dependent constant that specifies the quantum *quality factor* of the system, that is, how many quantum operations can be performed on average without an error (decoherence event).

As the speed of carrying out a given transformation is decreased, the kinetic energy associated with the system’s motion along the desired trajectory through configuration space decreases quadratically (in proportion to the square of the speed, since as we all know, kinetic energy is  $\frac{1}{2}mv^2$ ), and so the total adiabatic losses over the entire motion decrease in inverse proportion to the time taken for the transformation.

However, when the kinetic energy involved in carrying out transformations decreases to a level that is close to the static bit energies themselves, further decreases in speed do not help, because entropy generation from degradation of the static bits comes to dominate the total dissipation. That is, some of the energy whose job it is to maintain the very structure of the machine, and/or the state of its stored information, also leaks out, in a continual slow departure from the desired configuration (this is called *decay*), which must be periodically repaired using correction mechanisms if the computation is to continue indefinitely. For example, all of the following phenomena can be considered as simply different examples of decay processes:

- Charge leakage from DRAM (dynamic RAM) cells, requiring periodic refreshing.
- Bit errors due to thermal noise, cosmic ray impacts, *etc.*, requiring the use of error-correction algorithms.
- Decoherence of quantum bits from various unwanted modes of interaction with a noisy, uncontrolled environment, requiring quantum error correction.
- Gradual diffusion of the atoms of the devices into each other (*e.g.*, from electromigration), leading to eventual failure requiring remanufacture and replacement of all or part of the machine.

All of these kinds of decay processes incur a cost in terms of free energy (to periodically correct errors, or to repair or replace the machine) that is proportional to the *space-time* usage, or space to hold bits, times time occupied, of the computation. This spacetime usage cannot be adequately reduced to time alone, space alone, or even to the number of logical operations alone, since, depending on the computation to be performed, not all bits may be actively manipulated on every time step, and so the spacetime usage may not be simply proportional to the number of operations.

Adiabatic (or kinetic) losses, on the other hand, do effectively count the number of operations performed, but these are *quantum* operations, whose number is not necessarily directly proportional to the number of classical bit operations, even when the algorithm being carried out is a classical one. This is because the number of quantum operations involved in carrying out a given classical bit operation increases in proportion to the speed with which the desired trajectory through state space is followed.

There are two ways to see this. First, the de Broglie wavelength  $\lambda$  of the “particle” wave packet representing the system’s state in configuration space is inversely proportional to its momentum, according to the formula  $\lambda = h/p$ . Momentum is proportional to velocity, so following a given trajectory will involve a larger number of distinct transitions of the system’s wave packet (*i.e.*, translations through about a wavelength) the faster it is done; each of these can be considered a orthogonalizing quantum operation.

Second, recall that kinetic energy increases with the square of velocity, whereas the frequency or quickness with which a fixed-length classical trajectory is followed increases only linearly with velocity. Therefore, the interpretation of energy as the rate of quantum operations requires that the number of operations on a given trajectory must increase with the speed at which that trajectory is followed.

With this interpretation, the technology-dependent coefficients (such as frictional coefficients, *etc.*) that express the energy dissipation per unit quickness for an adiabatic process can be seen as simply giving the decoherence times for those qubits whose transitioning corresponds to kinetic energy. The decoherence of qubits carrying energy causes the dissipation of that energy. The adiabatic principle (which states that the total energy dissipation of an adiabatic process is proportional to its speed) can be derived from the postulate that a fixed fraction of kinetic energy is dissipated each time unit [22]. Adiabatic coefficients are therefore lower bounded by the decoherence rates that can be achieved for qubits whose transitions carry us from one logical machine state to another.

The adiabatic principle also tells us that whenever logical transitions are carried out by a process that uses multiple quantum operations (in place of a single one), we are doing extra unnecessary work, and thus generating more entropy (and energy dissipation) than necessary. This happens whenever we try to do a process faster than strictly necessary.

As a simple example, consider a hollow cylinder of radius  $r$  and mass  $m$ , rotating with rim velocity  $v$ . Let us consider a rotation of this wheel to carry out a “cycle” in our computer, a complete transition from one logical state to another. A simple calculation shows that the number of quantum orthogonal transitions (angle  $\pi/2$  rotations of the state vector in Hilbert space) that occur during one complete rotation is given by  $4L/\hbar$ , where  $L = mvr$  is the wheel’s angular momentum about its axis, and  $\hbar$  is Planck’s (reduced) constant,  $h/2$ . Total angular momentum for any system is quantized, and the minimum possible rotation speed occurs when  $L = \hbar$ . At this speed, the kinetic energy is just enough to carry out one quantum logic operation (an iop, for example, a bit toggle) per quarter-cycle. At this rate, the rotation of the wheel through a quarter-turn *is*, from a quantum mechanical

perspective, a bit flip. The decoherence rate of this spin qubit determines the rate at which the wheel’s energy dissipates.

In contrast, if the wheel were spun faster ( $L$  were higher), there would be proportionally more distinct rotational positions around 1 complete rotation, and the total energy is quadratically higher, so the average energy per location (or the generalized temperature) is proportional to  $L$ . With order  $L$  more locations, each carrying order  $L$  more energy, a fixed decoherence rate per location yields a quadratically higher total rate of energy dissipation, and thus a linearly higher amount of entropy generation per complete cycle. This is an example of why the dissipation of an adiabatic process is proportional to the speed at which it is carried out.

Simply put, a faster process has quadratically greater kinetic energy and so, given a fixed mean-free time or decoherence time for that energy, energy dissipates to heat at a quadratically faster rate, for linearly more energy dissipation during the time of the operation.

The minimum energy dissipation of an adiabatic process occurs when the speed of the transition is slow enough that the dissipation of kinetic energy is not much greater than the dissipation of static (potential) energy. If the decoherence rates are comparable for the two types of energy, then the kinetic energy for bit change should be of the same order as the static energy in the bits themselves, as in our previous wheel example.

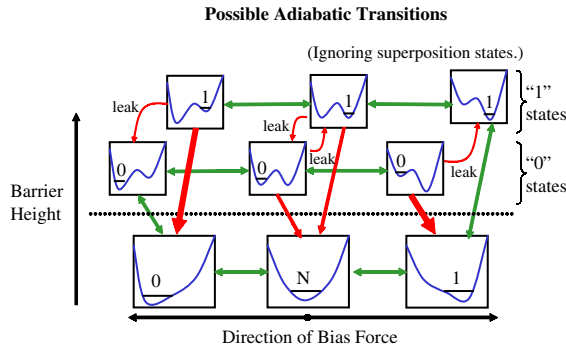

This makes sense, since if energy *is* computing, we want as much as possible of our available energy to be actively engaged in carrying out transitions at all times. Having a kinetic energy that is much larger than bit energy would mean that there was a lot of extra energy in the system that was not directly occupied in carrying out bit transitions. In such cases, a more direct and economical design would be preferable. This is what a good optimized adiabatic design attempts to accomplish.

#### 4.1.2. Device Implementation Technologies

Reversible, adiabatic logical mechanisms can be implemented in a wide variety of physical systems; indeed, nearly every type of bit-device technology that has been proposed (whether electrical, mechanical, or chemical) admits some sort of reversible variant. Virtually all of these technologies can be usefully characterized in terms of the bistable potential-well paradigm introduced by Landauer [19]. In this framework, a bit is encoded by a physical system having two distinct meta-stable states. The relative energies of these states, and the height of a potential barrier between them, is adjustable by interactions with nearby bits. Figure 1 illustrates this model.

Irreversible erasure of a bit in this model corresponds to lowering a potential-energy barrier (*e.g.*, by turning on a transistor between two circuit nodes) regardless of the state of the bit under consideration (say, the voltage on one of the nodes). Due to the energy difference between biased states, this in general leads to large, nonadiabatic losses (thick red arrows in the diagram), which reversible logic must avoid. Even the lowering of a barrier between two states of equal energy still creates at least 1 bit’s worth of entropy, even when done infinitesimally slowly, if the state of the bit was not already entropy (medium red arrows).

**Figure 1.** Possible adiabatic (green) and nonadiabatic (red) transitions between states of any device technology that provides a generic bistable potential well. Each box indicates a different abstract configuration of the system. Within each box, the  $x$  axis is some continuous state variable in the system (such as the position of a mechanical component or a charge packet), and the  $y$  axis is potential energy for the given value of the state variable. Small black horizontal lines show the energy level occupied (or the surface of a set of occupied levels). The  $x$  position of the occupied state encodes the value of the bit. Device configurations encoding logical values of 0, 1, and an in-between neutral level “N” are shown. Thick arrows between configurations indicate nonadiabatic active transitions, while thin arrows indicate possible leakage pathways (activated thermally or by tunneling). Note the lower three boxes show the potential barrier lowered, while the upper three show it raised. The left–right position of the box in the diagram corresponds roughly to the direction of an external force (e.g., from a neighboring device) that is applied to the system.

Of course, even in reversible logic systems, we must still contend with the smaller losses due to thermally excited transitions or tunneling of the bit system’s state over the potential energy barriers (thin red arrows labeled “leak”)

Now, a number of different reversible logical and storage mechanisms are possible within this single framework. We can categorize these as follows:

1. *Input-bias, clocked-barrier latching logic (type I):* In this method, the device barriers are initially lowered, and input data to the device apply a bias, pulling the device toward a specific bit value. Optionally in this stage, forces applied by several input bits can be combined together to carry out majority logic (or switch gates can be used to do logic, as in [40]). Next, a timing signal raises the barrier between the two states. This step can also serve to amplify and restore the input signal. After the barrier is raised, the input data can be removed, and the computed state of the device remains stored. Later, the stored data can be reversibly *unlatched*, if desired, by the reverse sequence of steps.

Specific physical examples of the type I technique include the adiabatic quantum dot cellular automaton of Lent and Tougaw [41], the complementary metal-oxide semiconductor (CMOS) transmission-gate latch of Younis and Knight [42], the reversible rod logic latch of Drexler [43], the reversible superconducting Parametric Quantron logic of Likharev [44], the mechanical buckled logic of Merkle [45], and the electronic helical logic of Merkle and Drexler [40].

2. *Input-barrier, clocked-bias retractile logic (type II):* In this technique, the input data, rather than applying a bias force, conditionally raise or lower the potential energy

barrier. Arbitrary AND/OR logic can be done in this stage, by using series/parallel combinations of several barriers along the path between bit states. Then, a timing signal unconditionally applies the bias force, which either pushes the system to a new state, or not (depending on whether the barrier between states was raised). Since the output state is not inherently latched by this timing signal, the input signal cannot then be removed (if this would lower the barriers) until other “downstream” devices have either latched a copy of the output or have finished using it. So these gates cannot by themselves perform sequential logic (e.g., memory, networks with feedback, or pipelined logic), although they can be used in combination with latching gates to do so.

Examples of the type II technique are Hall’s retractile electronic logic [46], the nonlatching portions of Younis and Knight’s CMOS SCRL gates [42], and Drexler’s rod logic interlocks [47].

3. *Input-barrier, clocked-bias latching logic (type III):* Finally, from Figure 1, one can immediately see that there is a third possibility, one that has not previously been considered. It is more efficient than either (1) or (2), in the sense that it combines AND/OR logic with latching in a single operation. In this scheme, as with the previous one, the input signal sets the barrier height, doing logic in series/parallel networks, and then a timing signal applies an unconditional bias force. But we note that the input signal can now be immediately removed, *if* in doing so we restore the barriers to a null state that consists of *barriers unconditionally raised*. Then, when the bias timing signal is removed, the output bit remains latched in to its new state. The bit can be unlatched using the reverse sequence along the same path, or a different one.

This general method for doing reversible logic apparently has not been previously described in the literature, but we have developed a straightforward technique for implementing this model in standard CMOS technology. It is significantly more efficient than previous truly adiabatic logic families, by several different metrics.

The bistable potential-well model is basically one in which we model one subsystem (the output bit) as being subject to a time-varying Hamiltonian (essentially, a matrix representing the forces on the system) that is provided by the device’s interaction with some other subsystems (the input and clock bits). However, one must stay aware that there is really just a *single* system that evolves according to an actual *underlying* Hamiltonian which is time-*independent*, being itself just an expression of the unchanging laws of physics. So, in general, one cannot ignore the back-reaction of the controlled system (the output bit) on the system that is doing the controlling (the input bit), especially if we want to be accurate about the total energy consumption in the entire system, including the controlling system, which in practice is just some other logic element within the computer. For example, it is easy to design adiabatic gates using transistors that dissipate almost no energy internally, whose transitions are

controlled by some large external signal generator. But it is much harder to integrate the signal generator and design a complete, self-timed system that is nevertheless almost reversible. For this reason, some authors have unjustly criticized the concept of adiabatic circuits in general, solely on the basis of the poor quality of the particular signal generators that were assumed to be used in the author's particular analysis. But the failure of a single short-sighted designer to imagine an efficient resonator does not mean that such a thing is impossible, or that alternative designs that avoid these timing-system inefficiencies are impossible to build.

For example, Bennett [2] illustrated a proof-of-concept mechanical model of a self-contained reversible computer by doing away with directed kinetic energy entirely, and instead letting the system take a random walk, forward or backward, along its nonbranching path through configuration space. Unfortunately, doing away with kinetic energy entirely is not such a good thing, because random walks are very slow; they take expected time that increases quadratically with the distance traveled. (Chemical computing techniques in which communication relies primarily on molecular diffusion in solution also have performance problems, for the same reason.) Thus, we would prefer to stick with designs in which the system *does* have a substantial net kinetic energy and momentum along the "forward" direction of its motion through configuration space, while yet dissipating  $\ll kT$  energy per logic operation performed, due to a high quality factor for the individual logic interactions. We call such trajectories *ballistic*.

I emphasize that we still know of absolutely *no* fundamental reasons why ballistic reversible computation cannot be done, and with arbitrarily high quality factors. A series of increasingly realistic models have been proposed that illustrate steps along the path toward actually doing this. Fredkin and Toffoli [34] described a ballistic "billiard ball model" (BBM) of reversible computation based on collisions between idealized elastic spheres. Their original model contained chaotic instabilities, although these can be easily fixed by confining the balls to travel along valleys in configuration space, and by keeping them time-synchronized through a few additional mechanical interactions. A concrete example of an electronic model similar to the BBM that avoids these instability problems entirely is described in [40]. Pure-mechanical equivalents of the same synchronization mechanism are also straightforward to design.

Now, the BBM was primarily just a classical model. Richard Feynman and Norm Margolus made some initial theoretical progress in devising a totally quantum-mechanical model of ballistic reversible computation, Feynman with a serial model [48], and Margolus with a self-synchronized parallel model [49]. However, Margolus' model was restricted to allowing parallelism in only one dimension, that is, with only a linear chain of active processors at any time. As of this writing, we do not yet have an explicit, fully detailed, quantum physical model of totally three-dimensional parallel reversible computing. But we *know* that it must be possible, because we can straightforwardly design simple classical-mechanical models that already do the job (essentially, reversible "clockwork") and that do not suffer from any instability or timing-system inefficiency problems. Since these models are *manifestly* physically realizable (obviously

buildable, once you have conceived them), and since all real mechanical systems are, at root, quantum mechanical, a detailed quantum-mechanical fleshing out of these classical-mechanical models, if mapped to the nanoscale, would fit the bill. But significant work is still needed to actually do this translation.

Finally, in general, we should not assume that the best reversible designs in the long run necessarily must be based on the adiabatic bistable-potential-well-type model, which may be unnecessarily restrictive. A more general sort of model of reversible computing consists simply of a dynamic quantum state of the machine's "moving parts" (which may be just spinning electrons) that evolves autonomously according to its own built-in physical interactions between its various subparts. As long as the evolution is highly coherent (almost unitary), and we can accurately keep track of how the quantum state evolves over time, the dissipation will be kept small. The devil is in figuring out the details of how to build a quantum system whose built-in, internal physical interactions and natural evolution will automatically carry out the desired functions of logic, communication, and synchronization, without needing a full irreversible reset of the state upon each operation. But as I stated earlier, we *can* be confident that this is possible, because we can devise simple mechanical models that already do the job. Our goal is just to translate these models to smaller sized and higher frequency physical implementations.

#### 4.1.3. Algorithmic Issues

For now, we take it as given that we *will* eventually be able to build bit devices that *can* operate with a high degree of thermodynamic reversibility (*i.e.*, very small entropy generation per operation), and that the details of ballistic signal propagation and timing synchronization can also be worked out. What, then, can we do with these devices?

One key constraint is that physically reversible devices are necessarily also logically reversible; that is, they perform invertible (one-to-one, bijective) transformations of the (local) logical machine state.

**Debunking Some Misunderstandings** First, the preceding statement (physical reversibility requires logical reversibility) has occasionally been questioned by various authors, due to some misunderstanding either of physics, or of the meaning of the statement, but it is not really open to question! *It is absolutely as certain as our most certain knowledge about physical law.* The reversibility of physics (which follows from the unitarity of quantum mechanics, or from the mathematical form of all Hamiltonian dynamical systems in general) *guarantees* that physics is reverse-deterministic, that is, that a given (pure, quantum) state of a closed system can only have been arrived at along a specific, unique trajectory. Given this fact, any time we have a mechanism that unconditionally erases a bit (*i.e.*, maps both of two distinct initial logical states onto a single final logical state), without regard to any other knowledge that may be correlated to that bit's state, there *must* be a compensatory splitting of some *other* adjoining system from one state into two distinct states, to carry off the "erased" information, so that *no* merging of possible state trajectories happens in the system overall. If the state distinction happens to become lost

somewhere, then it is, by definition, entropy. If the erased bit was itself not already entropy before the erasure, then this entropy is furthermore newly generated entropy, and the mechanism is then by definition not physically reversible. In contrast, if the state information remains explicitly present in the logical state that is transformed in the operation, then the mechanism is by definition logically reversible.

If you think that you have found a way to unconditionally erase known logical bits without generating new entropy (without having also disproved quantum mechanics in the process), then check your work again, a lot more carefully! Such a device would be exactly equivalent to the long-debunked perpetual motion machine [50]. I will personally stake my reputation on your having made a mistake somewhere. For example, did you analyze the “erasure” of a logical bit that was uncorrelated with any other bits and thus was *already* entropy? No new entropy need be generated in that case. Or did you just reversibly decrement a long counter until it was zero, but you forgot that an exactly equal amount of timing information about *when* you finished counting, relative to other subsystems, is still present and still must be got rid of in order to interact with outside systems? Or did you rely on an exponential number of high-energy states all “decaying” to a single slightly lower energy state, while forgetting that the exponentially larger *number* of higher energy states and slow decay rate will mean that there is an exactly equal chance to go the other way and make a transition to occupy the high-energy state instead, excited by thermal noise? These issues are rather subtle, and it is easy to make mistakes when proposing a complicated new mechanism. In contrast, the impossibility proof from basic, uncontroversial axioms of physics is straightforward and easily verified to be correct. If you want to erase logical bits without generating entropy, you will first have to go back and show why most of the basic physics that has been learned in the last 150 years (such as statistical mechanics and quantum mechanics) must be totally wrong, despite agreeing perfectly with all our myriad experiments!

**Algorithmic Overheads** Now, those misconceptions aside, let us take a clear look at the algorithmic issues that result from the need for logical reversibility. (These issues apply equally whether the logic of the particular computation is implemented in hardware or in software.) Apparently, the requirement of logical reversibility imposes a nontrivial constraint on the types of algorithms we can carry out. Fortunately, it turns out that any desired computation *can* be emulated by a reversible one [38], although apparently with some algorithmic overheads, that is, with some increases in the number of bits or ops required to carry out a given computation.

First, some history: Rolf Landauer of IBM realized, as early as 1961 [19], that information-“destroying” operations such as bit erasure, destructive (in-place) AND, and so forth can be replaced by analogous reversible operations that just move the “erased” information somewhere else rather than really erasing it. This idea is now known as a *Landauer embedding* of an irreversible computation into a reversible one. But, at the time, Landauer thought this approach would pointlessly lead to an accumulation of unwanted information in storage that would still have to be irreversibly erased

eventually. In 1963, Yves Lecerf [51], working independently on a related group theory problem, reinvented the Landauer embedding and furthermore noted that the intermediate results could also be reversibly *uncomputed* by undoing the original computation. We call this idea *Lecerf reversal*. In 1973, Charles Bennett independently rediscovered Lecerf reversal [38], along with the observation that desired results could be reversibly copied (known as a *Bennett copy*) before undoing the computation. Simple as it was, this was the final key insight showing that computation did not necessarily require entropy generation, as it revealed that a given area of working storage could indeed be reversibly reused for multiple computations that produce useful results. All of these ideas were independently rediscovered in a Boolean logic circuit context by Ed Fredkin and Tom Toffoli during their work on *information mechanics* at MIT in the late 1970s [34].

Unfortunately, although the extra storage taken up by the Landauer embedding can be reused, it does still at least *temporarily* take up space in the computation and thus contributes to economic spacetime costs. Even this temporary usage was shown not to be technically necessary by Lange et al. [52], who showed how to compute reversibly in general using virtually *no* extra space, essentially by iterating through all possible machine histories. (The technique is very similar to earlier complexity theory proofs showing that deterministic machines can simulate nondeterministic machines in-place, using the same space [53].) But unfortunately, the Lange et al. technique is not at all close to being practical, as it generally requires taking an exponentially longer time to do the computation.

Today, we know of a continuous spectrum of possible trade-offs between algorithmic space and time overheads for doing reversible computation. In 1989, Bennett described a space of trade-offs between his original technique and a somewhat more space-efficient one [54], and later work by Williams [55] and Burhman et al. [56] showed some ways to extrapolate between the Bennett-89 approach and the Lange et al. one. However, these latter approaches are apparently not significantly more efficient in terms of overall *spacetime* cost than the older Bennett-89 one. It is, however, possible to reduce the spacetime cost of the Bennett-89 algorithm by simply increasing its degree of parallelization (activity factor, hardware efficiency) so that less time is spent waiting for various subcomputations. But this apparently gives only a small improvement also.

At present, we do not know how to reversibly emulate arbitrary computations on reversible machines without, at least, a small polynomial amount of spacetime overhead. It has been conjectured that we cannot do better than this in general, but attempts (such as [57]) at a rigorous proof of this conjecture have so far been inconclusive. So, as far as we know right now, it is conceivable that better algorithms may yet be discovered. Certainly, we know that much more efficient algorithms do exist for many specific computations, sometimes with no overhead at all for reversible operation [4]. But Bennett’s algorithm and its variations are the best we can do currently for *arbitrary* computations.

Given the apparent algorithmic inefficiencies of reversible computing at some problems, as well as the limited quality factor of reversible devices even for ideal problems, it does not presently make sense to do all computations in a *totally*

reversible fashion. Instead, the computation should be broken into pieces that are internally done reversibly, but with occasional irreversible logical operations in between them. The size of the reversible pieces should be chosen so as to maximize the overall cost efficiency, taking into account both the algorithmic overheads and the energy savings, while optimizing the parameters of the emulation algorithms used. Examples of how to do this via analytical and numerical methods are illustrated in [5, 21, 58]. That work shows that reversible computing remains advantageous for overall cost efficiency, despite its algorithmic overheads, even for worst-case types of computations, for which we do not know of any better reversible algorithm than Bennett's.

In cases where the reversible devices have a high quantum quality  $q$ , it turns out to make sense to do a substantial amount of reversible computing in between irreversible operations. Since the most efficient use of these reversible computing resources may, in some cases, call for a hand-optimized reversible algorithm, the architecture and programming model should best include directives that directly expose the underlying reversibility of the hardware to the programmer, so that the programmer (as algorithm designer) can perform such optimizations [4]. In other words, the algorithm designer should be able to write code that the architecture *guarantees* will be run reversibly, with *no* unnecessary overheads. Some examples of architectures and programming languages that allow for this can be found in [4, 59, 60].

Can the machine's potential reversibility be totally hidden from the programmer while still preserving asymptotic efficiency? Apparently not. This is because the best reversible algorithm for a given problem may in general have a very different form than the best irreversible algorithm [4]. So we cannot count on the compiler to automatically map irreversible code to the best reversible code, at least, given any compiler technology short of a very smart general-purpose artificial intelligence which we could rely on to invent optimal reversible algorithms for us.

How hard is it to program in reversible languages? At first it seems a little bit strange, but I can attest from my own experience that one can very quickly become used to it. It turns out that most traditional programming concepts can be mapped straightforwardly to corresponding reversible language constructs, with little modification. I have little doubt that shortly after reversibility begins to confer significant benefits to the cost efficiency of general-purpose computation, large numbers of programmers, compiler writers, *etc.* will rush to acquire the new skills that will be needed to harness this new domain, of computing at the edge of physics.

However, even reversible computing does not yet harness all of the potential computational power offered by physics. For that, we must turn our sights a bit further beyond the reversible paradigm, toward *quantum computing*.

## 4.2. Quantum Computing

### 4.2.1. Generalizing Classical Computing Concepts to Match Quantum Reality

The core fact of quantum mechanics is that not all of the conceivable states of a physical system are actually operationally distinguishable from each other. However, in the

past, computer scientists artificially constrained our notion of what a computation fundamentally *is*, by insisting that a computation be a trajectory made up of primitive operations, each of which takes *any* given legal state of the machine and changes it (if at all) to a state that is *required* to be operationally distinguishable from the original state (at least, with very high probability). For example, a traditional Boolean NOT gate, or logical *inverter*, is designed to either leave its output node unchanged (if its input remains the same), or to change its output to a new state that is clearly distinct from what it was previously.

But really this distinguishability restriction on operations was an *extra* restriction that was, in a sense, arbitrarily imposed by early computer designers, because this type of operation is *not* the only type that exists in quantum mechanics. For example, when a subatomic particle's spin is rotated  $180^\circ$  around its  $x$  axis, if the spin vector was originally pointing up ( $+z$ ), it will afterward be pointing down ( $-z$ ), and this state is completely distinct from the up state. But if the spin was originally pointing at an angle *halfway between* the  $x$  and  $z$  axes, then this operation will rotate it to an angle that is only  $90^\circ$  away from its original angle (namely, halfway between the  $x$  and  $z$  axes). This spin state is *not* reliably distinguishable from the original. Although it is at right angles to the original state in 3D space, its *state vector* is *not* orthogonal to the original state in the *Hilbert space* of possible quantum state vectors. Orthogonality in Hilbert space is the technical quantum-mechanical requirement for distinguishability of states. Thus, the operation "rotate a spin by  $180^\circ$  around a given axis" does not change *all* states by orthogonalizing amounts, only *some* of them.

What if we allow a computation to be composed of operations that do *not* necessarily change all legal states by an orthogonalizing amount? Then the new state after the operation, although possibly different from the original state, will not necessarily be reliably observationally distinguishable from it. However, if we do not try to observe the state but instead just let it continue to be processed by subsequent operations in the machine, then this lack of distinguishability is not necessarily a concern. It can simply be the situation that is intended. In essence, by loosening our requirement that every state of the computation be distinguishable from the previous one, we open up the possibility of performing new types of operations, and thus traversing new kinds of trajectories through state space, ones that were not previously considered to be legal computations.

Does this new possibility confer additional computational power on the model? We cannot prove that it does, but it is currently strongly believed to. Why? Because specific, well-defined algorithms have been found that use these new types of trajectories to perform certain kinds of computational tasks using exponentially fewer operations than with the best classical algorithms that we know of [3]. In other words, opening up this larger space of operations reveals drastic "shortcuts" through state space; that is, transformation trajectories that get us to where we want to go using exponentially fewer steps than the shortest classical paths that we know of.

The two most important examples of these apparent exponential shortcuts that have been found so far are the

following: (1) Shor's quantum factoring algorithm [61] and (2) simulations of quantum systems [62].

Shor's factoring algorithm can factor  $n$ -digit numbers using a number of quantum operations that increases only quadratically with the number of digits  $n$ , whereas the best known classical algorithms require time that increases exponentially in the number of digits. The primary application of Shor's algorithm would be to break the public-key cryptosystems such as RSA [63] that are popularly used today for encryption and authentication of data for e-commerce and other purposes over the internet. For example, someone armed with a good-sized quantum computer and eavesdropping on your internet connection could steal your account information whenever you do home banking or credit-card purchases over a supposedly secure `https`: or secure socket layer connection that uses RSA for security. In other words, that little padlock icon in your web browser gives you no protection against a quantum computer!

However, perhaps a more widely useful application for quantum computers is to simulate quantum physics. This was the original motivation for quantum computers that was proposed by Feynman [64]. We now know that the statistical behavior of any quantum-mechanical system can be accurately simulated in polynomial time on a quantum computer [62], even though quantum systems in general seem to require *exponential* time to simulate accurately on *classical* (nonquantum) computers.

Another quantum algorithm that is useful, but that provides a less-than-exponential speedup, is Grover's quantum "database search" algorithm that can locate a specified item, out of  $n$  items, in  $\Theta(n^{1/2})$  lookup steps [65].

However, Grover's algorithm is, unfortunately, misnamed, since it is not really useful at all for real database searches, in the usual sense of the term "database," meaning an explicit table of arbitrary data. First, such a table, in general, requires just as much space to store in a quantum system as in a classical one (see "Myth #1"). Also, real commercial databases always include the capability to index the table by the most commonly used types of search keys, in which case a lookup, even on a classical computer, already requires only  $\Theta(1)$  lookup step. More precisely, the time required scales like  $\Theta(n^{1/3})$  or  $\Theta(n^{1/2})$ , if the speed-of-light travel time to the desired search item in 3D space or on a 2D surface is taken into account. But this is still less than in Grover's algorithm.

Also, even if the database is *not* indexed by the desired type of search key, if the data are stored in a processing-in-memory architecture, in which each area of storage of some constant size has an associated processor, then lookup can be done in parallel, achieving the same light-limited  $\Theta(n^{1/3})$  time, or at least  $\Theta(n^{1/2})$  time, if the machine must be laid out in two dimensions, rather than three. Anyway, in random-data-lookup applications where the speed-of-light travel time to the data is the limiting factor, Grover's algorithm cannot help us.

However, Grover's algorithm is still useful, not for database search, but rather for a different kind of application called *unstructured search of computed (not tabulated) search spaces*. This is because a search space can be much larger than the physical size of the machine if the "data values" (really, function values) are computed as a *function*

of the data's index, rather than being explicitly stored. In cases where no more efficient algorithm is known for "inverting" the function (that is, finding an index that maps to a given value), Grover's algorithm can still be used to obtain a speedup, although not one that is so large as is traditionally claimed. A simple classical parallel search can still outperform the *serial* Grover's algorithm in terms of time alone; for example, if  $\Theta(n^{3/4})$  processors simultaneously each search a different  $\Theta(n^{1/4})$ -size piece of the search space, the search can be completed in  $\Theta(n^{1/4})$  time classically in 3D space. However, given Grover's algorithm, we can use a smaller number  $\Theta(n^{3/5})$  of processors, each searching  $\Theta(n^{2/5})$  items in  $\Theta(n^{1/5})$  time. But note that the speedup is now only  $\Theta(n^{1/4})/\Theta(n^{1/5}) = \Theta(n^{1/20})!$  However, the benefit in terms of *spacetime* cost can be still as great as  $\Theta(n^{1/2})$ , since a single quantum processor searching for  $\Theta(n^{1/2})$  time consumes only  $\Theta(n^{1/2})$  spacetime, whereas the best classical unstructured search through  $n$  items requires  $\Theta(n)$  spacetime.

#### 4.2.2. Dispelling Some Myths

In addition to the misconceptions arising from the inappropriate association of Grover's algorithm with database search, there are a few other popular myths about quantum computers that, although widely repeated, are entirely false, and we would like to dispense with them here and now.

**Myth #1** "Quantum computers with a given number of bits can store exponentially more information than classical computers having the same number of bits."

This is patently false, because the maximum amount of information that can be stored in any physical system is just the logarithm of its number of *distinguishable* states. Although an  $n$ -bit quantum computer can be put into an infinite number of different quantum states, only  $2^n$  of these states can be reliably differentiated from each other by *any physical means whatsoever*, no matter how cleverly you try to design your measurement apparatus. In other words, the presence of all those extra, "in-between" superposition states can have *zero* causal impact on the total amount of information you can reliably extract from the system. This basic feature (or "bug" if you prefer) of all physical systems was demonstrated convincingly by Heisenberg long ago [25].

**Myth #2** "Quantum computers can perform operations at an exponentially faster rate than classical computers."

This is also false, because the Margolus–Levitin bound on processing speed [18] applies to quantum computers as well as classical ones. Operations (if defined as transformations that orthogonally transform some states) can only be performed, at best, at the rate  $4E/h$ , or  $2E/h$  for nontrivial ops, for a system of average energy  $E$  above its ground state. Small *pieces* of operations (small transformations that do not orthogonally transform any states) may be done more often [66], but these pieces arguably also perform correspondingly less computational work than do complete operations.

Why? Note that a *small piece* of a (primitive orthogonalizing) operation (which transforms *every* state into a new state that is almost completely indistinguishable from the original) can be omitted *entirely* from a computation, and the end result of the computation will necessarily be almost completely indistinguishable from the case where

that small “operation piece” was included. (This is because the property of the near-indistinguishability of the two states *must* be preserved by *any* subsequent operations on the system—otherwise, the states would not be indistinguishable! Mathematically, this is ensured by the linearity of quantum evolution.) So it is fair to count the computational work performed by a transformation by counting the number of *complete* operations, as we have defined them (transformations that at least orthogonalize *some* states). Whether or not a given operation orthogonalizes the actual computational state that is presented to it as its input in a specific situation is another question altogether. It need not do so in order for the operation to be considered useful. For example, an ordinary “AND” gate, upon receiving new inputs, is considered to be doing useful work even when its output does not change. Namely, it is doing the work of determining *that* its output should not change.<sup>1</sup> Similarly, a quantum operation that does not orthogonalize its actual initial state, but that might orthogonalize others, is, at least, doing the work of determining *that* that specific input is not one of the ones that was supposed to have been orthogonalized.

Therefore, the Margolus–Levitin bound does indeed give a valid limit on the rate of useful operations that can be performed in *any* computer (classical or quantum).

The correct interpretation of why a quantum computer provides exponentially faster algorithms for some problems (such as factoring, and simulating quantum physics) is *not* that the quantum computer is carrying out operations at an exponentially more frequent rate, but *rather* that the new *types* of operations that can be performed by the quantum computer make use of the fact that there actually exist exponentially shorter paths (requiring exponentially fewer total operations to traverse) leading from the input state to the desired final state than was previously recognized.

As an analogy: Suppose you have a computer with integer registers, but the only arithmetic operation provided is “decrement/increment,” which subtracts 1 from one register, while adding 1 to another register. With this operation, you could still add two registers together, by repeatedly performing this operation on the two registers, until the first one equals zero. But this would generally take exponential time in the length of the registers. Now, suppose we introduce a new operation, which is the standard direct bitwise ripple-carry add of one register into the other. Then, the add only takes time proportional to the length of the registers. Thus we have gained an “exponential speedup” for the add operation, but not by doing increment/decrement operations exponentially more frequently, but rather by choosing a type of operation that allows us to do an exponentially smaller number of steps in order to get to the result that we want.

The key insight of quantum computing was that nature provides for us a type of operation (namely, operations that might incompletely orthogonalize some input states) that was not previously recognized in any of our early computing models and that, moreover, adding this kind of operation allows some problems to be solved using exponentially fewer total operations than was previously realized. Therefore, omitting the capability of performing quantum operations from our future computer designs is, in a sense,

just as foolish as omitting the capability for bitwise addition (as opposed to just decrement/increment) from the design of our arithmetic units!

One caveat is that, at present, only a few kinds of problems (such as those mentioned previously) have been found so far for which quantum operations provide a drastic speedup. However, since a low decoherence rate will eventually be needed anyway, in order to allow for high-speed reversible operations that avoid excessive dissipation, it makes sense for us to aim toward a full quantum computing technology in the long run. Also, quantum computing is still only in its infancy, and many useful new quantum algorithms may yet be discovered.

**Myth #3** “Quantum computers are known to be able to solve nondeterministic polynomial (NP)-complete problems in polynomial time.”

If this were true, it would be wonderful, because all problems whose solutions can be *checked* in polynomial time (this is the definition of the NP problems) could then also be *solved* in polynomial time using a quantum computer. Among other applications, this would revolutionize the way we do mathematics, because very complex proofs of difficult mathematical theorems could be found very quickly by computer, that is, in time only polynomial in the length of the proof. Unfortunately, no one has shown a way to use quantum computers to solve NP-hard problems efficiently, and furthermore, a result due to Bennett et al. [67] provides some mild theoretical evidence suggesting that it is not possible. The factoring problem and other problems that apparently do have exponential shortcuts from using quantum computing have never been proven to be NP-complete, so they do not constitute examples of NP-complete problems that can be efficiently solved on a quantum computer. However, more research on this question is needed.

**Myth #4** “Quantum computers have been proven to be far more powerful than classical computers.”

First, we know that a quantum computer can be perfectly simulated by a classical computer, though most likely this requires exponential slowdown. So any problem solvable on a quantum computer can be *eventually* solved on a classical computer, given unbounded resources. So quantum computers are not *any* more powerful in terms of the *kinds* of problems that they can solve *at all* in principle; rather, at best, they are just exponentially *more efficient* at solving some problems. But even the exponential efficiency advantage has never *really* been proven. For all we know *for sure* today, there could still exist a (not yet discovered) polynomial-time classical algorithm for simulating all quantum computers, in which case every efficient quantum algorithm could be translated to a similarly efficient classical one. Other than in various artificial oracle scenarios, we still have no rock-solid proof that quantum computers confer *any* extra computational power, although most researchers expect that they do. Moreover, for practical purposes today, they *would effectively* confer that exponential extra power, because of the existing problems for which the best quantum algorithm we know is far more efficient than the best classical algorithm we know. But this situation could change someday, if equally efficient classical algorithms were eventually to be discovered, which has not (yet) been proven to be impossible.

<sup>1</sup> Seth Lloyd pointed out this analogy to me in personal discussions.

**Myth #5** “Quantum computers require exponential space to simulate on a classical computer.”

This myth is often quoted as the “reason” simulating a quantum computer on a classical one must also take exponential time. But the myth is simply not true; it has been recognized since at least 1992 [68] that a polynomial-space simulation of quantum computers on classical ones is easy. The technique used is pretty obvious to anyone who is familiar with Feynman’s path-integral formulation of quantum mechanics, which has been around much longer. It tells us that the amplitude of a given final basis state can be computed via a sum over trajectories (here, sequences of basis states) that terminate at that final state. A given sequence requires only polynomial space to store, and we can just iterate serially through all possible sequences, accumulating the final state’s net amplitude. This is all that is needed to compute the statistical behavior of the quantum system (*e.g.*, quantum computer) being simulated.

**Myth #6** “Large-scale quantum computers are fundamentally impossible to build, due to the phenomenon of decoherence.”

Our best models to date tell us that this is not so. We only require a quantum device technology that has a quality factor  $q$  that is above a certain finite threshold (currently estimated to be around  $10^3$ – $10^4$ ) [69] that allows known robust, fault-tolerant quantum error-correction algorithms to be applied, thereby allowing the scale of the achievable computations to be scaled up *arbitrarily*, just as classical error correction techniques allow classical computations to be scaled up arbitrarily, despite the small but not perfectly zero error rates in current-day bit devices. A high quality factor like this will be required anyway, if we wish to ever perform computation at rates well beyond those planned in the present semiconductor roadmap, which would imply computational temperatures that would quickly melt the computer’s structure, if the computational degrees of freedom were not extraordinarily well isolated from interactions with structural ones. So quantum computing is, in a sense, no harder than any technology that aims at capabilities well beyond the present semiconductor roadmap. Of course, many important engineering details remain to be worked out.

However, for a densely packed, 3D parallel quantum computer to be able to handle a noticeable rate of decoherence using fault-tolerant error correction techniques may require hardware implementation of the error correction algorithms, internally to the processor’s architecture, rather than just in software. Because of this, a quantum computer requires a somewhat different and more elaborate hardware architecture, as compared with a simple reversible computer, which would not need to maintain superposition states and so could make do with simple classical approaches to error correction, such as encoding computational bits redundantly in numerous physical bits, whose values can be “replenished” to stay locked with their nominal value by more trivial mechanisms (*e.g.*, by connecting a voltage-coded circuit node statically to a reference power supply, as is done in ordinary static CMOS logic circuits today).

### 4.2.3. Implementation Technologies

Many potential implementation technologies for quantum computers have been proposed and are being experimented on. These include nuclear spin systems [70], electron spin systems [71], superconducting current states of various sorts [72], and even mechanical vibrational systems [73]. To date, all of these approaches rely on an externally supplied signal for control and timing of operations. (As Lloyd says, “Almost anything becomes a quantum computer if you shine the right kind of light on it.”) But really, there seems to be no fundamental reason why the generator of the programmed control signal could not eventually be integrated with the actual devices, in a more tightly coupled fashion. For scalability to large arrays of self-timed processors, synchronization becomes a concern but can presumably be handled in much the same ways as we discussed for the case of reversible processors earlier.

### 4.2.4. Architectures and Programming Models

A self-contained quantum computer architecture looks very similar to a classical reversible architecture, but with some added instructions that can perform quantum operations that might not orthogonalize the input state. In principle, it suffices to include a single quantum instruction operating on a one-bit register, while keeping all other instructions simply coherent classical reversible [74], but a larger variety of quantum operations would probably also be useful. A self-contained, stored-program quantum architecture should probably have built-in support for fault-tolerant error correction algorithms, to avoid the overheads of implementing these in software. However, it is important to note that the entire architecture need not be coherent at all times, only the parts that are directly storing and manipulating the quantum data of interest. It may be beneficial to design each processor as a classical reversible processor (kept reversible and mildly coherent for speed and energy efficiency) paired with a relatively small quantum subprocessor whose state is kept highly coherent through the use of quantum error correction. The quantum component might be kept at a relatively low temperature to help avoid decoherence, since its speedups come from the use of superpositions in quantum algorithms, not from a fast operation rate (high computational temperature). Meanwhile, the classical part of the processor can perform in software, at relatively much higher frequencies, the meta-computation needed to determine which quantum operation should be performed next on the quantum subprocessor.

However, if a much wider range of useful quantum algorithms is eventually discovered, we may eventually find ourselves wishing to do quantum operations more pervasively throughout a wider range of applications, and also at higher frequencies, in which case the quantum functions might be integrated more thoroughly into the primary reversible processor. Without the availability of a classical processor running at higher speed, more of the low-level quantum algorithms such as error correction would need to be done “in hardware,” incorporated directly into the design, arrangement, and interactions of the individual quantum devices. The technique of using decoherence-free subspaces [75] provides one example of how to cope with errors

directly in the hardware design. Other methods may eventually be discovered.

Now, given our recognition of the need to incorporate the possibility of reversibility and quantum computing into our nanocomputer models, while respecting fundamental physical constraints as well, what will the resulting nanocomputer models look like? Let us take a look.

## 5. GENERIC REALISTIC MODEL OF NANOCOMPUTERS

In this section, we give a detailed example of what we consider to be a reasonably simple, realistic, and efficient model of computing which remains valid at the nanoscale. It is realistic in that it respects all of the important fundamental constraints on information processing except for gravity, which, unlike the other constraints, is not expected to become relevant yet within the coming half-century of technological development. The model is efficient in that it is not expected to be asymptotically less cost efficient (by more than a constant factor) than any other model that respects all of the same fundamental physical constraints. To achieve this, it must recognize the possibility of reversible and quantum computing.

The focus of this particular model is on enabling the analysis of the complete cost-efficiency optimization of parallel computer systems, when simultaneously taking into account thermodynamic constraints, communications delays, and the algorithmic overheads of reversible computing.

### 5.1. Device Model

A machine instance can be subdivided into logical *devices*. The total number of devices in the machine can be scaled up with the memory requirement of the given application.

Each device has a *logical state*, which is an encoded, desired classical or quantum state (possibly entangled with the state of other devices) for purposes of carrying out a classical or quantum computation. The logical state is encoded by a *coding physical state*, which is the portion of the device's physical state that encodes (possibly redundantly) the desired logical state. The device will probably also have a *noncoding physical state*, which is the rest of the device's physical state, which is not used for encoding computational information. The noncoding state can be further subdivided into a *structural state*, which is the part of the state that is required to remain constant in order for the device to work properly (if it is changed, the device becomes defective), and the *thermal state*, which is the unknown part of the device's physical state that is free to change because it is independent of the logical and structural state and so is not required to remain constant in order to maintain proper operation.

The device mechanism can be characterized by the following important parameters. In any given technology, the value of each of these parameters is assumed to be designed or required to fall within some limited range, for all devices in the machine.

- **Amount of logical information**,  $I_{\text{log}}$ , that is, information in the logical subsystem.

- **Amount of coding information**,  $I_{\text{cod}}$ , that is, information in the coding subsystem (in which the logical subsystem is represented).
- **Amount of thermal information**,  $I_{\text{therm}}$ , that is, information in the thermal subsystem, given the device's allowed range of thermal temperatures.
- **Computational temperature**  $T_{\text{cod}}$  of the coding state. This is the rate at which minimal desired changes to the entire coding state (*steps*) take place, that is, transitions which change all parts of the coding state in a desired way. Its reciprocal  $t_{\text{cod}} = 1/T_{\text{cod}}$  is the time for a step of updating the coding state to take place.
- **Decoherence temperature**  $T_{\text{dec}}$ . The rate at which undesired coding-state steps take place due to unwanted, parasitic interactions between the coding state and the thermal/structural state of the device or its environment. Its reciprocal  $t_{\text{dec}} = 1/T_{\text{dec}}$  is the decoherence time, the characteristic time for coding state information to be randomized.

Of course, it is desirable to select the coding subsystem in a way that minimizes the decoherence rate; one way to do this is to choose a subsystem whose state space is a *decoherence-free subspace* [75], or one that is based on *pointer states*, which are those states that are unaffected by the dominant modes of interaction with the environment [76]. The stable, "classical" states that we encounter in everyday life are examples of pointer states. Of course, even in nominal pointer states, some residual rate of unwanted interactions with the environment always still occurs; that is, entropy always increases, however slowly.

- **Thermal temperature**  $T_{\text{therm}}$ . The rate at which the entire thermal state of the device transforms. This is what we normally think of as the ordinary thermodynamic operating temperature of the device.
- **Decay temperature**  $T_{\text{struc}}$ . The rate at which decay of the device's structural state information takes place. It depends on the thermal temperature and on how well the structural subsystem's design isolates its state from that of the thermal degrees of freedom in the device. Its reciprocal  $t_{\text{struc}}$  is the expected time for the device structure to break down.
- **Device pitch**  $l_p$ . For simplicity, we can assume, if we wish, that the pitch is the same in orthogonal directions, so the device occupies a cube-shaped volume  $V_d = l_p^3$ . (This assumption can be made without loss of generality, since devices of other shapes can always be approximated by a conglomeration of smaller cubes. However, allowing alternative device shapes may give a simpler model overall in some cases.)

We are also assuming here that the region of space occupied by distinct devices is, at least, nonoverlapping, as opposed to (for example) different devices just corresponding to different degrees of freedom (*e.g.*, photonic vs electronic vs vibrational modes) within the same region. Again, this is not really a restriction, since such overlapping phenomena could be declared to be just internal implementation details of a single device whose operation comprises all of them simultaneously. However, we can loosen this no-overlap restriction if we wish. But if we do so, care should be taken not to

thereby violate any of the fundamental physical limits on entropy density, *etc.*

- **Information flux density**  $I_{\text{At}}$  (rate of information per unit area) through the sides of the device. This includes all physical information such as thermal entropy (flux  $S_{\text{At}}$ ) or redundant physical coding information (flux  $I_{\text{At,cod}}$ ) of logical bits (flux  $I_{\text{At,log}}$ ). Note that since the motion of information across the device boundary constitutes a *complete update step* for the location of that information, we know that  $I_{\text{At}} \ell_p^2 \leq IT$  where  $I$  is the information of a given type within the device, and  $T$  is the temperature (rate of updating) of the location information for that type of information.

Additionally, one of course also needs to define the specifics of the internal functionality of the device. Namely, what intentional transformation does the device perform on the incoming and internal coding information, to update the device's internal coding information and produce outgoing coding information? To support reversible and quantum computing, at least some devices must reversibly transform the coding information, and at least some of these devices must perform nonorthogonalizing transformations of some input states.

The device definition may also provide a means to (irreversibly) transfer the content of some or all of its coding information directly to the thermal subsystem, causing that information to become entropy.

For example, a node in static or dynamic CMOS circuit effectively does this whenever we dump its old voltage state information by connecting it to a new fixed-voltage power supply. However, a metal-oxide-semiconductor field effect transistor's (MOSFET) built-in dynamics can also be used to transform coding states *adiabatically*, thereby avoiding transformation of all of the coding information to entropy.

Most generally, the device's operation is defined by some reversible, unitary transformation of its entire state (coding, thermal, and structural), or, if the transform is not completely known, a statistical mixture of such. The actual transformation that occurs is, ultimately, predetermined solely by the laws of quantum mechanics and the state of the device and its immediate surroundings. So device design, fundamentally, is just an exercise of "programming" the "machine" that is our universe, by configuring a piece of it into a specific initial state (the device structure) whose built-in evolution over time automatically carries out a manipulation of coding information in such a way that it corresponds to a desired classical or quantum operation on the encoded logical information.

As we will see, this notion of a device is general enough that not only logic devices but also interconnects, timing sources, and power supply/cooling systems can be defined in terms of it.

## 5.2. Technology Scaling Model

The technology scaling model tells us how functional characteristics of devices change as the underlying technology improves. Just from basic physical knowledge, we already know some things about the technological characteristics of

our device model:

First,  $I_{\text{log}} \leq I_{\text{cod}}$ . That is, the amount of logical information represented cannot be greater than the amount of physical information used to do so. We can thus define the *redundancy factor*  $N_r \stackrel{\text{def}}{=} I_{\text{cod}}/I_{\text{log}} \geq 1$ .

Next, note that for devices that are *occupied* by information of interest (that is, actively maintaining a desired logical state), the rate  $S_{\text{dt}}$  of standby entropy generation is at least  $I_{\text{cod}} T_{\text{dec}}$  as coding information decays. The coding state of devices that are not occupied (not currently allocated for holding information) can be allowed to sit at equilibrium with their thermal environment, so their rate of standby entropy generation can be zero (or more precisely, some extremely low rate determined by the rate of structural decay  $T_{\text{struc}}$ ).

Next, if we assume that changing a logical bit is going to in general require changing all  $N_r$  of the physical bits used to redundantly encode it, we can immediately derive that logical bits, as well as physical bits, change at most at the rate  $T_{\text{cod}}$  [77]. If the computational temperature were only room temperature (300 K), then, expressed in terms of ops ( $h/2$ ) per bit ( $k_B \ln 2$ ), this temperature would allow a maximum rate of only one bit-op per 0.115 ps, that is, a bit-device operating frequency of at most 10 THz.

Note that this operating frequency is only about a factor of 3000 times faster than the actual  $\sim 3$  GHz working clock speeds in the fastest microprocessors that are currently commercially available, and furthermore it is only about a factor of 10 faster than the fastest present-day NMOS switches (which already have minimum transition times of  $\sim 1$  ps [6]) are theoretically capable of. By 2016, minimum transition times are planned to be almost as small as 0.1 ps, according to the semiconductor industry's roadmap [6]. So, in other words, taking device speeds significantly beyond the end of the present semiconductor roadmap will *require* temperatures in the computational degrees of freedom that are significantly *above* room temperature. This does not conflict with having *structural* temperatures that are relatively close to room temperature (to prevent the computer from melting), insofar as the computational degrees of freedom can be well isolated from interactions with the thermal and structural ones. But such isolation is desired anyway, in order to reduce decoherence rates for quantum computations and entropy generation rates for reversible classical computations.

Looking at the situation another way, given that increasing operating frequency significantly beyond the end of the semiconductor roadmap would require computational temperatures at significant multiples of room temperature, and given that solid structures melt at only moderate multiples of room temperature, the computational degrees of freedom *must* become increasingly well isolated from interactions with the rest of the system. This high-quality isolation, in turn, in principle enables reversible and quantum computation techniques to be applied. In other words, going well beyond the semiconductor roadmap requires entering the regime where these alternative techniques should become viable.

Let us look more carefully now at entropy generation rates. Since a step's worth of desired computation is carried out each  $t_{\text{cod}} = 1/T_{\text{cod}}$  time, whereas a step of unwanted

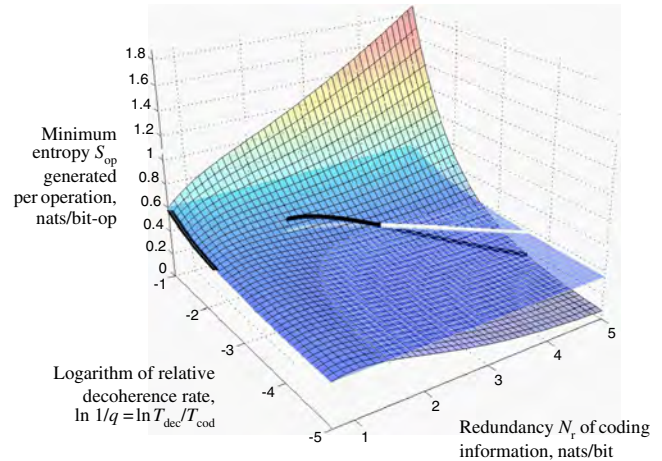

state modifications occurs each  $t_{\text{dec}} = 1/T_{\text{dec}}$  time, a key measure of the quality of the device technology is given by  $q = t_{\text{dec}}/t_{\text{cod}} = T_{\text{cod}}/T_{\text{dec}}$ , the ratio between decoherence time and state-update time, or in other words between state update rate and rate of state decay. Since the unwanted decay of a bit effectively transforms that bit into entropy, the entropy generated per desired logical bit operation must be at least  $N_r/q \geq 1/q$  bits, even for logically reversible operations. Note that our  $q$  is, effectively, just another equivalent definition for the quality ratio  $Q$  (the fraction of energy transferred that is dissipated by a process) that is already commonly used in electronics. We use lower case here to indicate our alternative definition in terms of quantum decoherence rates.

Now, for specific types of devices, we can derive even more stringent lower bounds on entropy generation in terms of  $q$ . For example, in [77], we show that for field-effect based switches such as MOSFETs, the entropy generated must be at least  $\sim q^{0.9}$ , with the optimal redundancy factor  $N_r$  to achieve this minimum growing logarithmically, being  $\sim 1.12 \lg q$ . However, it is reassuring that in this more specific device model, entropy generation can still go down *almost* as quickly as  $1/q$ . It may be the case that all reversible device models will have similar scaling. The key assumption made in that analysis is just that the amount of energy transfer required to change the height of a potential energy barrier between two states is of the same magnitude as the effected amount of change in height of the barrier. If this is true in all classes of reversible logic devices, and not just in field-effect-based devices, then the results of [77] hold more generally. See Figures 2 and 3.

However, in contrast to the reversible case, *irreversible* erasure of a bit of logical information by direct means (*e.g.*, grounding a voltage node) in general requires discarding *all*  $N_r$  of the redundant bits of physical information that are associated with that bit, and thus generating  $N_r$  bits of physical entropy which must be removed from the machine. At best, at least 1 bit of physical entropy must be generated for each logical bit that is irreversibly erased (see discussion in Section 5.2.5). Thus, when the device quality factor  $q$  is large (as must become the case when computational rates far exceed room temperature), the reversible mode of operation is strongly favored.

### 5.3. Interconnection Model

For simplicity, we can adopt an interconnection model in which interconnects are just another type of device, or are considered to be a part of the logic devices, and so are subject to the same types of characterization parameters as in our general device model. The machine need not be perfectly homogeneous in terms of its device contents, so interconnects could have different parameter settings than other types of devices. Indeed, they could be physically very different types of structures. However, it is critical that the interconnection model, however it is described, should at least accurately reflect the actual delay for a signal to traverse the interconnect. To save space we will not develop the interconnection model in detail here.

**Figure 2.** Minimum entropy generation per bit-op in field-effect devices, as a function of quality factor  $q$  and redundancy  $N_r$  of physical encoding of logical information. When  $q \leq e^2$ , the function is monotonically nondecreasing in  $N_r$ , but for larger  $q$ , it has a local minimum which first appears at  $N_r = 2$  nats per bit. The black line curving horizontally across the figure traces this local minimum from its first appearance as  $q$  increases. This local minimum becomes the absolute minimum when  $(1/q) \leq 0.0862651, \dots$  (numerically calculated), when the black line dips below the surface that we have visualized by sweeping the left edge of the figure (where  $N_r = 2$  nats/bit, its minimum) through the  $x$  direction. (The white line is there only to help visualize how far above or below that surface the black line lies at a given  $q$ .) The other black line, along the left edge of the figure, marks the approximate range of  $q$  values for which  $N_r = \ln 2$  nats/bit is indeed the optimal choice. Note that as  $q$  increases, ever-lower entropy generation per bit-op becomes possible, but only by increasing the redundancy of the encoding (which raises energy barriers and improves the achievable on/off power transfer ratios).

### 5.4. Timing System Model

Again, for simplicity, we can assume that timing synchronization functions are just carried out in special devices designated for this purpose or are integrated into the logical devices. Timing synchronization (correction of errors in timing information) can be carried out in an entirely local fashion. This is illustrated by the extensive literature on clockless (self-timed, or asynchronous) logic circuits. Reversible circuits cannot be allowed to operate in a completely *asynchronous* mode, in which substantial-size timing errors are constantly appearing and being corrected, since each synchronization operation would be irreversible and thus lossy, but they *can* be maintained in a closely synchronized state via local interactions only. Margolus showed explicitly how to do this in a simple 1D quantum model in [49]. But it is also clear that locally synchronized reversible operation can be generalized to three dimensions, just by considering simple mechanical models in which arrays of high-quality mechanical oscillators (*e.g.*, springs or wheels) are mechanically coupled to their neighbors (*e.g.*, via rigid interconnecting rods like those between the wheels on an old steam locomotive). An interesting research problem is to develop analogous reversible local-synchronization mechanisms that are entirely electronic rather than mechanical or, if this is impossible, prove it.

**Figure 3.** Scaling of optimal redundancy factor and maximum entropy reduction with decreasing relative decoherence rate. In the graph, the horizontal axis sweeps across different  $q$  factors (decreasing values of  $1/q$ ), and we show the corresponding optimal choice of  $N_r$  (found via a numerical optimization) and the natural logarithm of the maximum entropy reduction factor (factor of entropy reduction below the reference  $1 k_B = 1$  nat) that may be obtained using this choice. The thin, straight trend lines show that for large  $q$  (small  $1/q$ ), the optimal  $N_b$  (for minimizing  $\Delta S$ ) scales as roughly  $1.1248(\ln q)$ , while the minimum  $\Delta S$  itself scales as about  $q^{0.9039}$ .

### 5.5. Processor Architecture Model

For purposes of analyzing fundamental trade-offs, this need not be particularly restrictive. A processor should contain some memory, with a low standby rate of entropy generation for bits that are occupied but are not being actively manipulated, and zero standby rate of entropy generation in unallocated, powered-down bits (after they equilibrate with their environment). The processor should contain some logic that can actively process information in some way that can be programmed universally (any desired program can be written, given sufficiently many processors). It should be able to perform fully logically reversible operations which are carried out via reversible transformations of the coding state. Some examples of reversible architectures can be found in [4, 59, 60, 78, 79]. For convenience, the architecture should also permit irreversible operations which treat the information in the coding state as entropy and transfer it to a noncoding subsystem that is basically just a heat flow carrying entropy out of the machine. (There is no point in keeping unwanted information in a coded state and wasting error correction resources on it.) However, the reversible operations provided by the architecture should also allow an alternative, of *uncomputing* the undesired information, so as to return the coding state to a standard state that can be reused for other computations, without needing to ever treat the coding information as if it were entropy. The architecture should be able to be programmed to efficiently carry out any reversible algorithm.

Ideally, the architecture should also support performing nonorthogonalizing quantum operations (that is, operations

that create quantum superpositions of logical basis states), so that, in combination with classical coherent reversible operations, arbitrary quantum computations can be programmed. If quantum computation is to be supported, simply using classical pointer basis states in the device is no longer sufficient for representing the logical state, and full quantum superpositions of logical basis states (spanning some relatively decoherence-free subspace) should be permitted.

The key criteria are that the architecture should be both physically realistic and universally maximally scalable. These goals, together with ease of programmability, imply that it should look something like we described previously.

### 5.6. Capacity Scaling Model

An ordinary multiprocessor model can be adopted, scaling up total machine capacity (both memory and performance) by just increasing the number of processors. However, we must be careful to be realistic in specifying the interconnection network between the processors. It has been shown that no physically realizable interconnection model can perform significantly better than a 3D mesh model, in which all interconnections are local (*i.e.*, between processors that are physically close to each other) [17]. Moreover, although the planar width of the whole machine can be unlimited, the effective thickness or depth of the machine along the third dimension is inevitably limited by heat removal constraints [4]. However, insofar as reversible operation can be used to reduce the total entropy generated per useful logical operation, it can also increase the *effective* thickness of the machine, that is, the rate of useful processing per unit of planar area [20]. This, in turn, can improve the performance of parallel computations per unit machine cost, since a thicker machine configuration with a given number of processors has a lower average distance between processors, which reduces communication delays in parallel algorithms [4, 58].

### 5.7. Energy Transfer Model

The flow of energy through the model should, ideally, be explicitly represented in the model, to ensure that thermodynamic constraints such as conservation of energy are not somewhere implicitly violated. A piece of energy  $E$  that is changing state at average rate (temperature)  $T$  contains  $I = E/T$  amount of information, by our definitions of energy and temperature. Likewise, for  $I$  amount of information to be transitioning at rate  $T$  requires that energy  $E = IT$  be invested in holding that information. Entropy  $S$  is just information whose content happens to be unknown, so ejecting it into an external atmosphere where it will transition at room temperature, or  $\sim 300$  K, always requires that an accompanying  $S(300 \text{ K})$  energy (heat) also be ejected into the atmosphere. (Or, if the cosmic microwave background is used as a waste heat reservoir, an ambient temperature of  $2.73$  K applies instead.) The same relation between energy, information, and temperature of course applies throughout the system: Whenever an amount of information  $I$  is added to any subsystem that is maintained at a specific, uniform temperature  $T$ , an amount  $E = IT$  of energy must also be added to that subsystem.

Thus, the continual removal of unwanted entropy from all parts of the machine by an outward flow of energy (heat) requires that this lost energy be replenished by an inward-flowing energy supply going to all parts of the machine, complementing the outward heat flow. This inward-flowing supply also has a generalized temperature  $T_{\text{sup}}$  and carries information, which must be known information in a standard state, or at least contain less entropy than the outward flow (otherwise we could not impress any newly generated entropy onto the energy flow).

The total rate of energy flow to the machine's innards and back might be greater than the minimum rate needed for the entropy internally generated to be emitted, if the heat is being moved actively (e.g. by a directed flow of some coolant material). This may be required to keep the thermal temperature of internal components low enough to maintain their structure. If the coolant is flowing at such a speed that the effective temperature of its motion is greater than the desired internal structural temperature, then we must isolate this flow from direct thermal contact with the structure, in order to avoid its *raising* the structural temperature rather than lowering it. Nevertheless, a well-isolated coolant flow can still be used to remove heat, if the unwanted heat is sent to join the coolant stream by a directed motion.

Note that the extra, directed energy flow in an active cooling system (its moving matter and kinetic energy) can be *recycled* (unlike the heat) and directed back into the machine (after being cooled externally) to carry out additional rounds of heat removal. So all the energy contained in the inward coolant flow does not necessarily represent a permanent loss of free energy.

To minimize the total rate of free-energy loss needed to achieve a given internal processing rate, we should minimize the rate at which entropy is produced internally, the inefficiencies (extra entropy generation) introduced by the cooling system, and the temperature of the external thermal reservoir (for example, by placing the computer in primary thermal contact with outer space, if possible).

One way to approach the energy transfer model treats the energy flow pathways as just yet another type of information-processing device, subject to the same type of characterization as we discussed earlier in Section 6.1. The only difference is that there need be no coding information present or error correction taking place in a device whose only purpose is to carry waste entropy out of the machine to be externally dissipated.

## 5.8. Programming Model

For purposes of this discussion, we do not particularly care about the details of the specific programming model, so long as it meets the following goals:

- **Power.** Harnesses the full power of the underlying hardware (*i.e.*, does not impose any asymptotic inefficiencies). In the long run, this implies further that it supports doing the following types of operations, if/when desired and requested by the programmer:
  - Parallel operations.
  - Reversible classical operations (implemented with as little entropy generation as the underlying device quality permits in the given technology).

- Quantum coherent operations (with as little decoherence as the device quality permits).

- **Flexibility.** The efficiency of the machine will be further improved if it provides several alternative programming models, so that whichever one that is most efficient for a particular application can be used. For example, each processor might provide both a CPU running a fairly conventional style of instruction set architecture (although augmented by reversible and quantum instructions) which efficiently maps the most common operations (such as integer and floating-point calculations) to device hardware, as well as a section of reconfigurable logic (also offering reversible and quantum operation), so that specialized, custom application kernels can be programmed at a level that is closer to the hardware than if we could only express them using traditional software methods.
- **Usability.** The programming model should be as straightforward and intuitive to use by the programmer (and/or compiler writer) as can be arranged, while remaining subject to the previous criteria, which are more important for overall efficiency in the long run. At present, programmer productivity is arguably more immediately important than program execution efficiency for many kinds of applications (for example, in coding business logic for e-commerce applications), but in the long run, we can expect this situation to reverse itself, as fundamental physical limits are more closely approached, and it becomes more difficult to extract better performance from hardware improvements alone. When this happens, the efficiency of our programming models will become much more critical.

Also, there may be a period where our choice of programming models is constrained somewhat by the type of hardware that we can build cost-effectively. For example, processors might be forced to be extremely fine-grained, if it is initially infeasible to build very complex (coarse-grained) structures at the nanoscale. Papers on NanoFabrics [80] and the Cell Matrix [81] describe examples of fine-grained parallel models based on very simple processing elements. In the case of [80], the processing elements are ones that can be built by making heavy use of certain chemical self-assembly techniques that are deemed more feasible by the authors than other fabrication methods.

However, my own opinion is that the need for such fine-grained architectures, if there ever is one, will only be a short-term phenomenon, needed at most only until manufacturing capabilities improve further. In the longer run, we will want direct hardware support (*i.e.*, closer to the physics) for very common operations such as arithmetic, and so eventually our nanoarchitectures will also contain prefabricated coarse-grained elements similar to the integer and floating-point ALUs (arithmetic-logic units) which are common today, which will be naturally programmed using instruction sets that are, in large measure, similar to those of today's processors.

To see why, consider this: The cost efficiency of a very fine-grained architecture, such as the Cell Matrix, on any application is reduced by at most a factor of 2 if we take

half of the area that is devoted to these fine-grained reconfigurable cells and use it to build fixed 128-bit ALUs (say) directly in hardware instead, even in the worst case where those ALUs are never used. But those general applications that *can* use the ALUs (which is probably most of them) will run hundreds of times more cost-efficiently if the ALUs are directly available in hardware than if they have to be emulated by a much larger assemblage of simple reconfigurable cells.

However, including *some* amount of reconfigurable circuitry is probably also desirable, since there are some specialized applications that will probably run more cost-efficiently on top of that circuitry than in a traditional instruction set.

The most basic law of computer architecture, Amdahl's law (in its generalized form [82] which applies to all engineering fields, and to any measure of cost efficiency), can be used to show that so long as the costs spent on both reconfigurable circuitry and traditional hardwired ALUs are comparable in a given design, and both are useful for a large number of applications, there will be little cost-performance benefit to be gained from eliminating either one of them entirely. Furthermore, it seems likely that the business advantages of having a single processor design that can be marketed for use for either kind of application (ALU-oriented vs more special-purpose) will probably outweigh the small constant-factor cost efficiency advantage that might be gained on one class of application by killing the cost efficiency of the other class.

Since arithmetic-intensive computing drives most of the market for computers and will probably continue to do so, I personally think it most likely that we will follow a evolutionary (not revolutionary) manufacturing pathway that continues to make smaller and smaller ALUs, which continue to be programmed with fairly traditional (CISC/RISC/DSP) instruction-set styles, and that gradually evolves toward the point where these ALUs are composed of truly nanoscale devices. The alternative scenario promoted by these authors, that the majority of computing will suddenly change over to using some radically different alternative architecture which lacks efficient low-level hardware support for such application-critical operations as "add," does not seem very plausible.

Now, of course, above the instruction-set level, higher level programming models (languages) may take a variety of forms. For example, Skillicorn [83] discusses issues in the design of high-level parallel models that map efficiently to hardware.

Some discussion of reversible programming languages can be found in [4, 84, 85], and some examples of quantum programming languages are [86–91].

## 5.9. Error Handling Model

Typically, the physical coding state will be chosen in such a way that any errors that appear in the coding state can be detected and corrected, before enough of them accumulate to cause the logical state information to be lost.

Ordinary static CMOS logic provides a simple example of this. The coding state is the analog voltage on a circuit node. A fairly wide range of possible voltages (thus, a relatively large amount of coding state information) is taken

to effectively represent a given logical value (0 or 1). The *ideal* coding state is some power-supply reference voltage, GND or  $V_{dd}$ . If, through leakage, a node voltage should drift away from the ideal level, in a static CMOS circuit, the level will be immediately replenished through a connection with the appropriate power supply. A simple static CMOS storage cell, for example, may include two *inverter* logic gates that continuously sense and correct each other's state. This can be viewed as a simple hardware-level form of error correction.

In dynamic digital circuits, such as a standard DRAM chip, a similar process of error detection and correction of logic signals takes place, although periodically (during refresh cycles) rather than continuously.

Of course, many other coding schemes other than voltage-level coding are possible. Electron spin states [71], current direction states [72], AC current phase states [92], electron position states [41], and atomic position states are just some of the examples. Whatever the coding scheme used, a similar concept applies, of redundantly representing each logical bit with many physical bits, so that errors in physical bits can be detected and corrected before enough of them change to change the logical bit. This idea applies equally well to quantum computing [93].

If the architecture does support quantum computing and is self-contained, then, for efficiency, fault-tolerant quantum error correction algorithms [69] should probably eventually be implemented at the architectural level in the long term, rather than just (as currently) in software.

Note that to correct an error is by definition to remove the "syndrome" information that characterizes the error. Insofar as we do not know precisely how the error was caused, and thus how or whether it might be correlated with any other accessible information, this syndrome information is effectively entropy, and so we can do nothing sensible with it except expel it from the machine. Unless the error rate is negligibly small, the resources required for removal of this error information must be explicitly included in any realistic model of computing that takes energy costs or heat-flux constraints into account.

## 5.10. Performance Model

Given the care we have taken to recognize fundamental physical constraints in our model components, a correct performance model will fall out automatically, as the architectural details are filled in. As we compose a large machine out of individual devices characterized as described, our device model forces us to pay attention to how energy and information flow through the machine. An algorithm, specified by an initial coding state of all of the devices, runs at a rate that is determined by the device dynamics, while respecting the time required for signals to propagate along interconnects throughout the machine, and for generated entropy to flow out along cooling pathways.

## 5.11. Cost Model

As we described earlier, a good cost model should include both spacetime-proportional costs (which include manufacturing cost, amortized over device lifetime), and energy-proportional costs. The energy costs can easily be dominant,

if the machine is to be operated for a long lifetime, or in an environment where energy is hard to come by and thereof expensive (or, complementarily, where heat is hard to get rid of).

As a pragmatic example, suppose a battery in a 30-W laptop lasts 5 hours, thus supplying 0.15 kW-hrs of energy. Assuming the recharge process can be done very efficiently, the raw cost of energy for a recharge, at typical current U.S. electric utility rates, is therefore less than one cent (US\$0.01). However, the inconvenience to a business traveler of having to charge and carry extra batteries in order to make it through a long international flight could well be worth tens of dollars, or more, to him or her. Also, having a particularly hot laptop sitting on one's lap can be a significant discomfort that users may be willing to pay a significant amount of money to reduce. The effective cost of energy can thus be many orders of magnitude higher than usual in these scenarios.

As additional examples, think of the cost to supply fresh fuel for energy to soldiers in the field, or to wireless transponders that may be mounted on autonomous sensors, or on goods during warehousing and shipping, for electronic inventory and tracking systems. Or, think of the cost to supply extra energy to an interstellar probe in deep space. Moreover, space vehicles also can have difficulty getting rid of waste heat, due to the absence of convective or conductive modes of heat transport.

These examples serve to illustrate the general point that circumstances in particular application scenarios can inflate the effective cost of energy by a large factor, perhaps hundreds or thousands of times over what it would be normally.

Even at normal wall-outlet electricity rates, a 200-W high-performance multiprocessor desktop workstation that remained in continuous service would use up  $\sim$ US\$1,700 worth of electricity over 10 years, which may be comparable to the cost of the machine itself. (However, for as long as Moore's law continues, the computer would probably be replaced about every 3 years anyway, due to obsolescence.)

Also, the cost of energy could increase further if and when the rate of fossil fuel extraction peaks before energy demand does, if more cost-effective energy technologies do not become available sooner than this. However, such variations in the cost of energy may not affect the trade-off between manufacturing cost and energy cost much, because manufacturing costs are, probably, ultimately also dominated by the cost of energy, either directly or indirectly through the manufacturing tool supply chain. Also, offsetting the fossil fuel situation, nanotechnology itself may eventually provide us new and much cheaper energy technologies, in which case the cost of energy might never be significantly higher than it is at present.

However, even if the cost of energy always remains low, or even goes much lower than at present, the discomfort to a human user of holding or wearing a computer that is dissipating much more than  $\sim$ 100 W will always remain an important concern for as long as there remain biological humans who want to carry their computers around with them, and who comprise a significant part of the market for computing.

## 5.12. Some Implications of the Model

In some previous work that did a complete system-level analysis based on a model highly similar to the one just described [21], we demonstrated (based on some straightforward technology scaling assumptions) that the cost-efficiency advantages of reversible computing, compared to irreversible computing, for general-purpose applications in a 100 W, US\$1,000 machine could rise to a factor of  $\sim$ 1000 by the middle of this century, even if no more efficient algorithms for general-purpose reversible computing are found than those (specifically, [54]) that are already known. In the best case, for special-purpose applications, or if ideal general purpose reversibilization algorithms are discovered, the cost-efficiency benefits from reversibility could rise to a level  $\sim$ 100,000  $\times$  beyond irreversible technology. See Figure 4.

However, that particular analysis assumed that a very high  $q$  value of  $\sim 10^{12}$  could be achieved at that time and, further, that it could be maintained as manufacturing costs per device continued to decrease. If this does not happen, then the gains from reversibility will not be so great. Unfortunately, the exponentially increasing rate at which electrons tunnel out of structures as distances shrink [94] makes it seem that very high  $q$ 's—corresponding to very strongly confined electron states—will be very hard to achieve in any technology at the deep nanoscale ( $< \sim 1$  nm device pitch). The resulting fast decay rate of any meta-stable electronic states is a problem even for irreversible technologies. It essentially means that the performance density (ops per second per unit area) and even memory density (bits per unit area) of deep-nanoscale electronic computers would inevitably be *strongly* limited by high leakage power dissipation of individual devices.

Generally, electron tunneling becomes significant compared to desired electron motions wherever interdevice distances become on the order of the Fermi wavelength of electrons in the conductive material in question, which

**Figure 4.** Base-10 logarithm of cost efficiency, in effective logic operations per dollar, for irreversible (lower line), general reversible (middle line), and best-case reversible (upper line) computations, as a function of year, for a \$1,000/100 W “desktop” computing scenario, using a model similar to the one described in this chapter and assuming that a high  $q$  value for devices can be maintained. Frank, Nanocomputer systems engineering, in “Technical Proceedings of the 2003 Nanotechnology Conference and Trade Show.” © 2003, Nano Science and Technology Institute.

ranges from on the order of  $\sim 0.5$  nm for highly conductive metals to on the order of  $\sim 20$  nm for semiconductors.

But because of the substantial energy savings to be gained, it may, in fact, turn out to be better for overall performance *not* to make device pitch quite so small as may become physically possible to manufacture, and instead keep devices spread far enough apart from each other so that tunneling currents remain negligible. Even with this restriction, average interdevice interconnect lengths in complex circuits can still become far shorter than they are at present, especially if circuit buildout begins to use the third dimension significantly, which is in turn enabled by the exponential reduction in tunnel-current power that is made possible by keeping device pitch relatively large, and by the resulting large savings in total power that can be obtained by using reversible computing, if high-quality, self-contained coupled logic/oscillator systems can be built.

## 6. SPECIFIC NANOCOMPUTING TECHNOLOGY PROPOSALS

So far, most of our nanocomputing discussions have been fairly general and technology-independent. In this section, we proceed to review and summarize a variety of more specific nanocomputer technologies (that is, potential physical implementations of nanocomputer models and architectures) that have been proposed to date.

### 6.1. Taxonomy of Nanocomputing Hardware Technologies

In this list, we attempt to subdivide and categorize a sampling from the already vast spectrum of radically differing technologies that have been proposed to date for the physical implementation of future nanocomputers. Further discussion of some of these categories follows in subsequent subsections.

- Solid state
  - Pure electronic (only electrons moving)
    - Using inorganic (non-carbon-based) materials
      - Using semiconducting materials
        - Scaled field-effect transistors
          - Alternative device geometries
            - Double-gate, FinFET, *etc.*
          - Semiconductor nanowires
        - Single-electron transistors
          - Coulomb blockade effect devices
        - Resonant tunneling diodes/transistors
        - Quantum dot based
          - Quantum dot cellular automata
        - Spintronics (using electron spins)
      - Using conducting materials
        - Helical logic (Merkle and Drexler)
      - Using superconducting materials
        - Josephson-junction circuits
    - Organic (carbon-based) molecular electronics
      - Carbon nanotube electronics (can be conducting, semiconducting, or superconducting)
      - Surface-based organic-molecular electronics

- Mechanical (whole atoms moving)
  - Rod logic (Drexler)
  - Buckled logic (Merkle)
  - Brownian clockwork (Bennett)
- Electromechanical
  - Micro/nanoelectromechanical systems (MEMS/NEMS) technologies
    - Electrostatic relays, dry-switched
    - MEMS-resonator-powered adiabatics
  - Configuration-based molecular electronics
- All-optical (only photons moving)
- Opto-electronic (photons and electrons)
- Fluid state
  - Molecular chemical approaches (*in vitro*)
    - Biomolecular chemical computing
      - DNA computing
        - DNA tile self-assembly
  - Biocomputing (*in vivo*)
    - Genetic regulatory network computing
  - Fluidic (fluid flows confined by solid barriers)
  - High-level fluidity (solid-state devices suspended in fluid)
    - Hall's utility fog
    - Amorphous computing over ad hoc networks of mobile devices
  - Gas state
    - Gas-phase chemical computing
- Plasma state (speculative)
  - Smith-Lloyd quantum-field computer
- Black-hole state (speculative)
  - Beckenstein-bound black hole computer

### 6.2. Nanoelectronic Logic Technologies

By far, the most well-researched category of nanocomputer technologies at this time is the solid-state, purely electronic technologies. Pure electronic computing technologies are ones those in which the entities whose motions are involved in carrying out a computation are electrons only, not atoms or photons (aside from the virtual photons that implement the quantum-electrodynamic interactions between the charge carriers).

At around the 10 nm scale, the ordinary bulk materials models currently used in electronics, and the standard field-effect based semiconductor device operation mechanisms that rely on those models, begin to break down. At this technological *mesoscale*, surface effects and quantization effects become important, or even dominant. Some of the new effects that need to be considered include:

- Quantization of the number of atoms in a given structure. This is a problem for the low-density implanted dopants used today in semiconductor devices, as the statistical nature of the present dopant implantation processes means that there is a high variance in the dopant concentration in a sufficiently small structure, which leads to unpredictable variation in MOSFET threshold voltages, and possibly a low device yield. In principle, this problem can be dealt with if nanomanufacturing techniques allow the number and location of dopant atoms in a given structure to be chosen

- precisely, or by using alternative dopant-free device designs.
- Quantization of charge (number of electrons). This is realized today in a number of single-electron devices that have been demonstrated in the lab. It is also the basis for the *Coulomb blockade* phenomenon, which is the basis for some proposed device mechanisms.
  - Quantum tunneling of electrons through any very narrow, very low potential energy barriers. This is already a concern today that is preventing significant further thinning of MOSFET gate oxides, and ultimately this may be the key factor limiting shrinkage of overall device pitch. The problem is that electrons will tend to migrate easily between adjacent nanostructures, unless the potential energy barriers preventing this tunneling are extremely large, which may be difficult to arrange. This presents a problem for dense information storage using electrons. The densest possible forms of stable storage may therefore turn out to consist of states (position or spin states) of entire atoms or nuclei, rather than electrons.
  - Quantization of electron energies when confined to small spaces. That is, energy “bands” can no longer be treated as if they were continuous. Similarly, electron *momentum* does not vary continuously along any specific direction in which the electron is highly confined.
  - If the quantum quality factor of devices is low, so that there is a large interaction between the coding state and the surrounding thermal state, then thermal noise also becomes significant, since the redundancy of the coding information is necessarily reduced in small devices. Due to the lack of redundancy, the expected time for a coding state to change to an error state due to thermal interactions corresponds to a relatively small number of computational steps of the device, so there is less opportunity for computational error correction techniques to apply.

These small-scale effects can be considered to be obstacles, but we should also recognize that knowing how these effects work may also enable the development of entirely new operating principles upon which logic mechanisms can be based.

In the taxonomy in Section 7.1, we broke down the solid-state electronic technologies according to the conductivity properties of the material used for electron transfer (semiconductor, conductor, superconductor). But an alternative way to categorize them would be according to the primary physical principle that is harnessed in order to perform logical operations. We can do this as follows:

- Coulombic (electrostatic) attraction/repulsion effects:
  - Field effect devices:
    - Scaled bulk field-effect transistors
    - Carbon nanotube FETs
    - FETs made of crossed semiconductor nanowires
  - Charge quantization/Coulomb blockade effect
    - Single-electron transistors
  - Helical logic
- Energy quantization/resonant tunneling effects
  - Resonant tunneling diodes
  - Resonant tunneling transistors

- Quantum wells/wires/dots
  - Quantum dot cellular automata
- Atomic-configuration-dependent electronic properties
  - MEMS/NEMS electromagnetic switches/relays
  - Configuration-dependent conductivity of carbon nanotubes
  - Configuration-based molecular switches
- Superconductivity effects
  - Josephson effect
- Electron spin effects (in spintronics)
  - Spin-based transistors
  - Single-electron-spin-based quantum computing

### 6.2.1. Nanoscale Field-Effect Transistors

The *field effect* used in today’s MOSFETs is essentially just a result of the Coulombic attraction or repulsion between the static electric charge that is present on a *gate* electrode, and the charge carriers in a nearby semiconducting pathway (the *channel*). Depending on the applied gate voltage and the channel semiconductor characteristics, the concentration of mobile charge carriers in the channel may be either enhanced far above or depleted far below the default level that it would have if the gate were not present. Also, the types of the dominant charge carriers that are present in the channel (electrons versus holes) may even be inverted. The carrier concentration (and type) in turn affects the density of current flow through the channel when there is a voltage difference between the two ends (“source” and “drain”) of the channel wire, giving the transistor a larger or smaller effective resistance.

For fundamental reasons, the effective resistance of a minimum-size turned-on field-effect transistor, in any given technology, is roughly (within, say, a factor of 10, depending on the details of the device geometry) of the same magnitude as the quantum unit of resistance  $h/2e^2 \approx 12.9 \text{ k}\Omega$ , which is the built-in resistance of a single ideal quantum channel. But the effective resistance of a turned-off field-effect device can be much larger. For relatively large devices (above the nanoscale) in which electron tunneling across the channel is not significant, the off-resistance is limited only by the decrease in concentration that can be attained for whichever type of current carrier is available within the source and drain electrodes. By the equipartition theorem of statistical mechanics, the reduction in the channel concentration of these carriers scales with  $\exp(-E/kT)$ , where  $E$  gives the potential energy gained by a charge carrier that is in the channel, and  $kT$  is the thermal energy per nat at thermal temperature  $T$ . To increase the potential energy for a single charge carrier to be in the channel by an amount  $E$ , at least a corresponding amount  $E$  of electrostatic energy needs to be moved onto the gate electrode, even in the best case where the gate electrode was somehow occupying the same space as the channel (while somehow being prevented from exchanging charge with it). Actually, in real devices, the gate electrode will usually be only located next to (or at best, wrapped around) the channel, in which case some, but not all, of the energy of its electrostatic field will be contained inside the channel itself. Together with other nonidealities, this leads to an actual scaling of current with the exponential of only some *fraction*  $1/(1 + \alpha)$  of the ratio

between gate voltage and thermal energy. Empirically measured values of  $\alpha$  today are around 1.0 (*i.e.*, only about half of the gate's electrostatic energy is visible inside the channel) [95]. The results described in Section 6.12 assume that further device or materials improvements can reduce  $\alpha$  to be close to 0, so that field-effect devices are thus operated in a regime where their on/off ratios are close to  $e^{E/kT}$ . (If not, then those results need to be revised accordingly.)

The basic principles of operation of field-effect devices have been shown to remain valid at least in the near-nanoscale (1–32 nm) regime. As early as 2001, Intel reported field-effect operation of MOSFETs in the lab having channel lengths as small as  $\sim 20$  nm [96], and IBM just announced a working 6-nm channel-length MOSFET (called XFET) at the December 2002 International Electron Devices Meeting [97]. Furthermore, academic groups such as Lieber's at Harvard [98] have successfully demonstrated field-effect transistors and logic gates using chemically synthesized (rather than lithographically etched) inorganic semiconducting wires having similar diameters and channel lengths. Also, carbon molecular nanotubes in certain configurations can act as semiconductors and have been demonstrated to be usable as channels of field-effect transistors [99]. Finally, some theoretical studies have indicated that even a one-atom-wide "wire" of silicon atoms adsorbed on a crystal surface, with exactly periodic interspersed dopant atoms, can behave as a material having a semiconductor band structure [100], and thus serve as a transistor channel.

However, for scaling of channel length below about the 10 nm range, tunneling of charge carriers through the channel barrier may begin to become a limiting concern in semiconductors. This is because at that scale, the Fermi wavelength of the conduction-band electrons (that is, the de Broglie wavelength of those electrons traveling at the *Fermi velocity*, the characteristic velocity of the mobile electrons at the surface of the "Fermi sea" of conduction band states) begins to become significant.

In contrast, metals usually have relatively low Fermi wavelengths, under 1 nanometer, because they have a high level of degeneracy, meaning that their low-energy states are packed full, so these low-momentum states are unavailable for charge transport, and so all of their activated (mobile) electrons must travel relatively fast (at the *Fermi velocity*). For example, among pure elemental metals, cesium has one of the lowest Fermi energies, 1.59 eV, while beryllium has one of the highest, 14.3 eV. Taking these as kinetic energies of free electrons with mass  $m_e$ , the Fermi velocities  $v_F$  are 748 km/s for Ce and 2240 km/s for Be. The Fermi wavelength  $\lambda_F = h/m_e v_F$  scales as the inverse square root of the Fermi energy and comes out to be 0.97 nm for Ce and 0.32 nm for Be.

However, in semiconductors, the Fermi wavelength is typically much larger than this, because the activated electrons can occupy even the lowest energy of the conduction band states, since those states are not normally occupied. Typical kinetic energies of mobile electrons in semiconductors can thus be as low as on the order of the thermal energy  $kT$ , which is 0.026 eV at room temperature, corresponding to an electron velocity of only 95 km/s. The corresponding de Broglie wavelength for electrons moving in vacuum at room temperature speeds would be 7.6 nm. Furthermore, in

practice, Fermi wavelengths in semiconductors turn out to be even several times larger than this, typically in the range 20–60 nm, due in part to the reduced effective mass of the electron, as a result of its interactions with the surrounding crystal lattice structure.

Due to these relatively large wavelengths, mobile electrons in semiconductors will tend to spread out over regions of about the same size, unless confined by sufficiently high energy barriers. A turned-off transistor gate can provide such a barrier against electrons moving through the channel region. However, the effective confinement length of an energy barrier against electron tunneling is only on the order of the corresponding wavelength  $h(2mE)^{-1/2}$ , where  $m$  is the effective electron mass in the barrier region and  $E$  is the height of the barrier. Figure 5 graphs this relation, for electrons of effective mass  $m_e$  (in vacuum) or  $0.2 m_e$  (in some semiconductors). Notice that as the height of the energy barrier shrinks toward small multiples of the room-temperature thermal energy, the minimum width of the barrier increases, toward sizes on the order of 5–10 nm. The trend toward shorter channel lengths thus directly conflicts with the trend toward decreasing voltages in MOSFETs. For this reason, it seems that aggressively voltage-scaled field-effect devices are not likely to ever get much below  $\sim 10$  nm in channel length.

What about using higher barrier heights? From Figure 5, we can see that barriers narrower than even 1 nm may

**Figure 5.** Approximate lower limit of the width of an energy barrier of given height needed to prevent electron tunneling across the barrier from becoming significant, for both free electrons (lower curve) and electrons in a fairly typical semiconductor in which the effective electron mass is only  $m \approx 0.2 m_e$  (upper curve). The minimum width is estimated as being roughly equal to the de Broglie wavelength  $= h(2mE)^{-1/2}$  of electrons having kinetic energy equal to the barrier height. A more accurate calculation (specifically, based on Eq. 6-54 on p. 207 of [101]) would multiply this figure by  $\ln(1/p)/4\pi$  to give the width of a barrier that has probability  $p \ll 1$  of being tunneled through by an electron having an initial kinetic energy  $E$  less than the barrier height. Our graph here then corresponds to the case where the tunneling probability  $p = 3.5 \times 10^6$ , and where  $E$  represents the barrier height relative to the Fermi energy of the region on either side of the barrier. The dotted red line indicates the room-temperature (300 K) value of  $kT = 26$  mV; the energy barrier must be at least about this high anyway, in order to prevent thermally activated leakage from dominating.

still prevent tunneling, so long as the barrier has a height of several electron volts. Actual energy barriers of such heights, due to high molecular electron affinities, are exactly what prevent many everyday materials, such as plastics, from being good conductors, despite the sub-nm distances between adjoining molecules in these molecular solids. However, using such high voltages in the gates of nanoscale field-effect devices may backfire, by causing high gate-to-channel tunneling. Frank [94] looks carefully at all of these tunneling considerations and concludes that irreversible CMOS technology cannot scale effectively to less than  $\sim 10$  nm, given realistic power constraints. Alternative field-effect structures such as nanotubes [99] and nanowires [98], despite their very narrow linewidths, remain subject to identical kinds of source-to-drain and gate-to-channel tunneling considerations and so cannot really be expected to fare much better, in terms of the scaling of their overall device pitch.

How might we do significantly better than this? Arguably, this will require (eventually) abandoning the field-effect operating principle entirely. Field-effect devices are based on a controllable potential energy barrier, whose height is adjusted simply by moving a corresponding amount of static electrical energy onto or off of a nearby gate electrode. But the problem is that this mobile gate charge is subject to parasitic tunneling into the very system, the transistor channel, that it is supposed to be controlling. Decreasing the gate voltage reduces this tunneling but also increases leakage across the channel. Keeping the gate relatively far away from the channel is another way to reduce gate-to-channel tunneling, but it also reduces the gate's effect on the channel, due to decreased gate-channel capacitance and thus indirectly increases leakage. The use of high-dielectric-constant materials such as silicon nitride between the gate and channel can help keep to keep the capacitance high and the gate leakage low, but only to a limited extent. An extreme example would be if ultrapure water could be used as a gate dielectric, since its dielectric constant is  $\sim 80$  times vacuum, or 20 times higher than the usual  $\text{SiO}_2$  glass, while its resistivity is still  $> 10^{14} \Omega \cdot \text{nm}$ . However, even this would not permit gate voltage swings greater than about 1.23 V, since at that level, even pure water conducts, via electrolysis. And even a 1.23 V barrier in the channel would still not allow channel lengths less than roughly 2–3 nm (depending on the particular semiconductor's effective electron mass) without significant tunneling occurring between the source and drain electrodes.

But if we widen our perspective a bit, we can note that there are other ways to control a potential-energy barrier between two electron-position states, besides just the field effect, which, at root, is only a simple application of ordinary Coulombic repulsion, together with the carrier-depletion phenomenon in semiconductors. For example, one could mechanically widen or narrow the separation between two conductive regions—this is the principle used in old electromechanical relays. Or a piece of conductive material could be inserted and removed from the space between the source and drain—ordinary toggle switches work this way. One can easily imagine performing the same general types of electromechanical interactions at the molecular level, and thereby perhaps obtaining device sizes closer to 1 nm. Vacuum gaps between conductors constitute fairly high energy

barriers, due to the multi-eV electron affinities (work functions) of most conductive materials, and therefore such gaps can be made significantly smaller than semiconductor channel lengths, while still avoiding the electron tunneling problem.

So, ironically, electromechanical devices, which today we think of as being terribly antiquated, might, in the nanomolecular realm, turn out to scale to higher device densities than can our vaunted field-effect devices of today. However, whether this potentially higher device density may be enough to compensate for the relatively sluggish inertia of entire atoms, compared to electrons, when switching a gate, is still dubious. Nevertheless, one fortunate coincidence is that the relative slowness of the mechanical motions seems to be exactly what is needed anyway for efficient adiabatic operation in the electronics, which is necessary to maintain high performance in the face of heat flow constraints.

So my tentative (and ironic) nomination for the “most likely contender” to be the dominant nanocomputing technology a few decades hence is nanoscale electrostatic relays using a dry-switching discipline. “Dry-switching” is an old term from electromechanical relay technology, meaning “do not open (resp. close) a switch when there is a significant current through (resp. voltage across) it.” Historically, this was done to prevent corrosion of the relay contacts due to air-sparking. But this is also exactly the key rule for adiabatic operation of any switch-based circuitry. The thought of using electromechanical relays sounds slow at first, until you consider that, at the nanoscale, their characteristic speeds will be on the order of the rates at which chemical reactions occur between neighboring molecules—since both processes will consist of essentially the same kinds of operations, namely molecule-sized objects bumping up against each other, and interacting both electrostatically via conformational changes and via actual exchange of electrons. The molecule-size gate, moved into place by an impinging electrostatic signal, can be thought of as the “catalyst” whose presence enables a source–drain electron-exchange “reaction.” In other words, this technology could be thought of as a sort of “controlled chemistry,” in which the “chemical” interactions happen at predetermined places at predetermined times, and information flows not randomly, via a slow diffusive random walk through solution, but instead at near-lightspeed along hard-wired electrically conductive paths to specific destinations where it is needed. This NEMS vision of computing does not yet specifically include quantum computing capabilities, but it might be modified to do so by including some spintronic device elements [102].

We briefly discuss some of the other alternative switching principles that have been considered. See also [103] for an excellent review of most of these.

### 6.2.2. Coulomb-Blockade Effect Single-Electron Transistors

These devices are based on the quantum principle of charge quantization. They typically consist of a conductive island (although semiconductors may also be used) surrounded by insulator and accessed via some fairly narrow (typically 5–10 nm) tunnel junctions. The Coulomb blockade effect is

the observation that the presence of a single extra electron on these small, low-capacitance structures may have a significant effect on their voltage, which, if greater than thermal voltage, thereby suppresses additional electrons from simultaneously occupying the structure. The Coulomb blockade effect may be significant even in cases where the number of electron energy levels is not itself noticeably quantized. In these devices, a voltage applied to a nearby gate allows one to choose the number of electrons (in excess of the neutral state) that occupy the island to a precision of just a single electron out of the millions of conduction electrons that may be present in, say, a 20 nm cube of material. The Coulomb blockade effect has also been demonstrated on a molecular and even atomic [104] scale, at which even room-temperature manifestation of the effect is permitted.

### 6.2.3. Quantum Wells/Wires/Dots

These are typically made of semiconductor materials. They are based on confinement of electron position in one, two, or three dimensions, respectively. Increased confinement of electron position in a particular direction has the effect of increasing the separation between the quantized momentum states that are oriented along that direction. When all three components of electron momentum are thus highly quantized, its total energy is also; this leads to the quantum dot, which has discrete energy levels. In quantum dots, the total number of activated conduction electrons may be as small as 1! Based on a thorough understanding of the quantum behavior of electrons, some researchers have developed alternative, non-transistor-like quantum-dot logics. A notable example is the paradigm of quantum dot cellular automata (QDCA) introduced by the group at Notre Dame [105]. The name QCA is also sometimes used for these structures, but I dislike that abbreviation, because it can be confused with quantum cellular automata, which is a more general and technology-independent class of abstract models of computation, whereas the QDCA, on the other hand, comprise just one very specific choice of device and circuit architecture, based on quantum dots, of the many possible physical implementations of the more general QCA concept.

Also worth mentioning are the quantum computing technologies that are based on externally controlling the interaction of single-electron spins between neighboring quantum dots [71].

### 6.2.4. Resonant Tunneling Diodes/Transistors

These structures are usually based on quantum wells or wires, and therefore may still have 2 or 1 (resp.) effectively “classical” degrees of freedom. In these structures, a narrow-bandgap (conductive) island is sandwiched between two wide-bandgap (insulating) layers separating the island from neighboring source and drain terminals. When the quantized momentum state directed across the device is aligned in energy with the (occupied) conduction band of the source terminal, electrons tunnel from the source onto the island, and then to unoccupied above-band states in the drain terminal. But a small bias applied to the device can cause the quantized momentum state in the island to no

longer be aligned in energy with the source terminal’s conduction band, in which case tunneling across that barrier is suppressed, and less current flows. Since multiple harmonics of the lowest momentum state also appear in the spectrum of the device, these devices typically have a periodic dependence of current on bias voltage.

Resonant tunneling transistors are just like resonant tunneling diodes, except that there is an additional gate terminal near the island that provides an additional means for adjusting the energy levels in the island.

### 6.2.5. Electromechanical Devices

Several kinds of nanoscale devices have been proposed which use mechanical changes (movements of atoms or assemblages of atoms) to control electrons, or vice versa. The molecular switches of [106] fall in this category, as would NEMS switches and relays based on nanoscale solid-state structures. Electromechanical structures offer somewhat of a design advantage in that the mechanism of their operation is relatively easy to visualize, due to the explicit change in their structural configuration.

But the primary disadvantage of electromechanical operation is that atoms are many thousands of times as massive as electrons and therefore accelerate many thousands of times more gradually in response to a given force. As a result, the characteristic frequencies for oscillation of mechanical components tend to be many thousands of times less than those of similar-sized electrical ones.

However, this disadvantage might conceivably be offset if it turns out that we can design NEMS devices that have much higher quality factors than we manage to obtain using electronics alone. This is suggested by the very high  $Q$ ’s (in the billions) for a perfect diamond crystal vibrating in vacuum, and by the practical  $Q$ ’s in the tens of thousands that are achievable today for MEMS mechanical resonators (essentially, springs) in vacuum. In contrast, the  $Q$ ’s that have been obtained in simple microelectronic circuits such as  $LC$  oscillators tend to be much lower, usually in the tens or at most hundreds. We (or more precisely, I) do not (yet) know any *fundamental* reasons why a high- $Q$  all-electronic nanoscale oscillator cannot be built, but it is not yet clear how to do so.

In the meantime, hybrid electromechanical approaches might take up some of the slack. Resistive elements such as transistors naturally have high  $Q$  when they are operated at relatively slow speeds (*i.e.*, adiabatically). If these are coupled to high- $Q$  electromechanical oscillators, a high overall  $Q$  might be obtained for the complete self-contained system, thereby enabling  $\ll kT$  energy dissipation per bit operation. For example, if a mechanical oscillator with  $Q = 10,000$  is coupled to an adiabatic electronic FET which has a similarly high  $Q$  at the low frequency of the oscillator, so that the overall  $Q$  of the system is still 10,000, and if tunneling currents are kept negligible, then if we use a redundancy factor in the logic encoding of  $\sim 11.5$  nats/bit (*i.e.*, on the order of 0.3 eV switching energy per minimum-sized transistor gate at room temperature), then one could theoretically achieve an on/off ratio of order  $e^{11.5} \approx 100,000$  and a best-case minimum entropy generation per bit-op on the order of  $e^7$  nat  $\approx 0.001 k_B$  (refer to Fig. 3). This could be advantageous in

that it would permit a  $\sim 700 \times$  higher total rate of computation per watt of power consumption (and per unit area, given heat-flux constraints) than in *any* physically possible *fully irreversible* technology (even if all-electronic), in which the entropy generated per bit-op must be at least  $\sim 0.7k_B$ .

Another potential advantage of electromechanical operation is that mechanically actuated switches for electricity may be able to change electron currents by relatively large factors while using a relatively small amount of energy transfer. This is because a mechanical change may significantly widen a tunneling barrier for electrons, which has an exponential effect on electron tunneling rates. Therefore, it is not clear that an electromechanical system must be subject to the same kind of lower bound on entropy generation for given quality index as we discussed in Section 6.12. Thus, an electromechanical system with a  $Q$  of 10,000 might be able to achieve an even lower rate of entropy generation than we described in the previous paragraph, perhaps of the order of 1/10,000th of a bit of entropy generated per bit-op.

An interesting corollary to this electromechanical line of thought is this: If the operating frequency of the logic is going to be set at the relatively low frequency of nanomechanical oscillators anyway, in order to achieve low power consumption, then is there any remaining benefit to having the actual logic be carried out by electrons? Why not just do the logic, as well as the oscillation, mechanically? This leads back to the idea of using all-mechanical logic at the nanoscale, an idea that was first promoted by Drexler [47]. We will discuss this possibility further in Section 7.3.

However, there is still one clear advantage to be gained by using electrons for logic signals, and that is simply that the propagation speed of electronic signals can easily be made close to the speed of light, while mechanical signals are limited to about the speed of sound in the given material, which is much lower. Thus, communication delays over relatively long distances would be expected to be much lower in electromechanical nanocomputers than in all-mechanical ones. This is an important consideration for the performance of communication-dominated parallel algorithms.

### 6.2.6. Superconductive Devices

Complex integrated circuits using high-speed ( $\sim 100$  GHz) digital logic based on superconductive wires and Josephson junctions have already existed for many years [107], although they are unpopular commercially due to the requirement to maintain deep cryogenic (liquid helium) temperatures. Another problem for these technologies is that their speed cannot be further increased by a very large factor unless much higher temperature superconducting material can be effectively integrated. This is because flipping bits at a rate of 100 GHz already implies an effective coding-state temperature of at least 3.5 K; thus increasing speed by another factor of 100, to 10 THz, would require room-temperature superconductors, which have not yet been discovered.

Superconductive devices therefore might never have an opportunity to become competitive for general-purpose computing, since traditional semiconductor devices are expected to reach  $\sim 100$  GHz frequencies in only about another 15 years.

Also, it appears that it may be difficult to scale superconducting technology to the nanoscale, because ordinary

superconductivity is based on Cooper pairs of electrons, which have a relatively large spacing (order of 1 micrometer) in the usual superconducting materials [108]. However, this may turn out not really be a problem, since even carbon nanotubes have already been found to superconduct under the right conditions [109].

Even if superconductive technologies turn out not to achieve extremely high densities, they may still be useful at relatively low densities, for those particular applications that happen to require the special-purpose features of quantum computing. Superconductor-based devices for quantum computing are currently being aggressively explored [72], and this may turn out to be a viable technology for creating large scale integrated quantum computer circuits. But if the technology is not also simultaneously dense, low power, and high frequency, then it will likely be relegated to a “quantum coprocessor,” while the main CPU of the computer (used for more general-purpose applications) remains nonsuperconducting.

### 6.2.7. Spintronic Devices

Spintronics [102] is based on the encoding of information into the spin orientation states of electrons, rather than the usual approach of using energy (voltage) states. Spin information typically persists for nanoseconds in conduction electrons, compared with the typical  $\sim 10$  fs lifetime for decay of momentum information (except in superconductors). Spintronics requires various technologies for spin control, propagation of spins along wires, selection of electrons based on their spin, and detection of electrons. Some examples of spintronic devices are the Datta–Das [110] and Johnson [111] spin-based transistors. Electron spins are also a potential medium for quantum computation, as is illustrated by the spin-based quantum dot quantum computers being explored by Friesen et al. [71]. Nuclear spins have already been used for quantum computing experiments for some time [70]. It is currently still unclear whether spintronic nanoelectronic technologies might eventually outperform nanoelectronics based on other properties.

## 6.3. Nanomechanical Logic Technologies

Way back in the late 1980s and early 1990s, Drexler and Merkle proposed a number of all-mechanical technologies for doing logic at the nanoscale [43, 45, 47]. There is an argument why technologies like these might actually be viable in the long run, despite the slow speed of mechanical (atomic) signals. That is, if all-mechanical nanotechnologies turn out (for some reason) to be able to be engineered with much higher  $Q$ 's than electronic or electromechanical nanotechnologies can be, then the all-mechanical technologies would be able to operate with greater parallel performance per unit power consumed, or per unit surface area available for cooling. Presently, it is not yet clear whether this is the case. One approach called “buckled logic” [45] was specifically designed by Merkle to have very high  $Q$ , because it completely eliminates sliding interfaces, rotary bearings, stiction-prone contacts, moving charges, *etc.* and instead consists of an electrically neutral one-piece mesh of rods that simply flexes internally in a pattern of vibrational motions that is designed to be isomorphic to a desired

(reversible) computation. If the computational vibrational modes can all be well insulated from other, noncomputational ones, then in principle, the  $Q$ 's obtainable by such structures, suspended in vacuum, might even approach that of pure crystal vibrations, that is, on the order of billions. This may enable a level of entropy generation per bit-op that is so low (maybe billionths of a nat per bit-op) that a vastly higher overall rate of bit-ops might be packed into a given volume than by using any of the feasible alternatives. However, until many more of the engineering details of these interesting alternatives have been worked out, the all-mechanical approach remains, for now, as speculative as the others.

#### 6.4. Optical and Optoelectronic Technologies

For purposes of high-performance, general-purpose parallel nanocomputing, all purely optical (photonic) logic and storage technologies are apparently doomed to failure, for the simple reason that photons, being massless, at reasonable temperatures have wavelengths that are a thousand times too large, that is, on the order of 1 micrometer, rather than 1 nanometer. Therefore, the information density achievable with normal-temperature (infrared, optical) photons in 3D space is roughly  $1000^3$  or a *billion* times lower than what could be achieved using electronic or atomic states, which can be confined to spaces on the order of  $1 \text{ nm}^3$ . Light with comparable 1 nm wavelengths has a generalized temperature on the order of  $1000 \times$  room temperature, or hundreds of thousands of Kelvins! These 1-nm photons would have to be extremely stringently confined while remaining somehow isolated from interaction with the computer's material structure, in order to keep the computer from immediately exploding into vapor, unless a solid structure could somehow still be maintained despite these temperatures by (for example) applying extremely high pressures.

The only exception to this problem might be if mutually entangled photons can be used, as these behave like a single, more massive object and thus have a lower effective wavelength at a given temperature. This wavelength reduction effect has recently been directly observed experimentally [112]. However, we presently have no idea how to produce a conglomeration of 1000 mutually entangled photons, let alone store it in a box or perform useful logic with it.

Even if this problem were solved, photons by themselves cannot perform universal computation, since under normal conditions they are noninteracting, and thus only linearly superpose with each other (they cannot, for example, carry out nonlinear operations such as logical AND). However, photons may interact with each other indirectly through an intermediary of a material, as in the nonlinear photonic materials currently used in fiber optics [113]. Also, *extremely* high-energy photons (MeV scale or larger, *i.e.*, picometer wavelength or smaller) may interact nonlinearly even in vacuum, without any intermediary material, due to exchange of virtual electrons [15], but the temperatures at which this happens seem so high as to be completely unreasonable.

To deal with the problem of low information density and photon noninteraction, hybrid optoelectronic technologies have been proposed, in which electron states are used to

store information and do logic, while photons are used only for communication purposes. However, even in this case, we have the problem that the bit flux that is achievable with photons at reasonable temperatures is still apparently far lower than with electrons or atoms [114]. Therefore, it seems that light is not suitable for communication between densely packed nanoscale devices at bit rates commensurate with the operating speeds of those devices. This is again due to the limit on the information density of cool, nonentangled light. Communicating with (unentangled) photons therefore only makes sense for communications that are needed only relatively rarely, or between larger scale or widely separated components, for example, between the processors in a loosely coupled distributed multiprocessor.

#### 6.5. Fluid (Chemical, Fluidic, Biological) Technologies

##### 6.5.1. Chemical Computing

Not all proposed nanotechnologies rely primarily on solid-state materials. Computing can also be done in molecular liquids, via chemical interactions. Much work has been done on chemical computing, especially using DNA molecules as the information-carrying component, since it is naturally designed by evolution for the purpose of information storage. Universal computing in DNA appears to be possible; for example, see [115]. Unfortunately, it seems that chemical techniques in a uniform vat of solution can never really be viable for large-scale, general-purpose parallel nanocomputing, for the simple reason that the interconnects are much too slow. Information is propagated in 3D space only by molecular diffusion, which is inherently slow, since it is based on a random walk of relatively slow, massive entities (molecules). Information transmission is thus many orders of magnitude slower than could be achieved in, say, a solid-state nanoelectronic technology in which signals travel straight down predetermined pathways at near the speed of light. Chemical methods also tend to be difficult to control and prone to errors, due to the generally large numbers of possible unwanted side-reactions.

##### 6.5.2. Fluidics

However, the situation may be improved slightly in fluidic systems, in which the chemicals in question are actively moved around through microchannels. Desired materials may be moved in a consistent speed and direction and brought together and combined at just the desired time. This more direct method gives a much finer degree of control and improves the interconnect problem a bit, although transmission speeds are still limited by fluid viscosity in the channel.

One can also dispense with the chemical interactions and just use pressure signals in fluidic pipes to transmit information. Pressure-controlled valves can serve as switches. This technique is highly analogous to ordinary voltage-state, transistor-based electronics, with pressure in place of voltage, and fluid flow in place of electric current. Fluidic control and computation systems are actually used today in some military applications, for example, those that cannot use electronics because of its vulnerability to the electromagnetic pulse that would result from a nearby nuclear blast.

However, insofar as all fluid-based techniques require the motion of entire atoms or molecules for the transmission of information, one does not anticipate that any of these techniques will ever offer higher computational densities than the solid-state all-mechanical technologies, in which state changes are much more well controlled, or than the electromechanical or pure-electronic technologies in which signals travel at much faster speeds.

### 6.5.3. Biological Computing

Computing based on chemical interactions is, at best, likely to only be useful in contexts where a chemical type of input/output (I/O) interface to the computer is needed anyway, such as inside a living cell, and where the performance requirements are not extremely high. Indeed, a biological organism itself can be viewed as a complex fluidic chemical computer. In fact, it is one that can be programmed. For example, Knight and Sussman at MIT are currently experimenting with reengineering the genetic regulatory networks of simple bacteria to carry out desired logic operations [116].

Notice, however, that even in biology, the need for quick transmission and very fast, complex processing of information in fact fostered the evolution of a nervous system that was based on transmission of signals that were partly electrical, and not purely chemical, in nature. And today, our existing electronic computers are far faster than any biological system at carrying out complex yet very precisely controlled algorithms. For less precisely controlled algorithms that nevertheless seem to perform well at a wide variety of tasks (vision, natural language processing, *etc.*), the brain is still superior, even quantitatively in terms of its raw information processing rate. But by the time we have nanocomputers, the raw information-processing capacity of even a \$1,000 desktop computer is expected to exceed the estimated raw information-processing capacity of the human brain [117].

One attempt at a generous overestimate of the raw information-processing capacity of the brain is as follows. There are at most  $\sim 100$  billion neurons, with at most  $\sim 10,000$  synapses/neuron on average, each of which can transmit at most  $\sim 1000$  pulses per second. If each pulse can be viewed as a useful computational “operation,” this gives a rough maximum of  $\sim 10^{18}$  operations per second.

Conservatively, today’s largest microprocessors have on the order of  $\sim 100$  million transistors (Intel’s Itanium 2 processor actually has 220 million) and operate on the order of  $\sim 1$  GHz (although 3 GHz processors now can be bought off-the-shelf, in early 2003). Such densities and clock speeds permit  $\sim 10^{15}$  transistor switching operations to be performed every second. This is only a  $1000 \times$  slower raw rate than the human brain, assuming that the transistor “ops” are roughly comparable to synaptic pulses, in terms of the amount of computational work that is performed as a result. The historical Moore’s law trend has raw performance nearly doubling about every 1.5–2 years, so we would expect a factor of 1000 speedup to only take around 15–20 years.

So the nanocomputer that will be sitting on your desk in the year 2020 or so (just a little way beyond the end of today’s roadmap for traditional semiconductor technology) may well have as much *raw* computational power as

the human brain. Of course, it is another matter entirely whether software people will have figured out by then how to effectively harness this power to provide (for example) an automated office assistant that is anywhere close to being as generally useful as a good human assistant, although this seems rather doubtful, given our present relative lack of understanding of the organization and function of the brain, and of human cognition in general.

### 6.6. Very Long-Term Considerations

What are the ultimate limits of computing? As we have seen, to maximize rates of computation, both high computational temperatures and very precise control and isolation of the computation from the environment are simultaneously required. However, as computational temperatures increase, it becomes increasingly difficult to isolate these fast-changing, thus “hot,” computational degrees of freedom from the relatively cool degrees of freedom inherent in ordinary matter having stable structure (*e.g.*, solids, molecules, atoms, nuclei). At some point, it may be best not to try to keep these structures stable anymore, but rather to let them dissolve away into fluids, and just harness their internal fluid transitions as an intentional part of the computation. In other words, it may eventually be necessary to take some of the energy that is normally tied up in the binding energy of particles, and thus is not doing useful computational work (other than continually computing that a given structure should remain in its current state), and release that energy to actively perform more useful computations.

Smith [15] and later Lloyd [16] explored this hypothetical concept of a plasma-state computer and quantitatively analyzed the limits on its performance and memory capacity, which are determined by fundamental considerations from quantum field theory. As expected, performance is dependent on temperature. If material having the mass density of water is converted entirely to energy with no change in volume, it forms a plasma of fundamental particles (mostly photons) with a temperature on the order of  $10^9$  kelvins, hotter than the highest temperatures reached at the core of an exploding thermonuclear (hydrogen fusion) bomb.

How can such a violent, high-temperature state possibly be configured in such a way as to perform a desired computation? Of course, this is totally impractical at present. However, in principle, if one prepares a system of particles in a known initial quantum state and thoroughly isolates the system from external interactions, then the unitary quantum evolution of the system is, at least, deterministic and can be considered to be carrying out a quantum computation of sorts. In theory, this fact applies to hot plasmas, as well as to the relatively cool computers we have today.

However, even if the required exquisite precision of state preparation and isolation can someday be achieved, the question of how and whether any desired program can be actually “compiled” into a corresponding initial state of a plasma has not yet even begun to be explored. For the remainder of this section, we will pretend that all these issues have been solved, but alternatively, it may well be the case that we are never able to organize stable computation, without relying on an underlying infrastructure made of normal solid (or at least atomic) matter.

Lloyd [16] points out that at normal mass-energy densities (such as that of water), a plasma computer would be highly communication-limited, that is, heavily limited by the speed-of-light limit, rather than by the speed of processing. But in principle the communication delays could be reduced by compressing the computer's material beyond normal densities. As the energy density increases, the entropy density increases also, though more slowly (specifically, as energy density to the  $\frac{3}{4}$  power), and so energy per unit entropy is increased; that is, the temperature goes up.

The logical (if extreme) conclusion of this process, for a given-size body of matter, is reached when the ratio of the system's mass-energy to its diameter exceeds the critical value  $c^2/4G$ , at which point the system comprises a black hole, disappearing into an event horizon, and the effects of any further compression cannot be observed. For a 1-kg-mass computer, the critical size is extremely small, about  $10^{-27}$  m, or roughly a trillionth of the diameter of an atomic nucleus. (Needless to say, this degree of compression would be very difficult to achieve.)

Due to gravitational time dilation (redshifting), although the compressed matter would be very hot in its own frame of reference, it appears somewhat cooler than this to the outside world. In other words, the system's output bandwidth is decreased by gravitational effects. This is because, simply stated, the outgoing information tends to be pulled back by gravity.

Classically, in general relativity, the temperature of a black hole as measured from outside would by definition always be zero (no information can leave the hole), but, as shown in the now-famous work by Stephen Hawking [118], the temperature of a black hole is actually *not* zero when quantum uncertainty is taken into account. Effectively, particles can tunnel out of black holes ("Hawking radiation"), and the smaller the black hole, the quicker this rate of tunneling becomes. So smaller black holes have higher output temperatures and thus effectively make faster "computers," at least from an I/O bandwidth point of view. A 1-kg-mass black hole would have a temperature of about  $10^{23}$  K, and a presumed minimum-mass (Planck mass) black hole would have a temperature of  $\sim 10^{32}$  K.

This last temperature, the *Planck temperature*, may be a fundamental maximum temperature. It corresponds to a maximum rate of operation of  $\sim 10^{43}$  parallel update steps per second, or 1 step per Planck time. This may be considered the fastest possible "clock speed" or maximum rate of operation for *serial* computation. It is interesting to note that if processor frequencies continue doubling every 2 years, as per the historical trend, then this ultimate quantum-gravitational limit on clock frequency would be reached in only about 200 more years. At this point, the only possible improvements in performance would be through increased parallelism. Moreover, the parallel machine would have to be very loosely coupled, since Planck-mass black holes could not be packed together very densely without merging into a larger black hole, whose temperature, and output communication bandwidth, would be proportionately lower. The problem is that a black hole outputs information in only a single quantum channel, with bandwidth proportional to its

temperature [119]. However, its internal rate of operations can be considered to still be given by its total mass-energy. It is interesting to note that within a black-hole computer, the interconnection problem becomes a nonissue, since the time to communicate across the hole is comparable to the time to flip a bit [16].

Of course, all of these considerations remain extremely speculative, because we do not yet have a complete theory of quantum gravity that might be able to tell us exactly what happens inside a black hole, in particular, near the presumably Planck-scale sized "singularity" at its center. Conceivably, at the center is a busy froth of very hot fundamental particles, perhaps near the Planck temperature, which occasionally tunnel (although greatly gravitationally redshifted) out beyond the horizon. But we do not know for certain.

Regardless of the precise situation with black holes, another speculative long-term consideration is the potential computational capacity of the entire universe, in bits and in ops. Lloyd has estimated upper bounds on these quantities, over the history of the universe so far [28]. Other papers by Dyson [120], and more recently by Krauss and Starkman [121], attempt to characterize the total amount of future computation that an intelligent civilization such as ours might eventually harness toward desired purposes. Significantly, it is still a matter for debate whether the total number of future ops that we may be able to perform over all future time is finite or infinite. Krauss and Starkman present arguments that it is finite, but they do not seem to take *all* possible considerations into account. For example, it may be the case that, by engineering reversible computational systems having ever-higher quality factors as time goes on, an infinite *number* of operations might be performed even if only a finite total supply of energy can be gathered, a possibility which they do not consider. Memory capacity is not necessarily limited either, since as the universe expands and cools, our energy stores might be allowed to expand and cool along with it, thereby increasing without bound the amount of information that may be represented within them. In any event, whether the total number of future ops that we may perform is infinite or not, it is undoubtedly very large, which bodes well for the future of computing.

## 7. CONCLUSION

To conclude, we already have an arguably valid, if still rather rough, idea of what the most cost-effective general-purpose future nanocomputer architectures over the coming century should look like. Most concretely, high-performance nanocomputers will generally be flattened slabs of densely packed computing "material" (of limited thickness), consisting of 3D locally connected meshes of processors that include local memory and *both* traditional hardwired arithmetic-logic units *and* reconfigurable logic blocks, built from nanoscale, probably solid-state, electronic, or electromechanical devices. The device technology and architecture must also support *both* mostly reversible classical operation *and* fault-tolerant quantum algorithms, if it aspires to be universally maximally scalable.

Devices must be well insulated from their environment, that is, designed to have a very high quantum *quality* factor (*i.e.*, low relative decoherence rate) which allows their internal coding state to transition reversibly and coherently at a fast rate (thus, a high effective temperature) relative to the rate of undesired interactions between the coding state and the (probably cooler) thermal state of the machine's physical structure. Even when an application does not need to use quantum superposition states, well-isolated, high- $Q$  reversible operation remains particularly critical for general-purpose parallel computation, in order to maximize the effective computation rate and number of active processors per unit area enclosed, and thereby to minimize the communication delays in communication-limited parallel algorithms.

In these parallel architectures, the processors will be kept synchronized with each other via local interactions. Meanwhile, free energy will be supplied, and waste heat removed, by active flows of energy and/or coolant material which pass perpendicularly through the computing slab, and which are recirculated back through the machine to be reused, after their entropy and the accompanying waste heat are deposited in some external reservoir.

This vision, although it places a number of constraints on what nanocomputing will look like, still provides a lot of flexibility for device physicists to do creative engineering design and optimization of the specific device mechanisms to be used for logic, memory, interconnect, timing, energy transfer, and cooling, and it leaves a lot of room for computer engineers and computer scientists to come up with more efficient new processor organizations and programming models that recognize the need to support reversible and quantum, as well as parallel, modes of operation and that respect fundamental physical constraints.

Finally, if we are successful in converging on a nanocomputing technology that indeed approaches the quantum limits discussed in Section 2, and if our civilization's demand for computational power continues to increase beyond that point, then we can expect that the fraction of the available material (mass-energy) that is devoted toward nanocomputing will increase as well. If our civilization continues to thrive and grow, then eventually, in the extremely long term (perhaps hundreds or thousands of years hence), we may find ourselves wanting to build nanocomputers that are *so* massive (using many planets' or stars' worth of raw material) that their self-gravitation becomes a significant concern. This will bring a new fundamental physical concern into play, namely general relativity, which this chapter has not yet thoroughly considered. At that distant future time, the form of our computer models may need to change yet again, as we figure out how best to maximize cost-efficiency of computing in the face of this new, gravitational constraint. But in the meantime, until that happens, the simpler type of nanocomputer model that we discussed in Section 6 is expected to last us for a very long time. The primary goal for the current generation of nanocomputer engineers is, then, to flesh out and optimize the technological and architectural details of the general class of models that we have outlined, guided by our rapidly improving understanding of the basic principles of nanoscale science and technology, as documented throughout this encyclopedia.

## GLOSSARY

**Å** Standard abbreviation for *Ångstrom*.

**Adiabatic** A process is *adiabatic* to the extent that it can take place with arbitrarily little generation of entropy. Originally in thermodynamics, "adiabatic" literally meant "without flow of heat" and applied to any physical process in which there was no (or negligibly little) heat flow. However, today in applied physics, "adiabatic" means "asymptotically isentropic," that is, approaching zero total entropy generation, in the limit of performing the process more slowly, and/or with diminished parasitic interactions with its environment. The old and new definitions are not equivalent.

**Adiabatic losses** Energy that is dissipated to heat due to the imperfections present in a nominally adiabatic process, as opposed to energy that is necessarily dissipated due to logical irreversibility.

**Adiabatic principle** The total adiabatic losses of a given process scale down in proportion to quickness as the process is carried out more slowly.

**Adiabatic theorem** A theorem of basic quantum theory that says that so long as the forces on a system (expressed in its Hamiltonian) are changed sufficiently slowly, and some additional technical conditions on the spectrum of energy eigenstates are met, a system that is initially in a pure state will remain in an almost pure state, that is, with a total generation of entropy that is inversely proportional to the quickness of the transition. The theorem is very general; adiabatic processes are therefore nearly ubiquitously available, that is, in almost any reasonable nanodevice technology.

**Adjoint** A term from matrix algebra. The adjoint of a matrix is its conjugate transpose.

**Algorithm** A precise description of a particular type of computation, abstracted away from the specific inputs, and often also abstracted away from the machine architecture and the details of the programming model.

**Amplitude** Complex number giving the value of a quantum wavefunction at a given state. It can be broken into phase and magnitude components. The squared magnitude of the amplitude corresponds to the probability density at the given state.

**Amu** Unified atomic mass unit, equal to  $1.6605402 \times 10^{-24}$  g. About the mass of a proton or neutron. Originally defined as 1/12 the mass of a carbon-12 atom. In computational units, equal to 450 zettapops per second.

**Ångstrom** A unit of length equal to  $10^{-10}$  meters, or 0.1 nm. One Ångstrom is the approximate radius of a hydrogen atom.

**Angular momentum** In computational terms, this is the ratio between the number of quantum operations required to rotate an object by a given angle around a point, and the magnitude of the angle. It is quantized, so that a rotation by  $180^\circ$  or  $\pi$  radians always involves an integer number of  $\pi$ -ops (ops of magnitude size  $\hbar/2$ ), and a rotation by 1 radian involves an integer number of  $\pi$ -ops (ops of magnitude  $\hbar$ ).

**Architecture** An activity, namely, the functional and structural design of any complex artifact, such as a skyscraper or a computer. Within the field of computer architecture, a specific *architecture* refers to a particular computer design, which may include any levels of design from the logic circuits

up through the interconnection networks of a multiprocessor computer.

**Architecture family** A class of architectures of unbounded capacity (a specific architecture may have only constant capacity). That is, a recipe for creating architectures of any desired capacity. I also frequently use the phrase *capacity scaling model* rather than *architecture family*, since it is more descriptive.

**ASCII** American Standard Code for Information Exchange; a widely used standard for representing Latin alphabet characters, digits, and simple punctuation marks using 8-bit numbers.

**Ballistic** An adiabatic process that also has a nonzero net “forward” momentum along the desired trajectory through configuration space. This is opposed to adiabatic processes that have zero net momentum and progress only via a random walk (Brownian motion).

**Bandgap** In condensed matter theory, the bandgap in a semiconducting or insulating material is the magnitude of separation in energy level between the top of the valence band and the bottom of the conduction band. Insulators have a large bandgap; semiconductors have a relatively small one. In metals the bandgap is negative (meaning the bands overlap).

**Bandwidth** In computer science, a rate of information transfer (e.g., in bits per second). This meaning is closely related to the original, literal meaning, which was the width (in Hertz) of a frequency band used for wave-based communications. In communications theory, a single classical wave-based communication channel with a given frequency bandwidth can be shown to have a proportional maximum rate of information transfer.

**Basis** A term from linear algebra. A complete set of (often orthogonal, but at least linearly independent) vectors, sufficient to define a given vector space. In quantum theory, a complete set of distinguishable states forms a basis.

**Basis state** Any single state that is aligned along one of the axes of a given basis.

**Bennett’s algorithm** A reversibilization algorithm discovered by Bennett. The 1973 version of the algorithm (which takes linear time but polynomial space) is a special case of a more general version of the algorithm described in 1989.

**Bennett copy** To rescue desired information from being uncomputed during Lecerf reversal by reversibly copying it before performing the reversal.

**Binary number** A number represented in base-2 notation, using a series of bit systems.

**Binary tree** An interconnection network structure in which each node is connected to 1 “parent” node and 2 “child” nodes. Binary trees are not physically realistic with unit-time hops.

**Bistable** Having two stable states.

**Bit** Shorthand for *binary digit*, this is the log-base-2 unit of information or entropy. (The abbreviation *bit* for this concept was coined by John Tukey in 1946.) An *amount* of information can be counted by a *number* of bits. In addition, the word bit can also be used to mean a *bit system*; in this usage, a bit denotes not only a measure of amount of information, but also a specific *piece* of information.

**Bit device** Any device that is designed for storing and/or processing a single logical bit, or a small constant-size collection of logical bits, at any given time. For example, a transistor or a logic gate could be considered to be a bit device, but an *n*-bit adder is larger than that. (We sometimes use the term *bit device* when we wish to be clear that we are referring to individual logic devices, rather than to more complex “devices” such as CPUs or laptop computers.)

**Bit operation** An operation that manipulates only 1 or at most a small constant number of (physical or logical) bits.

**Bit system** A system or subsystem containing exactly 1 bit of physical information. That is, a specific instance of a type of system or subsystem having exactly two distinguishable states (see *qubit*) or with a particular pair of distinguishable states for the subsystem (i.e., a particular partition of a set of distinguishable states for the entire system into two equal sized parts).

**Bitwise ripple-carry add** In computer arithmetic, a hardware or software algorithm for adding two binary numbers using the base-2 equivalent of the traditional grade-school algorithm, with a carry from each place to the next.

**Black box** Name applied to a device, function, process, or transformation when one is allowed to use the entity to produce outputs from inputs but is not allowed to “open the box,” to directly determine anything about its internal structure.

**Black hole** An object whose escape velocity (due to its gravity) exceeds the speed of light.

**Boltzmann’s constant** See *nat*.

**Butterfly network** An interconnection network similar to a sort of unfolded hypercube. Butterfly networks are not physically realistic (see PR) given unit-time hops.

**Byte** Usually, 8 bits. Sufficient to denote 1 Latin character, number, or punctuation symbol in the ASCII character set.  
*c* See *speed of light*.

**CA (cellular automaton)** The cellular automaton is a model of computation, first envisioned by von Neumann [33], consisting of a regular mesh of finite-capacity processing elements operating in parallel. Two-dimensional cellular automata have the maximum scalability among fully irreversible models of computing. Three-dimensional reversible cellular automata are conjectured to be a universally maximally scalable model of computation, up to the gravitational limit.

**Calorie** Unit of energy originally defined as the heat required to increase the temperature of 1 g of water by 1 degree Kelvin. Equal to 4.1868 J.

**CAM (cellular automata machine)** A type of parallel computer architecture in which the programming model is based upon the cellular automaton model of computation. A number of CAMs were designed and built by the information mechanics group at MIT in the 1980s and 1990s. (See [122].)

**Capacity** The *computational capacity* or just *capacity* of a computer is measured by two parameters: (1) How many bits of logical information can it store? (2) How many bit operations per second can it perform?

**Carbon nanotube** Sometimes called *buckytubes* (for Buckminster Fuller), these are nanometer-scale (in diameter)

hollow tubes made out of pure carbon, consisting essentially of a graphene (graphite-like) sheet rolled into a cylinder. They have a higher strength-to-weight ratio than steel, conduct electricity better than copper, and have a high thermal conductivity, making them a promising component for future nanomechanical and nanoelectronic applications.

**Cellular automaton, cellular automata** See *CA*.

**Channel** The region of a transistor through which current flows (between source and drain) when the transistor is turned on.

**Characteristic length scale** For any engineered system, its characteristic length scale is defined as the average distance between neighboring instances of the smallest custom-designed functional components of the system (for example, the average distance between neighboring transistors in a densely packed electronic circuit). The characteristic length scale of a traditional semiconductor-based computer is determined by the minimum wire *pitch* (distance between center lines of neighboring wires) in integrated circuits, which in early 2003 is roughly 0.2 micrometers.

**Church's thesis** Also known as the Church–Turing thesis. This physical postulate claims that any reasonable (physically realizable) model of computation yields the same set of computable functions as does recursive function theory (Church's original model of computing) or (equivalently) the Turing machine model. See also the *strong Church's thesis* and the *tight Church's thesis*.

**Circuit node** In lumped models of electronic circuits, a node is a region of the circuit that is modeled as being at a uniform voltage level.

**Classical computing** Computing in which the only coding states used are pointer states.

**Classical information** Information that is sufficient to pick out a single basis state from a given basis, but that does not itself specify the basis.

**CMOS** Complementary metal–oxide–semiconductor, the dominant process/device technology for digital electronic computing today, involving PFET and NFET field-effect transistors, which complement each other (the PFETs conduct the high-voltage signals, and the NFETs conduct the low-voltage ones).

**Coding state** Also *coding physical state*. This is the state of the *coding subsystem* of a given system, that is, the physical information that represents (perhaps very redundantly) the logical information that is intended to be encoded.

**Coherent** Term for a quantum system that can remain in a superposition of pointer states for long periods, which requires a very low decoherence rate. Because of the low decoherence rate, a coherent system undergoing a definite evolution produces no entropy and evolves adiabatically, even ballistically. (In contrast, noncoherent adiabatic evolution occurs when the evolution is restricted to a trajectory consisting of only pointer states; superpositions of these must be avoided in order to achieve adiabatic operation if the system is decoherent.)

**Combinational logic** Digital logic in which outputs are produced by a combination of Boolean operators applied

to inputs, as soon as inputs are available, as fast as possible. Less general than sequential logic, because intermediate results cannot feed back into the inputs to be reused, and data cannot be stored.

**Communication** The movement of information from one physical system to another.

**Commute** Mathematical term. Two operators *commute* with each other if performing them in either order always gives the same result. Measurements in quantum theory are represented by observables, that is, Hermitian operators, which leave the eigenstates unchanged, except for scaling by the measured value. Two observables commute if one can measure them in either order and always obtain the same result. If this is not the case, then we can say that one measurement has disturbed the value that would have been obtained for the other, and vice versa. This fact is the origin of Heisenberg's uncertainty principle.

**Complete (parallel) update step** See *step*.

**Complex number** When the theory of the real numbers is extended by closing it under exponentiation, the result is a unique theory in which numbers correspond to real vectors (called *complex numbers*) in a 2D vector space over the reals, and the vectors corresponding to reals themselves all lie along a given axis. The other orthogonal axis is called the *imaginary* axis. The imaginary unit vector  $i$  is defined as  $i = (-1)^{1/2}$ . In complex vector spaces, complex numbers themselves are considered as being just scalar coefficients of vectors, rather than as vectors themselves.

**Complexity** In *computational complexity theory*, a major branch of theoretical computer science, “complexity” is simply a fancy name for *cost* by some measure. There are other definitions of complexity, such as the *algorithmic* or Kolmogorov complexity of objects, often defined as the length of the shortest program that can generate the given object. However, we do not make use of these concepts in this chapter.

**Compute** To *compute* some information is to transform some existing information that is in a known, standard state (e.g., empty memory cells), in a deterministic or partially randomized fashion, based on some existing information, in such a way that the “new” information is at least *somewhat* correlated with the preexisting information, so that from a context that includes the old information, the new information is not entirely entropy. See also *uncompute*.

**Computable** A function is considered *computable* if it can be computed in principle given unlimited resources.

**Computation** The act of computing. When we refer to computation in general, it is synonymous with computing, but when we reify it (talk about it as a thing, as in “a computation”), we are referring to a particular episode or session of information processing.

**Computational temperature** Also *coding temperature*. The temperature (update rate) of the coding state in a machine.

**Computing** Information processing. The manipulation and/or transformation of *information*.

**Computer** Any entity that processes (manipulates, transforms) *information*.

**Conductance** The ratio between the current flowing between two nodes and the voltage between them. A single

quantum channel has a fundamental quantum unit of conductance,  $2e^2/h$ , where  $e$  is the electron charge and  $h$  is Planck's constant.

**Conduction band** In condensed matter theory, the conduction band is the range of energies available to electrons that are free to move throughout the material.

**Conductor** An electrical *conductor* is a material in which the valence and conduction bands overlap, so that a significant fraction of electrons in the material occupy unbound states with wavefunctions that spread throughout the material. The electrons in the highest energy of these states can very easily move to other states to conduct charge. However, they have a minimum velocity called the *Fermi velocity*.

**Conjugate** The *conjugate* of a complex number is found by inverting the sign of its imaginary part. The conjugate of a matrix is found by conjugating each element.

**Cost** Amount of resources consumed. To the extent that multiple types of resources can be interconverted to each other (e.g., by trade, or by indifference in decision-making behavior), cost for all types of resources can be expressed in common units (e.g., some currency, or utility scale). This should be done when possible, because it greatly simplifies analysis.

**Cost measure** A way of quantifying cost of a process based on one or more simpler characteristics of the process (e.g., time or spacetime used).

**Cost efficiency** The cost efficiency of any way of performing a task is the ratio between the minimum possible cost of resources that could have been consumed to perform that task using the best (least costly) alternative method, and the cost of resources consumed by the method actually used. It is inversely proportional to actual cost.

**COTS** Commercial off-the-shelf; a currently commercially available, noncustom component.

**Coulomb blockade effect** The phenomenon, due to charge quantization, whereby the voltage on a sufficiently low-capacitance node can change dramatically from the addition or removal of just a single electron. This effect can be utilized to obtain nonlinear, transistorlike characteristics in nanoscale electronic devices.

**Coulombic attraction/repulsion** The electrostatic force, via which like charges repel and unlike charges attract, first carefully characterized by Coulomb.

**CPU** Central processing unit. The processor of a computer, as opposed to its peripheral devices, enclosure, *etc.* Today's popular CPUs (such as Intel's Pentium 4) reside on single semiconductor chips. However, the future trend is toward having increasing numbers of parallel CPUs residing on a single chip.

**Current** In electronics, the *current* is a rate of flow of charge; it is measured in units of charge per unit of time. The SI unit of current is the Ampere.

**Database** In the real world, a database means an explicit table listing arbitrary data (perhaps in a constrained format), or a collection of such tables. With this standard definition, quantum "database search" is misnamed; it is *not* actually beneficial for searching such databases. (See Section 5.2.)

**de Broglie wavelength** In quantum mechanics, a fundamental particle (or entangled collection of fundamental

particles) having total momentum  $p$  is described by a quantum wavefunction over position states having an associated wavelength  $\lambda = h/p$ , with the wave vector oriented in the same direction of the momentum vector. The wavelength is called the de Broglie wavelength of the particle.

**Decay temperature** The rate of decay of structural information.

**Decoherence** A quantum system *decoheres* (increasing the entropy of its density matrix) when it undergoes either an unknown unitary transformation, or a known interaction with an environment whose state is itself unknown. Maximum decoherence occurs when the state has become a Boltzmann maximum-entropy state (uniform distribution). Continuous decoherence can be factored into a superposition of discrete quantum decoherence *events*, each of which changes the sign or value of an individual qubit.

**Decoherence-free subspace** Some quantum systems that as a whole are highly decoherent may include natural subsystems (perhaps internally redundant ones) that are highly coherent, due to cancellation or interference effects that naturally suppress the subsystem's interactions with the environment. Quantum error correction is the algorithmic construction and maintenance of a decoherence-free subspace, achieved through explicit coding schemes.

**Decoherent** Having a high decoherence rate.

**Decoherence rate** A measure of the rate at which the off-diagonal elements of the density matrix approach zero, meaning that the quantum state is approaching a plain statistical mixture of pointer states. Can be characterized in terms of number of discrete quantum decoherence events per unit time.

**Decoherence temperature** The temperature (step rate) of decoherence interactions. Same thing as (one measure of) decoherence rate. The reciprocal of decoherence time.

**Density matrix** A representation of mixed states, generated by right-multiplying the state vector by its adjoint.

**Device** In general, this means any physical mechanism; however, in the context of computer architecture, it usually refers to the lowest level functional components of the design, such as (in electrical circuits) transistors, capacitors, resistors, and diodes, although sometimes even interconnecting wires are also explicitly considered as devices (since they do have physical characteristics that affect their functionality). In this chapter, I use the phrase *bit device* instead of just *device* when I wish to emphasize the primitive components of digital systems.

**Device pitch** The pitch between devices. See *device, pitch*.

**Dimensionality** A term from linear algebra. The maximum number of mutually orthogonal vectors in a given vector space.

**Distinguishable states** Two quantum states are considered to be entirely distinguishable from each other if and only if their state vectors are orthogonal (perpendicular to each other).

**Dopants** Impurities (sparse atoms) that are added to a semiconductor to adjust its equilibrium concentration of mobile charge carriers, and their dominant type (electrons vs holes).

**Dynamics** The *dynamics* of a system specifies a transformation trajectory that applies to the system over time.

**Effective mass** In condensed matter theory, it is found that an electron of given velocity has a longer wavelength than the de Broglie wavelength of a free electron with the same velocity. This phenomenon is concisely handled by ascribing an effective mass to the electron in matter that is smaller than the actual rest mass of the particle.

**Eigenstate** A state of a quantum system that remains unchanged by a given measurement, interaction, or time evolution. An eigenvector of the measurement observable, interaction Hamiltonian, or the unitary time-evolution matrix.

**Eigenvalue** A term from linear algebra. An eigenvalue of an eigenvector of a particular linear transformation is the scalar value that the vector gets multiplied by under that specific transformation. The eigenvalue of a measurement observable is the numerical value of the measured quantity.

**Eigenvector** A term from linear algebra. An eigenvector of a particular linear transformation is any vector that remains unchanged by the transformation apart from multiplication by a scalar (the corresponding *eigenvalue*).

**Electromigration** When the motion of a current through a solid material causes gradual rearrangement of the atoms of the material. A problem in today's microcircuitry. If a wire happens to be narrower than intended at some point, electromigration can accelerate the wire's degradation until it breaks. Note: adiabatic operation can help prevent this.

**Emulate** Simulate exactly (with complete digital precision).

**Energy** Energy (of all kinds) can be interpreted, at a fundamental level, as just the *performing of physical computation* at a certain rate in terms of quantum bit operations per second, according to the formula  $E = \frac{1}{4}hR$ , where  $h$  is Planck's (unreduced) constant and  $R$  is the rate of complete bit operations [16, 18]. For most forms of energy, we do not notice the computation that is associated with it, because that computation is only performing such familiar, everyday sorts of information processing as shifting a physical object through space (kinetic energy) or exchanging force particles between two objects (binding energy, a.k.a. potential energy). Also, depending on the state, much of the energy may have a null effect. Only a miniscule part of the energy in most computers is actually directed toward performing information transformations that are of interest for carrying out the logic of the application. As technology advances, we learn to harness an increasing fraction of systems' energy content for computational purposes. The *first law of thermodynamics* expresses the observation that total energy is conserved (*i.e.*, that the total physical computation taking place within a closed system proceeds at a constant rate), which we know from *Noether's theorem* is equivalent to the postulate that the laws of physics (as embodied in the global Hamiltonian) are unchanging in time.

**Energy eigenstate** An eigenstate of the energy observable.

**Energy transfer model** In a model of computation, the model of the flow of energy and information (including entropy) through the machine.

**Entangle** Two quantum systems are *entangled* if their joint state cannot be expressed as the tensor product (essentially,

a concatenation) of simple pure or mixed states of the two systems considered separately. This is really nothing more than a straightforward generalization to quantum systems of the simple classical idea of a *correlation*. For example, if I flip a coin and then, without looking at it or turning it over, chop it in half, then I may know nothing about the state of either half by itself, but I *do* know that the two halves will show the same face when I look at them.

**Entropy** Information that is unknown to some particular entity (unknown in the sense that the *amount* of information in the system can be known, but the specific *content* of the information is not).

**Equilibrium** A given system is considered to be at *equilibrium* if all of its physical information is entropy, that is, if it has maximum entropy given the constraints implicit in the system's definition. Due to the second law of thermodynamics, the equilibrium state (a mixed state) is the only truly stable state; all other states are at best *meta-stable*.

**Error correction** Through decay/decoherence interactions, the logical or coding state of an information-processing system may gradually accumulate unwanted departures away from the desired state. The information in these unwanted variations represents a form of entropy. Error correction is the removal of this entropy and recovery of the original, desired logical and coding state. Being an entropy removal process, it is just a special case of refrigeration. Error correction can be implemented physically (*e.g.*, by connecting a circuit node to a high-capacitance power supply reference node with a stable voltage), or algorithmically, by using redundant error correction codes and explicitly detecting and correcting bit errors one by one. Error correction techniques exist for quantum superposition states, as well as for classical state spaces.

**Euclidean space** A space in which the metric is *flat*, and classical flat-plane geometry like Euclid's remains valid. Measurements show that the physical spacetime that we live in is very nearly Euclidean.

**Far nanoscale** The range of pitch values between 0.032 and 1 nm. Contrast *near nanoscale*.

**Fat tree** Another interconnection network structure similar to a binary tree, except that each node is connected to several parent nodes for additional communication bandwidth and redundancy. Fat trees are not physically realistic with unit-time hops.

**Fermi level** The average energy of electrons at the "surface" of the Fermi sea.

**Fermi velocity** The average velocity of electrons having sufficient energy to be at the Fermi level.

**Fermi wavelength** The de Broglie wavelength of electrons moving at the Fermi velocity, that is, having enough kinetic energy to put them at the Fermi level (the surface of the Fermi sea of electrons).

**Fermi sea** Electrons, being Fermions, obey the Pauli exclusion principle (no two can occupy the same state at the same time), and therefore, given a set of available states, electrons will "fill up" the available states, from lowest to highest energy. This is called the "Fermi sea." The surface of the Fermi sea may be called the "Fermi surface"; it is at the Fermi level of energy. All the action (transitions of electrons

and holes to new states) happens near the Fermi surface, because the deeper electrons have no available states nearby to transition to.

**FET** Field-effect transistor; a transistor (voltage controlled current switch) whose operation is based on the field effect.

**Field effect** An effect seen in semiconductors where an applied electrostatic field significantly changes the mobile charge-carrier concentration in a material, as a result of moving the Fermi level farther toward or into the valence band or the conduction band.

**Flux** In general, for our purposes, a rate of transfer of some conserved substance or material per unit area of some surface it is passing through. Sometimes called *flux density* or *flux rate*. In nanocomputer systems engineering, we consider key quantities such as information flux (bandwidth density), entropy flux, energy flux, and heat flux. The former two are fundamentally limited as a function of the latter two.

**FPGA (field-programmable gate array)** A type of processor consisting of a regular array of low-level functional units or logic gates, which is programmed by configuring the function and interconnection of the individual elements. Commonly used today in embedded applications; major commercial manufacturers in 2003 include Xilinx and Altera. Many future general-purpose processors will likely include an FPGA-like module that can be reconfigured for efficient special-purpose processing.

**Free energy** For our purposes, the free energy in a system is its total energy minus the spent energy, that is, the amount of energy  $ST$  that would be needed to move all of the system's entropy  $S$  to the lowest temperature available thermal reservoir, at temperature  $T$ . Compare to *Gibbs free energy* and *Helmholtz free energy*.

**Frequency** The quickness of a process that continually repeats itself. In other words, periods or cycles per time unit. Typical unit: the Hertz (inverse second).

**G** Newton's gravitational constant,  $6.67259 \times 10^{11} \text{ Nm}^2/\text{kg}^2$ . Still used in Einstein's general relativity, the modern theory of gravity.

**g** Abbreviation for gram (the mass unit).

**Gate** There are two meanings used in this document. The gate of a transistor is the circuit node that controls its conductance. A *logic gate* is a bit device that carries out a specified Boolean logic operation. A logic gate today consists of several transistors and may contain several transistor gates.

**General-purpose processor** A processor that can be programmed to carry out any algorithm (up to the limit set by its storage capacity).

**General Theory of Relativity** Also just general relativity (GR), Einstein's theory of gravity, based on the principle that gravity is equivalent to an accelerated reference frame. GR predicts a number of surprising phenomena, such as curved spacetime, black holes, and gravity waves, all of which have been (at least indirectly) confirmed by experiment. Eventually GR needs to be unified with the Standard Model. GR provides the only fundamental physical limit to computer scaling that is not already incorporated into the model described in this chapter.

**Gibbs free energy** The Helmholtz free energy, plus the energy of interaction with a surrounding medium at pressure

$p$  given by  $pV$  where  $V$  is the volume of the system. See *free energy* for an even more comprehensive concept that includes all energies that are not clearly spent energy.

**Gram** SI mass unit originally defined as the mass of 1 cubic centimeter of water at a certain standard temperature and pressure.

**Ground state** The lowest energy state of a given system of variable energy. That is, the energy eigenstate having the lowest (most negative) possible energy eigenvalue.

**Grover's algorithm** A quantum algorithm originally characterized as a database search algorithm that is (more usefully) really an algorithm for the *unstructured search* problem.

**Hamiltonian** This is a term from classical mechanics that remains valid in quantum mechanics. The Hamiltonian is a function that gives a system's energy as a function of its state variables. The Hamiltonian incorporates all of the interactions between the subsystems of a given system. All of the dynamical laws of mechanics can be expressed in terms of the system's Hamiltonian. In quantum mechanics, this remains true; the dynamics is given by Schrödinger's equation. The Hamiltonian is an observable, an Hermitian transformation of state vectors. In quantum field theory, the Hamiltonian can be expressed as a sum of local interactions, which makes it consistent with special relativity.

**Hardware efficiency** The reciprocal of the spacetime cost of a computation. A figure of merit used in VLSI theory that is appropriate for some nanocomputer system optimizations, in limited contexts. However, in general, it is incomplete, because it ignores energy costs, as well as costs that are proportional to time alone (such as inconvenience to the user).

**Heat** Heat is simply that part of a system's total energy that resides in subsystems whose physical information is entirely unknown (entropy).

**Heisenberg's uncertainty principle** The most general form of this principle is that two quantum states that are not orthogonal to each other are not operationally distinguishable, by any physical possible means whatsoever. It manifests itself frequently in statements that two observables that do not commute with each other (*e.g.*, position and momentum of a particle) cannot both be precisely measured for the same system.

**Helical logic** A reversible logic scheme proposed by Merkle and Drexler in which a rotating electromagnetic field adiabatically shuttles charge packets around a network of wires in which they steer each other via Coulombic interaction.

**Helmholtz free energy** The free energy (see our definition) of a system, minus that portion that is not considered to be internal energy. To the extent that internal energy is less well defined than is total energy (for instance, how much of the rest mass-energy does it include?), Helmholtz free energy is less well defined than is our free energy.

**Hermitian operator** An operator on quantum states that is equal to its adjoint (conjugate transpose). Hermitian operators have real-valued eigenvalues. In quantum mechanics, Hermitian operators represent both measurements of observable characteristics and interactions (Hamiltonians)

between systems (which makes sense, since a measurement is just a type of interaction).

**Hilbert space** This is a term from linear algebra. A Hilbert space is simply a complex vector space that supports an inner product (dot product) operation between vectors. In quantum mechanics, the set of possible quantum states of a system is described mathematically as a Hilbert space. Not all states in the Hilbert space are operationally distinguishable from each other. Two states are distinguishable if and only if their state vectors are orthogonal.

**Hole** The absence of an electron in a state below the Fermi surface. (Think of it as a bubble in the Fermi sea.)

**Hop** The propagation of information from one node in an interconnection network to another node to which it is directly connected.

**Https** Hyper text transfer protocol, secure: a protocol for secure communication of web pages and form data based on the transport layer security (TLS) protocol, which may use RSA internally (thus being vulnerable to cracking by a quantum computer).

**Hypercube** An  $d$ -dimensional interconnection network formed by connecting corresponding nodes of a  $(d - 1)$ -dimensional hypercube. Hypercubes are not physically realistic with unit-time hops.

**Ideal gas constant** See *nat*.

**Information** That which distinguishes one thing from another, in particular, different (distinguishable) states of a physical system. We say that a system in a particular state *contains* the information specifying its state. An *amount* of information can be quantified in terms of the *number* of (equally probable) distinct states that it suffices to distinguish. The natural convention is that the information corresponds to the *logarithm* of the number of distinguishable states; this measure has the advantage of being additive whenever multiple independent systems are considered together as one system. Any real number  $r > 1$ , when used as the base of the logarithm, yields a corresponding unit of information. The unit of information corresponding to the choice  $r = 2$  is called the *bit*, whereas the unit corresponding to  $r = e$  (the base of the natural logarithms) is called the *nat*. (Boltzmann's constant  $k_B$  and the ideal gas constant  $R$  turn out to be simply alternative names for 1 nat.)

**Instruction set architecture (ISA)** A traditional type of programming model in which serial computations are expressed by a sequence of low-level instructions which tell the computer to do a simple arithmetic or logical operation (such as adding two numbers), or to transfer control to a different point in the instruction sequence. Other, very different types of programming models are also possible, such as models used in FPGAs and cellular automata machines.

**Insulator** An *insulator* is a material in which the bandgap between the valence band and the conduction band is so large that there is negligible charge-carrier concentration and therefore negligible conductivity. (Compare *semiconductor*.)

**Integrated circuit** A complex circuit manufactured as a single solid-state component.

**Interference** In any wave-based process, waves *interfere* when they add linearly in superposition; this interference can be either *constructive* with two waves have the same sign or *destructive* when they have opposite sign. Since everything is a wave in quantum mechanics, two different trajectories in a quantum computer can interfere destructively if they arrive at a given state out of phase with each other. Such interference between trajectories is necessary to get added power from quantum algorithms.

**Interconnect** A pathway for communication.

**Internal energy** Energy in a system other than the kinetic energy of its overall motion and energies of interaction with other external systems. Sometimes in the traditional thermodynamics definitions of this concept, rest mass-energy is also omitted from the definition, although this is an arbitrary and artificial step, since internal potential energy (which is usually included in internal energy) is technically (in relativity) an *indistinguishable* concept from rest mass-energy, which necessarily includes the binding energies (which *are* internal potential energies) of, for example, atoms, protons, and neutrons.

**Internal ops** Operations that are concerned with updating the internal state of an object, as opposed to propagating the object through space translationally or rotationally. The rate of internal ops is the rest mass-energy or internal energy of an object. The total number of internal steps taken, relative to that of a comoving reference object (clock), is the *proper time* experienced by the system.

**Invertible** A mathematical term. A function is invertible if its inverse relation is also a function, that is, if the original function is one-to-one.

**Iop** Short for "*inverting op*," a unit of computational work equal to one-half of a pop.

**Irreversible computing** The traditional computing paradigm, in which every computational operation erases some amount of known information and therefore necessarily generates a corresponding amount of new physical entropy.

**Isentropic** Literally, "at the same entropy." A process is *isentropic* if it takes place with no new generation of physical entropy.

**J** Abbreviation for Joule (the energy unit).

**Josephson effect, Josephson junction** A superconducting current can even pass through a sufficiently narrow tunnel barrier (Josephson junction) without resistance, up to some critical current at which the junction abruptly switches off (Josephson effect). This phenomenon is the basis for some superconducting logic technologies, such as the fairly successful rapid single-flux quantum technology developed by Konstantin Likharev's group at SUNY.

**Joule** A unit of energy defined as 1 N · m. In computational units, a Joule is equal to a potential computing rate of  $6.036 \times 10^{33}$  primitive operations (pops) per second.

**k** In Roman font, k, an abbreviation for kilo-. In italic font *k*, often used to represent Boltzmann's constant.

**kT** Called the *thermal energy*, this product of Boltzmann's constant  $k$  and the thermal temperature  $T$  is the average energy (or rate or operations) per nat's worth of state information in a thermal system. However, it also applies just as well to nonthermal systems at generalized temperature  $T$ .

**Kelvin** SI unit of absolute temperature, defined originally as 1/100th the absolute temperature difference between the freezing and boiling points of water at atmospheric pressure. In computational units, 1 Kelvin is equal to an average rate of state change of 28.9 billion steps (pops per bit) per second, that is, an update frequency of 28.9 GHz.

**Kilo** SI unit prefix meaning 1000.

**Kinetic energy** Energy associated with the overall motion of a system as a whole.

**Known** A given piece of information is *known* by a given entity (which can be any kind of entity, a human, organization, computer, or logic gate) to the extent that it is correlated with other information that is accessible by that entity, in a such a way that the entity can make use of this correlation in a well-defined way.

**Landauer embedding** The technique of embedding a desired logically irreversible computation into a logically reversible computation by simply keeping a copy of all information that would otherwise be thrown away.

**Latch** To store a copy of an input signal so that it remains available when the signal is removed. Conceptually, the information is “latched into place,” like a mechanical part can be.

**Latency** In computer architecture, the amount of time that passes while waiting for something.

**Latency hiding** A computer architecture trick of “hiding” delays to high-latency operations (*e.g.*, communicating with memory or distant processors) by finding other useful work to do in the meantime. Unfortunately, there are limits to the extent to which the technique can improve the overall cost efficiency of a computation.

**LC oscillator** A simple electrical circuit in which an inductance ( $L$ ) is connected to a capacitance ( $C$ ). In this circuit, energy oscillates between the magnetic field of the inductor and the electric field of the capacitor. Unfortunately, the  $Q$ 's obtainable in nanoelectronic inductors are quite limited.

**Lithography** Literally, “stone writing,” this refers generically to any technique for forming a patterned structure on a solid surface. *Photolithography* is a photochemical technique for etching specific patterns using projected light; it is the most widely used technique today. However, it is limited by the wavelengths of easily manipulated light. Other emerging lithography techniques such as electron-beam lithography, deep reactive ion etching (DRIE), and direct-imprint lithography are helping extend minimum feature sizes to the nanometer realm.

**Logical basis** The particular basis of a qubit's state space, chosen by convention, in which the two orthogonal basis vectors are taken represent a pure logic 0 and 1 respectively. If the qubit system contains natural pointer states, these may conveniently be selected as the basis (especially if the system is not highly coherent). Sometimes, it may be more convenient to use an alternative description of quantum architectures in which the logical basis is considered to change over time.

**Logical bit** Also *coded bit*, *computational bit*. This is a bit that the logical or coding state of a bit device is intended to represent. Note: Every logical bit that we can actually manipulate is also a physical bit!

**Lecerf reversal** To reversibly clear temporary storage used up by a reversible computation by running the steps of the computation in reverse. Used in Bennett's algorithm and in retractile cascade circuits.

**Logically reversible** A computational process is logically reversible if every logic operation performs an invertible transformation of the logical state.

**Logical state** The part of a bit device's state that corresponds to the intended digital information to be stored. May be determined redundantly by a large amount of physical coding-state information.

**Logic gate** A *bit device* that operates on logical bits of interest in a computation.

**Logic operation** A transformation that takes a logical state to a distinguishable logical state. May be implemented by a collection (in series or in parallel) of operations carried out on coding state information.

**Loop Quantum Gravity** The leading competitor to String Theory as a potential path toward the unification of the Standard Model and general relativity. Interestingly, in Loop Quantum Gravity, spatial area and volume are quantized, and the exact maximum number of quantum states (and thus the exact maximum information content) of any region of space can be counted and matches the limit found earlier by Bekenstein and Mayo [119]. In this limit, the maximum information capacity within a given surface is given by the surface area in Planck units. This suggests that a limiting model of computing in the high-density regime may be only two-dimensional. But it is still too early to tell.

**m** Abbreviation for meter (the length unit).

**Machine language** The language in which algorithms are expressed when they can be directly processed by a given machine. The *instruction set architecture* of a conventional machine specifies the rules of its machine language.

**Magnitude** The complex number  $c$  has *magnitude*  $m \geq 0$  if and only if  $c = me^{i\theta}$  for some real number. An equivalent definition: If  $c = a + bi$  for real numbers  $a, b$ , then  $m = (a^2 + b^2)^{1/2}$ .

**Majority logic** A type of logic operation in which the value of an output bit is set to the majority value of an odd number of input bits.

**Mass** Relativistic mass is total energy, converted to mass units (by dividing by  $c^2$ ). See also *rest mass*.

**MEMS** Microelectromechanical systems. Denotes a lithography-based technology for fabrication of mechanical or electromechanical structures and systems on surfaces. MEMS technologies are available today.

**Mesh** An interconnection network based on local (bounded-length) connections between nodes located in a space having (if realistic) three or fewer dimensions.

**Mesoscale** Literally, “middle scale,” an intermediate scale between the nanoscale and the microscale at which surface effects and quantum effects begin to become important but do not yet entirely dominate the physics of materials and devices.

**Meta-stable** A state is called meta-stable if it has a relatively slow rate of decay toward an equilibrium (maximum-entropy) state.

**Meter** Unit of length originally defined as ten-millionth of the distance from the Earth's equator to its north pole.

**Metric** A function that gives the distance, according to some method of measurement, between any two given points.

**Microcomputer** For our purposes, a computer whose *characteristic length scale* is anywhere between  $10^{-4.5}$  and  $10^{-7.5}$  meters (*i.e.*, between 32 and 0.032 m; *i.e.*, closer to 1 micrometer than to 1 millimeter or 1 nanometer on a logarithmic scale).

**Micrometer** A unit of length equal to  $10^{-6}$  meters. Typical length of a bacterial cell.

**Micron** Shorthand name for *micrometer*.

**Mixed state** A statistical mixture of (pure) quantum states, which may be represented by a *density matrix*, which can always be diagonalized or transformed to an alternative basis in which it consists of a mixture of orthogonal states. Therefore a mixed state can be understood as nothing more than a classical statistical mixture of pure quantum states.

**Mole** Quantity of molecules (or other objects) such that the collection's mass in grams is equal to the individual object's mass in atomic mass units (amu). Number of amus per gram. Equal to Avagadro's number,  $6.0221367 \times 10^{23}$ .

**Momentum** In computational terms, the physical momentum  $p$  is the total number of operations per distance required to translating a system spatially in a given direction. Such a transformation is orthogonal to any internal transformations, whose rate is given by the system's rest mass, so the total rate of operations  $E$  for a system of rest mass  $m_0$  with momentum  $p$  is given by the Pythagorean theorem as  $E^2 = m_0^2 + p^2$ , the correct relativistic formula.

**MOSFET** Metal-oxide-semiconductor field-effect transistor. A field-effect transistor structure constructed by sandwiching a layer of insulating material (usually silicon dioxide or another oxide) in between a metallic (or actually, often polysilicon) gate electrode and a semiconducting substrate.

**M-theory** A generalization and unification of several leading string theories in which  $d$ -dimensional membranes, rather than one-dimensional strings, are the fundamental entities. Like the individual string theories themselves, M-theory has made no confirmed predictions and therefore remains fairly speculative. Even if true, I do not expect it to radically change our understanding of the physical limits of computing.

**$\mu\text{m}$**  Standard abbreviation for *micrometer*.

**N** Abbreviation for Newton (the force unit).

**Nano-** SI unit prefix, denoting multiplication of the unit by  $10^{-9}$ . Abbreviated n.

**Nanocomputer** A computer whose characteristic length scale is between  $10^{-7.5}$  and  $10^{-10.5}$  meters (*i.e.*, between  $\sim 32$  and  $\sim 0.32$  nm, *i.e.*, closer to 1 nanometer than to 1 micrometer or 1 picometer on a logarithmic scale).

**Nanocomputing** Computing using nanocomputers.

**Nanometer** A unit of length equal to  $10^{-9}$  meters, or  $10 \text{ \AA}$ . A typical length for a small molecule, such as an amino acid. About five carbon-carbon bond lengths. About the radius of the smallest carbon nanotubes.

**Nanoscale** Although definitions vary, for purposes of this chapter, we define *nanoscale* as meaning a characteristic length scale that falls anywhere in the three-order-of-magnitude range between  $\sim 30$  and  $\sim 0.03$  nm. That is, the logarithm of the characteristic length scale is closer to 1 nm than to either  $1 \mu\text{m}$  or  $1 \text{ pm}$ .

**Nanowire** A wire (made of conductive or semiconductive material) that has a nanoscale diameter.

**Nat** The natural-log unit of information or entropy. Also known as *Boltzmann's constant*  $k_B$  or the *ideal gas constant*  $R$ .

**Near nanoscale** The range of pitch values between 1 and 32 nanometers. Contrast *far nanoscale*.

**NEMS** Nanoelectromechanical systems. Basically, just MEMS technology scaled down to the nanoscale. More generically, NEMS could be used to refer to any nanoscale technology for building integrated electromechanical systems.

**Newton** A unit of force equal to  $1 \text{ kg m/s}^2$ .

**NFET** A field-effect transistor in which the dominant charge carriers are negative (electrons).

**nm** Standard abbreviation for *nanometer*.

**NMR** Nuclear magnetic resonance, a technology used in chemical NMR spectrometers and modern medical (magnetic resonance imaging) scanning machines. In the mid 1990s, NMR technology was used to implement simple spin-based quantum computing (massively redundantly encoded) using nuclear spins of selected atoms of a molecular compound in solution.

**Noncoding physical state** The part of the physical state of a computing system or device that is uncorrelated with its logical state, for example the detailed state of unconstrained thermal degrees of freedom (see *thermal state*). However, another part of the noncoding state (the *structural state*) is correlated with the system's ability to *have* a well-defined logical state. For example, if a transistor gate is in a state of being shorted out then its nodes may no longer be able to maintain a valid logic level.

**Nondeterministic models of computing** The adjective "nondeterministic" is used misleadingly in computer science theory as jargon for models of computation in which not only is the computer's operation at each step nondeterministic, in the sense of not being determined directly by the machine's current state, but furthermore it is assumed to be *magically* selected to take the machine directly to the desired solution, if it exists (or equivalently, all solutions are magically tried in parallel, and the correct one is then selected). Computer scientists really ought to rename "nondeterministic" models as magical models of computing, to emphasize their total lack of realism. Probably this was not done historically for fear of scaring off potential funding agencies. In any case, the name seems intentionally misleading.

**NP** *Nondeterministic polynomial-time*, the set of problem classes in which a proposed solution can be checked or verified within an amount of time that is polynomial in the length  $n$  of the problem description in bits, that is, in which the time to check the solution grows as  $(n^k)$  for some constant  $k$ .

**NP-hard** The set of problems such that any problem in NP can be reduced (in polynomial time) to an instance of that problem. If any NP-hard problem can be solved in polynomial time, then all of them can.

**NP-complete** The set of problems that are both in *NP* and in *NP-hard*.

**Number of operations** A characteristic of a transformation trajectory that counts the total number of primitive orthogonalizing operations that occur along that trajectory. The number of operations can be counted in units of Planck's constant or pops.

**Observable** In quantum theory, an observable is just any Hermitian operator on states. The eigenstates of an observable are orthogonal (distinguishable), and its eigenvalues are real-valued (zero imaginary component). The eigenstates of the observable have a definite value of the measured quantity, and its numerical value is given by the eigenvalue.

**Omega network** Similar to a butterfly network. Omega networks are not physically realistic for unit-time hops.

**Op** Short for *operation*, or pop. We also sometimes use ops to refer to operation units of other sizes besides pops, such as rops and iops.

**Operation** In this document, shorthand for *primitive orthogonalizing operation*. Also used sometimes to mean the special case of *logic operation*, a primitive orthogonalizing operation, or series of such, that effects a single change in the logical state.

**Operational** In the scientific method, a defined characteristic of a system is called *operational* in nature if there exists a reliable, physically realizable procedure for measuring or confirming that characteristic. For example, two states are operationally distinguishable if there exists a definite experiment that can reliably distinguish them from each other.

**Operator** In mathematics, a function that operates on a sequence of a prespecified number of members of a given set and returns a member of that same set. Functions that operate on sequences of length 1 are called *unary* operators or *transformations*.

**Opportunity cost** In economics, the implicit cost of consumption of resources that results from foregoing the best alternative use of those same resources.

**Orthogonal** A term from vector mathematics. Two vectors are orthogonal if and only if, considered as lines, they are perpendicular, or (equivalently) if their inner product (dot product) is zero. Orthogonality is the requirement for two quantum state vectors to be operationally distinguishable from each other.

**Orthogonalize** To transform a vector (such as a quantum state vector) to another vector that is orthogonal to the original one.

**Parallel** Two processes are *parallel* if they take place simultaneously.

**p**— Short for *pico*, SI unit prefix meaning  $10^{12}$ .

**Performance** Performance is a figure of merit for computing. It is equal to the *quickness* of a reference computation.

**PFET** A field-effect transistor in which the dominant charge carriers are positive (holes).

**Phase** The complex number  $c$  has *phase*  $0 \leq \theta < 2\pi$  if and only if  $c = m \cdot e^{i\theta}$  for some real number  $m$ .

**Physical bit** Any bit of physical information.

**Physical entropy** Physical information that is entropy (unknown to a particular observer).

**Physical information** Information contained in a physical system, defining that system's state. Of course, all the information that we can access and manipulate is, ultimately, physical information.

**Physically reversible** Synonym for *adiabatic*, *isentropic*, and *thermodynamically reversible*.

**Physical realism** In this chapter, a property had by a model of computation when it does not significantly (by unboundedly large factors) overstate the performance or understate the cost for executing any algorithm on top of physically possible implementations of the architecture. WARNING: Many models of computing that are studied by computer scientists lack this important property and therefore can be very misleading as guides for computer engineering and algorithm design.

**Physical system** In essence this is an undefined term, based on intuition. But we can distinguish between abstract *types* of physical systems, constrained by their descriptions, and specific *instances* of physical systems embedded within our actual universe. For a specific instance of a system, we may in general have incomplete knowledge about its actual state. We should emphasize that a particular system might be defined to consist of only specified state variables within a particular region of space, as opposed to the entirety of the physical information within that region.

**Pico**— SI unit prefix, denoting multiplication of the unit by  $10^{-12}$ . Abbreviated p.

**Picometer** A unit of length equal to  $10^{-12}$  meters, or 0.01 Å. Roughly 1/100 the radius of a hydrogen atom, or 100 times the diameter of an atomic nucleus.

**Pipelined logic** A deep combinational network can be broken into a series of shorter stages which can be used simultaneously to process different sequential inputs, resulting in a higher overall hardware and cost efficiency for most irreversible computations. However, pipelined reversible logic is *not* always more cost efficient than is nonpipelined reversible logic.

**Pitch** The distance between the center lines of neighboring wires in a circuit.

**Planck energy** The fundamental constants  $h, G, c$  can be combined to give an energy unit,  $E_p = (\hbar c^5/G)^{-1/2} \simeq 1.956$  GJ. This energy, or something close to it, is believed to be a fundamental maximum energy for a fundamental particle in whatever turns out to be the current unified theory of quantum gravity. It is the energy of a particle when traveling at a velocity so high that that its de Broglie wavelength is equal to the Planck length.

**Planck length** The fundamental constants  $h, G, c$  can be combined to give a length unit,  $\ell_p = (\hbar G/c^3)^{-1/2} \simeq 1.616 \times 10^{-35}$  m. This length, or something close to it, is believed to be a fundamental minimum length scale in whatever turns out to be the correct unified theory of quantum gravity. For example, it is already known that the maximum information

in any region, in nats, is given by the area of the smallest enclosing surface around that region, in units of  $(2\ell_p)^2$ .

**Planck mass** The fundamental constants  $h, G, c$  can be combined to give a mass unit,  $m_p = (\hbar c/G)^{-1/2} \approx 2.177 \times 10^{-8}$  kg. This mass, or something close to it, is believed to likely be a maximum mass for a fundamental particle, and perhaps the minimum mass of a black hole, in whatever turns out to be the current unified theory of quantum gravity. It is the mass of a particle when traveling at a velocity so high that that its de Broglie wavelength is equal to the Planck length.

**Planck's constant** Expresses the fundamental quantum relationship between frequency and energy. Comes in two common forms, Planck's unreduced constant,  $h = 6.6260755 \times 10^{34}$  Js, and Planck's reduced constant,  $\hbar = h/2\pi$ . In computational terms, Planck's constant is a fundamental unit of computational work;  $h$  can be viewed as equal to two primitive orthogonalizing operations.

**Planck temperature** Dividing the Planck energy by Boltzmann's constant  $k$ , we get a temperature  $T_p \simeq 1.417 \times 10^{32}$  K. This temperature, or something close to it, is believed to be a fundamental maximum temperature in whatever turns out to be the correct unified theory of quantum gravity. It is the temperature of a Planck-mass (minimum-sized) black hole, or a single photon of Planck energy. In computational terms it corresponds to 1 radian-op per Planck time, or 1 pop per  $\pi$  Planck times, which gives a maximum possible frequency of complete state update steps in a computational process of  $\sim 5.9 \times 10^{42}$  steps per second.

**Planck time** The fundamental constants  $h, G, c$  can be combined to give a time unit,  $t_p = (G\hbar/c^5)^{-1/2} \simeq 5.391 \times 10^{-43}$  s. This time, or something close to it, is believed to be a fundamental minimum time unit in whatever turns out to be the correct unified theory of quantum gravity. It is the time for light to travel 1 Planck length and is the reciprocal of the angular phase velocity of a quantum wavefunction of a Planck-mass particle, or in other words the minimum time per rop. The minimum time for a primitive orthogonalizing operation is  $t_p \simeq 1.69 \times 10^{-42}$  s.

**pm** Standard abbreviation for *picometer*.

**Polynomial time** In computational complexity theory, having a time complexity that grows as  $\Theta(n^k)$  in input length  $n$  for some constant  $k$ .

**Pop** Abbreviation for *primitive orthogonalizing operation*  $\pi$ -op.

**Pointer state** A state of a quantum system that remains stable under the most frequent modes of interaction with the environment, that is, an eigenstate of the observable that characterizes the interaction. The states chosen to represent logical bits in a classical (nonquantum) computer are usually pointer states. Quantum computers, however, are not restricted to using only pointer states. This is what gives them additional power. However, it requires a high degree of isolation from unwanted interactions with the environment, which will destroy (decohere) nonpointer states.

**Polysilicon** Sometimes abbreviated just *poly*, this is polycrystalline silicon, a quasi-amorphous state of solid silicon, made of numerous nanoscale crystal grains. Often used for

local interconnect layers, in contrast with the single-crystal silicon forming the chip substrate.

**Power** Rate of energy transfer, often measured in Watts.

**PR** See *physical realism*.

**PRAM** Parallel variant of the RAM machine model of computation. There are several varieties of PRAM model. One simply has  $n$  RAMs accessing the same shared memory in parallel. PRAM models are not physically realistic, in the sense used in this chapter.

**Primitive orthogonalizing operation** Also pop,  $\pi$ -op. In this chapter, a unitary transformation that takes some quantum states to new states that are orthogonal to the original state. A  $\pi$ -op is equal to  $\pi$  rops or to  $\pi\hbar = h/2$ .

**Principle of locality** Casual effects can only happen through local interactions in space. This is a consequence of special relativity, and it is obeyed by modern quantum field theory, in which the global Hamiltonian is composed from local interaction terms only. Einstein thought that quantum mechanics was nonlocal, but it turned out he was wrong.

**Processor** Short for *information processor*, this refers either to a computer or to a part of a computer (e.g., a CPU) that is large and complex enough to be programmed to perform different types of computations.

**Program** Information specifying in complete detail an algorithm that a computer will perform. Relates to a specific *programming language* or to a computer's specific *programming model*.

**Programming model** Specifies how a given architecture can be *programmed* to carry out whatever computation is desired. Most computers today have a specific type of programming model called an *instruction set architecture*. Other kinds of programming models exist, such as those used in FPGAs, CAMs, and dataflow machines.

**Programming language** A standard language, usually textual (although graphical languages are also possible) for representing algorithms. A *compiler* translates a program from an easily human-readable programming language into a form that can be utilized by a given machine's programming model.

**Proper time** In relativity, this is the amount of time (number of reference-system update steps) to pass, as experienced in a reference frame moving along with a given object, rather than in some other arbitrarily chosen reference frame.

**Public-key cryptography** An approach to cryptography and authentication based on a complementary pair of keys, a public key and a private key, each of which decrypts the code that the other encrypts. The most popular known public-key cryptography algorithms are vulnerable to being broken by quantum computing.

**Pure state** See *quantum state*.

**Q3M** Quantum 3D mesh, a model of computing consisting of a three-dimensional mesh-connected network of fixed-size, arbitrarily reversible, and quantum-coherent processing elements. The Q3M is postulated by the author to be a UMS model. See *tight Church's thesis*.

**Quality** In this chapter, the *quality* or  $q$  factor of a device or process is defined as the ratio of energy transferred to energy dissipated, or (quantum) bit operations

performed to entropy generated, or quantum bit operations performed to decoherence events. It is also the ratio between the coding-state temperature and the temperature of the decoherence interaction, or the ratio between the coherence time and the operation time.

**Quantum algorithms** Algorithms for a quantum computer, which use superpositions of states and interference effects in an essential way. Quantum algorithms must be reversible to avoid decoherence.

**Quantum computer** A computer that uses superpositions of pointer states as intended intermediate states in a computation. Ordinary classical computers are restricted to only using pointer states. The less-constrained state space available in a quantum computer opens up exponentially shorter trajectories toward the solution of certain problems, such as the factoring problem. The more constrained state space available to a classical computer appears to require exponentially more steps to arrive at solutions to this problem.

**Quantum dot** A mesoscale or nanoscale structure in which conduction-electron energies are quantized.

**Quantum dot cellular automaton** Abbreviated QDCA or just QCA, this is a particular logic scheme using quantum dots which was invented at Notre Dame. Involves “cells” (made of four dots) which interact with each other locally; in this respect, it roughly resembles the cellular automaton model of computing. QDCA also includes adiabatic variants.

**Quantum electrodynamics** Abbreviated QED, this is the quantum field theory that deals with charged particles, photons, and the electromagnetic field. Now subsumed by the Standard Model of particle physics.

**Quantum field theory** When quantum mechanics is unified with special relativity, the result is a field theory. The Standard Model of particle physics is the modern working quantum field theory. Other, simplified models, which omit some details of the Standard Model, including quantum electrodynamics, the quantum field theory of electric charge and electromagnetism, and quantum chromodynamics, the quantum field theory of “color” charge (carried by quarks and gluons) and the strong nuclear force.

**Quantum information** The specific quantum information contained in a system can be identified with the actual quantum state of the system, itself. The total *amount* of quantum information is the same as the amount of classical information—namely, the logarithm of the number of orthogonal states—except it is measured in qubits rather than bits. The quantum information can be thought of as a choice of basis, together with the classical information inherent in the selection of one of the basis states. The classical information is only the selection of basis state, with the basis itself being fixed.

**Quantum mechanics** Modern theory of mechanics, initiated by Planck’s discovery of the fundamental relationship between frequency and energy, namely that a system performing transitions between distinguishable states at a given rate or frequency must contain a corresponding minimum amount of energy. (This fact was first discovered by Planck in the context of blackbody radiation.)

**Quantum state** Also called a pure state, the state of a quantum system is identified with a vector (normalized to

unit length) in the system’s many-dimensional *Hilbert space*. Two states are distinguishable if and only if their state vectors are orthogonal (perpendicular to each other).

**Qubit** A unit of quantum information, as well as a name for any particular instance of a physical system or subsystem that contains this amount of quantum information. A system that contains one qubit of information has only two distinguishable states. A qubit may be in a state that is superposition of pointer states, and this state may be entangled (correlated) with the states of other systems.

**Quickness** The *quickness* of any process is the reciprocal of the total real time from the beginning of that process to the end of the process. Quickness is measured in units of Hertz (inverse seconds).

**R3M** Reversible 3D mesh, a model of computing consisting of a three-dimensionally connected mesh network of fixed-size, arbitrarily reversible processors. The R3M is postulated to be a UMS model for nonquantum computations. See also Q3M.

**RAM** Random access memory, a memory in which any random element can be accessed (read or written) equally easily, by supplying its numeric address. Also stands for random access machine, an early non-PR, non-UMS model of computation in which any random element of an unboundedly large memory can be accessed within a small constant amount of time.

**Radian-op** See *rop*.

**Random access** To access (read or write) a bit of memory selected at random (*i.e.*, arbitrarily).

**Resonant tunneling diodes/transistors** Structures in which the rate of tunneling between source and drain electrodes is controlled by the resonant alignment of electron energy levels in an intervening island with the Fermi energies of free conduction electrons in the source terminal.

**Rest mass** Computationally, the rate of ops in a system that are concerned with the internal updating of the system’s state, rather than with net translation of the system in a particular direction (*i.e.*, that portion of a system’s total energy that is not kinetic energy).

**Retractile cascade logic** Or just retractile logic. A reversible combinational logic style in which inputs are presented and intermediate results computed and then (after use) are uncomputed by “retracting” the operations that produced the results, in reverse order.

**Reversibility** A process or dynamical law is reversible if the function mapping initial state to final state is one-to-one (that is, its inverse is a function). Reversible is synonymous with reverse-deterministic (deterministic looking backwards in time). It is *not* synonymous with *time-reversal symmetric*. A dynamical law is time-reversal symmetric if it has the identical form under negation of the time component. Modern particle physics actually has a slightly changed form under time reversal (namely, charges and handedness must also be changed), but it is still reverse-deterministic, thus still reversible.

**Reversible algorithms** Algorithms composed of reversible operations.

**Reversible operations** An operation is reversible if it transforms initial states to final states according to a one-to-one (bijective) transformation.

**Reversible computing** A paradigm for computing in which most logical operations perform a logically reversible (bijective) transformation of the local logical state; this transformation can then be carried out adiabatically (nearly thermodynamically reversibly).

**Reversibilize** To translate a computation described as an irreversible algorithm to an equivalent but reversible form, often by reversibly emulating the steps of the irreversible algorithm.

**Rop** Short for *radian-op*, a unit of computational work equal to Planck's reduced constant  $\hbar$ . Equal to  $1/\pi$  of a  $\pi$ -op (pop). An example would be the rotation of a quantum spin by an angle of 1 radian.

**RSA** Rivest, Shamir, Adleman, the abbreviation for a popular public-key cryptography algorithm whose security depends on the assumed hardness of factoring large numbers. The advent of large-scale quantum computing would falsify this assumption and permit RSA codes to be broken.

**RTD** See *resonant tunneling diode*.

**s** Abbreviation for second (the time unit).

**SI** Standard abbreviation for *Système Internationale d'Unites*, the International System of Units, adopted by the 11th General Conference on Weights and Measures (1960).

**Second law of thermodynamics** The law that entropy always increases in closed systems. The law can be proven trivially from the unitarity of quantum theory, together with von Neumann's definition of entropy for a mixed quantum state, by analyzing the effect when a quantum system evolves according to a Hamiltonian that is not precisely known or interacts with an environment whose state is not precisely known.

**Semiconductor** A semiconductor is a material in which there is (small but positive) gap (called the *bandgap*) between the highest energy levels of valence electrons that are bound to specific atoms, and the lowest energy levels of conduction electrons, electrons that are freely moving through the material. Due to the bandgap, only a small number of electrons will be free to move, and the material will not conduct electricity well. However, addition of dopants, applied fields, *etc.*, can significantly change the concentration of charge carriers in the material. The ease of manipulation of carrier concentration is what makes a semiconductor a useful material for controlling conductance in transistors. Contrast *conductor* and *insulator*.

**Sequential logic** Digital logic with feedback loops and storage capability, in which new results are produced sequentially, one at a time in definite steps, and in which a given piece of hardware is reused, in sequence, for calculating results of subsequent steps. Compare *combinational logic*.

**Shannon entropy** The appropriate definition of entropy for a situation in which not all possible states are considered equally probable. The Shannon entropy is the expected amount of information gain from learning the actual state.

**Single-electron transistor** A transistor whose conductance changes significantly upon the addition or removal of a single electron to/from its gate electrode. Can be built today.

**Space complexity** In traditional computational complexity theory, this is the machine capacity (in bits) required to perform a computation. In physical computing theory, this is seen as an inaccurate measure of the true economic cost of a computation; spacetime cost is a more accurate substitute.

**Spacetime** A volume of physical spacetime is measured as the physical volume of a region of space, integrated over an interval of time. Computational spacetime reflects the same idea, for the region of space actually utilized to perform computations or store intermediate results during a computation. It may be approximated in restricted contexts by just integrating the number of bits in use over the number of parallel update steps performed.

**Special relativity** Einstein's theory based on the principle that the speed of light is independent of the observer's velocity. It revolutionized mechanics with the discovery that space and time are interwoven with each other, and that moving objects slow down, shorten, and become more massive, and that mass itself is nothing but a bound form of energy. It predicts that nothing can go faster than light. Its predictions have been exhaustively confirmed to high accuracy by myriad experiments. It was later generalized to incorporate gravity and accelerated motion in the General Theory of Relativity.

**Speed of light** Denoted by  $c \simeq 3 \times 10^8$  m/s, the speed of light is the maximum propagation velocity of information and energy through space, as was discovered by Einstein in his theory of relativity. Computationally speaking, the speed of light is that speed at which *all* of the quantum operations taking place in a system are spatial-translation ops, which makes it clear why this speed cannot be exceeded and why nonzero rest-mass systems (which have a nonzero rate of internal ops) cannot achieve it. We should emphasize that modern quantum field theory, being entirely local, definitely and explicitly obeys the constraint that information (both classical and quantum information) can travel at most at the speed of light.

**Spent energy** The spent energy in a system is defined as the system's entropy  $S$  times the temperature  $T$  of the coolest available thermal reservoir of effectively unlimited capacity. At least  $ST$  energy must be permanently dedicated in order to remove the entropy to the reservoir (unless a cooler reservoir later becomes available). Spent energy is total energy minus free energy.

**Spin** Fundamental particles in quantum field theory have a *spin*, an inherent angular momentum whose absolute numerical value is always an integer multiple of  $\hbar/2$ . (This prediction arose from the unification of quantum theory and special relativity and was subsequently confirmed.) Spin states have an orientation; oppositely oriented spins are distinguishable, but other pairs of orientations are not. A spin can hold only 1 qubit of quantum information, and only 1 bit of classical information.

**Spintronics** Electronic technology in which electron and/or nuclear spin states (instead of or in addition to the position and momentum states of electric charges) are used to store, transmit, or process information. Magnetic storage

technology can be considered an early example of spintronics. NMR quantum computing is a more recent example. Spintronic diodes and switches are also being developed.

**Standard Model of particle physics** This is the consensus bedrock of modern physics. It treats electromagnetism and the strong and weak nuclear forces together in a single quantum field-theoretic framework. It encompasses all known fundamental particles, and all forces except for gravity. Its predictions have been verified to many decimal places. Aside from an eventual unification with general relativity, which would modify the theory's predictions only at extremely high-energy scales, there is no indication that any future developments in physics would change the Standard Model's ramifications for nanoscale engineering. In other words, the Standard Model seems to be a totally complete model so far as nanotechnology is concerned. This allows us to make confident predictions about the fundamental limits of computing based on the Standard Model.

**State** An exact configuration of a given type of physical system. States of quantum systems are identified with mathematical vectors. (See *quantum state*.)

**State space** The set of all possible states of a system.

**Statistical mechanics** Branch of mechanics dealing with the statistical behavior of large numbers of simple systems. The foundation of thermodynamics. Modern statistical mechanics is based on quantum-mechanical counting of distinguishable states and is sometimes called *quantum statistical mechanics*.

**Statistical mixture** An ensemble of systems, characterized by a probability distribution, that is, a function from states to their probability.

**Step** A *complete parallel update step* or just *step* of a quantum system or subsystem is a transformation that can be expressed as a trajectory (sequence) of quantum bit operations totaling an average amount of computational work performed of 1 pop per bit of physical information contained in the system. Physical temperature is just a measure of the rate at which steps are performed.

**Stored-program computer** A computer in which the program to be executed can be stored in the computer's memory along with the data to be manipulated.

**String Theory** A hypothetical extension of the Standard Model of particle physics in which fundamental particles of different masses are explained as different modes of vibration of tiny strings and closed loops. String Theory is not yet a complete theory that yields testable predictions, and so it has not yet been experimentally confirmed. It does, however, predict a number of surprising things such as the existence of extra "hidden" spatial dimensions. However, these are not expected to have a major bearing on the physical limits of computing beyond what we already know based on the Standard Model and general relativity.

**Strong Church's thesis** This early expectation of computer science theory claimed that any physically realizable model of computation has a time cost for all problems that is within at most a polynomially growing factor above or below the minimum time to solve the same problem on a Turing machine. However, if quantum computers can be built on arbitrarily large scales, and if no polynomial-time classical

algorithm exists for emulating them to arbitrary precision, then the strong Church's thesis is false. See also *Church's thesis*, *tight Church's thesis*.

**Structural state** The part of the noncoding physical state of a computer/device that is required to remain unchanged in order for the machine to even continue functioning as intended. For example, for a given circuit to function as intended, its wires must remain unbroken, although in practice they may actually break occasionally, due to electromigration effects, an example of state decay.

**Superposition of states** A superposition of states in a quantum system is a linear combination (with complex-valued coefficients) of those states, considered as vectors. The coefficients are normalized so that their squared magnitudes sum to 1. A superposition of states is therefore another vector and therefore is a quantum state, just as much as the states being superposed. However, a superposition of pointer states will not generally be a pointer state and thus may be subject to decay (decoherence) to a statistical mixture of pointer states upon interaction with the environment.

**Subsystem** Informally, a piece of a larger (physical) system. Often (but not always) identified with a particular region of space. May include some degrees of freedom but not others.

**Superconductor** In a superconducting material, pure electron momentum states occupy a decoherence-free subspace and therefore constitute pointer states that are immune from decoherence via ordinary modes of interaction with the environment. A current in a superconductor is therefore maintained indefinitely (with zero resistance). In the more well-understood superconductors, this occurs as a result of a pairing-up of electrons (into *Cooper pairs*) due to indirect mutually attractive interactions intermediated by phonon exchange through the material's crystal lattice.

**Syndrome** In error correction, when an error occurs, the syndrome is the information contained in the exact identity of the error (when/where/what/how it occurred). This information is entropy from the perspective of the designer of the error-correction mechanism and so must be removed from the device in question in order to free up space for desired computational purposes.

**Technology** For purposes of this chapter, a *technology* refers to a device-level technology, for example a specific fabrication process for circuits of electronic or electromechanical devices, or to another low-level physical mechanism used for communication, cooling, *etc.* Higher level design elements such as processor architecture or software algorithms also represent technology, in the broader sense of the word, but we will reserve the word for lower level technology in this chapter (the parts that are not traditionally the domain of the computer scientist).

**Technology scaling model** A part of a model of computing that describes how key characteristics of devices and systems change as the parameters of the underlying manufacturing process technology are varied, for example by scaling devices to smaller sizes, or by scaling cooling technology to effect higher or lower operating temperatures.

**Temperature** The physical temperature of any system can be interpreted as the average rate of quantum operations

per bit of physical information, that is, the average rate at which the system's quantum information is (potentially) completely updated. Usually in thermodynamics we are only interested in the temperature of an *entropic* subsystem (that is, a subsystem whose state information is all unknown); however, the temperature of the *known* information in a system (that is, of the subsystems whose state information is known) is related and also important. If the known information is transitioning at a much faster rate than is the entropy, then an increasing degree of thermal insulation of the known information from the entropy is necessary in order to prevent the entropic subsystem from becoming too hot (and causing the computer to melt).

**Tensor product** A term from vector algebra. The tensor product of two vectors of dimensionality  $d_1$  and  $d_2$  is a new vector of dimensionality  $d_1 d_2$  whose components in a given basis are obtained by pairwise multiplying components of  $d_1$  and  $d_2$ .

**Thermal energy** See  $kT$ .

**Thermal state** That part of the state of a physical system that is entirely entropy, and whose exact state under normal circumstances and intended operating temperatures is expected to fluctuate constantly and unpredictably. For example, a circuit node may be at a fairly definite average voltage level, and so its logic state (high or low) may have low entropy, but at the same time, the detailed occupancy numbers of all of the electron states within a few  $kT$ 's of the Fermi surface will be rapidly and unpredictably fluctuating, and so will constitute another, high-entropy part of the state.

**Thermal temperature** The temperature of those subsystems whose physical information happens to be entropy (*i.e.*, whose energy is heat). Thermal temperature is the traditional thermodynamic concept of temperature, but it is subsumed by the more general, modern definition of temperature given previously.

**Thermodynamically reversible** Synonym for *adiabatic* or *isentropic*. A process is thermodynamically reversible to the extent that it does not produce any new entropy, that is, to the extent that the modeler does not become increasingly uncertain about the identity of the actual state. Even though quantum physics itself is reversible, a quantum process can still be *thermodynamically* irreversible, to the extent that the state of known parts of the system become mixed up with and affected by the state of unknown parts.

**Theta**  $\Theta(f)$  is a mathematical *order-of-growth* notation denoting any function that is constrained to be within a constant factor of the given function  $f$ , for all sufficiently large inputs.

**Tight Church's thesis** This thesis (by the author) postulates that a reversible, quantum 3D mesh (Q3M) is a UMS model of computing, that is, that the minimum time cost to solve any problem in any physically realizable machine lies within a *constant* factor of the time cost in the Q3M model. See also *Church's thesis*, *strong Church's thesis*.

**Time** A quantity of physical time itself (specifically, relativistic proper time) can be defined computationally, in terms of the number of (parallel complete update) steps taken by a fixed reference subsystem (perhaps, a Planck-mass photon) over the course of a particular transformation

trajectory that is undergone by an entire system as it follows its dynamics.

**Time complexity** In traditional computational complexity theory, this is the number of update steps of the logical state of a computation. In physical computing theory, this quantity is seen as an insufficient basis for a correct engineering optimization, and we prefer to use the actual physical time cost, together with other components of true economic cost, instead. In an optimized family of adiabatic architectures, it turns out that time and number of logical steps are *not* always proportional to each other, since the optimum frequency varies with the machine capacity as well as the algorithm to be performed.

**Total energy** The total energy of all kinds in a system can be measured by weighing the mass of the system in a gravitational field and converting to energy units using  $E = mc^2$ . This includes rest mass-energy as well as thermodynamic internal energy.

**Transformation** A unary operator on a state space (or any other set), mapping states to states. The transformation corresponding to time evolution in quantum mechanics is unitary.

**Transformation trajectory** A transformation expressed as a sequence of simpler, irreducible local transformations (*e.g.*, bit operations). A *quantum logic network* is a description of transformation trajectories in a particular graphical language.

**Transistor** An electronic device that is a voltage-controlled current switch. That is, the conductance between two nodes is determined by the level of voltage (relative to some threshold) on a third *gate* node.

**Transmission gate** A circuit element buildable from parallel NFET and PFET transistors that conducts at any voltage level between logic high and low levels when turned on.

**Tunneling** Quantum mechanical phenomenon in which an electron of given energy can penetrate a potential energy barrier that would be too high for it to penetrate classically. This occurs because the inherent indistinguishability of nearby quantum states means that if a barrier is narrow enough, the electron wavefunction can have significant amplitude even on the other side of the barrier.

**Turing machine** A simple early mathematical model of computing due to Alan Turing, in which a fixed-size processor serially traverses an unbounded, one-dimensional memory. The Turing machine is a physically realistic model, but it is not universally maximally scalable.

**UMS** See *universal maximum scalability*.

**Uncompute** To *uncompute* some information that is correlated with other information is to remove the correlation, by undoing (performing in reverse) a transformation that could have computed the information to begin with. *Uncomputing* and related operations provide the *only* physically and logically reversible way to remove known information so as to return a memory cell to a standard state that can be reused for later computations. The ability to uncompute is a key capability for reversible algorithms. (However, uncomputing an old result and computing a new one can sometimes be combined in a single operation, so uncomputing *by itself* is not always strictly necessary for reversible operation.)

**Unitary transformation** A term from linear algebra. An invertible, length-preserving linear transformation of a vector space. All quantum systems evolve over time via a unitary transformation  $U = \exp(iHt/\hbar)$  of their state vector in each unit of time  $t$ , where  $i^2 = -1$ ,  $H$  is the system's Hamiltonian, and  $\hbar$  is Planck's reduced constant.

**Universal** A model of computation is called *universal* if it can emulate any Turing machine, given sufficient resources.

**Universal maximal scalability (UMS)** A model of computation has this property if there is no physically realizable algorithm that is asymptotically more cost efficient (by unboundedly large factors) than all algorithms possible in a physical realization of the given model. None of the models of computation that have been traditionally studied by computer scientists in the past have this property. Nevertheless, it is a desirable property to have, from a computer engineering and algorithm-design standpoint. A reversible 3D mesh that supports quantum operations is conjectured to be a physically realistic, UMS model.

**Unstructured search** A class of problems characterized by the following general description: Given a black-box function  $f$  over some domain, and a target element  $y$ , find a value  $x$  in the domain such that  $f(x) = y$ .

**Valence band** In condensed matter theory, the valence band is the range of energies accessible to electrons that are bound to specific atoms and therefore not free to move throughout the material.

**Velocity** Computationally speaking, velocity is a dimensionless quantity whose square gives the fraction of ops taking place in a system that are devoted to the spatial translation of the system in a particular direction. There is therefore a maximum velocity for all systems of 1, which is equal to the speed of light. Only systems with zero rest mass can actually attain this speed. Of course, we all know that velocity also expresses the distance traversed per unit time.

**Virtual particles** In quantum field theories, fundamental forces are transmitted via the exchange of "virtual" particles (called such because they are not directly observed). For example, the electromagnetic force is transmitted via the exchange of virtual photons.

**VLSI** Very large scale integrated circuits. That is, monolithic chips fabricated with tens of thousands to millions of devices.

**VLSI theory** A model of computation, invented by Charles Leiserson of MIT, that is appropriate for a wide variety of VLSI design applications that focuses on concerns with circuit area and hardware efficiency. It is more suitable for engineering purposes than is traditional computational complexity theory. However, VLSI theory is still not the most comprehensive possible model, because it does not take energy costs and heat-dissipation considerations into account and also does not always account adequately for communications delays. The example model presented in this chapter removes these limitations.

**Voltage** The *voltage* between two circuit nodes or points is the electrostatic potential energy difference between those points per unit charge, for an imaginary infinitesimal test charge located at either point.

**Voltage coding** A simple physical logic coding scheme (the one used today in digital electronics) that considers all voltage states above a certain threshold to represent a logic 1, and all voltage states below a certain threshold to represent a logic 0. However, many other coding schemes are possible (e.g., using superconducting current states, or electron spin states).

**von Neumann entropy** The appropriate definition of entropy for an uncertain quantum state, or mixed state. It is equal to the Shannon entropy of the mixed state when expressed in the diagonalized basis, as a statistical mixture of orthogonal pure states.

**von Neumann machine** A simple computer architecture often attributed to von Neumann, consisting of a single fixed-capacity serial processor that accesses an external memory of arbitrary capacity. Closely related to the RAM machine model of computation.

**Watt** A unit of power (rate of energy transfer) equal to 1 Joule per second.

**Wavefunction** A particular quantum state can be identified with a function that maps all state vectors to the corresponding complex number that arises when the given state vector is combined by a dot product with the state vector of the particular state in question. This function is called the state's *wavefunction*. The wave has nonzero amplitude for most states (all except the ones that are orthogonal to the particular state). It is a consequence of this wave aspect of quantum mechanics that states can never be totally localized with infinite precision; any system of finite size and energy can have only a certain finite number of distinguishable states, corresponding to different normal modes of vibration of the given wave [15, 16] up to the maximum energy.

**Wave packet** A wavefunction whose magnitude approaches zero for all position states outside of a given region of space. A system whose position is localized is in a wave packet state.

**Zetta** SI unit prefix meaning  $10^{21}$ .

## 1. INTRODUCTION

Design and synthesis of materials with micrometer (microscopic) and nanometer dimensions (mesoscopic) with well-defined structures in the sub-micrometer region have attracted increasing interest recently. The idea in this context is to tailor the composition, structure, and function of materials with control at the nanometer level, which may lead to new properties for well-known standard materials and hence to new applications. In addition, increasing progress has been attained in the last decade in nanostructured materials using block copolymers.

The amount of research on this area is at constant growth, which makes a comprehensive or exhaustive review almost impossible; therefore, we intend here to give mainly the outlines of the field and some interesting illustrative examples.

In the following we will focus on nanometer-sized hollow spheres, or so-called nanocontainers. Such particles produce great interest due to their potential for encapsulation of large quantities of guest molecules or large-sized guests within their empty core domain. They can be useful for applications in areas such as biological chemistry, synthesis, or catalysis. In this context monodispersity of the capsule's

size, stability of the particle, and permeability of the shell are key parameters in order to obtain materials with enhanced performance.

Nature itself uses similar and very effective nanocontainers like micelles, vesicles, and viruses in biological systems, for example, for transport and delivery of sensitive compounds such as hormones or DNA [1]. However, these highly functionalized assemblies of proteins, nucleic acids, and other (macro)molecules perform very complicated tasks that are still too complex to be completely understood. Although the particles are perfectly designed to fulfill their tasks in biological environment after millions of years of evolution, their direct use in many technical applications is often not feasible. In many cases this is due to the non-covalent interactions responsible for their formation and hence their limited stability. This leads, for example, to a rapid clearance of conventional lipid vesicles (liposomes) from the blood after their intravasal administration [2]. Many applications require, however, more stable particles. Therefore, a great effort has been devoted within the last years to prepare size- and shape-persistent nanocontainers and up to now a huge variety of different techniques has been described, each of them having its special advantages and of course also disadvantages. This chapter is divided into different subsections according to the different approaches that are commonly used to attain the desired particle morphology. This division is somewhat arbitrary, especially since a certain overlap between the different methods exists. However, the first part of the chapter gives a short introduction to natural nanocontainers, which, besides their limited technical applicability, are of major importance for the understanding of natural processes. Although they are naturally occurring substances, the use of lipids and liposomes will be considered together with polymer amphiphiles since both share analogous characteristics such as self-organization. The following three sections describe approaches in which mainly non-covalent interactions (i.e., van der Waals, electrostatic, or hydrophobic interactions) are used to imprint the characteristic shape

onto the resulting particles. Once obtained, though, these self-assembled superstructures based on the aforementioned non-covalent interactions can be further stabilized by cross linking, thus obtaining shape-persistent particles. The last section deals with single polymers that have, by design of their architecture, intrinsic hollow-sphere morphology in the nanometer range.

## 2. NATURAL NANOCONTAINERS

Although many naturally available nanocontainers are not suited for technical applications, much interesting research work has been published within the last years that describes the use of various natural systems in nanomaterial science [3].

Especially in the field of biomineralization a significant progress has been made with so-called bio-nanoreactors [4–7]. Among the different types of possible mineralization vessels, ferritin is probably the most intensively studied and best understood [8]. Nature uses ferritin as a storage device for iron, where it is encapsulated as hydrated iron (III) oxide within a multisubunit protein shell. After the iron has been removed from inside the protein shell, the remaining cavity has been successfully used to generate various nanometer-sized inorganic particles, such as, for example, manganese oxide or uranyl oxyhydroxide crystals [9].

Virus particles are another type of biological structures that can be applied as a template for biomineralization processes, like the tobacco mosaic virus (TMV) or the cowpea chlorotic mottle virus (CCMV). As indicated in Figure 1, several routes were explored for the synthesis of nanotubes composites that use TMV templates [10].

The spherical protein cage of the CCMV shows a completely reversible pH-induced swelling transition of approximately 10%, in case it is incubated in media of a pH value above 6.5 (Fig. 2) [11]. During this swelling, gated pores are opened along the viral shell that allow a free molecular exchange between the viruses interior and the surrounding bulk medium. In contrast, no exchange of larger molecules occurs at pH values lower than 6.5. This property has successfully been used for controlled host-guest encapsulation

and crystal growth of inorganic and organic materials within such virus [12].

These examples demonstrate clearly that biological nanocontainers are well suited for the formation of new materials. However, in addition to their low mechanical stability, it seems that their major drawbacks are the isolation and handling of larger quantities of such bioreactors.

## 3. NANOCONTAINERS FORMED BY SELF-ASSEMBLY

### 3.1. Lipids

Due to their amphiphilic nature and molecular geometry, lipid molecules can aggregate in dilute aqueous solution into different morphologies, depending on many factors such as the molecular shape of the lipid, concentration, and temperature. Particularly spherical morphologies, micelles and vesicles, have attracted considerable interest in the scientific community. Micelles consist of aggregates in which the nonpolar chains of the lipid form a core surrounded by their polar heads [2]. In case of micellar structures in aqueous solutions, the inner core represents a hydrophobic domain capable of solubilizing hydrophobic substances. This solubilization of sparingly soluble substances is widely used, for example, in drug delivery [13, 14]. However, we will not discuss this here in detail.

Spherically closed lipid bilayer structures enclosing an aqueous compartment are called vesicles or liposomes [2]. Here we reserve the term vesicle for polymer vesicular structures, while vesicles constituted from lipids are preferably referred to as liposomes. Owing to their similarity to the cell membrane, liposomes are widely employed as models and mimetic systems for biological membranes [15]. The aqueous volume entrapped within the liposome can serve as a reservoir for sensitive water-soluble compounds, protecting them from hostile environments. Enzymes, for instance, have been long protected by this procedure [16]. To make use of the catalytic activity, either the enzyme has to be released from the protecting vessel in order to enter into

contact with the substrates in the surrounding milieu, or the substrates have to permeate the membranes to be able to undergo the reactions catalyzed by such enzymes in the interior of the vesicular structure. Since the membrane acts as a diffusion barrier for the substrates, this usually decreases the turnover of the enzyme.

A great deal of research has been devoted to the use of liposomes as drug carriers; it is not the intention to cover this area here in detail. The interested reader may consult some recent reviews [17–20]. The main disadvantage of liposomes is their inherent instability to both mechanical and environmental changes [19, 20]. One strategy to overcome this is to polymerize the constituent lipids within the membrane, thus producing robust entities. However, stabilizing the structure usually renders a decrease in its permeability, which is also a crucial parameter in the context of drug delivery [19]. Thus ways have to be found to overcome this.

Lipid vesicles can be regarded as spherical capsules comprising a shell of the lipid bilayer and an aqueous core. Hence, it is straightforward to use them as precursors for the preparation of size- and shape-persistent nanocontainers. This can be achieved using different concepts. Figure 3 gives an overview of various methods. For example, lipids that are functionalized with polymerizable groups can be polymerized within such vesicular structures. As a result of the polymerization reaction, the individual lipid molecules are interconnected via covalent bonds, which stabilizes considerably the liposome membrane [21, 22]. In some sense the polymerized lipids can be regarded to mimic the role of the cytoskeleton or of the murein network (i.e., the polymer structures which Nature uses to stabilize biological cell membranes) [23]. In contrast to these natural polymer scaffolds that are simply attached to the lipid membrane via

**Figure 3.** Schematic representation of the different possibilities for stabilizing lipid vesicles. Reprinted with permission from [21], H. Ringsdorf et al., *Angew. Chemie* 100, 117 (1988). © 1988, Wiley-VCH.

hydrophobic interactions, the polymerized lipids are, however, all covalently connected to each other. Cross-linking converts the structures held together solely by van der Waals forces into covalently bonded macromolecules. As a result of this procedure, a considerable obstruction of the lipid lateral mobility within the membrane is observed, leading to a reduced permeability of encapsulated substances [22].

Interestingly, the polymerization of reactive lipids in bilayers formed from mixtures of different lipids may induce phase separation phenomena within the membranes. This can be exploited to produce labile domains in a controlled manner in the shell of the polymerized vesicles. These domains can be plugged or unplugged using external stimuli, which renders such particles suitable for applications in the area of controlled or triggered release. Since the pioneering studies on polymerized vesicles derived in the late 1970s and early 1980s, this area has developed into a broad and active field of research. A detailed discussion of all its different aspects would lead too far here, all the more since several recommendable reviews and books have already appeared on this topic, to which the interested reader may refer [21, 22, 24, 25].

Even though liposomes are biocompatible and biodegradable materials and structurally and chemically closely related to cell membranes, they are recognized as foreign bodies in living systems. This recognition by the reticuloendothelial system (RES) accounts for their low circulation times after parenteral administration [2].

One important milestone in the development of liposome and liposome-related structures was the discovery of so-called stealth liposomes [26, 27]. These particles are ignored by the reticuloendothelial system and, hence, they show prolonged circulation times [28, 29]. Additionally, they are more stable towards oxidation, enzyme degradation, and reaction with plasma lipoproteins [2]. The stealth liposomes comprise “pegylated” lipids, that is, lipids covalently attached to poly(ethylene glycol) (PEG) chains [30]. This external brush of hydrophilic polymer chains at the surface of the lipid bilayer shields them from the recognition by opsonins and plasma lipoproteins. Additionally, the hydrophilic coating of the surface of the liposomes produces a steric repulsion towards adhesion to other surfaces (e.g., opsonins). In contrast to adsorbed polymers on liposomes, which also yield certain steric stabilization, the sterically stabilized liposomes are covalently bonded, thus increasing, for instance, the stability towards dilution. By the conjugation of lipids with polymers one obtains not only a more stable structure but also a very versatile system, that can easily be modified at its outer surface; that is, the system can be decorated with antibodies, receptors, and ligands, by using heterobifunctional PEG [26, 27]. A comprehensive collection of papers dealing with the theory and applications of liposome steric stabilization can be found in [26].

Recently an interesting application-relevant approach has been presented to release encapsulated material from liposomes under controlled conditions. Using a synthetic triple-chain amphiphile to produce stable vesicles, pH-influenced release of encapsulated substrates was achieved. The artificial lipid used carried carboxylic end-groups. Interestingly, less than 10% of the encapsulated water-soluble probe was

released at pH 7.5 over a year of storage. However, by lowering the pH to 3.5, the vesicles were disrupted, thus expelling their content into the surrounding medium [31].

Functional materials with enhanced properties can be obtained by properly combining different starting materials. Composite materials are a good example of this approach. For example, by inserting Prussian blue, a well-known ferromagnet at low temperatures, into a bilayer of photoresponsive azobenzene containing vesicles, a very interesting kind of composite is obtained. The magnetic properties of such composites can be triggered by photoillumination. Upon irradiation the azobenzene-containing vesicles undergo a cis-trans photoisomerization. This in turn has an effect on the electrostatic interactions between the incorporated Prussian blue and the lipid membrane, thus providing a tunable system [32].

### 3.2. Nanocontainers from Amphiphilic Block Copolymers

Similarly to lipids, also synthetic amphiphilic block copolymers may form superstructures, like vesicles, in aqueous media [33–43].

The most simple block copolymer architecture consists of a sequence of repetitive units of the homopolymer A tethered to a sequence of repetitive units of homopolymer B. However, also more sophisticated polymer architectures are accessible, such as, for instance, triblock, multiblock, graft, and star copolymers, and combinations thereof.

The characteristic molecular design of amphiphilic block copolymers consists of a minimum of two blocks of different chemical composition connected one to the other through a covalent bond. A good review of the synthetic pathways for the production of amphiphilic block copolymers can be found in [44, 45].

Block copolymers consisting of blocks with different solubility, that is, amphiphilic block copolymers, exhibit self-assembly behavior in solution. Within the self-assembled superstructures, the insoluble blocks are shielded as far as possible by the soluble ones from the surrounding solvent. Depending on block length ratio, the hydrophilic-to-lipophilic balance (HLB), concentration, temperature, preparation method, etc., different morphologies can be observed in solution.

Generally, the morphology of their self-assembled superstructures can be regarded as core-shell micellar structures in which the core and the shell consist of the insoluble block and the soluble one, respectively. It has been observed [34, 40] that in aqueous solutions, decreasing the relative length of the hydrophilic block leads to a transition from spherical (micelles) to cylindrical (rods) and later to lamellar (vesicular) structures.

Generally, the self-assembly of amphiphilic block copolymers follows the same principles as that of low-molecular-weight amphiphiles. However, block copolymer aggregates and particularly vesicles may be significantly more stable than those formed from conventional lipids due to the larger size and the slower dynamics of the underlying polymer molecules [46].

In contrast to lipid bilayers, the longer underlying polymeric chains with higher conformational freedom of

polymeric membranes gives the latter not only increased toughness, elasticity, and mechanical stability but also a considerably rather low permeability [46].

An excellent and very recent review on the field of polymeric vesicles can be found in [47].

Nanocontainers based on block copolymer vesicles possess great potential in a broad area of applications, such as controlled release systems [48–54], confined nanometer-sized reaction vessels, or templates for the design of new materials. In this context it is particularly interesting that the physical properties of their polymer shells can be controlled to a large extent by the block length ratio or the chemical constitution of the underlying polymer molecules [34, 45]. Furthermore, synthetic polymers provide a wide spectrum of alternatives to design materials with responsive behavior towards external stimuli.

Similarly to conventional lipid self-assembled morphologies, block copolymer vesicles are held together solely by non-covalent interactions. Hence they can disintegrate under certain conditions (e.g., dilution or presence of detergent) and dissolve as individual block copolymer molecules. It is obvious that, analogous to the reactive lipids, also block copolymer molecules could be modified with polymerizable groups. A subsequent polymerization of the resulting “macromonomers” interconnects them via covalent bonds, which stabilizes the whole particle.

Up to now, however, only a few papers dealing with such particles have appeared. In one reported case, using a diblock copolymer consisting of poly(1,2-butadiene)-*b*-poly(ethylene oxide), vesicular structures were locked in by  $\gamma$ -irradiation in aqueous solutions. The resulting cross-linked vesicles could be dispersed in solvents that are good for both blocks, without losing the fixed vesicular structure [39].

In another paper, the formation of vesicles from a poly(isoprene)-*b*-poly(2-cinnamoyl methacrylate) (PI-PCEMA) diblock copolymer in hexane-tetrahydrofuran mixtures has been exploited as a starting point [55]. Converting these vesicles into stable, water-soluble polymer nanocapsules requires, however, a rather costly procedure. The PCEMA blocks were photocross-linked and then, in a second step, the PI blocks had to be hydroxylated to make these hollow nanospheres water-soluble. The radii of the nanocapsules were about 50 to 60 nm and changed only very slightly during these conversions. After loading the nanocontainers with Rhodamine B, the dye could be quantitatively released in water and water-ethanol mixtures in a way that the release rate could be tuned by the composition of the water-ethanol mixtures. Ethanol seems to be a good solvent for the underlying block copolymers. Hence higher ethanol content in the solvent mixture increases the solvent quality and the cross-linked shell of the cross-linked particles swells increasingly. As a result, the shell permeability increases and release of the dye becomes faster. This feature makes such systems attractive for applications, since prefabricated particles can be loaded effectively in an organic solvent and subsequently the encapsulated material slowly released in water.

In a similar approach, a rather simple one-step procedure has been used to prepare vesicular structures from

poly(2-methyloxazoline)-*b*-poly(dimethylsiloxane)-*b*-poly(2-methyl-oxazoline) (PMOXA-PDMS-PMOXA) triblock copolymers directly in aqueous solution. One remarkable characteristic of this type of triblock copolymers, in contrast to diblock copolymers, is that the resulting vesicles are composed of a single layer of polymer instead of a bilayer. The size of the resulting vesicles could be controlled from 50 nm to 100  $\mu\text{m}$  [33]. The underlying triblock copolymers were modified with polymerizable methacrylate end-groups without changing their aggregation behavior in water. These “macromonomers” were polymerized within the vesicles using a UV-induced free-radical polymerization, which did not lead to any measurable changes in size, size distribution, or even molecular weight of the particles [33]. Obviously the polymer chain reaction occurs mainly intravesicularly. Intervesicle reactions such as exchange of individual triblock copolymer molecules or a chain propagation reaction involving more than one vesicular aggregate play only a minor role on the time scale of the experiment.

The covalently cross-linked polymer network structures result in particles that possess solid-state properties such as shape persistence. Therefore they are able to preserve their hollow-sphere morphology even after their isolation from the aqueous solution and redispersion in an organic solvent, such as chloroform, tetrahydrofuran, or ethanol. This is documented in Figure 4, which shows a transmission electron micrograph of polymerized triblock copolymer vesicles isolated from water and redispersed in ethanol. Ethanol is a good solvent for the whole underlying block copolymer molecule. Hence, nonpolymerized vesicles would immediately disintegrate under such conditions into singly dissolved polymer molecules. In contrast to their fluid-like, nonpolymerized precursors, a shear deformation of the polymerized vesicles may lead to cracks characteristic for solid materials [56]. This is directly demonstrated in the reflection intensity contrast micrographs of Figure 5 that show a giant polymerized triblock copolymer vesicle before and after shear-induced rupture. This shape-persistence allows the use of such vesicles as a delivery system since they can be loaded with guest molecules in an organic solvent. After isolation of the loaded polymer shells and redispersion in aqueous media, the encapsulated material can be subsequently released.

**Figure 5.** Reflection intensity contrast micrograph of a giant, polymerized PMOXA-PDMS-PMOXA triblock copolymer vesicle before (left) shear-induced rupture and after (right) shear-induced rupture.

A more specific uptake and release of substances could be achieved by reconstitution of membrane proteins in the completely artificial surrounding of the block copolymer membrane [57–59]. It has been shown that the functionality of the incorporated proteins is fully preserved even after polymerization of the vesicular membrane. With regard to the wide range of membrane proteins Nature provides, such copolymer-protein hybrid materials possess a great potential in many areas of application, such as, for example, gene therapy [60] or biomineralization [61].

By encapsulating an enzyme ( $\beta$ -lactamase) in the aqueous core domain of the nanocapsule and reconstituting a membrane protein (OmpF) in the polymer shell, a novel kind of nanoreactor could be designed (see Fig. 6) [58]. Furthermore, the channels of this protein close reversibly above a critical transmembrane potential. By simply adding a large enough polyelectrolyte to the external solution, that cannot pass the protein channels, a Donnan potential is created across the vesicular membrane. If this potential exceeds

**Figure 6.** Schematic view of a PMOXA-PDMS-PMOXA nanoreactor with encapsulated  $\beta$ -lactamase and of the Donnan potential induced by polyelectrolyte present in the external solution.

the critical voltage necessary for closure of the protein, also small substrates can no longer enter the vesicular interior and the reactor is deactivated. Decreasing the potential below the critical voltage (e.g., by dilution) reactivates the reactor. The possibility to trigger the activation (or deactivation) of such systems is highly interesting for applications since it allows local and temporal control on the uptake and release of substrate.

Very recently the use of polypeptide-based diblock copolymers, poly(butadiene)-*b*-poly(L-glutamate) (PB-PGA) for the preparation of vesicular structures has been described [62, 63], Figure 7. Particularly interesting here is that the solvating chains are polypeptides and form vesicles, or so-called "peptosomes," composed of modified protein units. A subsequent polymerization of the poly(butadiene) block leads to shape-persistent nanocontainers that possess, due to their polypeptide block, a certain pH- and ionic strength-sensitivity [63]. By changing these parameters, the particles dimension changes reversibly as a result of the polypeptide block transition from a compact helical secondary structure at low pH values to a more extended random-coil conformation in basic media.

### 3.3. Nanocontainers Derived from Lipid Vesicles

Alternatively to the stabilization of lipid vesicles via intrapolymerization of cross-linkable lipids [21, 22], also known as polymerization of vesicles [64], another strategy makes use of the vesicular morphology simply as a template to imprint its hollow structure to other materials. Here two main approaches can be differentiated.

One concept uses just the geometry of the vesicular aggregates as a template [64–72]. In this case the amphiphilic molecules themselves are not polymerized to freeze in

**Figure 7.** Freeze-fracture electron micrograph of a vesicular solution of poly(butadiene)<sub>85</sub>-*b*-poly(glutamate)<sub>55</sub> in pure water (pH ~ 6.0). Reprinted with permission from [62], H. Kukula et al., *J. Am. Chem. Soc.* 124, 1658 (2002). © 2002, American Chemical Society.

the whole superstructure of the supramolecular aggregate; they just provide a geometrically restricted environment for dissolving and polymerizing conventional monomers. This approach is also known as polymerization in vesicles or morphosynthesis [64–73]. In a second approach, vesicular templates are used solely to impart a surface onto which materials are grown from. This is known as transcriptive synthesis, since the structure of the vesicle is transcribed onto the new material, or sometimes called vesicle directed growth [73].

It is well known that vesicles or liposomes are able to solubilize hydrophobic substances to a certain degree. Such compounds are usually dissolved in the hydrophobic part of the lipid bilayer. If such substances also carry polymerizable groups, their subsequent polymerization should lead to the formation of polymer chains entrapped in the interior of the membrane. In contrast to polymerizable lipids, the polymer chains are now simply dissolved within the alkane part of the bilayer forming lipids. Hence, they are of minor influence on the overall physical properties of the membranes.

One special feature of vesicular polymerization of conventional hydrophilic or hydrophobic monomers is that the different compartments provided by the self-assembly of the lipid molecules generally serve only as a template, which determines size and shape of the resulting polymers. Thus, it is possible to use nearly every natural or synthetic lipid, without any modification. Although in most reported studies on vesicular polymerization of conventional monomers, synthetic lipids like dioctadecyl diammonium bromide (DODAB), chloride (DODAC), sodium di-2-ethylhexyl phosphate (SEHP), or even spontaneously formed vesicles prepared from mixtures of cationic and anionic surfactants have usually been used, any natural lipid would provide a suitable matrix. Moreover, a combination of polymerizable lipids and conventional monomers could be incorporated in templating vesicles to yield hybrids with interesting new polymer structures [64, 74, 75]. Of course, the incorporation of hydrophobic substances into lipid bilayers should not exceed certain saturation concentration [76]. Above this concentration the monomer is no longer homogeneously distributed within the bilayers. This has been shown for toluene in phospholipid vesicles at concentrations above the saturation level. Moreover, exceeding this saturation concentration may also disrupt the whole bilayer structure, thus converting the system into a conventional emulsion or even leading to the formation of a separate monomer phase in the presence of intact vesicles.

It is obvious that the overall thickness of the lipid membranes has to increase upon the solubilization of hydrophobic substances. The maximum swelling of the membrane leads typically to an increase from about 3 to 5 nm [77]. This is, however, a negligible effect compared to the overall diameter of typical small unilamellar vesicles, which is about 100 nm. Therefore no dimensional changes of the underlying vesicles can usually be detected upon swelling the lipid bilayers of the vesicles, as long as the monomer concentration stays below the saturation value in the membranes.

It has been shown that the hydrophobic portion of lipid bilayers can be selectively swollen by a variety of hydrophobic monomers, such as styrene [65, 66, 68, 69], alkyl(meth)acrylates [67, 70, 71], or even lipofullerenes

carrying polymerizable octadecadiene side chains [72]. A cross-linking polymerization of such monomers leads to the formation of two-dimensional polymer networks in the interior of the membranes. Such networks can act as a polymeric scaffold that increases the mechanical stability of lipid membranes considerably without impeding the mobility of the lipid molecules within the aggregates.

The free-radical polymerization of the hydrophobic monomers incorporated into the lipid membranes of vesicles can be initiated, similarly to the polymerization of reactive lipids, by UV irradiation, thermal, or redox chemical radical generation. The polymerization process itself seems, however, to be rather sensitive towards the composition of the system, that is, the chemical constitution of the monomer and the lipid and the concentration of the monomers in the bilayer, which, of course, limits its possible applications. While polymerization of alkyl (meth)acrylates in dioctadecyl-ammonium chloride vesicles [70, 71], the reaction of lipofullerenes in dipalmitoyl-phosphatidylcholine vesicles [72], or styrene/divinyl benzene mixtures in equilibrium vesicles formed by CTAT/SDBI or CTAB/SOS mixtures [79] clearly lead to the formation of polymer hollow spheres, in case of styrene/divinylbenzene in dioctadecyl-ammonium bromide vesicles, an intravesicular phase separation occurs during polymerization, thus leading to the formation of so-called parachute-like structures [69, 78].

An interesting aspect of the formation of cross-linked polymer particles in vesicular dispersions arises from the fact that, in contrast to linear polymers, they should be able to retain their structure even after their isolation from the lipid matrix [70, 79]. Although the particles contract considerably after their isolation from the lipid membrane, they preserve their spherical shape. Their dimensions always remain, however, directly proportional to those of the underlying vesicles. This is not too surprising since the polymer chains are expected to be forced into a nearly two-dimensional conformation in the interior of the lipid membrane. After their liberation from the membrane, the polymer chains can gain entropy by adopting a three-dimensional conformation. To do this, such spherically closed polymer shells have to shrink and the thickness of their shells increases.

The extent of the observed contraction of the particles depends sensitively on the cross-linking density of the polymer network structure. The contraction increases with increasing cross-linking density, thereby showing the same scaling behavior as branched polymers upon variation of their number of branches. For the highest cross-linking densities, the particles contract to about 1/10 of the original size of the templating vesicles.

In context with possible applications, it would be of great interest to have detailed information about the permeability of these polymer hollow spheres. It has to be expected that, besides the chemical constitution of the polymer backbone, the mesh size, that is, the cross-linking density of the polymer network structure, also plays an important role. Only molecules that are smaller than this mesh size should be able to diffuse across the polymer shell. Molecules which are larger cannot pass the polymer membrane for geometrical reasons.

Whereas the templating vesicles directly determine the size and shape of the resulting polymer particles, the

polymer scaffold can be modified rather easily using conventional chemical reactions. This allows, for example, sulfonation of poly(styrene) containers [79] or the conversion of poly(*tert*-butyl acrylate) hollow spheres into poly(acrylic acid) hollow spheres. The resulting polyelectrolyte nanocapsules can swell as a response to changes in the pH of their environment [80]. This pH-dependent transition influences considerably the permeability of such polyelectrolyte shells and can be used to selectively entrap and release specific substances.

Although such a vesicular polymerization represents a rather elegant approach to produce polymeric nanocontainers, their possible technical application is expected to be rather limited. The reason for this lies in the low economical efficiency of this method. Apart from the often energy-consuming vesicle preparation procedure, the synthesis of one gram of pure polymer nanocapsules already requires approximately 1.5–2 times their weight of lipid, a reaction volume of about 300–400 milliliters of water, and additionally several liters of organic solvents (for purification).

### 3.4. Nanocontainers Derived from Polymer Micelles

Since block copolymers are very versatile materials, they are broadly used as scaffold structures to construct sophisticated and complex materials with new properties. The richness of the block copolymer field relies on the fact that by choosing different repeating units to form each of the blocks, a great variety of starting materials is at hand. Additionally, synthetic polymers provide a wide spectrum of alternatives to design materials with responsive behavior towards external stimuli; this combined with their supramolecular aggregation makes polymers very interesting raw materials.

Not only vesicular structures but also micelles can be used for the controlled formation of nanocontainers. It is, for example, well known that block copolymers may assemble into polymeric micelles with diameters in the 10- to 100-nm range. An important issue in making these self-assembled systems useful for specific applications is again their capability to respond to external stimuli, that is, to interact with their surrounding environment. Very recently the formation of three-layer micelles in water from polystyrene-*b*-poly(2-vinylpyridine)-*b*-poly(ethylene oxide) (PS-*b*-P2VP-*b*-PEO) triblock copolymers was reported [81]. It was demonstrated that the pH sensitivity of the P2VP shell can be used to tune the micelle size from a hydrodynamic diameter ( $D_h$ ) of 75 nm at pH > 5 to 135 nm at pH < 5. This effect is based on the electrostatic repulsion between the charged P2VP blocks and is not completely reversible because of the formation of salt with each pH cycle. Although this feature makes this system useful for encapsulation and release of active species and has already been used for the synthesis of well-defined gold nanoparticles, its long-term stability is still questionable.

One major aspect of block copolymers is that they can be modified so that either the interior or the exterior blocks within the micelles contain polymerizable groups. For example, poly(isoprene)-*b*-poly(acrylic acid) (PI-PAA) diblock copolymers form micelles in aqueous solution with a PI core and a PAA shell. It has been shown that the PAA

shell can be cross-linked with  $\alpha,\omega$ -diamino-poly(ethylene glycol), giving shell-cross-linked nanoparticles also known as shell-cross-linked knedels (SCK) [82, 83]. Similarly, a poly(isoprene)-*b*-poly(2-cinnamoyl ethyl methacrylate)-*b*-poly(*tert*-butyl acrylate)(PI-PCEMA-PTBA) triblock copolymer forms micelles with a PTBA corona, PCEMA shell, and a PI core in THF-methanol mixtures [84]. In this case the micellar structure could be locked in by UV-cross-linking of the PCEMA within the micelles. Subsequently the PI cores of both the cross-linked PI-PAA and the PI-PCEMA-PTBA micelles could be degraded by ozonolysis into small fragments that could diffuse into solution and leave nanospheres with a central cavity. A schematic representation of the whole process is given in Figure 8. The potential of such systems for encapsulation of small molecules has been demonstrated by loading the cross-linked PCEMA-PTBA capsules with Rhodamine B [84]. The incorporation of the dye into the central cavity of the particles could readily be visualized by transmission electron microscopy (TEM).

The degradation of the shell-cross-linked PI-PAA micelles leads to water-soluble cross-linked poly(acrylamide) hollow spheres which considerably increase the  $D_h$  of their shells after removal of the core [83]. The increase of  $D_h$  from 27 to 133 nm has been explained by the fact that the cross-linked poly(acrylamide) shells can be regarded as a hydrogel that swells when the core domain fills with water after the PI core has been removed. The diameter of the hollow-sphere products depends sensitively on both the degree of polymerization of the block copolymers originally used to form the micelle and the nature of the cross-linking diamine used to prepare the shell-cross-linked micelles.

By the same approach, poly( $\epsilon$ -caprolactone)-*b*-poly(acrylic acid)-co-poly(acrylamide) SCKs with a biodegradable core were prepared [85]. The synthetic approach included initially the hydrolysis of poly( $\epsilon$ -caprolactone)-*b*-poly(*tert* butyl acrylate) to give poly( $\epsilon$ -caprolactone)-*b*-poly(acrylic acid), followed by micellization. Cross-linking

**Figure 8.** Procedure for the preparation of nanocages from amphiphilic diblock copolymers. The shell of the final nanocages consists of cross-linked poly(acrylamide). Reprinted with permission from [83], H. Huang et al., *J. Am. Chem. Soc.* 121, 3805 (1999). © 1999, American Chemical Society.

of the carboxylic groups present in their corona was performed with 2,2'-(ethylenedioxy)bis(ethylamine) to render finally the poly( $\epsilon$ -caprolactone)-*b*-poly(acrylic acid)-co-poly(acrylamide) SCK, while hydrolysis of the core was achieved by either acidic- or basic-promoted degradation of the ester linkages to produce the hollow capsules. Such mild core removal is of particular interest in biological applications, especially since the monomers released are biocompatible [85]. Moreover, these shell-cross-linked particles were surface functionalized to promote cell binding [86] via conjugation with a peptide sequence.

Using also the SCK technique as above but without removal of the core, such shell-cross-linked particles have been modified in order to respond to environmental stimuli [87]. Interestingly, here the hydrophobic core consisting of poly(methyl acrylate) is hydrolyzed to give hydrophilic poly(acrylate) chains. The nanoparticles thus obtained, although not completely hollow, have a nanocage-like structure, due to the fact that the shell swells considerably after the hydrolysis of the core chains. Additionally, the nanocage-like particles undergo a pH-controllable swelling, due to electrostatic repulsive forces acting among the ionized core chains [87]. The extent of swelling depends on the percentage of cross-linking of the shell. In contrast with the initial core-shell particles, the particles with modified core are capable of encapsulating hydrophilic guest molecules.

One can produce hollow capsules not only by degradation of the core to monomer or oligomers, but also by selectively detaching both core- and shell-forming block copolymer chains. Obviously, the particles have to be previously stabilized in some way, to prevent disruption of the whole self-assembled superstructure. For example, this concept has been used to prepare SCK in which the core was cleaved by thermolysis of the bond connecting it to the shell. Surprisingly, the polymeric chains are able to permeate the cross-linked shell membrane, and this permeability is found to be inversely dependent on the degree of cross-linking of the shell. Nevertheless, the removal of the core by this approach is not complete, since less than 30% of the total poly(styrene) chains were released even for the lower cross-linking densities [88].

One “block-copolymer free strategy” to prepare micelles solely by hydrophobic interactions between the core and the shell of the structures instead of using covalent attachment, has been described by Liu et al. [89]. They report the preparation of hollow capsules via self-directed assembly of a homopolymer (poly( $\epsilon$ -caprolactone)) and a random graft copolymer comprising a hydrophilic backbone of poly(methylmethacrylate) and poly(methylacrylic acid) and hydrophobic branches of poly( $\epsilon$ -caprolactone). Upon addition of water to a DMF solution of the above mentioned polymers, micelles form in which the poly( $\epsilon$ -caprolactone) constitutes the core and the graft copolymer arranges as the shell. The structure is achieved only by the anchoring of the branches of the graft copolymer into the poly( $\epsilon$ -caprolactone) core; thus, no covalent or hydrogen bonding is needed. Although they report a block-copolymer free approach with no need of covalent bonding between the core and the shell, they use a further stabilization of the system by (covalent) cross-linking the carboxylic and amino groups present in the shell, via a carbodiimide derivative.

The structures thus obtained resemble the shell-cross-linked micelles described by Wooley and co-workers [82]. Removal of the core to give the hollow counterparts was achieved by enzymatic degradation of the poly( $\epsilon$ -caprolactone) with a lipase [89].

Another approach used self-assembled superstructures as templates for the production of inorganic  $\text{MoO}_3$  nanospheres. A micelle forming triblock-copolymer, comprising poly(oxyethylene)-*b*-poly(oxybutylene)-*b*-poly(oxyethylene), served as the templating matrix for the formation of thin-layered hollow nanospheres. The latter were obtained with  $\text{MoO}_2(\text{OH})-(\text{OOH})$  which upon decomposition affords  $\text{MoO}_3$  and  $\text{O}_2$ , a precipitation crystallization process taking at least two weeks for completion. The template forming triblock-copolymer was removed by solubilization in excess water. Apparently and against expectation, the crystallization of  $\text{MoO}_3$  occurs at the interface between the core and the shell of the micellar scaffolds. This follows from the observation of smaller radii for the inorganic cages obtained in comparison with the external radius of the micellar templates used [90].

#### 4. TEMPLATE-DIRECTED PREPARATION OF NANOCONTAINERS

Another possibility for generating polymer nanocapsules is to form a polymer shell around a preformed template particle that can subsequently be removed, thus leaving an empty polymer shell. There are several methods of conducting such a template synthesis of hollow polymer particles. Different templates have been used so far, including silica micro and nanoparticles (usually prepared by Stober synthesis) [91], colloidal or latex particles, gold nanoparticles, etc.

##### 4.1. LbL Deposition

A convenient way to produce nanocapsules is to exploit the well-known polyelectrolyte self-assembly at charged surfaces. This chemistry uses a series of layer-by-layer (LbL) deposition steps of oppositely charged polyelectrolytes [92]. The driving force behind the LbL method at each step of the assembly is the electrostatic attraction between the added polymer and the surface. One starts with colloidal particles carrying surface charges, for example, a negative surface charge. Polyelectrolyte molecules having the opposite charge (e.g., polycations) are readily adsorbed due to electrostatic interactions with the surface. Not all of the ionic groups of the adsorbed polyelectrolyte are consumed by the electrostatic interactions with the surface. As a result, the original surface charge is usually overcompensated by the adsorbed polymer. Hence, the surface charge of the coated particle changes its sign and is now available for the adsorption of a polyelectrolyte of again opposite charge (i.e., a polyanion). As sketched in Figure 9, such sequential deposition produces ordered polyelectrolyte multilayers.

The size and shape of the resulting core-shell particles is determined by the template colloidal particle, where the formation of particles with diameters ranging from 0.2 to 10  $\mu\text{m}$  has been reported. The thickness of the layered shell is determined by the number of polyelectrolyte layers and can be adjusted in the nanometer range.

**Figure 9.** Illustration of the procedure for preparing hollow spheres using layer-by-layer deposition of oppositely charged polyelectrolytes on colloidal particles. Reprinted with permission from [92], E. Donath et al., *Angew. Chem. Int. Ed.* 37, 2201 (1998). © 1998, Wiley-VCH.

Up to now, a variety of charged substances, such as synthetic polyelectrolytes, biopolymers, lipids, and inorganic particles have been incorporated as layer constituents to build the multilayer shell on colloidal particles [93–95]. As templates for this approach, mainly colloids consisting of polystyrene latexes or melamine formaldehyde particles [96] have been used, but also gold [97] and proteins [98] have been tested.

To avoid, however, a polyelectrolyte-induced particle flocculation, one has to work at rather low particle concentrations and excess polyelectrolyte not adsorbed to the surface has to be removed carefully after each step by washing, which makes this technique rather tedious.

After completed deposition of a predefined number of layers, the colloidal core can be dissolved and removed. If one uses human erythrocytes as colloidal templates, they can be oxidatively decomposed in an aqueous solution of sodium hypochlorite. When using weakly cross-linked melamine-formaldehyde particles, the core is dissolved upon exposure to an acidic solution of  $\text{pH} < 1.6$ . Products of both decomposition methods are expelled through the shell wall and removed by several centrifugation and washing cycles. Although the core removal takes place under harsh conditions, neither the acid treatment nor the oxidative decomposition affects the polyelectrolyte layer shells, as can be seen in Figure 10 [92]. They clearly preserve their hollow-sphere

**Figure 10.** Transmission electron micrograph of polyelectrolyte hollow spheres. The shell of the particle consists of 9 layers ((poly(styrene sulfonate)poly(allylamine hydrochloride))<sub>4</sub>/poly(styrene sulfonate)). Reprinted with permission from [92], E. Donath et al., *Angew. Chem. Int. Ed.* 37, 2201 (1998). © 1998, Wiley-VCH.

morphology and are shape-persistent. It has been shown that small dye molecules can readily permeate such layered polyelectrolyte shells while larger-sized polymers with molecular weights larger than 4000 Da obviously do not [99–101].

Nevertheless, it has to be expected that their long-term stability will depend sensitively on the surrounding environment of the particles. Especially in biological fluids (e.g., blood plasma), or in media of high ionic strength, which may screen the ionic interactions responsible for maintaining their integrity, the long-term stability of such polyelectrolyte shells may be rather limited.

However, this sensitivity towards the physico-chemical conditions of the surrounding medium, in particular to pH and ionic strength changes, was successfully used to get control over the permeability of multilayer shells consisting of poly(styrene sulfonate) and poly(allylamine) hydrochloride [103, 104]. By this control it is possible to release from these capsules in a controlled manner prior encapsulated biomacromolecules or fluorescent probes, even with molecular weights of 70,000 Da, or to use them as templates for the selective crystallization of various dyes [102, 103, 105]. Even loading and releasing of substances was accomplished by pH-induced or salt-triggered permeability of the mentioned polyelectrolyte capsules.

Another interesting point is that the capsules could be filled with oils by sequential exchange of the solvent. These oil-filled capsules could be dispersed in water due to their amphiphilic nature, thus leading to a stable, surfactant-free oil-in-water emulsion [106, 107]. Additionally, applying this concept of polyelectrolyte layering onto substrates, a protein aggregate has been encapsulated in a process similar to that already described for other templates such as latex particles. Although the hybrid aggregates obtained were amorphous and removal of the core-forming template was not attempted, this shows the potential of the LbL approach, where, for instance, the encapsulating substrate and templating material can be the same and one [98, 102].

Functionalized polystyrene latex particles carrying surface charges are also suitable substrates for the polyelectrolyte self-assembly technique. In one case, inorganic particles

were incorporated into the adsorbed shells by a sequential adsorption of nanometer-sized SiO<sub>2</sub> particles with negative surface charge and cationic poly(diallyldimethyl-ammonium chloride) (PDAD-MAC) [96, 108]. Layers with a thickness ranging from tens to hundreds of nanometers could be prepared by this procedure. Removing the polystyrene core, either with acid solutions or with solvents such as THF or DMSO, leaves SiO<sub>2</sub>/PDAD-MAC hybrid nanocomposite shells and after calcination even pure SiO<sub>2</sub> hollow spheres. Both the inorganic-organic composite and the pure inorganic capsules can be expected to show interesting physical properties such as enhanced mechanical stability or exceptional permeability behavior. By exactly the same strategy but using melamine formaldehyde as templates, micrometer-size hollow hybrid organic-inorganic capsules and hollow silica spheres were also obtained [96].

With a similar approach, void spheres of titania, iron oxide (magnetic hollow nanocapsules), zeolite, clay, and their respective composites were also prepared [109–112]. Using the LbL technique, gold nanoparticles were used as templates for the production of polymer multilayer shells [97]. In the first reported case of metal particles as templates using the LbL method, the particles had to be surface modified to allow good deposition of the polyelectrolyte. Such functionalization of the gold particles was achieved by covalent bonding of alkanethiols, which also possessed ionic moieties that promoted the adsorption of the layers of polyelectrolytes. In this context, core dissolution via etching with cyanide produced the desired hollow polymeric nanoparticles, with reported diameters ranging from 15 to 50 nm.

Not only stabilization due to electrostatic interactions of the polyelectrolyte forming shells may be used but also their stability can be enhanced by a subsequent cross-linking procedure. For example, by using diazoresins and alternating its deposition with poly(styrenesulfonate) or poly(acrylic acid) onto a sacrificial core, followed by UV irradiation to covalently cross-link the shells, and subsequent removal of the core, hollow polymeric capsules with enhanced stability were obtained [113]. Comparison of ionically cross-linked and covalently cross-linked capsules upon exposure to organic solvents and high-ionic-strength solutions shows a considerable increase of the stability of the latter ones, which is attributed to the covalent attachment. Although the capsules seem to retain to some extent their permeability, since removal of the core could be done either prior to the cross-linking step or after it, their permeability appears to be lower than in other polyelectrolyte capsules. Moreover, in contrast to poly(allylamine hydrochloride)-poly(styrenesulfonate) containers, osmotic pressure resulted in almost no deformation for both polymerized and nonpolymerized diazoresin-poly(styrenesulfonate) capsules [113].

As already mentioned, one of the main interests in this field is to control the permeability and encapsulation of substrates. One way to achieve this is to modify the capsules' shells, particularly their internal walls. With this aim in view, polymerization of monomers was carried out in the void volume of such polyelectrolyte capsules. While polymers cannot, monomers easily permeate the shell [99–101]. If monomers are introduced in the empty volume of the containers, followed by a polymerization reaction, the resulting macromolecules are entrapped inside the capsules.

By using this approach to encapsulate a polyelectrolyte macromolecule, it was possible to obtain a pH of about 2 in the interior of the spheres. This is of interest, for example, in the context of nanoreactors, to carry out acid catalyzed reactions within the capsules. Interestingly, swelling and shrinking of the shells could be tuned by changing the osmotic pressure. Moreover, it was observed that the polymerization of encapsulated monomers took place mainly within the walls of the capsules which gave, for poly(styrenesulfonate), the possibility to modify the ionic selectivity of the shells. Thus, fluorescent anions could not translocate the functionalized walls, while cationic probes did. Surprisingly, the adsorption of oppositely charged ions on the walls resulted in an increase of the permeability of the shell, through the formation of pores which finally released the encapsulated macromolecules into the bulk of the solution. Therefore a tunable control of the permeability is achieved [114].

#### 4.2. *In-Situ* Polymerization

Similarly, poly(N-vinylpyrrolidone)-stabilized polystyrene latex particles were coated with thin overlayers of poly(aniline) to produce electrically conductive core-shell particles [115]. In contrast to the LbL deposition method where preformed polymers are adsorbed to a surface, here the polymer is formed *in-situ* by oxidative coupling of monomers at the particle surface. The poly(aniline) layers had, however, a rather nonuniform and inhomogeneous morphology. Therefore extraction of the polystyrene core left poly(aniline) shells that displayed a so-called “broken egg-shell morphology”; that is, they were largely disrupted. Also gold nanoparticles have successfully been used as templates for nucleation and growth of surrounding poly(pyrrole) and poly(N-methylpyrrole) shells [116, 117]. Etching the gold leaves structurally intact hollow polymer particles with a shell thickness governed by the polymerization time. This formation of polymer-coated colloids involves trapping and aligning the particles in the pores of membranes by vacuum filtration and a subsequent polymerization of a conducting polymer inside the pores (Fig. 11).

In a first step, the gold nanoparticles are being filtered into a porous  $\text{Al}_2\text{O}_3$  support membrane with a pore size of 200 nm. After an initiator ( $\text{Fe}(\text{ClO}_4)_3$ ) has been poured into the top of the membrane, monomer (pyrrole or N-methylpyrrole) is placed underneath the membrane. Upon diffusion of the monomer vapor into the membrane, it contacts the initiator to form polymer, preferentially at the surface at the gold particles. The resulting polymer-encapsulated nanoparticles can be isolated by dissolution of the membrane in basic media. The shell thickness depends on the polymerization time and can be controlled in a range from 5 to 100 nm. In order to obtain hollow particles, the gold was etched, for example, with a  $\text{KCN-K}_3[\text{Fe}(\text{CN})_6]$  solution, prior to dissolution of the membrane material. Thus hollow cores with a diameter of 30 nm were seen by TEM, where the 30-nm Au particle was previously located, indicating that almost no reorganization, collapse, or shrinkage takes place when the empty shells are dried. Indeed, the diameter of the hollow core could be tuned by choosing an appropriate Au particle of different size. In this context it was shown that the gold particles are not only

**Figure 11.** Schematic diagram of the membrane-based method for synthesizing gold-core/polymer-shell nanoparticles. The particles are first trapped and aligned in the membrane pores by vacuum filtration and subsequently coated with poly(pyrrole), which occurs via polymerization of the monomer vapor when it diffuses into the membrane and interacts with the initiator ( $\text{Fe}(\text{ClO}_4)_3$ ). The membrane is then dissolved, leaving behind nanoparticle composites. The gold can also be etched first and the membrane then dissolved, resulting in hollow poly(pyrrole) nanocapsules. Reprinted with permission from [116], M. Marinakos et al., *J. Am. Chem. Soc.* 121, 8518 (1999). © 1999, American Chemical Society.

useful as a template material but can also be used to deliver guest molecules into the capsule core. For example, ligands attached to the gold surface, via alkanethiol-Au bonds or simply by physisorption, prior to polymerization remained trapped inside the hollow particles after gold etching, which demonstrates their potential as protective shells for sensitive compounds like enzymes. Indeed, the ability of the capsule to protect an encapsulated enzyme was studied [118].

Obviously the ions of the gold etchant were able to diffuse across the polymer shell, the permeability of which could even be tuned by the oxidation state of the polymer or the counter ion present during polymerization of the pyrroles. However, even rather small organic guest molecules like Rhodamine B [116] or anthraquinone-terminated hexanediol [118] were not released again from the interior of the particles, even over periods of up to three weeks. That means that there is only very restricted access to enclosed substances in the interior of the shells. In addition, the particle type appears to be limited to those that fit into the membrane supports used, which also restricts its applications. Nevertheless, it shows promise for coating of various templates like metals and biomacromolecules. One advantage in the use of conductive polymers, from the triggering or stimuli-response point of view, is that they could be interchanged from their cationic, anionic, and neutral forms, either chemically or electrochemically. Interestingly, quasi-1D arrays of the Au-polymer composite and the hollow polymeric particles fabricated by this method could be obtained [117], which could be of advantage in the production of sensors, for example.

### 4.3. Surface Initiated Living Polymerization

In another approach, hollow cross-linked polymeric nanoparticles are obtained by a template-assisted surface initiated living free-radical polymerization [119]. In this procedure, the surface silanol groups of silica nanoparticles, used as templates, are initially reacted with trichlorosilyl-substituted alkoxyamines as radical initiator groups. Subsequently, this layer of surface initiator groups is used to start linear polymer chains of poly(styrene) or poly(styrene-co-maleic anhydride) by free-radical polymerization, thus leading to a hybrid core-shell morphology. In a following step, the shell is cross-linked and still covalently attached to the silica core; then removal of the core by HF treatment gives hollow polymeric particles, whereas the non-cross-linked particles after etching of the core gave linear polymers with loss of the capsular structure. Two different approaches were used to cross-link the shells; one involved thermal reaction of polystyrene with 4-vinylbenzocyclobutene, the other a two-step reaction in which a poly(styrene-co-maleic anhydride) is cross-linked with a diamine. This last cross-linking procedure resembles the one used by Wooley [82]. The obtained nanocapsules are stable against solvent dissolution and thermal treatment due to their cross-linked structure, although some disruption of the particles was observed and the solvent treatment followed by drying led to collapse of the spheres [119].

A similar approach was carried out [120] by using initiating sites for atom transfer radical polymerization (ATRP) [121] at the surface of silica microparticles, with a subsequent dissolution of the silica core to render hollow polymeric nanocapsules. Silica microspheres (3  $\mu\text{m}$  diameter) were used as templates to achieve hollow polymeric microspheres via surface initiated living radical polymerization of benzyl methacrylate followed by core dissolution. In a first step, living atom transfer radical polymerization was conducted via initiators attached to the surface of the template, leading thus to hybrid core-shell particles in which the template and the shell were covalently attached. In a following step, the sacrificial cores were dissolved, giving then hollow polymeric microcapsules. In this case control over the shell thickness was achieved by variation of the reaction time [120]. In both approaches the attained polymer chains are well defined in terms of polydispersity due to the living nature of the polymerization process [119, 120], thus leading to highly uniform shell thickness. Again cross-linking of the shells provides extra stabilization of the structures which otherwise would disintegrate upon dilution or during the subsequent manipulations necessary to obtain the hollow particles.

### 4.4. Nanocontainers from Inorganic Templates

Taking into account the usually low permeability of nanocapsules and the difficulties encountered to load or to release molecules from them in a controlled way, some strategies have been proposed to overcome these disadvantages. For instance, Zha et al. [122] have used the well-known thermoresponsive poly(N-isopropylacrylamide) to obtain stimuli-responsive containers. Poly(N-isopropylacrylamide), which has a rather low (32° C) lower

critical solution temperature (LCST), undergoes a conformational change from coil to globule at its LCST [123]. The strategy used for obtaining the capsules was a colloid templated polymerization with a posterior removal of the core. As templates, silica particles (obtained by Stober synthesis [91]) with diameters from 10 to 100 nm were utilized, the surface of which was modified by 3-(trimethoxysilyl)propyl methacrylate, thus rendering a surface decorated with double bonds. In a seed precipitation polymerization, using the functionalized particles as seeds, N-isopropylacrylamide was polymerized in the presence of N,N'-methylene bisacrylamide as cross-linker, in order to obtain hybrid particles, with a silica core and a cross-linked poly(N-isopropylacrylamide) shell structure. Hollow polymeric capsules were achieved by an etching step using HF. The hollow particles could maintain their shape after the dissolution of the core since they were cross-linked. While the size and shape obtained was found to be related to the templating particle, the shell thickness depended on different variables such as the amount of poly(N-isopropylacrylamide) and the size and concentration of the template particles. Also the degree of cross-linking influenced the morphology of the structures achieved. In this context, discs and dented structures, both due to collapsed capsules and intact spheres were observed. Most interestingly, the temperature dependence of the nanocapsules was investigated. In general, for all cross-linking densities, the capsules shrank as the temperature increased and their volume phase transition was 32 °C. Additionally, the degree of shrinkage was found to be a function of the cross-linking density. Important is the fact that the swelling and shrinking cycles were repeatable and reproducible. Although it would be very interesting for applications like drug delivery, since the LCST of the polymer is close to biologically related applications, no attempt of encapsulation was reported [122].

Silica hollow spheres were synthesized by seeded polymerization of tetraethoxysilane on the surface of polystyrene particles followed by calcination [124]. Also microcapsules with magnetic interiors have been reported. By deposition of iron salts, coating of a crystalline shell of  $\text{Fe}_3\text{O}_4$  on polystyrene template particles was achieved. Following a posterior calcination of the core, hollow magnetic capsules were obtained. The stability of the spheres produced was low; nevertheless, this could be improved by additionally coating the spheres with a shell of silica nanoparticles via seeded polymerization of tetraethoxysilane according to the Stober technique [91]. Interestingly, these capsules are hydrophilic and thus can be dispersed in water, whereas heating to 100 °C produces hydrophobic capsules by silica conversion to siloxane [124]. A similar approach to obtain submicron-sized hollow inorganic microcapsules consisting of yttrium was described by Kawahashi and Matijevic [125]. In this particular case, coating polystyrene latex with basic yttrium carbonate layers and subsequently calcining at elevated temperatures in air, resulted in the desired inorganic hollow particles.

A self-aggregating polymer can be also used as a template for the formation of inorganic hollow spheres. Poly(L-lysine) in conjugation with hydrophobic amines was found to form

aggregates in solution, and this was used to imprint their structure into silica [126].

Additionally, poly(L-lysine) is a well-known biocompatible polymer, which has the interesting property of showing strong pH-dependent behavior. In acidic solutions it adopts a random coil conformation, while at higher pH it undergoes a transition to  $\alpha$ -helix or  $\beta$ -sheet conformations [127–129]. When tetraethyl ortosilicate was added to an aqueous solution of poly(L-lysine) in the presence of benzylamine, at pH 11.6, hybrid polymer core–silica shell capsules were formed with diameters from 100 nm to 1.5  $\mu\text{m}$ . The high polydispersity is a direct consequence of the broad size distribution of the template aggregates used, as confirmed by light-scattering techniques. Elimination of the core was achieved by subsequent calcination of the hybrid structures. Apparently both the poly(L-lysine) and the benzylamine are necessary to obtain the hollow silica structures, since attempts to use the individual components separately or other amines led only to the formation of silica particles or mixtures of particles and capsules. The advantages of this preparation method are the use of commercially available reactants, a biocompatible and biodegradable polymer, and a simple procedure in comparison with more established strategies like LbL in which many steps are required [126].

The advantages of inorganic hollow nanocapsules are their higher mechanical and thermal stabilities compared to the organic counterparts. However, encapsulation of molecules in their interior is quite challenging due to their rather impermeable shells.

Zeolites have the advantage of imprinting micro pores on the shells of the nanospheres rendering readily permeable structures, and great research has been done in this area. We do not intend to cover this vast research field in detail. Nevertheless, it should be mentioned that very recently a new approach for the production of hollow zeolite microcapsules has been presented. Dong et al. [130] report the preparation of novel zeolite nanocapsules that comprise functionalized interiors. This is achieved by pre-encapsulating a specific substrate, followed by a vapor phase treatment (VPT). Mesoporous silica spheres (3–6  $\mu\text{m}$ ) were coated with nano zeolite particle seeds (60 nm) and then these particles were treated with amine vapor in an autoclave (VPT). In this process the surface of the particle grows at expense of the silica core and finally once the silica is consumed, a hollow crystalline zeolite shell with a thickness on the order of 200 nm is obtained. Guest molecules, inorganic species like iron oxide ( $\text{Fe}_2\text{O}_3$ ), were encapsulated into the pores of the templating mesoporous silica, prior to the vapor phase treatment, thus rendering hollow capsules with an interior decorated by clusters of iron oxide [130].

Similarly, also porous carbon containers were prepared [131]. Using silica particles with solid core and mesoporous shell as templates, phenol resin or poly(divinylbenzene) was polymerized on their surface, thus giving a polymer-silica composite with the polymers being located inside the pores of the silica particles. A posterior carbonization of the polymer leads to carbon aluminosilicate nanocomposites. In a following step, hollow carbon capsules of 220 to 500 nm diameter and shell thickness of 55 to 90 nm were obtained by dissolution of the silica core with HF or NaOH when using phenol formaldehyde or poly(divinylbenzene), respectively.

Additionally, the diameter of the sphere and thickness of the capsule wall could be adjusted by careful choice of the silica templates. Interestingly, these carbon nanocapsules contain pores with size on the order of 2.8 to 4 nm, and constitute an inverse replica of the silica templates used [131].

One interesting approach using gold particles as templates has been reported by Sun et al. [132]. Hollow monolayer-thick organic spheres were obtained by attaching thiolated  $\beta$ -cyclodextrines to gold particle templates. The Au particles are synthesized *in-situ* by reduction of Au (III) in the presence of thiolated  $\beta$ -cyclodextrines; this gives in turn particles coated with the thiolated substrate. Subsequent oxidation of the Au particles with iodine leads to dissolution of the gold and formation of disulfide bonds between the thiolated substrates. A key strategy in this approach is the use of molecules with many thiol groups to provide good cross-linking since, after dissolution of the Au core, the structure is held together solely by S—S bonds. Confirmation of the hollow structures was done by solubility experiments; while the  $\beta$ -cyclodextrines are insoluble in water, the hollow shells are soluble since they expose only their hydrophilic portions towards the bulk of the solution. The internal wall of the shells is hydrophobic, due to the disulfide bonds present, and to prove this, encapsulation of ferrocene was studied. As a result of disproportionation of the disulfide bonds, long storage in aqueous solution led to a precipitate of an insoluble disulfide polymer. This in turn could be used as a way of controlling the release of molecules encapsulated in such nanocontainers [132].

## 5. NANOCONTAINERS PREPARED BY EMULSION/SUSPENSION POLYMERIZATION

In this section the formation of nanocontainers which can be achieved by several suspension and emulsion polymerization techniques is described. Although in most cases these methods have been shown to lead to particles with diameters of several micrometers, recent developments demonstrate that nanometer-sized polymer hollow spheres are also accessible.

One example was described by Okubo et al. [133, 134] where the penetration and release behavior of various solvents from or into the interior of monodisperse cross-linked poly(styrene)/poly(divinylbenzene) composite particles could be investigated. The hollow structure of the particles is in this case achieved by a seeded polymerization utilizing the so-called dynamic swelling method. For example, the polymerization of divinylbenzene in toluene/divinylbenzene swollen polystyrene latex particles or in poly(styrene) containing toluene droplets leads to the formation of hollow poly(divinylbenzene) (PDVB) particles. This is a result of a micro phase separation due to the limited compatibility of the chemically different polymers in solution, which leads to the formation of a PDVB shell around a toluene-polystyrene core. After evaporation of the toluene, a cavity remains in the center of such particles.

Another rather convenient method leading to hollow polymer particles proceeds via emulsion polymerization. Usually a two-stage process via seeded latex particles with physical or time separation between the two steps is applied.

In a first step, the core particles are synthesized by a conventional emulsion polymerization. Then in a second step, a different monomer or monomer mixture is added and a cross-linked shell is polymerized around the previously formed core particle. Although the preparation of such core-shell particles seems to be quite simple in theory, it is rather difficult in practice. This holds particularly if one is interested in well-defined and homogeneous particle morphologies, which is a basic requirement for the preparation of hollow polymer particles. It has been demonstrated that in this context both thermodynamic and kinetic factors are of crucial importance [135, 136]. The direct influence of many process parameters controlling the particle morphology, such as surface polarity, mode of monomer addition, role of surfactant and chain transfer agent, effect of polymer cross-linking and initiator, has already been demonstrated [137–143]. Additionally, to end up with a hollow polymer sphere one has finally to remove the core-forming material. Since core and shell are, however, frequently chemically rather similar, this is another critical step of the preparation procedure. Usually rather aggressive reaction conditions, like a prolonged alkali and acid treatment at high temperatures, are required to degrade the particle core [144, 145]. Although by using these methods clearly hollow particles can be formed, the question remains to what extent the polymer shells survive intact under these conditions.

A rather elegant approach to remove the core under very mild conditions has recently been demonstrated. The authors report the synthesis and characterization of nanometer-sized hollow organosilicon particles [146]. The synthesis of these particles followed a two-step procedure similar to that described above. The core of the particles was formed by a rather low-molecular-weight poly(dimethylsiloxane) (PDMS) around which a cross-linked organosilicon shell was formed in a second step. The PDMS core-forming material from the interior of the particles could be removed quantitatively by ultrafiltration. The remaining organosilicon nanoboxes possess typical diameters of 50 nm and a shell thickness of about 6 nm (Fig. 12).

Interestingly, they could be refilled with PDMS chains with a molecular weight of about 6000 Da, that is, rather large molecules, which reflects an obviously high porosity of the polymer shells. Hence, typical low-molecular-weight substances are expected to be released very quickly from such particles. Nevertheless, these organosilicon capsules represent a very promising system for applications in various areas.

The formation of nanocontainers with a stimuli-sensitive permeability could be achieved in a slight variation of this approach. Here, a poly(ethyl-hexylmethacrylate) (PEtHMA) core was covered by a cross-linked poly(tertiary butylacrylate) shell. Due to their low molecular weight, that is, below 10,000 g/mol, the single PEtHMA chains are able to diffuse across the particles shell and can be removed by ultrafiltration. The isolated poly(tertiary butyl)acrylate spheres could successfully be used for encapsulation of dye molecules (Fig. 13) and converted into stimuli-responsive polyelectrolyte nanocapsules by selective saponification of the tertiary butyl ester groups [147].

The preparation of nanometer-sized hollow polymer particles as a one-step emulsion process was recently

**Figure 12.** Preparation of organosilicon nanocapsules. M1:  $\text{MeSi}(\text{OMe})_3$ , M2:  $\text{Me}_2\text{Si}(\text{OMe})_2$ , M3:  $\text{Me}_3\text{SiOMe}$ , HMN: hexamethyldisilazane. described by applying a miniemulsion technique [148]. Such miniemulsions are typically formed by subjecting an oil/water/surfactant/co surfactant system to a high shear field created by devices such as an ultrasonifier and a microfluidizer. The thereby-formed droplets generally range in size from 50 to 500 nm, in contrast to the thermodynamically stable microemulsions where the droplet sizes vary usually from 10 to 100 nm. When monomer is used as the oil phase, free-radical polymerization can be carried out after the phase has been broken by high shear into droplets. If one uses for the synthesis an oil and a monomer in such a way that the two components are miscible in the monomeric state, but immiscible as soon as polymerization takes place, phase separation occurs and results in an oily core surrounded by a polymer shell. Figure 14 shows an image of nanocontainers that encapsulated a liquid during their formation [149].

As already mentioned, one crucial step in emulsion polymerization is to obtain a reproducible formation of the particles structure and homogeneity. In conventional emulsion polymerization, this is mainly controlled by the concentration of surfactant and initiator. Although it was expected that in miniemulsions the particle formation would be independent of these parameters, this has been proven not to be the case [150]. However, the use of miniemulsions is of increasing interest and shows a great potential for the design of new materials, since it is not restricted to a single (radical) polymerization procedure and allows a low-cost reaction process (e.g., compared to microemulsions, considerably lower amounts of surfactant have to be employed).

## 6. DENDRIMER NANOCONTAINERS

Dendrimers are highly branched cascade molecules that emanate from a central core through a stepwise repetitive reaction sequence [151–156]. Dendritic macromolecules are also termed starburst dendrimers, denoting their characteristic radial symmetry. The question of the existence of a central cavity within dendrimers, that would make them a true nanocapsule, has been debated frequently. Indeed, molecules have been encapsulated within dendrimers, but this does not mean that dendrimers have a permanent and rigid cavity. However, by design such a molecule consists of three topologically different regions: first, a small initiator core of low density; second, the multiple repetitive branching units, whose density increases with increasing separation from the core, thus eventually leading to the third region, a rather densely packed shell constituted by the terminal functional groups. Characteristic of dendrimers are their well-defined structure, a three-dimensional globular shape, and a high density of terminal groups. In the context of dendrimer synthesis the term generation is used to describe each of the following stepwise reactions that give rise to the concentric growth of the macromolecule. Thus each of the subsequent layers of branched monomer units is termed a generation.

From their topology it follows that at some stage in the synthesis of a dendrimer, the space available for formation of the next generation is not sufficient to accommodate all of the atoms required for complete conversion. That means, dendrimers that have internal cavities with a dense outer shell may be synthesized by controlling the chemistry of the last step. This has been demonstrated by the preparation of the fifth-generation poly(propylene imine) dendrimer [157] shown in Figure 15.

Due to their dense outer shell, these molecules can be regarded as dendritic boxes [158] that are capable of retaining guest molecules trapped during synthesis. Subsequent guest diffusion out of the box was slow, since the dendrimer shell is close packed due to the bulky H-bonded surface groups. Guest molecules could diffuse out of the boxes if the tertiary butyl groups were removed, but only if the molecules were sufficiently small. Thus Rose Bengal remained in the containers while *p*-nitrobenzoic acid leaked out [157].

By synthetic design, dendrimers with tailored structures can be obtained. While the repeat units in the interior determine the solubilization characteristic of the dendrimer, that is, the capability to solubilize a molecule in the internal cavity, the outer units and functional terminal groups influence the solubility of the dendrimer itself in a given solvent. Thus by designing amphiphilic dendrimers, in which the interior is composed of hydrophobic moieties and the external groups consist of hydrophilic units, one can envision

**Figure 15.** A dendritic box capable of encapsulating small guest molecules during construction. Reprinted with permission from [157], J. F. G. A. Jansen et al., *J. Am. Chem. Soc.* 117, 4417 (1995). © 1995, American Chemical Society.

**Figure 16.** Dendritic “unimolecular micelle” used for the slow release of indomethacin. Reprinted with permission from [166], J. M. Fréchet, *Proc. Nat. Acad. Sci. USA* 99, 4782 (2002). © 2002, National Academy of Science.

potential encapsulation devices resembling micellar structures. It is straightforward that an inverted polarity construction of such dendrimers can be also possible.

Closely related to the already described dendritic boxes are amphiphilic dendrimers or hyperbranched molecules consisting of a hydrophobic (hydrophilic) core and a hydrophilic (hydrophobic) shell, so called unimolecular micelles [159–165]. In contrast to classical micelles that are aggregates of amphiphilic molecules and therefore dynamic assemblies of small molecules, these unimolecular micelles are static and retain their cohesion regardless of concentration. Due to their amphiphilic nature, these systems are able to solubilize selectively guest molecules within their core domain. For example, dendritic molecules with a hydrophobic interior and an oligoethylene glycol periphery have been used to entrap hydrophobic drugs, such as indomethacin (Fig. 16) [166]. For an overview of dendrimer application in diagnostics and therapy see [167].

A different type of encapsulation involving the formation of metal nanoparticles within dendrimers has been used to prepare inorganic-organic composite structures that are useful in catalytic applications. The formation of Cu-nanoparticles could be achieved by the use of poly(amidoamine) starburst dendrimers as a kind of nano-reactor. Due to the permeability of the outer shell for small molecules and ions,  $\text{Cu}^{2+}$  ions could diffuse into the interior of the dendritic boxes, where they were converted into Cu-nanoparticles upon reduction. Because of their rather large dimension, compared to single ions, with diameters of ca. 2 nm, the Cu-nanoparticles were too bulky to leak out of the dendritic cavity [168].

A different dendritic nanoreactor, a reverse micellar dendrimer, consists of a nonpolar aliphatic periphery and a polar inner functionality that has been used to catalyze the  $\text{E}_1$  elimination of a solution of tertiary alkyl halides in a nonpolar solvent. The alkyl halide has some polarity and becomes concentrated within the polar dendrimer, where it is converted into an alkene. As a result of its low polarity and the existence of a gradient of polarity between the dendrimer interior and the surrounding medium, the alkene product is readily expelled from the dendrimer back into the nonpolar solvent [169].

Recently also dendrimers with stimuli-response characteristics have been reported. Functionalization of the groups

**Figure 17.** Preparation of a cored dendrimer. Reprinted with permission from [171], M. S. Wendland and S. C. Zimmermann, *J. Am. Chem. Soc.* 121, 1389 (1999). © 1999, American Chemical Society.

of amphiphilic dendrimers renders thus dendritic boxes with switchable permeabilities. The introduction of quaternary ammonium groups led to increased solubility in aqueous solutions and, due to the bulkiness of the added groups and their pH dependence, the desired release control of encapsulated molecules was achieved [170].

Although dendrimers show interesting and unique properties, they are, however, generally not real hollow particles, due to the fact that their core is covalently linked to the dendritic wedges of the molecule. It is obvious that this core is of crucial importance for the integrity of the whole molecule. Hence, removing the core requires another connection between the outer zones of the dendrimer. Indeed, applying similar concepts as shown in the approaches of Wooley [83] and Liu [84], it is also possible to produce real hollow structures from dendrimers. This has been recently demonstrated using a polyether dendrimer with a trimesic acid ester core. This polymer contains three cleavable ester bonds at its core and robust ether bonds throughout the rest of the molecule. As shown schematically in Figure 17 [171], the hollow particles were formed by selective cross-linking of homoallyl ether groups at their periphery and subsequent degradation of the core region by hydrolysis. An interesting possibility offered by this method is that the remaining functional groups in the interior of the container system could serve as endo-receptors available for molecular recognition. This approach allows a high control over the size and geometry of the formed nanocapsules. However, the preparation of the particles requires a rather costly and tedious procedure, which clearly presents a limiting factor for possible applications. Nevertheless, the quest for practical applications for dendrimers is becoming increasingly intense, but is still limited to highly specific areas.

## GLOSSARY

**Amphiphilic** Molecules consisting of two moieties, one hydrophobic (water-hating), the other hydrophilic (water-loving). Amphiphilic molecules show surfactant behavior.

**Block copolymer** A polymer in which at least two different constituting repeating units are joint in a block fashion; that is, a sequence of monomer A linked together to give a block of homopolymer A is followed by a sequence of linked monomer B (homopolymer B).

**Copolymer** A polymer in which the constituting units are two or more different ones.

**Critical micelle concentration (CMC)** Lowest concentration above which micellization can occur.

**Dendrimer** From dendro- branched and -mer part, a perfectly radial branched polymer molecule.

**Diblock copolymer** A (usually) linear block copolymer with only two types of repeating units.

**Generation** Each of the iterative reaction steps that give rise to a new layer of branched points in a dendrimer molecule.

**Graft copolymers** One special kind of comblike branched polymer, consisting of a linear chain of homopolymer A (backbone) from which shorter side chains of a different type of repeating unit (homopolymer B) emanate.

**Liposome** A vesicle-like structure composed of one or more concentric phospholipid bilayers.

**Micelle** Spherical or elongated aggregates of amphiphilic molecules, showing a core-shell structure. The hydrophobic inner core is shielded from the surrounding water media by the shell or corona formed by the hydrophilic part of the molecules that constitute the micelle.

**Polymer** From poly- many and -mer part, that is, consisting of many parts. A macromolecule consisting of individual repeating units, monomers, covalently linked together.

**Vesicle** Hollow aggregate consisting of a shell of one or more amphiphilic bilayers. Vesicles which have only one bilayer are termed unilamellar vesicles; if they show more bilayers, then they are called multilayered vesicles.

## 1. INTRODUCTION

The technologies that have been developed over the years in realizing data storage can be divided into semiconductor types (MOS, bipolar, and charge-coupled devices) and moving media types (magnetic disk, optical disk) which require mechanical equipment operation. Compared to disk devices, semiconductor memories exhibit superior characteristics in terms of cost and performance [1]. Furthermore, due to the advantages of MOS technology in device manufacturability and miniaturization, most ultralarge-scale integration (ULSI  $\geq 10^7$  transistors on a chip) memory circuits are made at the present time using MOS memories. The most important device for MOS memory technology today is the metal-oxide semiconductor (MOS) field-effect transistor (FET) [2, 3]. A simplified cross section of an *n*-channel MOS transistor is shown in Figure 1. It consists of a *p* ("positive")-type silicon substrate with a surplus of holes and a top gate electrode made of conducting material, between which an insulating dielectric (usually, a thermally grown silicon dioxide film) is formed. Two junctions, the source and the drain, that have an abundance of electrons are fabricated with a small overlap to the gate by *n* ("negative")-doped ionized

regions. When a positive voltage is applied to the gate, an electric field is set up that penetrates through the insulator, attracting electrons toward the surface of the substrate. An inversion layer designated as the channel is formed, allowing current to flow between the source and the drain regions.

Ideal memory devices ought to be low cost, nonvolatile, able to retain data without external power, have random access that features read-write access to any individual data location, high speed, high density, low power consumption, be easy to test, highly reliable, and compatible with established industrial manufacturing routes. Unfortunately a single type of memory device having all of these characteristics remains unfeasible to this day. Instead, the MOS memory devices that are used as the best alternatives in today's electronics systems can be classified in terms of their volatility and access speed as volatile random-access memories (RAMs) and nonvolatile non-RAMs. Volatile RAMs permit data to be stored and retrieved at comparable speeds. They include the two most common memory types: dynamic RAM (DRAM) and static RAM (SRAM). DRAM has a small cell size and a reasonably short access (read) time ( $<20$  ns), but the stored information in each cell must be refreshed more than once per second. The refreshing operation is what makes the difference between a dynamic and a static RAM. SRAM has the fastest access time ( $<5$  ns) and does not require refreshing, but has a larger cell size than DRAM. On the other hand, a nonvolatile non-RAM memory, more commonly called nonvolatile memory (NVM), is a device that can program (write) data electrically, and does not require any power for the maintenance of the data ("retention"), but for which the access operation is restricted in some sense. At present, the dominant technology for NVM implementation is based on the floating-gate (FG) concept [4]. All of the FG NVM memory cells have the same generic cell structure, and are roughly classified following their erasing

**Figure 1.** Schematic cross-section representation of an *n*-channel MOS transistor structure.

mode, to ultraviolet light UV-erasable EPROM (electrically programmable read-only memory) and EEPROM (electrically erasable PROM), including the most recent and important version of Flash EEPROM where the complete memory array is erased very quickly. Today, the name Flash EEPROM is used for all EEPROMs in which the erase operation is done not for every single cell, but for a whole memory array, or for a memory block (sector). The Flash memory has a small size, and does not require refresh, but has slow access time and even slower write/erase times ( $\sim 80$  ns access and  $\sim 1 \mu\text{s}/>10$  ms write/erase times for the case of NOR Flash). The slow write speed and the limited number of write/erase operations ( $10^5$ – $10^6$  write/erase cycles) preclude the usage of Flash memory as a RAM memory.

### 1.1. Dynamic RAM

The DRAM memories are commonly used as a main memory for personal computers because of their low cost and high-density capability. The modern one transistor/one capacitor (1T-1C) DRAM memory cell that emerged in the 1970s [5] consists of one MOS transistor (access or pass transistor) in series with one MOS storage capacitor [Fig. 2(a)]. Binary data are stored on the capacitor in the form of charge  $Q_s$ . By assuming that the capacitor's common node is biased at  $V_{CC}/2$ , a logic "0" in the cell requires a capacitor with a voltage of  $-V_{CC}/2$  across it, while a logic "1" in the cell requires a capacitor with a voltage of  $+V_{CC}/2$ . Therefore, the charge stored in the capacitor is  $Q_s = (-V_{CC}/2)C_s$  for logic "0" and  $Q_s = (V_{CC}/2)C_s$  for the case of logic "1," where  $C_s$  is the capacitance of the storage capacitor. In the memory-array configuration, shown in Figure 2(b), each capacitor is accessed through a transistor connected to an array of word lines and bit lines. A circuit called a sense amplifier is used to distinguish whether the memory cell is storing "0" or "1" information (read operation). During reading, the stored information is lost, and thus a write cycle must always follow. Even during normal operation, the stored charge can be slowly depleted due to several leakage mechanisms inevitably present, such as *p-n* junction leakage, subthreshold conduction in the pass transistor, leakage through the capacitor dielectric, or through high-energy-particle events (alpha particles, neutrons). Thus, essential

**Figure 2.** Schematic of (a) conventional planar one-transistor one-capacitor DRAM cell, and (b) DRAM circuit in a memory-array configuration (two memory cells are shown).

to the proper operation of a DRAM is the refresh operation. During refresh, the cell content is read, and the data bit is rewritten, thus restoring the capacitor voltage to its proper value. The refreshing operation increases the device power consumption, and also imposes a serious limitation in transistor scaling. In order to reach a long refresh time, the leakage of the access transistor must be low, thus requiring relatively high threshold voltages ( $>0.5$  V). This is the reason why DRAM transistors have not scaled as fast as logic transistors, and generally have longer channel lengths, thicker gate oxides, and higher operating voltages. An additional constraint in DRAM cell scaling is imposed by the scaling of the storage capacitor. Because the voltage available to the sense amplifier for signal detection is proportional to the  $C_s/C_b$  ratio, the storage capacitance  $C_s$  needs to be as large as possible in order to create a large enough signal ( $\sim 100$  mV) on the bit line.  $C_b$  is an unavoidable parasitic bit line capacitance coming from the transistor junction capacitance and bit-line wire capacitance.  $C_s$  also must substantially remain large enough to minimize the sensitivity of the cell to soft errors that originate from high-energy-particle events. Typical  $C_s$  values are in the range of 25–30 fF, and these values have remained constant over many generations of DRAM technology. According to the equation for the memory cell capacitance,  $C_s = \epsilon\epsilon_0 A/d$ , where  $\epsilon$  is the relative dielectric constant of the capacitor film material,  $\epsilon_0$  is the dielectric constant of free space,  $A$  is the capacitor area, and  $d$  is the thickness of the capacitor film, the approaches that have been used in order to maintain a constant  $C_s$  are as follows. First, in the simple planar cell [Fig. 2(a)], the pure oxide capacitor film with a dielectric

constant of 4 is replaced by a multilayer oxide/nitride/oxide (ONO) or nitride/oxide (NO) film with a dielectric constant of 7, followed by capacitor film thickness  $d$  scaling. Then, three-dimensional (3D) capacitor structures (stack or trench) in place of the conventional planar cell are developed to increase the capacitance per unit area. It is expected that future DRAM capacitors will need dielectric materials having high  $\epsilon$  values such as  $\text{Ta}_2\text{O}_5$  (tantalum pentoxide  $\epsilon = 25$ ) and, eventually, materials with even higher  $\epsilon$  values such as BST (barium strontium titanate,  $\epsilon = 500$ ) [6]. Although these exotic materials would significantly increase the capacitance per unit area, and thus the device integration density, they are not at this time compatible with the existing DRAM manufacturing process. All in all, it is unclear whether the DRAM memory cell will scale at gigabit densities due to the inherent constraints of low-leakage access transistors and the need for large storage capacitance.

## 1.2. Static RAM

The SRAM memory cell is a bistable circuit utilizing a pair of inverters connected back to back, and is mostly used as on-chip cache memory on microprocessors because of its faster speed compared to the DRAM cell. The most common version of the SRAM memory cell is the full complementary MOS (CMOS) with PMOS loads illustrated in Figure 3. It is a six-transistor (6T) memory cell consisting of two cross-coupled inverters and two access transistors connected to complementary bit lines. Since the inverters are cross coupled, the SRAM memory cell is a two-state circuit with excellent stability; either the “1” or “0” state will be maintained indefinitely by a continuous small dissipation of power in the cell unless changed by another write operation. The access transistors are turned on when the word line is selected, and they connect the inverters to the bit lines, allowing the read and write operations to be performed. One important parameter for the stability of the SRAM cell and a serious concern in SRAM scaling is that the two cross-coupled inverters must have well-matched transistor characteristics. Random variations of the transistor properties, mainly fluctuations of the transistor threshold voltages ( $V_{\text{TH}}$ ), result in an increased bit-fail rate of the memory

**Figure 3.** Circuit schematic of a six-transistor SRAM cell in a memory array configuration (one memory cell is shown).

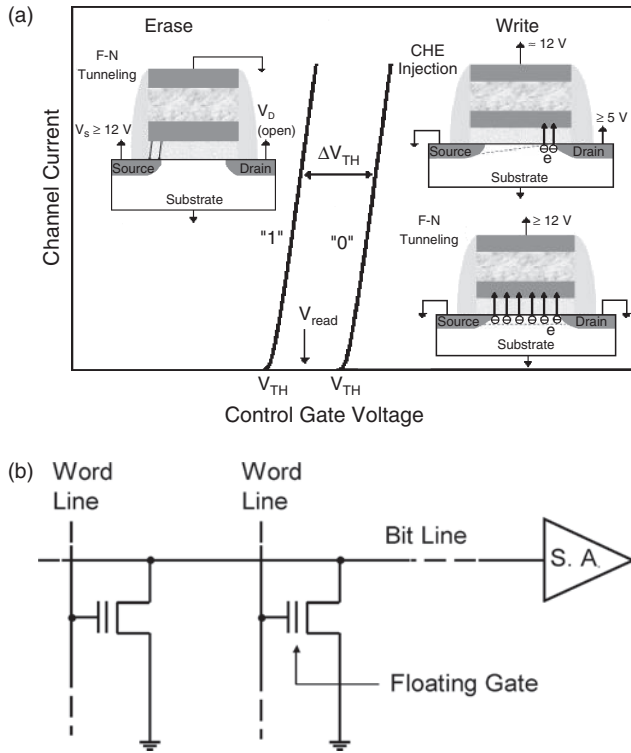

cell [7]. Such fluctuations of  $V_{\text{TH}}$  MOSFETs are unavoidably caused by discrete dopant atoms or by the finite ability to control the fabrication process, and ultimately limit the number of devices which can be integrated on one chip. In addition, similar to the DRAM case, cosmic rays, mostly neutrons, can cause soft errors (temporary random errors) in SRAM cell operation, and thus impose another constraint in future cell scaling as the soft error rate increases as feature size and operating voltage decreases.

## 1.3. Flash EEPROM

The Flash memory appeared in 1984 [8], and was designed to be the solution to the scaling problem of EEPROMs by trading off memory size with functionality. It has already become the largest market in nonvolatile technology due to a high competitive tradeoff between functionality and cost/bit, and it is expected to be the optimum choice for mass storage in personal mobile systems. The generic Flash memory cell is a single stacked-gate MOS transistor, as illustrated in Figure 4. The conductive polysilicon layer between the externally accessible gate (called a control gate) and the substrate is denoted as the floating gate. The dielectrics between the FG and the substrate (usually a thermal silicon oxide) and between the FG and the control gate are usually referred to as the tunneling and the interpoly or control dielectrics, respectively. The idea of using an FG device to obtain a nonvolatile memory device was suggested for the first time in 1967 by Kahng and Sze [9]. The basic operation principle of the FG device is the storage of charge in the FG [Fig. 5(a)]. During programming (writing), electrons (for the case of an  $n$ -channel device) from the silicon conduction band are injected through the tunneling oxide, and subsequently stored on the floating gate. The stored electrons in the FG screen the mobile charge in the underlying channel, thus inducing a change in the conductivity of the channel, allowing the transistor threshold voltage to be electrically altered between a low and a high value, conventionally defined as the “1” or erased state and the “0” or written state [Fig. 5(a)]. The threshold voltage shift  $\Delta V_{\text{TH}}$  caused by the storage of the charge  $Q_{\text{FG}}$  is given by  $\Delta V_{\text{TH}} = -Q_{\text{FG}}/C_{\text{CG}}$ .  $C_{\text{CG}}$  is the capacitance between the control and the floating gates, and is given by  $C_{\text{CG}} = \epsilon A/t$ ,

**Figure 4.** Generic stacked-gate MOS transistor Flash memory cell cross section.

**Figure 5.** (a) Read and write/erase operation principles of a Flash memory. The schematic of the memory transistor illustrates the bias conditions that are employed for the case of CHE injection or F–N substrate electron injection write modes, and for the case of source-side electron extraction erase mode. (b) Circuit schematic of a one-transistor Flash memory cell in a memory array configuration (two memory cells are shown).

where  $A$  is the capacitor area, and  $\epsilon$  and  $t$  are the dielectric constant and thickness of the control dielectric, respectively. The information content of the cell is read by sensing the current through the bit line, while accessing the cell is achieved by applying a read voltage  $V_{\text{read}}$  at the gate or word line with a value between the two possible threshold voltages. In one state, the transistor is ON (“1”) (conducting current), while in the other, the transistor is OFF (“0”). An erase operation involves removing electrons from the FG, hence returning the device  $V_{\text{TH}}$  to a low state. The Flash memory cell can be erased electrically, but not selectively. The content of the whole memory chip is always cleared (Flash erase) in one step, and this design allows a single-transistor memory cell to be constructed [Fig. 5(b)]. In order to allow byte-selective write and erase, a select transistor, is added to the memory transistor, leading to the so-called two-transistor EEPROM memory cell. Therefore, Flash memories abandon the feature of single-cell erasability in favor of lower cost large-scale integration memory circuits. Once programmed, the cell is guaranteed to retain information for at least ten years (the industrial standard for nonvolatile memories), either under operation or with power turned off. Information can be lost if electron leak occurs, mainly through the tunneling dielectric. To maintain nonvolatility, relatively thick (about 10 nm) tunneling oxides are required, a feature that causes difficulty in charging the

FG as a very large amount of energy is needed for electrons to move into or from the FG. The physical mechanisms that are commonly used for this charge transfer are the field-induced (Fowler–Nordheim, F–N) tunneling [10] or channel hot-electron injection (CHE) [11] for the write operation and F–N tunneling for the erase operation. During CHE injection, a large drain  $V_D$  bias causes the generation of highly energetic electrons at the drain side in the channel, while a large control gate  $V_G$  bias, with  $V_G > V_D$ , generates an oxide field that favors the injection of the heated electrons over the Si–SiO<sub>2</sub> energy barrier [Fig. 5(a)]. F–N tunneling is the flow of electrons through the energy barrier of the tunneling oxide that has been modified by a high electric field for effective narrowing of the oxide barrier width. During F–N programming, a high voltage applied to the top control gate causes electrons from the source, drain, or substrate (depending on the voltages at that terminals) to be injected into the FG. A schematic description of write by F–N tunneling for the case of electron injection from the whole channel region is shown in Figure 5(a). The erase process can be accomplished by applying a high voltage to the source, drain, or to the substrate of the well with the control gate grounded. It can also be accomplished by applying a negative voltage to the control gate with the other terminals connected at different positive voltages. Depending on the programming mechanism, Flash memory arrays have two different configurations: NAND and NOR. NAND cells use F–N tunneling to program the FG, while NOR cells use CHE injection for write operation. Both NOR and NAND cells utilize F–N tunneling to erase the cell. The generation of highly energetic carriers during both programming operations introduces permanent damage, referred to as degradation, due to charge trapping in the tunneling oxide. As a result, the Flash memory can withstand a limited number, typically  $10^5$ , of write/erase cycles (called its endurance). Additionally, due to the small currents flowing through the tunneling oxide during both the CHE injection and F–N tunneling processes, the charging times are slow, resulting in typical write times in the microsecond and millisecond ranges, respectively. Although Flash memories have been designed as a solution to the scaling problem of conventional EEPROM devices, aggressive scaling of the transistor dimensions and the dramatic increase in the memory array size demand a lower voltage memory cell design for the future. As the technology for the CHE injection or F–N tunneling process has to support relatively high voltages (e.g., 8–9 V minimum and  $>12$  V for CHE and F–N tunneling programming, respectively), Flash memory cell scaling presents severe limitations. Constraints in vertical scaling of the memory cell, and therefore in scaling of the applied operating voltages, are imposed by the extreme requirements of incredibly low dielectric leakage (less than  $\sim 10^{-14}$  A/cm<sup>2</sup>) to ensure a ten-year data retention time. In the case of the control dielectric, an ONO composite dielectric is typically used, and allows for thinner control layers compared to silicon oxide layers, with much lower leakage currents. In the case of the tunneling oxide, the requirements are even more stringent as it must be thin enough to allow a fast write/erase speed at reasonable voltage levels with negligible degradation after  $10^5$  programming cycles, and thick enough to avoid charge loss during read or normal

operations. Thus, all scaling issues pertinent to Flash memories are ultimately related to the reliability of the tunneling oxide. Theoretically, in order to ensure ten-year data retention time, the tunneling oxide could be scaled until electron flow through the full oxide thickness becomes significant (i.e., down to ca. 5 nm). However, stress-induced leakage current (SILC) [12, 13] imposes a more stringent limitation on the tunneling oxide thickness as a single point of high leakage in the oxide can discharge the conducting polysilicon FG layer. This is the reason why the tunneling oxide of Flash memories was set as thin as about 10 nm from the beginning, and has scarcely been thinned over five successive generations to limit its thickness to 7–8 nm at the present state of nonvolatile memory technology. As a result, the dimensions of the FG transistor have been scaled much more slowly than those of the logic transistor, and therefore, the Flash memory performance in terms of access time, write/erase speeds, and operating voltages has not been substantially improved with device scaling. The increase in Flash memory capacity (thus, the decrease in the cost/Mbit) has been mainly achieved through different array architectures such as the NAND structure [14], which reduces the cell size by connecting the cells in series between a bit line and a source line. Another option for higher bit storage density without the need for aggressive technology scaling is the multilevel charge storage (MLCS) approach, where more than one bit is stored inside a single memory transistor [15].

## 2. NANOCRYSTAL MEMORY APPROACH

In order to overcome the technological constraints imposed as the device size approach dimensions below the 100 nm range, new memory concepts are needed for ultrahigh-density, low-voltage, low-power, and fast write/erase data storage. For this reason, various memory alternatives are actively investigated. The ferroelectric RAM (FRAM) [16] that replaces the DRAM capacitor's dielectric with ferroelectric material, and the one-transistor magnetic RAM (MRAM) [17] that replaces the capacitor with a magnetoresistor structure are two potential solutions. For such devices, the compatibility of the ferroelectric and magnetic materials with standard CMOS processes is an important technological issue that remains a subject of debate. Another promising alternative for low-cost ultradense data storage lies in the use of modified Flash memory structures. Nanocrystal memories are one particular implementation of this approach. In the subsections that follow, the operation principle and challenges of this new memory concept are reviewed, as well as the electrical characteristics of nanocrystal memory devices obtained through the use of various fabrication techniques of synthesizing nanocrystalline floating-gate layers.

### 2.1. Charge Storage in Spatially Isolated Trap Sites

Two different approaches for improving the performance of “scaled-Flash” memory have been proposed. The first includes the nonvolatile RAM (referred to as NOVORAM) suggested by Likharev [18], and the phase-state low-electron-number drive random (PLEDM) proposed by

Hitachi and the University of Cambridge [19]. NOVORAM uses a “crested” tunnel barrier that replaces the usual uniform oxide barrier (often called a “rectangular” barrier) with a stack of dielectric materials in order to create a special barrier shape for an effective F–N tunneling into/out of the floating gate. Thus, enhanced barrier height suppression is present during write/erase operations, while a higher barrier is present during the retention and read modes. In the PLEDM device, electrons are injected into the memory node through stacked multiple tunnel junctions. A second polysilicon gate that surrounds the memory cell is used to modulate the current flow through the tunnel junctions. For both devices, simulations have indicated write times potentially faster than DRAM and ~ten-year retention time. NOVORAM and PLEDM devices are currently in the concept stage since no memory operation has been experimentally demonstrated.

The second approach for overcoming scaling limitations of conventional Flash memory cells is based on the storage of charges in isolated charge-trapping sites in place of the conventional FG layer. Excellent immunity to oxide defects is thus ensured since, even if a pinhole exists in the tunneling oxide, leakage will only cause a few storage nodes to lose their charge. This allows the implementation of memory devices with thinner tunneling oxides, operating at lower voltages and/or faster programming speeds. In addition, compared to conventional FG memory devices, the single-transistor charge-trapping structure exhibits other important advantages such as: (1) the memory array requires only one level of polysilicon that simplifies the fabrication process and lowers the cost, (2) the memory cell permits further scaling (the cell size can be  $2F^2$ , where  $F$  is the minimum feature size), and (3) the absence of drain-to-FG coupling allows the use of higher drain reading voltages for faster memory access times, and also reduces the bit-line disturb as only storage nodes directly over the drain overlap region will be affected.

Historically, the first charge-trapping device was introduced in 1967 by Wegener et al. [20], almost simultaneously with the FG memory cell, and was the metal–nitride–oxide–silicon (MNOS) cell, where the discrete charge-storage elements are traps distributed in the nitride layer. Today, two types of charge-trapping memory devices are actively investigated: the polysilicon-blocking oxide–nitride–tunneling oxide–silicon (SONOS) device, including the most recent version of nitride read-only memory (NROM) and the nanocrystal memory. The SONOS [21] and NROM [22] storage transistors utilize an oxide–nitride–oxide trapping material instead of the normal gate dielectric of a conventional  $n$ -channel MOSFET. The difference between the two devices lies in the physical mechanisms involved during programming operations that are related to the thickness of the bottom tunneling oxide. For SONOS devices, charge injection (removal) into (from) the dielectric storage layer is performed by direct tunneling through thin tunneling oxide (~2–3 nm in thickness), while for NROM devices with tunneling oxide greater than 5 nm, program (erase) operation takes place by localized charge trapping (removal) of channel hot-electron injection (tunnel-enhanced hot-hole injection) in the dielectric storage layer.

The nanocrystal memory cell, proposed in the early 1990s by Tiwari's team at IBM [23, 24], consists of a single MOS transistor with an array of laterally uncoupled crystalline silicon or germanium nanoparticles embedded in the gate oxide in close proximity to the channel. A schematic cross section of the memory cell is shown in Figure 6. A thin tunneling dielectric, usually thermal oxide ( $\leq 5$  nm in thickness), separates the channel of an otherwise conventional MOSFET from a distributed charge-trapping layer that covers the entire transistor channel area. A thicker control oxide layer is used to electrically isolate the nanocrystal storage nodes from the control gate.

## 2.2. Operation Considerations and Challenges

The storage of charges in a layer made of mutually isolated nanocrystals (in analogy to a conventional floating-gate device) is the basic operating principle of a nanocrystal memory. Stored charge changes the conductivity of the transistor by shifting the threshold voltage  $V_{TH}$  of the device, for the case of negative stored charge, to more positive values. This single-transistor memory device has been introduced as an alternative structure to conventional DRAM for high-storage density and low-power operation, as well as to nonvolatile memories such as Flash EEPROMs for faster write/erase speed, lower write/erase bias, and better endurance [23]. There are, however, key issues to be solved before the practical implementation of this kind of memory. Of importance are: data retention, memory window, and device characteristic deviations. Here, we will briefly discuss the role of some of the main features that affect the operation of the device and its performance, as well as the progress in the area of nanocrystal memories.

### 2.2.1. Programming Mechanism

Figure 7 shows schematic energy band diagrams for Si nanocrystal memories during: (a) write (electron injection), and (b) erase (electron removal). During write (erase) operation, electrons are injected (removed) to (from) the nanocrystals by applying a positive (negative) voltage bias to the gate with respect to source and drain electrodes. The thickness of the control oxide must be relatively thin for reasonable low voltage operation, but not so thin as to cause the charge to eventually leak to the control gate. These constraints make an optimum control oxide thickness on the order of 5–15 nm [25]. For the case of thin tunneling oxides with

**Figure 6.** Schematic cross-section representation of a one-transistor nanocrystal floating-gate memory cell.

**Figure 7.** Potential diagrams of the conduction bands for an Si nanocrystal memory device during: (a) write (nanocrystal electron injection) mode, (b) erase (nanocrystal electron extraction) mode, (c), (d) charge-retention mode (at a reading gate voltage) for the case of (c) electron storage in a quantized nanocrystal energy level, (d) electron storage in deep energy level located in the nanocrystal or/and at the nanocrystal/SiO<sub>2</sub> interface.

thicknesses less than 3 nm, charge transfer takes place via direct tunneling (electron flow through the full oxide thickness, as illustrated in Fig. 7) instead of F–N tunneling. Since a large amount of current can pass through these thin oxides at low electric fields ( $< 3$  MV/cm) [26–27], superior performance characteristics compared to Flash memories can be achieved in terms of operation voltages and/or write/erase speeds. The generation of lower energetic carriers during programming operations (much less than 3 eV, that is, the threshold for several of the major hot carrier degradation mechanisms) reduces the oxide degradation encountered in F–N injection, resulting in better endurance and charge-to-breakdown characteristics [28].

### 2.2.2. Coulomb Blockade and Quantum Confinement

In addition to the direct tunneling programming mechanism, charge storage in nanocrystals offers several attractive characteristics that are absent in the conventional floating-gate structure. Charging the dots with an extra electron requires a charging energy  $E_C = e^2/2C + \Delta E_n$  [29, 30]. The first term is the classical electrostatic charging energy associated with placing a charge particle onto a small dot capacitance  $C$ , and varies inversely with dot dimension. The second term,  $\Delta E_n$ , due to quantum confinement, is the characteristic energy spacing between two adjacent energy levels of the dot. For metal dots where the density of states is enormous, confinement does not impose severe restrictions. In contrast, few “free-electron” systems, such as semiconductors, exhibit strong size-dependent quantization effects. When the characteristic length of an electron (or hole) wavefunction is on the order of the particle diameter, discrete energy levels appear near the conduction (valence) band edge (as shown in Fig. 7), with an approximate magnitude varying as the inverse square of the dot dimension, thus causing an increase of the energy bandgap. Resonant tunneling through oxide barriers involving discrete quantum states in Si nanocrystal and

the effect of quantized charge accumulation in ground-state energies of “few-electron” silicon dots have been experimentally demonstrated and discussed in [31–33].

The consequence of the Coulomb blockade and quantum confinement effects in a nanocrystal memory device is a reduction of the number of charged carriers used in the operation of the device that improves power and speed performance. To allow “few-electron” device operation, the charging energy must be greater than the thermal energy  $k_B T$  (where  $k_B$  is Boltzmann’s constant and  $T$  is the operation temperature). Room-temperature ( $k_B T$  ca. 26 meV) “few-electron” operation can be accomplished if the semiconductor nanocrystals have dimensions below ca. 10 nm. However, for the programming voltage and write time of interest, a minimum dot size is required. Neglecting band bending of the substrate in the inversion region, the write voltage  $V_{\text{write}}$  needed for a channel electron to tunnel into a dot state is approximately given by  $(E_C/e)(1 + t_{\text{ctrl}}/t_{\text{tun}}) + V_{\text{TH}}$ , where  $t_{\text{ctrl}}$ ,  $t_{\text{tun}}$  are the control and tunneling oxide thickness respectively, and  $V_{\text{TH}}$  is the threshold voltage. The large increase of the charging energy  $E_C$  (through the increase of the eigenenergies and the electrostatic charging energy) with dot size reduction increases the amount of gate voltage needed for charging. In addition, the reduced density of states restricts the states available for electrons to tunnel at a given voltage, resulting in lower programming speed. Thus, for an efficient operation at write voltages of  $\sim 3$  V, an optimum nanocrystal size in between 3–10 nm is estimated (for reasonable control-to-tunneling-oxide-thickness ratio on the order of 3–5) [25].

### 2.2.3. Memory Window

The resulting memory window  $\Delta V_{\text{TH}}$  due to single-electron storage in each nanocrystal is given by  $\Delta V_{\text{TH}} = eN_{\text{dot}}/C_{\text{gd}}$ , where  $e$  is the electron charge and  $N_{\text{dot}}$  is the aerial density of the nanocrystals (number of nanocrystals per  $\text{cm}^2$ ).  $C_{\text{gd}}$  is the capacitance per  $\text{cm}^2$  between the control gate and the nanocrystal, and is approximately given by [34]  $C_{\text{gd}} = \epsilon_{\text{ox}}/[t_{\text{ctrl}} + (\epsilon_{\text{ox}}/2\epsilon_{\text{dot}})t_{\text{dot}}]$ , where  $\epsilon_{\text{ox}}$  ( $\epsilon_{\text{dot}}$ ) are the oxide (nanocrystal) dielectric constants, and  $t_{\text{dot}}$  is the linear dimension of the nanocrystal. For spherical Si nanocrystals with 5 nm diameter, located at a distance of 7 nm from the control gate, the threshold voltage shift for one electron per nanocrystal is estimated to be  $\Delta V_{\text{TH}} \sim 0.36(N_{\text{dot}}/10^{12})$  V. The nanocrystal aerial density must be high enough in order to provide a large threshold voltage window, as well as to minimize low-resistance percolation paths in the channel underneath for an effective channel current modulation, but not so large as to cause lateral conduction between the dots. The maximum aerial density can be estimated from the nanocrystal size by setting optimum internanocrystal spacing (for negligible direct-tunneling probability between dots) on the order of 4–5 nm (i.e., for the case of dots of 5 nm in size, 5 nm apart, an optimum nanocrystal density of  $1 \times 10^{12} \text{ cm}^{-2}$  is estimated).

### 2.2.4. Channel Area

By shrinking the entire floating-gate transistor to nanoscale dimensions, the quantum dot or single-electron memory cell (SEMC) is obtained. It consists of a single floating quantum

dot located very close to the transistor nanoscale channel. Due to the ultrascale dimensions of the storage node, once an electron enters and becomes trapped in the quantum dot, quantum confinement and Coulomb blockade effects inhibit the tunneling of another electron. The addition of a single electron can change the transistor current considerably, resulting in an ultimate memory device that stores one bit of information by one electron. The precise control of the number of electrons on the storage node can be achieved by varying the voltage on the control gate electrode. The stored electrons on the floating dot electrostatically screen the entire channel from the potential on the control gate, which in turn changes the flow of electrons in the channel, resulting in a discrete shift in the device threshold voltage (see Fig. 8). The first SEMC based on GaAs was demonstrated at very low temperatures ( $\sim 4.2$  K) [35]. Room-temperature operation of SEMC based on Si was first demonstrated in MOSFETs with a nanometer-sized granular Si channel [36].

A more reliable technique to obtain room-temperature operation of Si-based SEMC uses electron-beam lithography and a self-aligned process to define narrow Si channels and quantum dots on silicon-on-insulator (SOI) material [34, 37–38]. A schematic cross section of this structure is illustrated in Figure 8. Despite these exciting experimental results and disregarding the reliability of the device fabrication process, the use of charge quantization effects in ULSI circuits remains uncertain in view of background charge (e.g., surface states on the nanocrystal), dopant fluctuations in the channel depletion region, and intrinsic statistical charge variations due to the Poisson nature of electron injection. These effects can lead to substantial variation of the threshold voltage from device to device. New architectures have been proposed to circumvent this problem [29, 39–40], but no devices have been demonstrated yet. In order to ensure reliable memory operation, the threshold voltage shift due to stored electrons must be significantly higher than that due to the other fluctuations. Calculations and experimental results indicate that “few” stored electrons (on the order of five–ten electrons, depending on dot and size dimensions) instead of a single electron are required for each memory state [25, 41–42]. As a result, the voltage of storing a single bit is increased, and it becomes even higher for multiple bit storage operation. In addition, because the electric field across the tunneling oxide increases with the number of stored electrons on the dot, a relatively thick tunneling oxide (i.e.,  $>5$  nm) must be used

**Figure 8.** Schematic cross section of a self-aligned quantum-dot memory transistor, together with an illustration representing the discrete shifts in the device threshold voltage caused by the different number of electrons stored in the dot.

in order to ensure a long data-retention time. Since high voltages are required for multiple-level memory storage, the tradeoff is between integration density and operation power. Note that, for the case of a multiple-dot device, the presence of a sufficient number of nanocrystals in the memory operation suppresses cell-to-cell variation. This is an important advantage of multiple-dot structures as it allows effective operation at a lower number of stored electrons per nanocrystal compared to quantum dot memory. However, although single-electron charging effects have been demonstrated in large-area channel multiple-dot memories [43], even at room temperature [44–45], there are important technological issues to be resolved, such as high dot density and extremely high uniformity in dot size and dot position from the channel, before the practical exploitation of single-electron phenomena in nanocrystal memories.

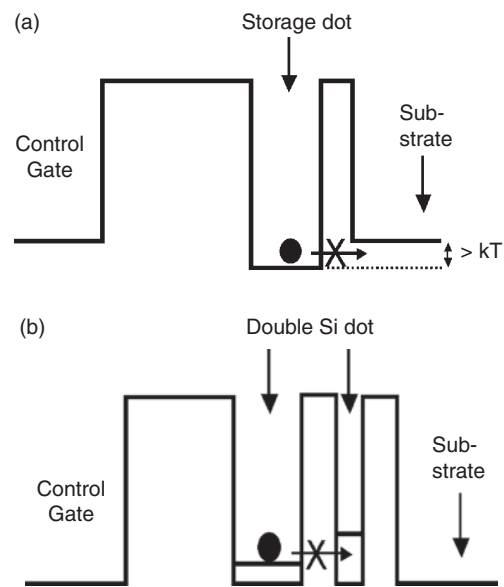

### 2.2.5. Charge Storage

A major challenge of nanocrystal memory using thin tunneling oxides lies in the realization of long charge-retention times. Because of the sharp increase of the direct tunneling current at arbitrarily low voltages, a tradeoff exists between the write/erase time and retention time. By making the injection oxide thicker for a long retention time, the advantages of high-speed write/erase at reasonable voltage levels and of high endurance are lost rapidly. For the case of Si nanocrystals, an additional constraint for long-term charge retention is introduced by quantum confinement. This can be understood by reference to Figure 7(c), which illustrates an energy band diagram of Si nanocrystal memory under charge storage condition. After write operation [Fig. 7(a)], injected electrons that may initially tunnel into higher nanocrystal energy levels eventually will fall into lower energy states. Due to energy quantization, the lowest energy level at flat-band condition is above the conduction band edge in the channel region. Thus, a finite probability exists for an electron to tunnel back into the channel, affecting the retention characteristics of the device. It should be noted that most experimental results to date have shown significantly longer erase times than write times, reflecting relatively longer retention times than what was theoretically expected if both the write and erase process are due to direct tunneling. Several works attempting to explain the charging/discharging phenomena involved in Si nanocrystal memories have been carried out. Theoretical approaches, based upon [46] a master equation including quantum confinement and Coulomb blockade effects in Si dots [46], or on a semiclassical current continuity model [47, 48], have been proposed to describe the observed time-dependent charging/discharging behavior. Other work has shown that the influence of channel-depletion effects on carrier charging characteristics is very important for long charge retention in Si dot memory [49]. The presence of traps inside the nanocrystal or/and at the nanocrystal/SiO<sub>2</sub> interface [that causes electrons to be relaxed to lower trap states in the bandgap after injection, as illustrated in Fig. 7(d)] has been suggested to explain the observed relatively long-time charge-retention behavior [50]. However, the role of interface states on the charging/discharging phenomena in nanocrystal memories is still not entirely understood, and is possibly dependent

on the process conditions of nanocrystal formation. Experimental results related to the storage and erase process in these structures indicate two distinct time constants, which could be interpreted as fast nanocrystal-related emission followed by a slower interface state-related emission [51]. Another work has shown a small temperature dependence on the dynamic charging, at room/low temperatures, suggesting that Si-dot/SiO<sub>2</sub> interface states do not dominate the charge exchange between the Si dot and the channel [48]. Similar results, but for the case of a single Si nanocrystal, supporting the nanocrystal-related emission process were obtained in another work [52]. Recently, simulation results concerning the charging time response in silicon nanocrystal memory (obtained from the self-consistent solutions of the three-dimensional Kohn–Sham and Poisson equations) have shown write, erase, and retention time characteristics that are very sensitive to the shape of the Si nanocrystal storage nodes [53].

### 2.2.6. Storage Dot Engineering

In order to improve the performance of Si nanocrystal memory for high-speed nonvolatile applications, two different alternatives are actively investigated: a material and a structural engineering. Material engineering replaces the Si nanocrystal with a storage node composed of a material that allows long charge retention, while keeping the operation speed at acceptable levels. For example, this can be achieved if we use a storage node composed of a material having a conduction band edge (for the case of semiconductor material) or Fermi energy (for the case of metal) at least 26 meV (the room-temperature thermal energy) below the conduction band edge of the channel region [Fig. 9 (a)]. The energy band-edge difference creates an asymmetrical barrier

**Figure 9.** Potential diagrams of the conduction bands of a nanocrystal memory device during the charge-retention mode for the case of: (a) nanocrystalline material having a conduction band edge at least 26 meV below the conduction band edge of the channel region, and (b) double-stacked layer consisting of perfectly self-aligned (but different in size) Si nanocrystals.

between the channel and the storage node that combines the high transparency necessary for fast write/erase times with the low transparency necessary for long retention times at low voltages. This can be achieved if the storage nodes are composed of a material that has a larger electron affinity than the silicon substrate (i.e., metal, semiconductor-like Ge nanocrystals, or semiconductor heterostructures such as Ge/Si nanocrystals). Operation of Au, Ag, and Pt nanocrystal memories working in the F–N tunneling regime (as in the case of relatively thick tunneling oxides) has been demonstrated [54–55]. However, metal contamination (especially for the case of thin tunneling oxides) and CMOS process integration compatibility are important technological issues for such structures. For the case of Ge nanocrystals, charge-storage advantages over the corresponding Si case are not clear, as similar results have been obtained for Ge and Si nanocrystal-based memory structures [56]. Up to now, only simulated charge-retention data exist for the case of Ge/Si storage nodes [57].

Another particular implementation of material engineering is a memory structure with silicon nitride ( $\text{Si}_3\text{N}_4$ ) storage dots proposed in 2001 [58]. Charge storage in  $\text{Si}_3\text{N}_4$  dot memory takes place, as in the case of a SONOS device, at nitride traps distributed in the  $\text{Si}_3\text{N}_4$  dot. However, due to restricted dot dimensions, a finite number of traps is expected (e.g., two or three traps for the case of a 10 nm diameter dot), allowing (as for the case of Si dot memory) small and controllable numbers of electrons to be involved in the memory operation. Moreover, the absence of Coulomb blockade and confinement effects in an  $\text{Si}_3\text{N}_4$  dot allows charging with more than one electron at a low write voltage, resulting in a larger memory window compared to the Si dot device [58]. The exact number of traps involved and a fabrication route of forming well-controlled, in terms of size and position,  $\text{Si}_3\text{N}_4$  dots are key issues for practical use of this new memory concept.

Structural engineering replaces the single storage layer with a double-stacked layer consisting of perfectly self-aligned Si nanocrystals. The fabrication process and the memory characteristics of this structure are discussed in [59, 60]. For the case of a smaller dot at the lower stack with ultrathin tunneling oxides below and between the two stacks, fast write/erase speeds with a much better charge retention compared to single-dot memory have been demonstrated. Coulomb blockade and quantum confinement in lower dots [Fig. 9(b)] inhibit electrons in the upper dots to tunnel back into the channel. The smaller the size of the lower dots, the larger the improvement in data retention. An important point of this doubly stacked floating-dot memory device is its self-aligned structure. In addition, this concept is also applicable in the case of  $\text{Si}_3\text{N}_4$  dot memory for further improvement of data retention [58].

### 3. NANOCRYSTAL FLOATING-GATE TECHNOLOGY

The atom-like behavior of semiconductor nanocrystals embedded in  $\text{SiO}_2$  matrices is expected to lead to interesting optical and electronic properties. As a result, many applications and synthesis techniques are being explored.

The possibility of using Si or Ge as a light source in optoelectronic devices is very attractive because of the compatibility of these materials with existing Si-based MOS technologies [61–62]. Luminescent  $\text{SiO}_2$  films consisting of Si or Ge nanocrystals have been fabricated through the use of various deposition techniques [63–68] or, more recently, through Si or Ge ion implantation [69–75]. Implanted impurities have been used to shift the emission wavelength of Si nanocrystals (i.e., absorption of the nanocrystal emission, 0.81  $\mu\text{m}$  luminescence peak, from implanted Er causes strong excitations of  $\text{Er}^{3+}$  at 1.54  $\mu\text{m}$  [76]), indicating the potential of Si nanocrystals as sensitizers for use in Er-doped waveguide amplifiers or lasers [77]. A major effort has been directed toward the understanding of the origin of luminescence and electroluminescence spectra obtained from these materials. The sources of visible-range luminescence are still not entirely clear, and continue to be a subject of debate. The recombination of quantum-confined excitons in nanocrystals, defects in the surrounding matrix, electronic states at the nanocrystal surface, and foreign compounds have been named as sources. The origin of optical emission in the nanocrystals should be well understood, and a fabrication route of forming well-controlled depth and size distributions of nanocrystals should be established in order to optimize and control the optical properties for device applications.

Besides the attractive light-emitting property, semiconductor nanocrystals embedded in  $\text{SiO}_2$  matrices have regained interest due to their potential in future electronic devices. Resonant tunneling diodes [33, 78] and memory devices [23–24, 34–38] exploring quantum confinement and single-charge effects in Si nanocrystals have been demonstrated. For such applications, the nanocrystal characteristics have to satisfy certain specifications in order to provide reliable device operation. In particular, for multiple-dot memory applications, a fabrication route of forming high-density two-dimensional arrays of small, uniform size, noninteracting nanocrystals, and with well-controlled location without introducing defects at the  $\text{SiO}_2/\text{Si}$  interface or into the channel region, are important technological points. In addition, the synthesis technique should be as simple as possible (for low cost per bit) and compatible with existing CMOS processes. Because the optimum mean size of the storage dots is below the current lithography resolution, an attractive approach to fabricate a nanocrystal floating gate is through a self-assembling process [79]. This method also takes advantage of the whole-wafer nature of dot formation suitable for practical device implementation. Self-assembled semiconductor nanocrystal floating gates have been fabricated through various techniques, including Si-dot formation by low-pressure chemical vapor deposition (LPCVD) [24, 43], nanocrystal formation by a precipitation process during the annealing of a semiconductor-rich oxide layer (formed either by Si (Ge) ion implantation [56], or by deposition techniques such as LPCVD [80] or cosputtering of Si (Ge) and  $\text{SiO}_2$  [81–82]), rapid thermal oxidation either of a thin deposited amorphous Si [83] film or of amorphous silicon films deposited by ion-beam-assisted electron-beam deposition [84], molecular beam epitaxy combined with rapid thermal processing [85], aerosol deposition [86], and thermal oxidation of  $\text{Si}_{1-x}\text{Ge}_x$  [87]. Nanocrystal memory transistors

have been realized using these various self-assembling processes in combination with conventional MOS transistor fabrication steps. In the paragraphs below, nanocrystal synthesis through direct deposition techniques such as direct seeding on dielectric layers, or using a silicon-rich oxide layer, or through ion implantation techniques are briefly reviewed because of their advantages in terms of integration. In particular, we examine the case of the ion beam synthesis approach, as it is a simple and well-established technique within the semiconductor industry.

### 3.1. Direct Deposition Technique

#### 3.1.1. Direct Nanocrystal Seeding on Dielectric Substrates

Low-pressure chemical vapor deposition by pyrolysis of silane ( $\text{SiH}_4$ ) is a well-established technique within the microelectronic industry, and is commonly used for the fabrication of polycrystalline Si gates in MOS transistors and of thin-film transistors (TFTs). By controlling the early stages of Si film growth, a single layer of isolated Si nanocrystals a few nanometers in diameter can be formed on various dielectric substrates [88]. The size and density of the nanocrystals depend on the deposition parameters (pressure, temperature, and time) [77, 88, 89], as well as on the chemical treatments or on the chemical nature of the surface [77, 89–92]. Deposition on pure oxide substrates exhibits relatively low nanocrystal aerial density, while higher values have been observed for the case of deposition on nitride surfaces [89, 44]. The highest dot density, of  $10^{12} \text{ cm}^{-2}$  for optimized deposition conditions, has been obtained for the case of a pure  $\text{Si}_3\text{N}_4$  substrate [89] or, more recently, for an  $\text{Al}_2\text{O}_3$  surface [91]. A thermal oxidizing step after deposition is shown to improve dot size uniformity. A control oxide, formed by a second deposition step of  $\text{SiO}_2$ , covers the nanocrystals. The in-plane dot formation allows for excellent control of the tunneling oxide thickness without affecting the integrity of the oxide or of the oxide/channel interface. For these reasons, the LPCVD technique is an attractive option for nanocrystal memory device implementation. However, optimization of the deposition process (especially on  $\text{SiO}_2$  surfaces) and of the ultrathin tunneling dielectric formation step (especially for the case of  $\text{SiO}_2/\text{Si}_3\text{N}_4$  or  $\text{SiO}_2/\text{Al}_2\text{O}_3$  dielectric stacks) is still required in order to achieve high nanocrystal aerial density onto highly reliable dielectrics.

#### 3.1.2. Deposition and Precipitation of SRO

Silicon-rich oxide (SRO) or nonstoichiometric oxide is considered a solid solution of  $\text{SiO}_2$  and Si supersaturated in Si ( $\text{SiO}_x$ ,  $x < 2$ ). SRO films are usually prepared through chemical vapor deposition (either LPCVD or plasma-enhanced CVD) using a mixture of silane and  $\text{N}_2\text{O}$  or  $\text{SiH}_4$  and  $\text{O}_2$ . Changing the gas flow ratio controls the excess Si content in the SRO film. Thermal annealing during preparation processing or during an additional annealing step causes excess Si to precipitate in the form of amorphous or crystalline Si nanoclusters, depending on the annealing conditions (time, temperature) and the amount of excess Si [93, 94]. The diffusion of Si atoms in the nonstoichiometric oxide matrix has been found to control the precipitation of

Si clusters [94]. SRO layers have been proposed as interpoly dielectrics for enhanced electron injection [95–98], or as ultrathin tunneling oxide alternatives [99] in conventional nonvolatile memory devices for low-voltage operation. In addition, the electron trapping characteristics of SRO make it useful as a charge-storage material for memory applications. The charge-storage properties and charge transport through these films have been related to the Si quantum dots of the SRO film [93, 100]. For memory applications, a thin SRO layer ( $< 10 \text{ nm}$ ) is formed on top of oxidized Si substrates. In order to decrease the deposition growth rate for better control of the deposited SRO thickness, a dichrosilane gas instead of silane has been used [101]. By changing the gas ratio, a control oxide can also be deposited during the same furnace step. Because of the distributed nature of small Si grains in the film, charge storage takes place through the whole film volume. For better control over the tunneling oxide thickness, the in-plane growth of the charge-storage elements is required. This can be achieved if ultrathin SRO layers are used. However, certain limitations are imposed on making such ultrathin SRO layers reproducible with currently used CVD systems.

### 3.2. Ion Beam Synthesis

Ion implantation is a widely used technique in the semiconductor industry, and is commonly employed for doping silicon wafers. Because of the versatility and flexibility of this technique, ion beam synthesis (IBS) has recently become a popular method for synthesizing various types of nanocomposite materials (for a review, see [102]). In this technique, a given number of selected ions are introduced into a given dielectric layer. High-dose implantation can create a solid-state supersaturation of the implanted ions, and the subsequent thermal annealing can induce the implanted material to precipitate in the form of nanoparticles dispersed within the dielectric layer. Well-controlled depth and size distributions of nanocrystals can be achieved by adjusting the ion implantation conditions (dose, dose rate, and energy) and postimplantation annealing processing (temperature, time, and annealing environment). Moreover, a variety of embedded nanocrystal systems can be realized by changing the implanted ion element and the host material. In particular, regarding approaches targeting MOS memory devices, ion implantation of group IV semiconductor elements (e.g., Si or Ge) in an  $\text{SiO}_2$  matrix is fully compatible with Si microelectronic technology. In addition, from a device fabrication point of view, IBS is a quite simpler technique compared to the sophisticated multistep deposition ones, offering superior process controllability (i.e., the implanted ion concentration can be easily controlled through beam current adjustments), and thus better reproducibility of the resulting memory device characteristics. However, key points such as the in-plane size uniformity and arrangement of the nanocrystals, the precise adjustment of the control and tunneling oxide, and the implantation-related oxide and  $\text{SiO}_2/\text{Si}$  interface damage remain to be solved in order to implement practical memory devices through IBS technique. For this purpose, a substantial amount of experimental work on the charge-storage behavior of MOSFETs with Si- or Ge-implanted and annealed

gate oxides has been carried out over the past few years. A brief overview of the various implantation conditions and gate oxide thicknesses that have been explored follows in the paragraphs below.

### 3.2.1. MOSFETs with Si- or Ge-Implanted Gate Oxides

Following early investigations on the memory properties of SRO films [96], Kalnitsky et al. studied the electrical behavior of MOS structures with Si-implanted and annealed thin gate oxides (20–35 nm in thickness, implanted at energy ranging from 10 to 25 keV) [103]. Similar to the case of SRO films, this system was found to exhibit hysteresis in current–voltage ( $I$ – $V$ ) and capacitance–voltage ( $C$ – $V$ ) characteristics; however, no Si precipitates were observed for the Si-implanted oxides. Charge trapping and transport in this material were attributed to the trap-like behavior of excess Si atoms [104, 105]. The implanted Si atom was considered to serve as a neutral trap (a single trap capable of storing both positive and negative charge) that electrically communicates with both the conduction and valence bands of the Si substrate and the polysilicon gate via direct tunneling. This trap-assisted direct-tunneling model was used to describe most of the conduction effects experimentally observed in this material, such as a deviation of the slope of  $I$ – $V$  curves from the Fowler–Nordheim tunneling characteristics and a negative dynamic resistance effect [104]. From the fit of the experimental  $I$ – $V$  characteristics to the theoretical model, the energy level of the trap was estimated about 3 eV below the SiO<sub>2</sub> conduction band. The effect of Si implant-induced interface states on MOSFET characteristics was also discussed in [105]. Further investigations on such gate oxides (20–50 nm in thickness) implanted under various Si implantation conditions (10–50 keV/0.1–3 × 10<sup>16</sup> Si<sup>+</sup> cm<sup>-2</sup>) have revealed electrical characteristics (in terms of reliability, endurance, retention, programming window, and speed) potentially usable for MOS memory applications. Depending on the Si dose and the distance of the Si-implanted region from the Si/SiO<sub>2</sub> interface, the Si-implanted gate oxides have been introduced as gate dielectrics for realizing nonstacked gate, Flash EEPROM [106–109], analog-storage EEPROM [110], or nonvolatile RAM [111] devices. The origin of parasitic currents observed after large positive write voltages in these Si-implanted devices was also analyzed for practical memory device applications [112]. Note that the trap-like behavior of the implanted Si atoms that do not form Si islands was the major difference between these earlier charge-trapping studies on silicon-implanted oxides and those concerning deposited Si-rich oxides.

Hanafi et al. [56, 113] first interpreted the nonvolatile memory characteristics of MOSFETs with Si<sup>+</sup>- or Ge<sup>+</sup>-implanted gate oxides, in terms of electron charge storage in isolated nanoclusters formed by precipitation of the implanted material during postimplantation annealing treatment. Since that time, many studies have been performed in order to correlate the device electrical characteristics with the microstructure of the Si<sup>+</sup>- [114–119, 45] or Ge<sup>+</sup>- [120–123] implanted and annealed oxide layers. The charge-storage mechanism has been found to vary with the degree of precipitation of the implanted material and

the structural features of the nanoclusters (size, density, crystallinity), which in turn depend on the implantation and annealing conditions. By using an atomic-force microscope (AFM) [119] to locally inject and detect charge in annealed, Si-implanted SiO<sub>2</sub> films containing Si nanocrystals (2–6 nm in size), charge trapping due to the presence of Si nanocrystals has been inferred. In addition, a discrete build up of charge in the implanted oxide with gate bias has been recently observed for the case of well-crystallized and densely arranged Si grains with an average linear dimension of about 8 nm (the case of heavy Si implantation in SiO<sub>2</sub>), an indication of a nanocrystal-related charge-trapping process [117, 45]. On the other hand, the formation of Ge or Si/SiO<sub>2</sub> nonseparated glass [114, 120, 122] or of a Si or Ge band composed of amorphous and/or ill-crystalline grains [115–118, 121] has been shown to exhibit a continuous charge-storage process with gate bias indicative of a defect-related charge-trapping mechanism. However, the atomic structure of such defects and their exact location within the implanted oxide layer are not entirely clear. Si implant-related defect microstructures were recently studied experimentally and theoretically in [124]. Four possible molecular defect structures associated with excess Si in thermal oxides have been examined with ground and excited states within the bandgap of the amorphous SiO<sub>2</sub> structure. In addition, the observation of memory window narrowing after postmetallization annealing treatment in forming gas (N<sub>2</sub>/H<sub>2</sub> gas mixture) is an indication of hydrogen-related saturation of the defects acting as charge traps [115, 118]. Such defects could be associated with the nanocluster formation process, that is, Si dangling orbitals at the Si cluster/SiO<sub>2</sub> interface. The latter is further supported by the significant concentration of  $P_b$ -like centers that have been experimentally inferred from electron paramagnetic resonance studies ( $g \cong 2.005$  resonance) of Si-implanted SiO<sub>2</sub> films [125]. Despite these studies, further effort is needed in order to correlate the charge-trapping behavior of the implanted layers with the spatial state and structural arrangement of the implanted material after annealing, for the control and optimization of the memory characteristics of the resulting memory devices through adjustment of the IBS conditions.

### 3.2.2. Very-Low-Energy IBS Approach

For practical nanocrystal memory devices, the formation of an extremely narrow band of nanocrystals within thin SiO<sub>2</sub> layers is needed. In addition, the controllability of the location of such nanocrystalline bands from the SiO<sub>2</sub>/Si interface, as well as the elimination of implantation-related oxide and SiO<sub>2</sub>/Si interface damage, are necessary for the optimization of device performance. A promising approach to achieve this goal is to apply very-low-energy Si ion implants in thin SiO<sub>2</sub> films. Because the ion strangling decreases with implantation energy, the use of energies less than 2 keV is very attractive for making well-controlled depth and size distributions of nanocrystals with precise control of the tunnel oxide thickness [126–127]. The potential of this approach was first explored in experiments by our team at the Institute of Microelectronics of NCSR “Demokritos” in close collaboration with the University of Salford, in which well-localized layers of 2D arrays of Si nanocrystals are successfully formed both in thin (8–11 nm) and thick (35 nm) oxide

layers by 1 keV Si<sup>+</sup> implants at doses ranging from  $5 \times 10^{15}$  to  $5 \times 10^{16}$  cm<sup>-2</sup> and subsequent thermal annealing [128–130]. A short summary of the major characteristics of the resulting microstructures follows in the paragraph below.

For the case of implanted samples with an initial SiO<sub>2</sub> layer of 8 nm in thickness, an ultrathin layer of Si clusters (3–4 nm in thickness) located at a tunneling distance (ca. 2 nm) from both the oxide surface and the SiO<sub>2</sub>/Si substrate interface has been observed after postimplantation annealing at temperatures ranging from 900 to 1000 °C. Cross-sectional TEM observations for the case of a  $5 \times 10^{16}$  cm<sup>-2</sup> dose (Fig. 10) suggest that the presence of a protective polysilicon-capping layer during annealing does not significantly affect the evolution of the Si-nanocrystalline structures. In addition, related TEM work on very-low-energy Si-implanted and annealed thick oxide layers (Fig. 11) reveals Si nanocrystals with characteristics (size, density, and location) similar to those found for very thin oxides, indicating that the growth of the nanocrystals does not depend on the location of the SiO<sub>2</sub>/Si interface. The resulting microstructures have been found to exhibit a broad semiconductor domain-size distribution that depends upon the implanted dose and anneal temperature. Examples are shown in Figure 12. The amount of crystallized Si (proportional to the sum of white domains) appears to increase with the dose and temperature. Comparison of the (b), (f) and (d), (h) [or (c)/(g)] micrograph pairs shows clearly that, upon raising the annealing temperature, the extent of Si crystallization is enhanced much more for the former pair, that is, for the lower dose. Furthermore, although planar-view TEM micrographs in Figure 12(a) and (e) show no distinct structure, electron diffraction patterns [see inset

**Figure 10.** Cross-sectional TEM and HRTEM micrographs of 8 nm thick oxide implanted with  $5 \times 10^{16}$  Si<sup>+</sup> cm<sup>-2</sup> at 1 keV, capped with polysilicon, and subsequently annealed at 1000 °C for 30 min showing a 4 nm thick nanocrystal layer. **Figure 11.** Cross-section TEM micrograph of 35 nm thick oxide implanted with  $5 \times 10^{16}$  Si<sup>+</sup> cm<sup>-2</sup> (1 keV), annealed at 1000 °C for 30 min, and subsequently capped with polysilicon. The presence of a 4 nm nanocrystal layer is shown in the inset. Reprinted with permission from [130], P. Normand et al., *Nucl. Instrum. Meth., Phys. Res. B* 178, 74 (2001). © 2001, Elsevier Science.

of Fig. 12(a)] hint at the presence of Si domains. Moreover, a strong correlation between the shape and size of the nanocrystals has been observed. Arrows in (g) shows Si nanocrystals of 12–14 nm diameter (compared to a 3.5 nm thickness of the Si-rich layer observed in cross-sectional TEM analysis), which suggests that, with increasing size, the nanocrystals change from quasispheres to platelet like. Details about the observed lateral crystallite growth (coarsening) are given in [129]. Note that, because of the dense arrangement, the large nanocrystals are almost in touch with each other [Fig. 12(d) and (h)], causing the narrow nanocrystal band to appear as a quasicontinuous polycrystalline layer (Fig. 10).

The potential of the very-low-energy IBS approach as a technique for implementing nanocrystal memories was explored in [115]. This work gave attractive results, but also revealed the need for further effort in order to optimize and control the performance of the resulting memory devices for practical applications. Because the electrical

**Figure 12.** TEM micrographs from samples with 8 nm thick SiO<sub>2</sub> layer implanted with  $5 \times 10^{15}$  (a), (e),  $1 \times 10^{16}$  (b), (f),  $2 \times 10^{16}$  (c), (g) and  $5 \times 10^{16}$  (d), (h) Si<sup>+</sup> cm<sup>-2</sup> at 1 keV after thermal annealing at 900 °C for 60 min (a)–(d) and at 1000 °C for 30 min (e)–(h). Electron diffraction patterns of (a) and (d) are shown in insets (arrow indicates (111) Si ring). A silicon nanocrystal is shown in the inset of (h). Arrows in (b), (f), and (g) denote Si grains of 4–5, 8–9, and 12–14 nm diameter, respectively. Reprinted with permission from [130], P. Normand et al., *Nucl. Instrum. Meth., Phys. Res. B* 178, 74 (2001). © 2001, Elsevier Science.

characteristics of such devices are closely related to the microstructural features of the implanted gate oxides after annealing, an in-depth understanding of the structural evolution of the implanted Si material upon different implantation conditions and annealing treatments is necessary. For this purpose, theoretical works attempting to explain the mechanisms involved in the progress of phase transformations accompanying annealing have been carried out recently. The effect of the glass transition temperature ( $T_g$ ) of the as-implanted structure on the phase separation and crystallization of the implanted material was qualitatively discussed in [130, 131]. Process simulation based upon a combination of binary collision code [132] (for the study of the  $\text{Si}^+$  implantation process) and a kinetic lattice Monte Carlo code (for the study of phase separation process of Si from  $\text{SiO}_2$ ) [133] has revealed two regimes of Si nanocrystal formation for the case of 1 keV  $\text{Si}^+$ -implanted and annealed thin oxide layers. For a low implantation dose (below  $2 \times 10^{15} \text{ cm}^{-2}$ ), Si nanocrystals form by nucleation and growth, while at higher doses, spinodal decomposition occurs. It is interesting to note that the simulation results show the formation of Si nanocrystals at much lower Si concentrations than those observed in the previous experimental works. This is because annealing causes loss of the implanted Si material, resulting in a reduction of the implanted Si concentration. During annealing, part of the Si content of the initially single-phase Si– $\text{SiO}_2$  nanolayer (formed by very-low-energy Si implantation) can be lost either because it escapes from the top oxide surface or because it becomes captured by the Si/ $\text{SiO}_2$  substrate interface. In addition, part of the Si content can be lost by oxidation during annealing due to traces of moisture in the as-implanted sample or due to residual oxidizing species in the furnace. The later loss mechanism of implanted Si material can also explain the significant oxide swelling that has been reported [129, 134], and discussed in [134, 136], for the case of very-low-energy Si-implanted oxide layers.

Besides the thorough comprehension of the mechanisms involved during nanocrystal formation through the very-low-energy IBS technique, another important issue to be resolved before the practical application of this method is related to the damage induced by implantation. Such damage strongly affects the integrity of the implanted gate oxide, a fact that limits the operation of the memory device at relatively high voltages, as an additional deposited control oxide is unavoidable for proper operation. In addition, this oxide deposition step complicates the device fabrication process. In order to overcome this drawback of the IBS technique, an annealing step under an oxidizing environment ( $\text{N}_2/\text{O}_2$  gas mixture) was recently proposed [135]. MOS structures with very-low-energy ( $\leq 2$  keV)  $\text{Si}^+$ -implanted thin gate oxides ( $\leq 10$  nm in thickness) subjected to such an annealing treatment exhibit lower leakage currents and a large memory window at low gate voltages. The observed effective charge storage without the need for an additional deposited oxide indicates that postimplantation annealing in a diluted oxygen environment significantly restores the gate oxide integrity. In addition, TEM work for a high  $\text{Si}^+$ -implanted dose ( $1 \text{ keV}/2 \times 10^{16} \text{ cm}^{-2}$ ) reveals that the aforementioned annealing treatment increases the top control oxide thickness and narrows the size distribution of the

synthesized Si nanocrystals [136]. These promising results suggest that a combination of very-low-energy Si implants and annealing in diluted oxygen may lead to very-low-energy Si nanocrystal memory versions of substantial practical interest.

In contrast to the optimistic prospect of the Si-nanocrystal IBS technique, the possibility of forming a Ge nanocrystalline floating-gate layer by IBS remains questionable from a process reliability point of view. Several investigations indicate that the microstructure of Ge-implanted and annealed  $\text{SiO}_2$  oxide layers strongly depends on the processing parameters [120–122, 130–131, 137–140]. A narrow band composed either of crystalline or amorphous Ge clusters located very close to the Si/ $\text{SiO}_2$  interface has been reported for the case of  $\text{Ge}^+$ -implanted (at energies  $\geq 20$  keV) and annealed thick ( $\geq 30$  nm) oxide layers. However, this Ge nanocluster band is found to be metastable; it is only observable under specific implantation and annealing conditions. An interpretation regarding the existence and evolution of such a near interface nanocluster band is given in [137–139]. Note that, in some cases, implantation with various ions (e.g.,  $\text{Ag}^+$  [102],  $\text{Sn}^+$  [141], or  $\text{Sb}^+$  [142]) and subsequent annealing of the oxide layers result in localized precipitation of nanoparticles close to the Si/ $\text{SiO}_2$  interface, regardless of the implanted oxide thickness, indicating that migration of the implanted ions towards the interface during thermal processing is independent of the implanted species. On the other hand, initial attempts using very-low-energy (3 keV)  $\text{Ge}^+$  implantation in thin  $\text{SiO}_2$  films and subsequent annealing have produced an amorphous and single-phase Ge– $\text{SiO}_2$  nanolayer instead of the desired Ge nanocrystalline layer [120, 122, 130]. However, phase separation for this case can be induced under intense electron irradiation. Details of the structural evolution of the Ge– $\text{SiO}_2$  glass band upon TEM observation are presented in [131, 140]. All in all, the experiments up to now show that forming a technologically practical narrow Ge nanocrystalline band in  $\text{SiO}_2$  layers by the IBS technique remains a challenge.

#### 4. NANOCRYSTAL MEMORY: EXPERIMENTAL RESULTS

During the last few years, a large amount of experimental results on MOS capacitor and single-MOS transistor memory devices, with nanocrystal charge-storage nodes embedded in the gate oxide (and fabricated by various techniques), have been published. The reported memory characteristics (e.g., retention, endurance, programming voltage, and speed) have been found to vary significantly, depending on the oxide quality and thickness (mainly of the tunneling oxide), as well as on the structural characteristics of the nanocrystal charge-storage sites, parameters that in turn are closely related to the memory device fabrication process. Depending on these parameters, memory operation ranging from quasivolatile to long-refresh-time dynamic functions has been demonstrated. In addition, discrete threshold voltage shifts with programming voltage have been observed, a behavior that may allow a more reliable multibit-per-cell storage compared to the Flash multilevel storage approach.

In this section, we will discuss some of the main experimental results that reveal the key attributes of the nanocrystal memory in order to understand the potential gains and tradeoffs associated with this type of memory device. Selected experimental results of nanocrystal memory devices obtained by various techniques are listed in Table 1. For comparison, the tunneling and control oxide thicknesses of the structures and the characteristics of state-of-art Flash and DRAM memory devices are also included.

### 4.1. Quasinonvolatile Behavior—From NVRAM to Flash-Like Functions

Tiwary and his co-workers studied the memory properties of *n*-channel MOSFETs with self-assembled Si nanocrystals onto ultrathin thermally grown gate oxide films with different thicknesses and approximately comparable density [23, 24, 43, 56]. A control oxide exceeding 7 nm in thickness covers the nanocrystals. Memory operation with a programming window in the range of 0.5 V or higher at direct tunneling programming voltages ( $\leq 4$  V) is demonstrated with

write speeds dependent on the tunneling oxide thickness. By using ultrathin tunneling oxides ( $< 2$  nm in thickness), write times of 200 ns or faster and excellent endurance behavior (e.g., no observable memory window closure after more than  $10^9$  write/erase cycles at low programming voltages) are realized. In addition, for this case, a quasinonvolatile charge retention of days is measured at room temperature, demonstrating the advantage of the distributed nanocrystal charge-storage devices over the continuous polysilicon floating-gate EEPROM ones of comparable tunneling oxide thickness [56]. Similar fast write time ( $\sim 300$  ns) operation with limited nonvolatile data retention of hours at low programming voltage (4 V) also has been shown (by the same research group) for the case of MOSFETs with Si- or Ge-implanted and annealed gate oxides [56]. In contrast to the fast write operation, the erase speeds of the deposited and implanted devices are found to be relatively low (in the range of microseconds to seconds, depending on the gate erase voltage). By increasing the tunneling oxide thickness, programming in the microsecond (or millisecond) range at still lower voltages compared to Flash devices and limited endurance

**Table 1.** Selected experimental results of nanocrystal memory devices obtained by various techniques, including the tunneling and control oxide thicknesses of the structures. For comparison, state-of-the-art NOR Flash and DRAM memory attributes are listed.

Nanocrystal Float. Gate Technology	Tunnel Oxide	Control Oxide	Write Time	Erase Time/Voltage	Refresh Time (Room Tem.)	Endurance cycles	Write Voltage	$\Delta V_{TH}$

can be achieved to compete with Flash memory performance. For the case of tunneling oxide thicknesses comparable to, but still thinner than conventional Flash devices (e.g., ca. 6 nm), encouraging results in terms of disturb behavior and stress-induced leakage current have been obtained for aerosol deposition nanocrystal memory devices operating in the F–N tunneling regime [86]. In addition, the feasibility of hole-programming operation has been demonstrated for the case of *p*-channel deposited nanocrystal memory devices with 4 and 20 nm tunneling and control oxide thickness [92, 143]. Depending on the tunneling oxide thickness, nanocrystal memory devices have been introduced (similar to the case of scaled SONOS device [144]) as promising low-power operation candidates in applications ranging from Flash-like functions (slow programming in the millisecond range with long nonvolatile retention of years) to nonvolatile RAM (NVRAM)-like functions (fast programming in the microsecond range with limited nonvolatile retention). In addition, since the write/erase voltage pulses (for injection/extraction of charge into/from the nanocrystals) is not applied between the source or the drain of the memory cell, a reduced “punchthrough” effect can be achieved, allowing a shorter channel length and a smaller cell area than is possible in conventional floating-gate-type structures. Single-transistor nanocrystal arrays (organized in word lines, bit lines, and source lines, each connected to control gates, drains, and sources, respectively) with byte-addressable write/erase operations (or block-erase schemes for the case of very slow erase times) have been proposed for the incorporation of these structures into large-scale integration memory circuitry [56, 145]. However, the very stringent requirement for long-term charge retention (in particular, for the case of Flash functions) imposes serious constraints on the practical application of these structures in nonvolatile memory functions. Although promising charge-retention data have been published (e.g., retention times of hours have been measured at 200 °C [146]), the ultimate goal of true nonvolatility (e.g., data retention > ten years) at low voltage and at acceptable write/erase speeds still remains an important issue to be verified for nanocrystal memory devices. Due to the inherent constraint of back tunneling charges through thin tunneling oxides, it is unclear whether nanocrystal memories will ever meet the industrial data-retention standard, and further effort and process optimization are necessary in order to demonstrate the feasibility of this target.

#### 4.2. Volatile Behavior Long-Refresh-Time DRAM-Like Functions

Besides the potential in nonvolatile functions, another application of nanocrystal memory device is for a dynamic RAM concept of lower power dissipation (long refresh time), simpler operation, smaller cell area, and lower cost fabrication process than the conventional DRAM structures. Since the information, or charge, is stored into the gate oxide of a single transistor, no additional storage capacitor is needed, thus minimizing the cell size for higher packing densities. For applications targeting DRAM-like functions, fast write and erase speeds (in the nanosecond range) at low voltages

and endurance cycles exceeding  $10^{13}$  are important. In addition, for the case of the long (compared to conventional 1T-1C DRAM memory cell) refresh time requirement, data retention can be shortened to minutes or seconds; thus, quasinonvolatile retention is desired for DRAM functions, in contrast to the long-term retention of Flash and NVRAM functions. Hu and his co-workers at the University of Berkeley experimentally demonstrated the possibility of implementing DRAM functions by using single charge-trapping memory transistor structures with ultrathin tunneling oxides [101, 147]. For the case of SONOS devices with 1.2 nm tunneling oxide (the case of charge storage at traps distributed in the nitride layer), data-retention times as long as 1000 s are measured at 80 °C after a  $10^{11}$  cycle endurance test with 7 V/–7 V, 500 ns write/erase pulses [147]. For the case of nanocrystal-type memory with thin tunneling oxide (of ca. 1.5 nm) and a deposited SRO film as a charge-trapping layer, a fast write/erase speed that reaches 100 ns at 5 V write/erase voltage with a 0.5 V threshold voltage shift is reported [101]. In addition, a long refresh time of 1000 s is observed at room temperature after  $10^8$  write/erase cycles. Superior electrical characteristics in terms of write/erase speed/voltage and retention time (properties that also suggest the possibility of nanosecond programming range quasinonvolatile applications) have been recently reported for Ge nanocrystal memory devices obtained by thermal oxidation of  $S_{1-x}Ge_x$  [87]. For this case, data retention longer than one day at room temperature and about 1 h at 85 °C after a  $10^9$  cycle endurance test with 4 V/–4 V, 100 ns write/erase pulses are measured. Encouraging results suggest that DRAM-like functions also have been obtained for the simple and CMOS-compatible nanocrystal processing case of a very-low-energy Si nanocrystal memory device [148]. Fast write/erase characteristics at low electric fields with a large threshold voltage window under dynamic operation (using a gate-bias sine wave or pulsed signal) are measured in MOSFETs with embedded 2D arrays of Si nanocrystals at a distance ca. 3 nm from the channel obtained by 1 keV  $Si^+$  IBS in initially 8 nm thick gate oxides, and subsequently covered by 30 nm thick deposited control oxide. Endurance and retention-time characteristics of this memory cell using 15 V/–5 V, 100 ns write/erase pulses are shown in Figures 13 and 14. No degradation, even after a  $10^{10}$  cycle endurance test (Fig. 13) and less than 5% (20%) reduction in the memory window (Fig. 14) after 1 s (10 s), is observed at room temperature. Further process optimization (e.g., adjustments of the deposited control oxide thickness and improvements of the implanted oxide quality) is expected to reduce operation voltage and to increase the refresh-time characteristics of such devices [135, 136].

#### 4.3. Single-Electron Charging Effects

Similar to the case of single-dot device structures, single-electron charging phenomena also have been reported, and for the case of multiple-dot structures, consistent with the self-limiting charging process in nanocrystal storage nodes. However, in contrast to the former case, where a single dot is involved for screening the transistor channel, in the latter case (as discussed in Section 2), the uniformity of the size and depth distribution of the nanocrystals, as well as their density are critical parameters for

**Figure 13.** Endurance characteristic of a nanocrystal memory device obtained by implantation of 1 keV Si ions at a dose of  $1 \times 10^{16} \text{ cm}^{-2}$  into 8 nm thick oxide and subsequent annealing at 950 °C. A 30 nm thick oxide layer was deposited before annealing.

the observation of such discrete charging effects. Furthermore, concerning the magnitude of the threshold voltage shift caused by one stored electron in each nanocrystal, besides the nanocrystal size and the control oxide thickness (as in the single-dot case), the nanocrystal density is also very important for the case of a multidot memory device. Plateaus in the pulsed threshold voltage with static gate voltage characteristics have been observed at temperatures below 120 K in MOSFET structures with Si nanocrystals embedded in the gate oxide by deposition onto 1.9 nm thin tunneling oxide, and covered by a control oxide of ca. 9 nm in thickness [43]. The observation of threshold voltage plateaus in equidistant steps (of ca. 0.3 V) is found consistent with single-electron storage in the nanocrystals for the case of nanocrystal density of ca.  $6 \times 10^{11} \text{ cm}^{-2}$ , a value within the error margins of that estimated by structural observations. In addition, the temperature range wherein this phenomenon becomes pronounced is in agreement with the relatively large observable nanocrystal size (>10 nm). Room-temperature discrete threshold voltage

**Figure 14.** Charge-retention time characteristics after  $10^{10}$  cycle endurance test with +15 V/−5 V, 100 ns write/erase pulses of a nanocrystal memory device obtained by implantation of 1 keV Si ions at a dose of  $1 \times 10^{16} \text{ cm}^{-2}$  into 8 nm thick oxide and subsequent annealing at 950 °C. A 30 nm thick oxide layer was deposited before annealing.

shifts of 0.48 V have been observed for Si nanocrystal memories formed by LPCVD onto 2 nm in thickness oxide–nitride tunneling dielectric and covered by a 20 nm thick control oxide [44, 149–150]. The room-temperature single-electron charging phenomena in these structures have been attributed to the extremely small size (ca. 4.5 nm in diameter), the good size uniformity, and the aerial density of  $5 \times 10^{11} \text{ cm}^{-2}$  of the Si dots. Recently, Si-nanocrystal memory devices obtained by a high-dose ( $2 \times 10^{16} \text{ Si}^+/\text{cm}^2$ ) very-low-energy (1 keV) IBS technique have been found to exhibit step-like source–drain current versus time ( $I_{DS}$ – $t$ ) and periodic staircase plateau source–drain current versus gate voltage ( $I_{DS}$ – $V_G$ ) characteristics, both in support of the notion of room-temperature discrete electron storage in Si nanocrystals [45]. Structural study for this case reveals the formation of well-crystallized Si grains of about 7–8 nm average linear dimensions in a dense arrangement. The observation of discrete threshold voltage shifts of ca. 2 V in the  $I_{DS}$ – $V_G$  curves obtained during slow forward (Fig. 15)/fast backward (inset of Fig. 15) gate voltage sweeps is found to be consistent with successive single-electron injection/ejection into/from each nanocrystal for the case of nanocrystal density of ca.  $1 \times 10^{12} \text{ cm}^{-2}$ .

In spite of the inherent difficulties of controlling single-electron storage phenomena at a realistic level of integration, the experimental evidence of such effects at room temperature supports the pursuit of technologically practical large-channel devices operating on the basis of the Coulomb blockade principle. Successful exploitation of the discrete threshold voltage changes in multiple-dot structures may lead to the development of memory cells with a multi-level storage capability and current drive much higher than nanoscale Si channel FET devices with single (or few) nanocrystal storage nodes.

**Figure 15.** Room-temperature transfer characteristics for the very-low-energy Si nanocrystal memory devices (case of 1 keV/ $2 \times 10^{16} \text{ cm}^{-2}$   $\text{Si}^+$  implants). With decreasing sweep rate, the  $I_{DS}$ – $V_G$  curves show a clear staircase structure. The arrows indicate voltage regions  $\Delta V_{GS}$  with one and two stored electrons per nanocrystal ( $n = 1, 2$ ), while the initial part of the fast swept  $I_{DS}$ – $V_G$  curve corresponds to  $n = 0$ .  $\Delta V_{TH}$  is the threshold voltage shift caused by the storage of a single electron per nanocrystal. Inset:  $V_G$  is swept forward and backward after discharging at a rate of 0.8 V/s. The dot lines show  $I_{DS}$ – $V_G$  curves with  $n = 1$  and  $n = 2$  stored electrons per nanocrystal and are obtained by shifting the forward swept curve ( $n = 0$  stored electrons per nanocrystal) by 1.9 V and 3.8 V respectively.

## 5. CONCLUSIONS

Fundamental limits in (a) gate oxide thickness due to tunneling currents, (b) transistor channel length due to subthreshold leakage constraints, and (c) storage capacitor due to the need for large capacitance values, will become an important concern in the future scaling of conventional volatile and nonvolatile memory devices. Aggressive exploration of an alternate device architecture offers the best hope for continuing the current performance scaling trends seen in the last 20 years. A nanocrystal memory structure is one of the new promising memory concepts for overcoming the fast-approaching scaling limits of Flash and DRAM memories.

In this short chapter, the current status and challenges of this approach for memory applications have been presented. The self-limiting charging process in laterally uncoupled nanocrystal storage nodes (due to the Coulomb blockade effect), together with the distributed nature of the storage nodes (in contrast to the conventional continuous poly-Si floating-gate layer) promise the implementation of memory devices with thinner tunneling oxides for ultrahigh-density, low-voltage, low-power, and fast write/erase data storage. The progress in the area of practical nanocrystal floating-gate technology has been reviewed, and the potential of the very-low-energy ion beam synthesis approach has particularly been discussed. Encouraging electrical results of prototype nanocrystal single-transistor memory structures have been presented, indicating an optimistic prospect for applications ranging from Flash to DRAM-like functions, with the exotic possibility of multilevel storage capability.

However, the experimental memory characteristics up to now (e.g., data retention time, endurance, write/erase speed, programming voltages) span a very wide range of values, and definite conclusions concerning the scalability advantages of this type of memory device over the conventional DRAM or Flash ones cannot be fully evaluated at present. More extensive study and fabrication process optimization are required in order to realize the applicability of the nanocrystal memory concept. Important issues such as reliable low-voltage operation with long-term charge retention or fast write/erase speeds at low programming voltages with high endurance remain to be verified beyond doubt before the practical implementation of this device in nonvolatile or volatile memory circuitry, respectively. That is, it has yet to be clarified whether or not nanocrystal memories will be used for information data storage in place of the conventional memory devices.

## GLOSSARY

**Charge-trapping devices** Memory technology that stores binary information in the form of electric charge in discrete traps distributed in the gate insulator of a MOS transistor

**Coulomb blockade** Phenomenon in which the flow of current through a metallic quantum dot is inhibited until the electrostatic energy needed to move an electron onto the dot is overcome through an applied bias. For the case of a semiconductor quantum dot (a system with much lower electron densities, and larger electron wavelengths at the Fermi energy), the kinetic energy of the added electron (due to

quantum confinement) also must be supplied for overcoming current suppression.

**Dynamic random access memory (DRAM)** Memory technology that stores binary information in the form of presence and absence of electric charge on capacitors. The DRAM cell consists of a single capacitor and a single transistor to access the capacitor. This technology is considered dynamic because the stored charge degrades over time due to leakage mechanisms. Therefore, the cell data must be read and rewritten periodically (*refresh operation*), even when the memory cell is not accessed to replace the lost charge.

**Floating gate (FG)** Conductive polysilicon layer, completely embedded inside the gate oxide of a MOS transistor. As it is not externally connected to any other part of the device (rather, it is left floating), it is appropriately called a floating gate.

**Ion beam synthesis (IBS)** Method for synthesizing various types of quantum dots. In this technique, an appropriate number of selected ions are introduced into a given dielectric layer, and a subsequent thermal annealing can induce the implanted material to precipitate in the form of small particles dispersed within the host layer.

**Metal oxide semiconductor (MOS)** Sandwich structure consisting of three layers: the metal *gate electrode* (usually made of polysilicon), the insulating oxide ( $\text{SiO}_2$ ) layer, and the bulk semiconductor (*p*- or *n*-type Si), called the *substrate*, that make up the MOS capacitors and MOS transistors.

**MOS field-effect transistor (MOSFET) (or briefly, MOS transistor)** Synonym for insulated-gate FET. A four-terminal MOS device with the terminals designated as *gate*, *source*, *drain*, and *substrate* or *body* electrodes. Usually, the substrate terminal is connected to the source terminal. As a field-effect device, the electric field established by the voltage applied to the gate terminal controls the current flow in the transistor *channel* (the region between the source and drain electrodes).

**Nonvolatile memory (NVM)** Type of memory device in which the stored data are not lost when the power supply is off, and refresh operation is not required. Nonvolatile memories are classified into two main categories: FG NVMs and charge-trapping devices.

**Quantum confinement (or briefly, confinement)** Quantization of the kinetic energy of charge carriers, when their motion in a particular spatial dimension is confined to a region comparable to the de Broglie wavelength of the carriers.

**Quantum dot (or briefly, dot)** Synonym for island. An electrically insulated object, for example, a metal or semiconductor nanocrystal, in which charge can be transferred only through a tunneling mechanism. The confinement in all three spatial directions completely confines the motion of charge carriers, giving rise to a discrete energy spectrum much like an isolated atom or molecule. This is, in particular, the case of very small dots with a size close to or less than the electron wavelength on the Fermi surface  $F$ . In semiconductors,  $F \sim 50$  nm, and in metals,  $F \sim 1$  nm.

**Static random access memory (SRAM)** Memory technology that utilizes the bistable characteristics of a two cross-coupled inverter circuit (a circuit with two stable operating points) to store binary information. The most popular SRAM cell consists of two cross-coupled CMOS inverters and two access transistors. The memory cell is considered static because the cell data are kept as long as the power is turned on and refresh operation is not required.

**Tunneling** Quantum mechanical charge-transport process in which electrons are able to penetrate through a narrow potential energy barrier, when their energies happen to be smaller than the height of the potential energy barrier.

**Volatile memory** Type of a memory device in which the stored data are lost when the power supply voltage is turned off. Volatile memories are classified into two main categories: DRAMs and SRAMs.

## 1. SYNTHESIS OF NANOCRYSTALLINE MATERIALS

### 1.1. Introduction

In order for a material to be defined nanocrystalline the size of its grains must be of the order of less than 100 nm. Such materials can be constituted by one or more phases distributed in one, two, or three dimensions. Examples are nanowires, layers either deposited on top of a substrate as coatings or stacked in suitable sequences, and bulk objects. If the material is fully made of nanograins the number density of crystals scales with their size (e.g., it can range from  $10^{25}$  to  $10^{21}$  m<sup>-3</sup> for sizes of 5 and 100 nm respectively). Correspondingly, a high density of grain boundaries (usually  $6 \times 10^{19}$  cm<sup>-3</sup>) is implied so a large quantity of the atoms constituting the material can be situated on interfaces (simple calculations provide estimates of 50% for grains of 5 nm; 30% for grains of 10 nm; 3% for grains of 100 nm) [1]. As a consequence, nanocrystalline systems can be looked at as if they contained two types of atoms: those resident on a crystal lattice and those belonging to interfaces. Analogous densities of crystals can be obtained in two-phase materials where the fine particles are dispersed in a matrix either crystalline or glassy. Here the interface and its properties have relevance in determining the rate of nucleation and of attachment kinetics during growth.
